Milk proteins have found numerous applications in food systems due to their ability to form and stabilize emulsions. Caseins possess high surface hydrophobicity with a well-balanced distribution of hydrophilic and hydrophobic domains and possess a high degree of conformational flexibility, which allows them to interact strongly at the oil-water interface (87). However, the caseins have high aggregative tendencies and low solubilities around their pI (88). Whey proteins also adsorb rapidly to, unfold and reorientate at oil-water and air-water interfaces, forming emulsions which are only slightly less stable than those formed with casein under the same conditions. Emulsions formed with pure β-lactoglobulin may increase in stability over time, due to intermolecular linking of disulphide groups which are in close proximity at the oil-water interface.

Due to the excellent surface activity of milk proteins, they have found numerous applications in several food products in which incorporation of oil/water/air into the continuous system is required. Examples of these include salad dressings, mayonnaise, liqueurs, meringues, soufflés, whipped toppings, confectionary, sponge cakes, etc. Caseinates generally give emulsions with increased droplet coverage and high foam expansion but produce less stable emulsions and foams than those formed with whey protein concentrate (WPC). Preheat treatment may be used to improve the emulsifying and foaming characteristics of WPC, while enzymatic hydrolysis to different extents has been shown to significantly improve both the emulsifying and foaming properties of sodium caseinate-stabilized emulsions and foams at certain pH values (84). However, extensive hydrolysis generally results in the loss of emulsifying and foaming activity. Combinations of enzymatic hydrolysis and cross-linking, using a novel cross-linking enzyme transglutaminase, have resulted in products which exhibit significantly greater emulsifying properties than the products of hydrolysis or cross-linking per se (89).

The foaming and emulsifying properties of milk proteins are also affected by many extrinsic or environmental factors, such as protein concentration, energy input, state of protein aggregation, pH, ionic strength, temperature, calcium ion concentration and the presence of contaminants which may destabilize the oil-water or air-water interface. In addition, the ratio of oil:water phase used during emulsion formation is of major importance to emulsion properties.

C. Heat Stability

Due to their limited secondary structure, the caseins possess excellent heat stability. Na, K and NH_4 caseinates are extremely heat stable and aqueous solutions of Na caseinate may be heated up to 140°C for 60 min without precipitation; however, Ca caseinate has much lower heat stability by comparison. Consequently, caseinates may be used in food products which experience thermal treatments, such as soups and sauces. The effects of heating on sodium caseinate have been extensively studied (90–92). Whey proteins, on the other hand, are readily denatured above 70°C, leading to aggregation and, depending on pH and

protein concentration, precipitation or gelation. Factors such as pH, protein concentration, total solids content and the presence of sugar may influence the denaturation of milk proteins.

A common method for measurement of heat stability involves heating a protein solution of known concentration and pH, in an oil bath or autoclave for a given period of time at defined temperatures. Changes in free amino nitrogen, soluble ammonia, turbidity, and trichloroacetic acid soluble and pH 4.6 soluble amino nitrogen have been attributed to the effects of heating on protein solutions. Enzymatic modification with transglutaminase has been shown to improve the heat stability of both reconstituted skim milk (93) and Na caseinate (94).

D. Aggregation/Coagulation/Gelation

Milk proteins also have the ability to form rigid, heat-induced irreversible gels that hold water and fat, and provide structural support (80). Coagulation and/or gelation are required in some cultured milk products, and may be brought about on addition of acid or rennet to milk to form casein gels. Caseinates per se are rarely used as gelling agents in formulated food products; however, the ability of whey proteins to form gels under a range of conditions have found many applications in food products.

Gelation of whey proteins occurs on heating (usually in the range 80–100°C) depending on the concentration (normally above 8%) and purity of the whey protein. The initial steps of gelation include unfolding of the globular protein molecules, followed by aggregation in the aqueous medium. Once aggregation exceeds a certain level, a three-dimensional self-supporting network is formed which traps the solvent within the system, resulting in an irreversible thermo-induced gel.

While Ca caseinate solutions at concentrations greater than 15% form reversible gels on heating to 50–60°C, Na caseinate may also be used to form gels in conjunction with κ-carrageenan (95). The introduction of covalent cross-links using transglutaminase has also been used to induce gelation in Na caseinate (96,97).

Important attributes of gels are gelling time, opacity (or lack of) and gel hardness and strength which may be measured using rheological methods; these are affected by extrinsic factors such as pH and ionic salt concentration. Lipids and lactose may adversely affect whey protein gelation.

Further applications of milk protein gels include the immobilization of enzymes or entrapment of drugs or bioactive peptides for the purpose of oral drug delivery systems.

E. Viscosity

Milk proteins, either in solution or incorporated into a food matrix, provide physical stability to emulsions and to other suspended particles in foods by influencing the viscosity of the system, whilst also contributing to mouthfeel (98). The viscosity of a protein system depends on the proteins' intrinsic properties such as heterogeneity, size, shape and charge; these properties are further affected by extrinsic conditions, such as temperature, concentration, pH, ionic strength and previous processing history. Randomly coiled structures, such as caseins, generally display greater viscosity in solution than whey proteins which have a compact globular structure.

Na caseinate solutions are highly viscous at 15% concentrations and display pseudoplasticity above this concentration. Viscosity of Na caseinate solutions increases exponentially with protein concentration, and generally decreases with increasing temperature, depending on concentration. Viscosity of Na caseinate solutions is also highly dependent on pH, with minimum viscosity observed at pH 7. Native whey protein solutions have very low viscosities compared to caseinates; however, viscosity increases at higher temperatures (>70°C) due to unfolding and aggregation of the globular whey protein. The viscosity of milk protein solutions is usually expressed as relative or apparent viscosity and may be measured using a variety of viscometers.

F. Water-Binding and Hydration

The ability of proteins to hydrate and entrap water without syneresis is utilized in many food applications. Water molecules bind to both polar and non-polar groups in proteins to different extents, depending on the charge and polarity of the amino groups. Due to the globular tertiary structure of the whey proteins, the majority of the amino acid residues are buried within the protein interior. Thus, the hydration capacity of the whey proteins arises predominantly from binding of water to amino acid residues on the protein surface. Hydration values for native individual whey proteins range from 0.3 to 0.6 g H_2O per g protein (99,100). Casein micelles, on the other hand, can bind up to 4 g H_2O per g protein, mainly due to the enormous amount of void space within the casein micelles' structure and binding of water to the hydrophilic surface of the micelles.

Solution conditions, such as pH, ionic strength, and temperature, affect hydration of proteins (101). Hydration capacity is minimal at the pI, where protein-protein interactions are favored over protein-water interactions. Low salt concentrations can also increase the hydration capacity of proteins.

Milk proteins have found numerous applications in food products due to their ability to bind water and swell, thereby resulting in an increase in viscosity in the food system. Whey proteins are used as water-binders in food systems which will receive sufficient heat treatment to denature the globular protein and increase its hydration capacity. These food systems include meat patties,

sausages, bread and cakes. Caseins and caseinates have found application in products such as imitation cheeses, confectionary and comminuted meat products.

Aside from hydration capacity of proteins, large amounts of water may also be held within a food matrix such as a gel. This water mainly includes physically entrapped water and it is this water which provides juiciness and tenderness to the final product.

VIII. MILK PROTEIN-DERIVED BIOACTIVE PEPTIDES

In addition to the biologically active proteins indigenous to milk, all the principal milk proteins contain sequences which, when released on proteolysis, exhibit biological activity. These biological activities include opiate, antithrombotic, antihypertensive, immunomodulatory, metal-binding and antimicrobial activities (Table 26.5).

A. Opioid Activities

Opioid peptides are short peptides (5–10 amino acids) termed casomorphins or exorphins for their ability to bind opioid receptors on intestinal epithelial and other cells (103) and have an opiate-like effect. The major opioid milk peptide β-casomorphin is a fragment of the β-casein sequence 60–70, while α_{S1}-casein (α-casomorphin), β-lactogobulin (β-lactorphin) and α-lactalbumin (α-lactorphin) also contain peptides which display opiate-like activity. Although opioid peptides derived from milk may be generated by proteolytic digestion of milk proteins *in vitro*, only β-casomorphin has been found in digesta after *in vivo* digestion of milk in calves (104) but not in humans (105). Milk protein-derived opioid peptides prolong gastrointestinal transit time (106), exert anti-diarrhoeal action (107), modulate intestinal transport of amino acids (108) and influence postprandial metabolism by stimulating secretion of insulin (109) and somatostatin (110).

TABLE 26.5
Bioactive Peptides Derived from Milk Proteins

Bioactive Peptide	Protein Precursor	Bioactivity
Casomorphins	α_{S1}-, β-Casein	Opioid agonist
α-Lactorphin	α-Lactalbumin	Opioid agonist
β-Lactorphin	β-Lactoglobulin	Opioid agonist
Lactoferroxins	Lactoferrin	Opioid antagonist
Casoxins	κ-Casein	Opioid antagonist
Casokinins	α_{S1}-, β-Casein	ACE-inhibitory
Lactokinins	α-Lactalbumin, β-Lactoglobulin, serum albumin	ACE-inhibitory
Immunopeptides	α_{S1}-, β-Casein	Immunomodulatory
Lactoferricin	Lactoferrin	Antimicrobial
Casoplatelins	κ-Casein	Antithrombotic
Phosphopeptides	α_{S1}-, β-Casein	Mineral binding

Source: Fitzgerald and Meisel, Milk protein hydrolysates and bioactive peptides, pp 675–698, 2003. In Advanced Dairy Chemistry Volume l: Proteins, 3rd ed., part A. Kluwer Academic/Plenum Publishers.

B. Opioid Antagonist Activities

Opioid antagonistic peptides are also found within the structure of milk proteins. Termed casoxins and lactoferroxins, they are derived from peptic digestion of κ-casein and lactoferrin, respectively. Opioid antagonists may antagonize the inhibition of gut motility as induced by casomorphins (111). Opioid antagonists have been found in bovine and human κ-casein (111) and in human α_{S1}-casein (112).

C. Inhibition of Angiotensin-I-Converting Enzyme (ACE)

The casein-derived ACE inhibitors, or casokinins, have been isolated from bovine α_{S1}- and β-casein and from human β- and κ-casein (103,114). Opioid fragments relating to β-casomorphin-7 (115) and β-lactorphin (116) have also been identified as ACE inhibitory peptides with moderate activities. ACE is a multifunctional enzyme that is located in different body tissues and is associated with the renin-angiotensin system, which regulates peripheral blood pressure. Inhibition of ACE has been shown to block the conversion of angiotensin-I to angiotensin-II, a potent vasoconstrictor.

D. Immunomodulatory Effects

α-Lactalbumin, β- and α_{S1}-casein-derived immunopeptides have been found to enhance phagocytosis and modulate proliferation and differentiation of lymphocytes (117). Immunomodulation appears to be a particularly important bioactivity of the developing, involuting or inflamed mammary gland. Hormones, growth factors and cytokines found in milk also appear important in immunomodulation and immuno-development (111).

E. Antithrombotic Effects

Casoplatelins, peptides derived from the C-terminus of bovine κ-casein, have been shown to exhibit antithrombotic activity, i.e., inhibition of blood clotting. These peptides function by inhibiting the aggregation of ADP-activated platelets as well as binding of human fibrinogen γ-chain to a specific receptor site on the platelet surface (118).

F. Mineral Binding Properties

While intact casein has been shown to bind zinc and calcium, tryptic hydrolysates of α_{S1}-, α_{S2}-, β- and κ-casein also display mineral binding properties. Termed caseinophosphopeptides (CPPs), these peptides can bind and solubilize high concentrations of calcium due to their highly polar acidic domain. Consumption of high concentrations

of calcium in early life contributes to development of maximal bone density, which in turn can prevent osteoporosis in later life (102). In addition, calcium-binding CPPs can have an anticariogenic effect in that they inhibit caries lesions through recalcification of the dental enamel (119).

G. Antimicrobial Activity

Lactoferrin is an iron-binding glycoprotein present in the whey fraction in milk from which antimicrobial peptides have been derived (120). It is considered to be an important component of the host defense against microbial infections. The antimicrobial ability of lactoferricin may be correlated with the net positive charge of the peptides. These cationic peptides kill sensitive microorganisms by increasing cell membrane permeability (121). Lactoferricin displayed antimicrobial activity against yeast, filamentous fungi (122), *Escherichia coli, Listeria monocytogenes* (123) and clinical isolates of *E. coli* 0157:H7 (124). Recently, fragments from α_{S1}- and α_{S2}-casein have been found to inhibit the growth of *E. coli* (125) and *Staphylococcus aureus* (126).

IX. CONCLUSION

Bovine milk protein fulfills important nutritional, functional and physiological roles in both the developing neonate and man. From a nutritional viewpoint, milk protein is a balanced source of all the essential amino acids. The functional properties of milk proteins are exploited in many food products and the ability of milk protein to act as surface active agents, contribute to texture or to bind water or fat, is determined, in part, by its unique structure. Milk also contains an array of enzymatic activities; these enzyme activities are important from both a functional and physiological perspective. Finally, all the principal milk proteins contain sequences which, when released on proteolysis, may confer beneficial physiological effects.

27 Enzymes of Significance to Milk and Dairy Products

A.L. Kelly and P.L.H. McSweeney
Department of Food and Nutritional Sciences, University College Cork

CONTENTS

I. INTRODUCTION

When considering the processing and quality of milk and dairy products, a number of enzymes are of significance. These fall broadly into 3 categories:

1. Indigenous enzymes: Fresh raw bovine milk contains a heterogeneous group of enzymes, derived from various sources. While different authors may use different nomenclature to indicate the origin of enzymes, in this chapter, enzymes of bovine origin that are found in milk will be referred to as indigenous. While the complement of milk enzymes has not been completely classified, and gaps in knowledge and understanding clearly occur, the principal classes of enzymes include proteolytic and lipolytic enzymes, phosphatases, antimicrobial enzymes, e.g., lysozyme and lactoperoxidase, and a number of other enzymes, such as xanthine oxidase. Approximately 60 indigenous enzyme activities have been reported in bovine milk, of which ca. 20 have been characterized (1, 2). The milk of mammals other than the cow probably contains similar enzyme profiles, although most have not been studied in detail (2).
2. Exogenous enzymes: A number of enzymes are added to milk during processing (3); these will be referred of hereafter as exogenous. The oldest example of such use of an enzyme in the dairy industry is the application of extracts of stomachs of calves, kids or lambs (containing chymosin) to coagulate milk in cheesemaking. Today, a range of milk coagulants is used (e.g., rennet extracts, recombinant calf chymosin, microbial rennets, etc.). Other enzymes that are commercially available today can be used to manipulate and accelerate cheese ripening (e.g., added protease and lipase preparations), to hydrolyze lactose in milk (lactases or β-galactosidases) and, most recently, to manipulate the

texture of milk products through the creation of new covalent inter-protein cross-links (transglutaminase).

3. Endogenous enzymes. Endogenous enzymes in this case refer to those that are present in a food but are not part of it, e.g., enzymes produced by microorganisms that grow in milk, either as natural contaminants (e.g., psychrotrophic bacteria, mastitis pathogens) or following deliberate inoculation (e.g., the lactic acid bacteria used in the manufacture of fermented dairy products). While such microorganisms possess a wide range of enzymes, which can contribute either negatively (e.g., lipases and proteases of *Pseudomonas*) or positively (e.g., the proteolytic system of *Lactococcus*) to the characteristics of dairy products, they will not be considered in this chapter. The reader is directed to reviews in this area (4–8).

In this chapter, the indigenous and exogenous enzymes of importance to milk and dairy products will be discussed. The significance of these enzymes to dairy product manufacture and quality will be emphasized.

II. INDIGENOUS ENZYMES

It has long been recognized that there is a significant and heterogeneous mixture of enzymes in fresh milk. Today, many of these enzymes have been characterized but our understanding of the significance of all these enzymes for product quality is incomplete.

In terms of indigenous enzymes, the key questions to be considered may be summarized as follows:

(i) What enzymes are present and from where do they originate?

As stated already, a number of enzyme activities have been identified in milk, which will be listed and described in detail below; however, it is unlikely that all enzymes in milk have been identified. Indigenous enzymes differ in their origin (e.g., blood or lysosomes of somatic [white blood] cells) and distribution in milk. Indigenous enzymes in milk originate from:

(a) Blood (via leaky junctions between mammary secretory cells)
(b) Somatic cells, particularly during mastitic infection
(c) Mammary cell cytoplasm, as a result of the way in which milk is expressed in the udder

Indigenous enzymes in milk are found in, or associated with, casein micelles, the milk fat globule membrane (most enzymes), milk serum or somatic cells.

One of the major challenges in studies of indigenous milk enzymes is the requirement for suitable methodologies and assays to allow evaluation of their nature and significance.

(ii) At what level are these enzymes found, and what factors affect their activity?

The enzyme complement in raw milk is far from constant, and may vary qualitatively and quantitatively due to several factors, including individual variation between cows, health status (particularly incidence of mastitis), stage of lactation, nutritional status, breed and physiological or nutritional stress. Thus, fresh milk as a raw material for production of dairy products may exhibit considerable, potentially significant, variation in its complement of indigenous enzymes. For some indigenous enzymes (e.g., plasmin), the factors affecting its activity in milk are quite well defined; in the cases of many other enzymes, such as the acid protease cathepsin D, this information is incomplete. Many of these factors, where known, will be discussed in the relevant section for each enzyme hereafter.

(iii) What is their significance in dairy products?

The most significant features of indigenous enzymes with respect to dairy products are (2):

(a) Indices of animal health (especially mastitis)
(b) Indices of the thermal history of milk
(c) Deterioration of product quality
(d) Desirable changes in dairy products
(e) Protective (antibacterial) effects.

This review will concentrate on the effects of indigenous enzymes on the technological properties of milk and dairy products.

Perhaps the principal issue to be addressed in terms of evaluating the significance of indigenous milk enzymes for the majority of modern dairy products is whether the activity remains following pasteurization, which is the primary processing step commonly applied to most milk. Many studies have shown that milk is not rendered enzymatically inert by such thermal processing. Indeed, the activity of the principal proteolytic enzyme in milk, plasmin, may be increased during storage of milk post-pasteurization, as will be discussed below. Post-pasteurization, the residual activity of indigenous enzymes have been linked to a wide range of positive or negative effects in dairy products (e.g., in the case of plasmin, from the ripening of cheese to coagulation and instability of UHT milk products). Furthermore, when it occurs, inactivation of enzymes by pasteurization or other processing steps may not be sufficient to eliminate completely the activity of certain enzymes in milk; in many cases, the enzymes already have had significant opportunity to act on milk

constituents (e.g., to hydrolyze casein in such a manner as to affect product quality) prior to pasteurization, either rapidly at temperature near their optimum (i.e., in the udder at 37°C, prior to milking) or more slowly during refrigerated storage at the farm or factory.

In the following sections, the significance of indigenous enzymes will be discussed in the above light, under each of the major groups known to be present in raw milk.

A. Indigenous Lipase Activity in Milk

Lipoprotein lipase (LPL) is found as an indigenous enzyme in the milk of all mammals, although its level varies from species to species; LPL is the only indigenous lipase in bovine milk (9–11). It plays an important role in milk production in the udder, as the products of its action on triglycerides in lipoproteins, i.e., fatty acids and monoglycerides, are taken into the cell for the production of energy, synthesis of tissue components or milk lipids, or storage. LPL activity in the mammary gland is low before and during pregnancy but increases soon after parturition and remains high throughout lactation (12). This elevated LPL activity means that triglycerides are diverted to the mammary gland for the synthesis of milk lipids. LPL is probably synthesized mainly and secreted into milk together with the casein micelles; some transfer of LPL to the milk fat globules may occur, particularly after milking (9). To date, no role has been proven for LPL in milk utilization by the neonate; Olivecrona et al. (9) speculated on possible roles for this enzyme, including assisting with the binding of milkfat to the intestinal mucosa, catalysis of the transfer of lipids into cells, facilitating the action of pancreatic lipase by partial hydrolysis of milkfat and perhaps an anti-parasitic function.

Bovine LPL is a non-covalent homodimer of glycosylated subunits containing 450 residues, 5 disulphide bridges and 2 oligosaccharide chains. The structure of LPL has been deduced by comparison of its sequence with that of the closely related pancreatic lipase (9). The active site of the enzyme is in a hydrophobic pocket protected by a surface loop ("lid"). LPL requires apolipoprotein CII (apoCII) for activity on lipoprotein substrates; apoCII is not related to the co-lipase needed for the action of pancreatic lipase. The exact mechanism by which apoCII activates LPL is unknown, but it has been speculated that it helps to orientate the lipase molecule at the oil-water interface at which the enzyme acts (9).

LPL binds strongly to heparin and related polysaccharides (13) *via* a groove on the side of the enzyme opposite the active site. The role of heparin binding appears to be to anchor the enzyme to heparin sulphate proteoglycans of the vascular endothelium (9). The catalytic mechanism of LPL is similar to that of pancreatic lipase and it preferentially releases fatty acids from the *sn*-1 and *sn*-3 positions of mono-, di- and triglycerides in emulsified lipid substrates. Since short- and intermediate-chain fatty acids are esterified mainly at these positions, the action of LPL results, in particular, in the release of these fatty acids. The apparent pH optimum of LPL on milk fat globules as substrate is ca. pH 8 (9).

In common with many lipases, LPL is subject to strong product inhibition (9). Since LPL can also catalyze the synthesis of ester bonds between fatty acids and partial glycerides, if the products of the hydrolysis (fatty acids) are not removed or complexed, LPL will spend much time producing fatty acids by hydrolysis and then using them as substrates for synthesis. In addition, fatty acids interfere with the binding of the enzyme to lipid droplets (14).

LPL in milk is associated mainly (>80%) with the casein micelles and its presence is of significance for lipolysis in milk and dairy products (9). Lipolysis occurs slowly in milk during storage, principally due to the action of LPL; it is only on prolonged storage or in cases of poor hygiene that bacterial lipases become important. Under ideal conditions (37°C, pH 7, in the presence of activators), raw milk should become rancid within a few minutes (9). Lipolysis in milk may be classified as spontaneous (i.e., without mechanical damage) or induced. Most milks do not exhibit spontaneous lipolysis. The incidence of induced lipolysis in milk has been reduced by improvement in design and operation of mechanical pipeline milking systems to avoid foaming or excessive shear forces during pumping. However, lipolysis may remain a problem if the milk is held for a long period before being transported to the dairy for processing.

LPL may cause lipolysis in raw milk but, since this enzyme is largely inactivated by pasteurization, its contribution to lipolysis in products made from pasteurized milk is minor. It is essential to pasteurize milk either before, or immediately after, homogenization, as the changes to the milk fat globule membrane would facilitate rapid lipolysis unless LPL is inactivated (9, 11).

LPL plays a role in lipolysis during ripening of cheese made from raw milk, or from sub-pasteurized milk (15). The presence of active LPL in raw milk cheese is one of the factors responsible for the difference in flavor between cheeses of the same variety made from raw or pasteurized milk, although heat-induced changes to the indigenous microflora of the cheesemilk are probably of greater importance (16).

A second lipase, bile salt-stimulated (or activated) lipase (BSSL), is found in the milks of humans and some primates, but not in those of domesticated milk-producing animals. BSSL is also present in pancreatic juice where it is referred to as "non-specific lipase" or "cholesteryl ester hydrolase." BSSL is found at high concentrations in human milk, where it is thought to improve the utilization of milk lipids by the neonate. Efforts are under way to produce this enzyme by fermentation with a view to supplementing infant formulae (9).

B. Indigenous Proteinases in Milk

1. The Plasmin/Plasminogen System

Babcock and Russel (17) first recognized the presence of indigenous proteolytic activity in raw milk. Today, the principal indigenous proteinase in milk is recognized to be the alkaline proteinase, plasmin (EC 3.4.21.7), which was first identified in milk by Kaminagowa et al. (18). Several reviews of the nature and significance of plasmin in milk have been published in recent years (19–23).

Plasmin is identical to the enzyme of the same name (which is also known as fibrinolysin) found in blood. That enzyme is a key element of the blood clotting mechanism (its role is in dissolving blood clots), and in that role its activity is, perhaps unsurprisingly, under the control of a complex and interconnected system of activators and inhibitors (24). It is thought that plasmin in milk originates from blood through leakage across the mammary gland secretory cell membranes, and to date almost all of the components of the blood plasmin system have also been found in milk, presumably through leakage (23). The principal elements of the plasmin system in milk are:

- Plasmin, the active enzyme, a serine proteinase of molecular weight 88,092 Da
- Plasminogen, its inactive zymogen (precursor)
- Plasminogen activators (PA), which proteolytically cleave plasminogen to yield active plasmin; there are two classes of PA in milk: tissue-type PA (tPA) and urokinase-type PA (uPA)
- Inhibitors of plasminogen activators (PAI)
- Inhibitors of plasmin (PI)

The properties of these elements of the plasmin system, where known, are summarized in Table 27.1. All the parts of the plasmin system listed above are indigenous to milk. In addition, some pathogenic bacteria associated with mastitis, i.e., infection of the mammary gland, such as *Streptococcus uberis*, possess PA activity, which they use to accelerate proteolysis in the infected udder (25). Furthermore, the proteolytic activity of some psychrotrophic bacteria can release plasmin from the casein micelles, where it is normally located, into the serum phase of milk, or whey (26, 27).

TABLE 27.1
Principal Constituents of the Plasmin System in Milk

Constituent	Function	Location
Plasmin	Active enzyme	Casein micelle
Plasminogen	Inactive zymogen	Casein micelle
Plasminogen activators (PA)		
Tissue-type (tPA)	Convert plasminogen to plasmin	Milk serum
Urokinase-type (uPA)	Convert plasminogen to plasmin	Somatic cells
Plasminogen activator inhibitors (PAI)	Inhibition of PA	Milk serum
Plasmin inhibitors (PI)	Inhibition of plasmin	Milk serum

a. *Proteolysis of Milk Proteins by Plasmin*

There are two principal classes of proteins in milk. The caseins (α_{s1}-, α_{s2}-, β- and κ-) are relatively hydrophobic proteins which occur, in milk, in the form of spherical micelles containing thousands of molecules of each casein, plus nanoclusters (small particles) of (colloidal) calcium phosphate; the structure of the caseins has been described as rheomorphic, which means that they have a high degree of conformational flexibility (28). The casein micelles are stabilized in the aqueous environment of milk by a "hairy layer" comprising the hydrophilic C-terminal glycoprotein moiety of κ-casein. The second class of milk proteins, the whey proteins, are globular proteins, the principal of which are β-lactoglobulin and α-lactalbumin.

Plasmin is an alkaline serine proteinase, with a temperature optimum of 37°C and a pH optimum of 7.5. It preferentially hydrolyzes peptide bonds of the type Lys-X and, to a lesser extent, Arg-X; of the caseins (CN), β-CN is its preferred substrate. Hydrolysis of this protein by plasmin yields three polypeptide products known as the γ-caseins (β-CN f29-209, f106-209, f108-209), as well as proteose peptones (PP) PP 5 (β-CN f1-105/7), PP8 fast (f1-28) and PP8 slow (f29-105/7) (29). In solution, plasmin also readily degrades α_{s2}-CN (30, 31), but peptides derived from it have not been identified in milk. While plasmin acts more slowly on α_{s1}-CN (32), a number of α_{s1}-CN-derived peptides, collectively known as the λ-caseins, have been identified in milk (33). κ-CN is resistant to hydrolysis by plasmin. The whey proteins are also resistant to proteolysis by plasmin, and β-lactoglobulin can, in fact, act as an inhibitor of plasmin activity.

b. *Factors Affecting Plasmin Activity in Milk*

Plasmin activity is usually measured in a citrate dispersion of milk or cheese, using either a fluorogenic or chromogenic substrate (34–36). Total activity (plasminogen plus plasmin) is measured after activation of plasminogen by added urokinase, and the level of plasminogen calculated by difference. Assays have also been described for activity of PA (37); the ratio of plasminogen to plasmin in milk is also frequently used as an indication of the extent of plasminogen activation.

One problem with enzymatic assays for plasmin is the presence of protease inhibitors in milk. Some methods for assaying this activity avoid such interference by centrifugation of plasmin, bound to casein, from milk and re-suspending the pellet in a buffer containing ε-amino-caproic acid, which releases the enzyme from the micelles, prior to assay (37). A new modified method uses a clarifying

reagent to reduce the turbidity of milk before fluorimetric analysis, without the need for more complex sample preparation (38). Alternatively, ELISA methods have been used to quantify plasmin levels in milk (39). However, different approaches will yield different information, for example, the exact concentration of plasmin in milk versus its actual proteolytic potential, as determined by all inhibitory substances present.

The activity of plasmin in milk is not constant, but varies due to a number of factors. Furthermore, there are several mechanisms by which plasmin activity can be modulated in milk, which leads to a complex multi-factorial system influencing the net plasmin activity in fresh raw milk.

The two principal routes by which plasmin activity in milk may be increased are (40):

- Increased transport of active plasmin from blood
- Increased conversion of plasminogen to plasmin by PA

These two routes are not independent; the increased permeability of the blood/milk barrier which facilitates the first route also increases the levels of PAs (41, 42). For example, somatic cells in milk possess PA activity, and can thereby activate plasminogen.

The principal factors which affect plasmin activity in milk are summarized in Table 27.2.

When milk is refrigerated, proteolysis is reduced greatly, although β-casein dissociates from the casein micelles into the serum (43), which should, in theory, facilitate proteolysis. However, at 4°C, no activation of plasminogen occurs and the activity of plasmin decreases over time (44).

Plasmin activity is further affected by the processing of raw milk. The effect of pasteurization on plasmin activity in milk is complex. The heat treatment per se (typically heating to 72–74°C for 15–30 s in a plate heat exchanger) slightly reduces the activity of plasmin. However, inhibitors of PA are believed to be inactivated by pasteurization, which accelerates the subsequent conversion of plasminogen to plasmin (in the absence of down-regulation by these inhibitors), and eventually causes a net increase in plasmin activity in pasteurized milk relative to raw milk (45).

More severe heat treatments than pasteurization result in far more significant inactivation of plasmin in milk. In general, the inactivation of plasmin in milk is thought to be linked to the denaturation of the whey protein, β-lactoglobulin (β-lg); thermal denaturation of the latter protein exposes a highly reactive sulphydryl group, which can undergo disulphide-sulphydryl interchange reactions with disulphide bonds which are key structural features of the molecular conformation of plasmin. In the absence of β-lg, plasmin is very heat resistant, and will refold to an active state after thermal unfolding; however, in the presence of β-lg, heat-induced formation of heterologous disulphide-linked complexes prevents such refolding, and leads to loss of enzyme activity. In ultra-high-temperature (UHT)-treated milk, for example, plasmin activity is very low (46, 47).

In fact, heating milk to a temperature sufficient to denature β-lg reduces proteolysis therein by two mechanisms: enzyme inactivation, as discussed above, and complexation of denatured β-lg with casein micelles, which may sterically hinder access of the enzyme to cleavage sites on the caseins (48).

c. Significance of Plasmin in Milk and Dairy Products

In pasteurized liquid milk, proteolysis of casein by plasmin during storage has little direct impact: while, in principle, such action could result in physical instability (as will be discussed below for UHT milk) or development of bitterness (through the liberation of small hydrophobic peptides), the growth of psychrotrophic bacteria, such as *Bacillus* species, is generally the principal determinant of shelf life (49).

However, in long shelf-life milk products (such as UHT milk), where bacterial growth and activity do not occur, and the product is often stored at ambient temperature, even the low residual activity of plasmin remaining

TABLE 27.2
Farm-level Factors Affecting Plasmin Activity in Milk

Factor	Comments on Known Effects
Stage of lactation	Plasmin activity generally increases in late lactation
Mastitis	Plasmin activity is generally well correlated with milk somatic cell count (SCC); levels of protease inhibitors in milk also increase mastitis
Diet	Restricted diets increase plasmin activity, especially in late lactation
Breed of cow	Milk from Fresian cows has higher plasmin activity than that of Jersey cows
Age of cow	Plasmin activity is higher in milk from older cows
Genotype	Milk with different genotypes of β-lactoglobulin can vary in plasmin activity
Hormone usage	Somatotrophin suppresses plasmin in milk; estrogen increases activation of plasminogen to plasmin.

after the severe heat treatment applied (typically, 135–140°C for 2–4 sec) can contribute to proteolysis, albeit at a very low level, during storage. Furthermore, it has been suggested that such slow hydrolysis of caseins may be linked to the occurrence of physical changes in the milk, such as irreversible gelation during storage (46, 47).

Plasmin activity can potentially influence cheese quality in two main ways. Firstly, pre-manufacture hydrolysis of the caseins has been shown to affect the rennet coagulation properties of milk (50, 51); while rennet coagulation times can actually be reduced by plasmin action, gels formed from hydrolyzed milk are weaker than those from control milk (although these effects may be confounded by other changes in milk with elevated plasmin activity, such as late lactation or mastitic milk). Secondly, plasmin in curd is an important contributor to primary proteolysis of the caseins during cheese ripening. The activity of plasmin in cheese is directly affected by the cheese manufacture protocol (e.g., a high curd cooking temperature increases the relative contribution of plasmin to ripening) and the physicochemical environment of the cheese (e.g., pH, temperature, etc.). Studies involving either inhibition or augmentation of plasmin activity in cheese (the latter to investigate the possibility of using plasmin to accelerate cheese ripening) have shown that it probably does not contribute directly to cheese flavor, being principally involved in production of large polypeptides, rather than amino acids (52).

2. Other Indigenous Proteinases in Milk

Milk from a healthy cow contains a low level (<200,000 cells/ml) of white blood (somatic) cells. On mastitic infection, the somatic cell count (SCC) of milk increases rapidly and markedly, principally due to a massive influx of one type of white blood cell, polymorphonuclear leucocytes (PMN). Somatic cells in milk possess lysosomes which contain a range of proteolytic and other enzymes, the significance of which for the quality of dairy products is ill-defined (21).

Proteolytic activity in milk is correlated with its SCC; while part of this is unquestionably due to increased plasmin activity (Table 27.2), it is acknowledged that lysosomal proteinases contribute to proteolysis. This can be estimated by using specific assays for a range of proteolytic enzymes, or by examining the nature and origin of hydrolytic products in milk samples with different SCC (53, 54).

The second proteinase to be identified conclusively in milk was the lysosomal aspartic proteinase cathepsin D (55, 56). This enzyme is present in a number of different molecular forms in milk, not all of which are proteolytically active, and is located in the serum phase of milk (57). Cathepsin D activity in milk may be assayed using haemoglobin or synthetic chromogenic peptides as substrate; its activity is actually quite low, relative to that of plasmin (proteolysis patterns in fresh milk quite closely reflect those of the latter enzyme). Cathepsin D at least partially survives pasteurization (58, 59).

The proteolytic activity of cathepsin D and chymosin on α_{s1}-casein are very similar; cathepsin D is quite active on this substrate (60, 61). β-Casein is also hydrolyzed readily by cathepsin D, yielding a pattern similar, but not identical, to those produced by chymosin (60, 61). The action of cathepsin D on bovine α_{s2}-casein produces a hydrolysis pattern quite different from that produced from this substrate by chymosin (60, 61). As for plasmin, the whey proteins are relatively resistant to the action of cathepsin D, compared with the caseins (60).

κ-Casein, the micelle-stabilizing protein, is hydrolyzed by cathepsin D at the Phe_{105}-Met_{106} position, the bond cleaved by chymosin during the rennet coagulation of milk (60, 61). Thus, it might be expected that cathepsin D could coagulate milk; however, exogenous cathepsin D coagulates milk very slowly (60, 61). The ability of cathepsin D to coagulate milk is strongly pH-dependent and is faster at lower pH, reflecting the low pH optimum of the enzyme. The level of indigenous cathepsin D in milk (ca. 0.4 μg ml^{-1}) is much lower than that required to cause coagulation of milk within a reasonable time, even under ideal conditions; thus, the action of indigenous cathepsin D probably does not significantly influence rennet coagulation, particularly if cheese is made from pasteurized milk (60). However, the enzyme may contribute to the degradation of κ-casein in other dairy products during prolonged storage.

In terms of the significance of cathepsin D for other products, most studies to date have focused on cheese, where it is extremely difficult to discern its contribution due to its close resemblance to chymosin. However, evidence of its activity has been reported in Swiss cheese and, most significantly, in Feta-like cheese made from thrice-pasteurized milk without the use of rennet (59) and in Quarg made from pasteurized milk without use of rennet (62).

Cathepsin D is probably only one of a number of lysosomal proteolytic enzymes in milk; it seems almost inevitable that other enzymes from this source are present in milk, at levels proportional to the SCC of milk. However, this area has received little attention to date. Many lysosomal proteinases are cysteine proteinases (including cathepsins B, L and H); cysteine proteinase activity in milk, due to the presence of at least two separate enzymes, and strongly correlated with SCC, has been reported by two independent groups (63, 64). The presence of immunoreactive cathepsin B in normal milk has been demonstrated (63). The specificity of cathepsin B on the caseins has also been determined recently (65).

The principal serine proteinase in the polymorphonuclear leucocytes (PMN), the principal type of somatic cell found in milk during mastitis (66), is elastase, an inhibitor of which has been found in milk (67); another important

somatic cell proteinase is cathepsin G. There have also been sporadic reports of other indigenous proteolytic enzymes in bovine milk, such as an indigenous lysine aminopeptidase (68), but the presence of this enzyme has not been confirmed.

In general, it may be argued that the levels of proteinases other than plasmin in normal milk are too low to have an influence on the quality of dairy products; however, this area warrants further attention.

C. Enzymes Involved in Phosphoryl Transfer

Four categories of enzymes are involved in the transfer of the phosphoryl group: phosphatases (EC 3.1.3…), phosphodiesterases (EC 3.1.4…), kinases (EC 2.7.1…– EC 2.7.6…) and phosphorylases (EC 2.4.1… and EC 2.4.2…). The most important phosphohydrolyases in milk are two types of phosphomonoesterases (phosphatases), alkaline phosphatase and acid phosphatase. A number of other activities have been found in milk, including 5′-nucleotidase, glucose-6-phosphatase, phosphodiesterase I, deoxyribonuclease (DNase), ribonuclease (RNase), inorganic pyrophosphatase, adenosine triphosphatase and nucleotide pyrophosphatase. This class of enzymes in milk has been reviewed regularly (69–71).

The major indigenous phosphomonoesterase in milk is alkaline phosphatase (EC 3.1.3.1). This enzyme is a dimeric glycoprotein (85 kDa subunits), requiring 4 Zn atoms per molecule for activity; it is activated by divalent metal ions (Ca^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, Mg^{2+}) and inhibited by metal chelators and orthophosphates. The enzyme is present mainly in the milk fat globule membrane. Alkaline phosphatase is optimally active in the pH 9–10.5 range and at 37°C (70).

The thermal inactivation kinetics of alkaline phosphatase have been studied thoroughly as residual alkaline phosphatase activity is widely used as an index of pasteurization (72). The enzyme is slightly more heat-resistant than *Mycobacterium tuberculosis*, which for many years was the most heat-resistant vegetative pathogen known in milk and the target organism for pasteurization. Results of "phosphatase tests" below certain limits are required for certification of pasteurized milk in many countries. However, the use of alkaline phosphatase as a marker enzyme for pasteurization suffers from a number of drawbacks (73):

- Some microorganisms in certain types of cheese (e.g., some lactic acid bacteria and *Penicillium roqueforti*) have alkaline phosphatase activity and thus certain cheeses, made from properly pasteurized milk, may exhibit a positive phosphatase test.
- Reactivation of alkaline phosphatase can occur following certain heat treatments equivalent to, or greater than, pasteurization (e.g., temperatures of 82–180°C for milk or 74–180°C for cream for a short time).
- The enzyme appears to be inactivated fully by sub-pasteurization conditions (70°C × 16 s).
- The relationship between pasteurization equivalent and log (% residual activity) is less linear for alkaline phosphatase than for some other indigenous enzymes in milk (e.g., lactoperoxidase or γ-glutamyl transpeptidase).

The major technological importance of alkaline phosphatase is its use as a marker enzyme for pasteurization; no other technological roles have been confirmed (70).

An indigenous acid phosphatase (EC 3.1.3.2) in milk was reported first in the 1940s. A high proportion of the total acid phosphatase activity in milk is in skim milk, although cream contains a higher specific activity. This enzyme is a glycoprotein with a molecular mass of ca. 42 kDa and a pI of 7.9, containing a high level of basic amino acids but lacking methionine. It is inhibited by several heavy metals, F^-, oxidizing agents, orthophosphates and polyphosphates, activated by thiol reducing agents and ascorbate and is unaffected by metal-chelating agents (70). The enzyme is active against phosphoproteins, including the caseins, and is quite heat-stable, surviving HTST pasteurization but being inactivated by UHT treatments. Although a lower level of acid phosphatase activity than alkaline phosphatase activity is found in milk, acid phosphatase may be technologically important, due to its lower pH optimum (ca. 3.5–5), which is closer to the pH of many fermented dairy products (70).

There have been reports that milk contains more than one indigenous acid phosphatase (70), although it is likely that this heterogeneity is due to leukocyte enzymes from somatic cells, some of which are always present in milk.

As discussed by Shakeel-Ur-Rehman et al. (70), several small partially dephosphorylated peptides have been isolated from a number of cheese varieties, although it is not entirely clear whether indigenous or endogenous (starter) phosphatases are responsible for their production. However, the activity of the indigenous acid phosphatase is thought to be important.

Milk also contains two indigenous acid phosphatases of leukocyte (somatic cell) origin; the acid phosphatase activity of milk increases 4–10 fold during mastitis (74–76).

Nucleases are particular types of phosphodiesterases which hydrolyze the phosphodiester linkages in nucleic acids. As reviewed by Stepaniak et al. (77), milk is a rich source of RNase, which is almost entirely located in the serum phase, and is optimally active at ~pH 7.5. A number of isoenzymes of RNase are present in milk, principally RNase A (which is identical to pancreatic RNase A) and RNase B, in a ratio of about 4:1. Bovine milk contains approximately 3 times as much RNase as human, ovine or

caprine milk. Most of the RNase activity in milk survives HTST pasteurization, although activity is essentially completely lost on UHT treatment. There has also been one report of indigenous DNase activity in milk (77).

D. Lactoperoxidase

Milk contains natural inhibitors ("lactenins") of the growth of susceptible strains of starter bacteria. Further study has shown the lactenins to be antibodies (which cause susceptible bacteria to aggregate and localized acid production) and lactoperoxidase. Lactoperoxidase, an oxidoreductase, is a glycoprotein consisting of a single peptide chain with a molecular weight of 78,000 Da; it is a haem protein, with one iron molecule bound per mole of enzyme, and its stability depends on binding of a chelated calcium ion (78–80).

This enzyme catalyzes the following reactions:

(1) $$H_2O_2 + 2HA \rightarrow 2H_2O + 2A \qquad (27.1)$$

where the substrate, HA, can be one of several compounds, including aromatic amines, phenols, vitamin C.

(2) oxidation of thiocyanate (CNS^-) by H_2O_2 (27.2)

The products of reaction 27. 2, particularly the hypothiocyanate anion ($OSCN^-$), inhibit many bacteria; this inhibition is particularly effective against bacteria which produce H_2O_2, such as lactic acid bacteria. It is believed that hyopthiocyanate can oxidize vital bacterial enzymes and sulphydryl groups in the cytoplasmic membrane, impairing its transport properties (81). Lactoperoxidase itself has no antibacterial action, but merely catalyzes the formation of antibacterial substances (e.g., the hypothiocyanate anion) from precursors.

The inhibition may be temporary (especially for Gram-positive bacteria such as streptococci and lactobacilli) or permanent and lethal (for Gram-negative catalase-positive bacteria such as *E. coli*, *Salmonellae* and *Pseudomonas* spp.) (78, 82).

However, while there is always a relatively constant and high level of lactoperoxidase in milk (30 mg/L, a 30-fold excess of the minimum required to achieve microbial inhibition), the concentrations in milk of other critical components and substrates of the system can vary widely (79). For example, the level of thiocyanate is generally limiting and depends on the availability of precursor substances (such as cyanoglucosides) in the feed (plants of the brassica family, e.g., cabbage, are rich in these); the origin of the very low level of H_2O_2 naturally present in milk is unclear, but may be related to the action of milk leucocytes and mammary tissues, the presence of catalase-positive microorganisms or the action of xanthine oxidase (79). The total antibacterial action is proportional to the production of the inhibitory end-products, and hence this can also vary (78).

The lactoperoxidase system can be exploited to prevent the spoilage of raw milk by adding thiocyanate (typically 10 mg kg^{-1} of a powdered preparation), followed by thorough mixing and addition of a small amount of H_2O_2 (often in the form of granular sodium carbonate peroxyhydrate) (83). This method has particular applications in countries with a warm climate, where it can allow milk to be stored at a relatively high temperature (e.g., 30°C for 7–8 hours, or 20°C for 16–17 hours) (84). This allows producers without cooling facilities to transport milk to central cooling and processing centers, and has significant economic implications for milk-producing farmers in developing countries. A Code of Practice for the application of this method for preserving milk was approved by the FAO/WHO Expert Committee on Food Additives in 1989 and by the Codex Alimentarius Commission in 1991. Ideally, the natural thiocyanate content of the milk should be determined, in a centralized testing facility, before determining the level of thiocyanate to be added.

The effectiveness of the lactoperoxidase system can also be enhanced by adding xanthine oxidase to milk, an indigenous oxidizing enzyme which can produce H_2O_2 from substances such as xanthine and hypoxanthine.

Lactoperoxidase treatment of milk is not regarded as a treatment suitable for liquid milk, but rather as a processing aid which merely enhances a naturally occurring functionality of the milk; quality of the raw milk must still be good. The lactoperoxidase system has also been exploited in mastitis therapy during the dry period, control of post-fermentation acidification of yoghurt, preservation of HTST pasteurized milk and stabilization of dairy emulsions. The system has also been applied in cosmetics, ophthalmic solutions, dental and wound treatments, toothpastes and mouth rinses, and anti-tumor, anti-bacterial and anti-viral products (for a review of applications of lactoperoxidase, see Ref. 85).

Lactoperoxidase is considerably more heat-resistant than, for example, alkaline phosphatase, having a D-value at 80°C of 4 sec, and a very high Q_{10} value (72, 86).

E. Other Indigenous Enzymes

Approximately 60 enzyme activities have been identified in milk, although most have not been studied in detail. As discussed by Fox (2) and Farkye (87), some indigenous enzymes present at low levels in milk have an established function for the development of the neonate, while others may be present in milk simply because of the way in which it is synthesized in the udder or through leakage from the blood. A partial list of minor enzyme activities identified in milk is shown in Table 27.3; most of these enzymes have no technological significance.

Putative roles have been suggested by Farkye (87) for some indigenous enzymes in milk present at low concentrations, although it should be stressed that many of these

TABLE 27.3
Partial List of Minor Enzyme Activities in Milk (Modified from Ref. 87)

EC No.	Enzyme	Reaction Catalyzed	Location in Milk
1.1.1.14	L-Iditol dehydrogenase	L-Iditol + NAD^+ ⇆ L-sorbose + NADH	SM
1.1.1.27	L-Lactate dehydrogenase	L-lactate + NAD^+ ⇆ pyruvate + NADH + H^+	?
1.1.1.37	Malate dehydrogenase	Malate + NAD^+ ⇆ oxaloacetate + NADH	SM
1.1.1.40	Malic enzyme (oxaloacetate-decarboxylating) ($NADP^+$)	Malate + $NADP^+$ ⇆ pyruvate + CO_2 + NADPH	SM
1.1.1.42	Isocitrate dehydrogenase ($NADP^+$)	Isocitrate + $NADP^+$ ⇆ 2-oxogluterate + CO_2 + NADPH	SM
1.1.1.44	Phosphoglucuronate dehydrogenase (decarboxylating)	6-Phospho-D-gluconate + $NADP^+$ ⇆ D-ribulose 5-phosphate + CO_2 + NADPH	SM
1.1.1.49	Glucose-6-phosphate dehydrogenase	D-Glucose-6-phosphate + $NADP^+$ ⇆ D-glucono-1,5-lactone 6-phosphate + NADPH	SM
1.1.3.22	Xanthine oxidase	Xanthine + H_2O + O_2 ⇆ uric acid + $O_2^{(-\cdot)}$ Xanthine + NAD^+ + H_2O ⇆ uric acid + NADH	FGM
1.4.3.6	Amine oxidase (Cu-containing)	RCH_2NH_2 + H_2O + O_2 ⇆ RCHO + NH_3 + H_2O_2	SM
_	Polyamine oxidase	Spermine → spermidine → putrescine	SM
_	Sulphydryl oxidase	2RSH + O_2 → RSSR + H_2O_2	SM
_	Fucosyltransferase	Catalyzes transfer of fucose from GDP L-fucose to specific oligosaccharides and glycoproteins	SM
1.6.99.3	NADH dehydrogenase	NADH + acceptor ⇆ NAD^+ + reduced receptor	FGM
1.8.1.4	Dihydrolipomide dehydrogenase (diaphorase)	Dihydrolipomide + NAD ⇆ lipoamide + NADH	SM/FGM
1.11.1.6	Catalase	$2H_2O_2$ ⇆ $2H_2O$ + O_2	SM/FGM
1.11.1.9	Glutathionine peroxidase	2GSH + H_2O_2 → GSSH + $2H_2O$	SM
1.15.1.1	Superoxide dismutase	$2O_2^{(-\cdot)}$ + $2H^+$ → H_2O_2 + $O_2^{\bullet}$	SM
2.3.2.2	γ-Glutamyl transferase	(5L-Glutamyl)-peptide + amino acid ⇆ peptide + 5-L-glutamyl-amino acid	SM/FGM
2.4.1.22	Lactose synthetase A protein UDP-galactose: D-glucose, 1-galactosyl-transferase B protein: α-lactalbumin	UDP galactose + D-glucose ⇆ UDP + lactose	SM
2.4.1.38	Glycoprotein 4-β-galactosyltransferase	UDP galactose + *N*-acetyl-D-glucosaminyl-glycopeptide ⇆ UDP + 4-β-D-galactosyl-*N*-acetyl-D-glucosaminylglycopeptide	FGM
2.4.1.90	*N*-Acetyllactosamine synthase	UDP galactose + *N*-acetyl-D-glucosamine ⇆ UDP + *N*-acetyllactosamine	
2.4.99.6	CMP-N-acetylneuraminate-galactosyldiacyl-glycerol α-2,3-sialyltransferase	CMP-*N*-acetylneuraminate + β-D-galactosyl-1,4-*N*-acetyl-D-glucosaminyl-glycoprotein ⇆ CMP + α-*N*-acetylneuraminyl 1-2,3-β-D-galactosyl-1,4-*N*-acetyl-D-glucosaminyl-glycoprotein	SM
2.5.1.3	Thiamin-phosphate pyrophosphorylase	2-Methyl-4-amino-5-hydroxy-methylpyrimidinediphosphate + 4-methyl-5-(2-phosphonooxyethyl)-thiazole ⇆ pyrophosphate + thiamine monophosphate	FGM
2.6.1.1	Aspartate aminotransferase	L-Aspartate + 2-oxoglutarate ⇆ oxaloacetate + L-glutamate	SM
2.6.1.2	Alanine aminotransferase	L-Alanine + 2-oxoglutarate ⇆ pyruvate + L-glutamate	SM
2.7.7.49	RNA-directed DNA polymerase	n Deoxynucleoside triphosphate ⇆ n pyrophosphate + DNA_n	SM
2.8.1.1	Thiosulphate sulphurtransferase	Thiosulphate + cyanide ⇆ sulphite + thiocyanate	SM
3.1.1.8	Cholinesterase	An acylcholine + H_2O ⇆ choline + a carboxylic acid anion	FGM
3.1.3.4	Phosphatidate phosphatase	A 3-*sn*-phosphatidate + H_2O ⇆ a 1,2-diacyl-*sn*-glycerol + orthophosphate	FGM
3.1.3.5	5′-Nucleotidase	5′-Ribonucleotide + H_2O ⇆ ribonucleoside + Pi	FGM
3.1.3.9	Glucose-6-phosphatase	D-Glucose 6-phosphate + H_2O ⇆ D-glucose + Pi	FGM
3.1.4.1	Phosphodiesterase I	Removes 5′-nucleotides successively from the 3′-hydroxy terminal of 3′-hydroxy-terminated oligonucleotides	FGM
3.1.6.1	Arylsulphatase	A phenol sulphate + H_2O ⇆ a phenol + sulphate	
3.2.1.1	α-amylase	Hydrolyzes 1,4-α-D-glucosidic linkages in polysaccharides containing at least three 1,4-α-linked D-glucose units	?

(*Continued*)

TABLE 27.3 (*Continued*)

EC No.	Enzyme	Reaction Catalyzed	Location in Milk
3.2.1.17	Lysozyme	Cleaves 1,4-β-linkages between *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine residues in peptidoglycan	?
3.2.1.21	β-Glucosidase	Hydrolysis of terminal non-reducing β-D-glucose	FGM
3.2.1.23	β-Galactosidase	Hydrolysis of terminal non-reducing β-D-galactosides	FGM
3.2.1.24	α-Mannosidase	Catalyzes the hydrolysis of terminal, non-reducing residues from α-D-mannosides	SM
3.2.1.30	*N*-Acetyl-β-D-glucosaminidase	Hydrolysis of terminal non-reducing *N*-acetyl-β-D-glucosamine residues from glycoproteins	SM??
3.2.1.31	β-Glucuronidase	β-D-glucuronoside + H_2O ⇆ alcohol + D-glucuronic acid	?
3.2.1.51	α-L-Fucosidase	An α-L-fucoside + H_2O ⇆ alcohol + L-fucose	—
3.4.11.1	Cystol aminopeptidase (leucine aminopeptidase)	Aminoacyl-peptide + H_2O ⇆ amino acid + peptide	SM
3.4.11.3	Cystinyl-aminopeptidase (oxytocinase)	Cystinyl-peptide + H_2O ⇆ amino acid + peptide	SM
3.4.21.4	Trypsin	Hydrolyzes peptide bonds, preferentially Arg-X, Lys-X	SM
3.6.1.1	Inorganic pyrophosphatase	Pyrophosphate + H_2O ⇆ 2 orthophosphate	SM/FGM
3.6.1.3	Adenosine triphosphatase	ATP + H_2O → ADP + Pi	FGM
3.6.1.6	Thiamine pyrophosphatase (nucleoside diphosphatase)	A nucleoside diphosphate + H_2O ⇆ a nucleotide + orthophosphate	FGM
3.6.1.9	Nucleotide pyrophosphatase	A dinucleotide + H_2O ⇆ 2 mononucleotides	SM/FGM
4.1.2.13	Fructose-biphosphate aldolase	D-Fuctose-1,6-biphosphate ⇆ glycerol phosphate + D-glyceraldehyde-3-phosphate	SM
4.2.1.1	Carbonate dehydratase	H_2CO_3 ⇆ CO_2 + H_2O	SM
5.3.1.9	Glucose-6-phosphate isomerase	D-Glucose 6-phosphate ⇆ D-fructose 6-phosphate	SM
6.4.1.2	Acetyl-CoA carboxylase	ATP + acetyl-CoA + HCO_3^- ⇆ ADP orthophosphate + malonyl-CoA	FGM

SM = skim milk; FGM = fat globule membrane.

hypotheses are highly speculative and that further research is necessary for their validation.

Some of these are summarized below:

- L-Lactate dehydrogenase, catalase, β-glucuronidase and *N*-acetyl-β-D-glucoseaminidase have been suggested as marker enzymes for mastitis.
- Inactivation of α-mannosidase has been suggested as a method to monitor heat treatment of milk at a temperature between 80 to 90°C.
- Glutathione peroxidase is a selenoenzyme and thus is a source of Se in milk.
- Indigenous lysozyme may have an antibacterial effect. Lysozymes (muramidase, peptidoglycan-*N*-acetylmuramoyl hydrolase) cleave the glycosidic linkage between *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine in the peptidoglycan of bacterial cell walls.
- Sulphydryl oxidase in milk produces H_2O_2, which may be involved in the antibacterial lactoperoxidase system in milk.
- Superoxide dismutase may play a role in maintaining the oxidative stability of milk by scavenging the superoxide ions produced by xanthine oxidase.
- Xanthine oxidase, one of the most well-studied indigenous enzymes in milk, plays a role in the metabolism of purines, catalyzing the oxidation of hypoxanthine to xanthine, of xanthine to uric acid and the superoxide anion. It has been suggested that xanthine oxidase might be involved in the development of a spontaneous oxidized flavor in milk, although studies disagree on its role in this defect. It had been suggested that xanthine oxidase plays a role in the development of atherosclerosis, but this hypothesis has been disproved.
- Catalase, which contains iron, may act non-enzymatically to promote lipid oxidation.

III. EXOGENOUS ENZYMES

A. Milk Coagulants

It is speculated that rennet-coagulated cheese developed accidentally, due to the separation into curds and whey of milk stored in bags made from animal stomachs. Scientific study of this phenomenon revealed that such stomachs contain enzymatic activity with milk-clotting activity (MCA). The nature and composition of this activity changes with age of the cow; an extract of calf contains predominantly

the aspartic proteinase, chymosin, with a small amount of pepsin. With increasing age, however, the proportion of chymosin decreases, while that of pepsin increases.

While many proteinases will coagulate milk under suitable conditions, many decades of investigation of other enzymes suitable for coagulation of milk for industrial cheesemaking failed to uncover an enzyme better than chymosin. The first commercially available standardized calf-derived coagulant preparation was produced by Christian Hansen in 1874. Rennet was the first enzyme industrially produced and sold with a standardized enzyme activity. The characteristics of chymosin as a milk coagulant have been reviewed (88–93).

Calf chymosin has a very high specificity for the Phe_{105}-Met_{106} bond of bovine κ-casein; this is thought to be partly due to electrical attraction between the positively charged region of the protein from residues 98 to 111 and the negatively charged active site of the enzyme, and also to structural conformation of the binding pocket of the enzyme relative to this region of the substrate protein. Cleavage of this bond removes the glycosylated region of the protein (glycomacropeptide, GMP); the remainder of the molecule is referred to as para-κ-casein (κ-CN f1-105). The enzymatic reaction is first-order and diffusion-limited in nature; the velocity of the reaction depends greatly on pH and temperature.

The portion of the molecule removed by chymosin, known as the caseinomacropeptide (CMP), stabilizes the hydrophobic caseins as micelles in the aqueous environment of milk, by mutual electrostatic and steric repulsion of individual micelles. Removal of the GMP reduces the zeta potential of casein micelles, and greatly destabilizes them. When denuded of a critical level (~80%) of this protective coating, in the presence of a sufficient level of calcium and at a temperature above 18°C, the casein micelles begin to aggregate, at first into chains and clusters, but finally coalescing into a three-dimensional network, which results in the gelation of the milk (for a review of the manner in which coagulants destabilize the casein micelle, see Ref. 94).

Chymosin is an aspartic proteinase (MW 35,600 Da) with a pH optimum for proteolytic activity around 4. Chymosin has been very well characterized at the enzymatic and molecular levels. While it exhibits a very high specificity for the Phe_{105}-Met_{106} bond of κ-casein, chymosin is also generally proteolytically active on the caseins. However, during the coagulation of milk, the reaction which causes milk coagulation occurs at such a relatively rapid rate that very little additional proteolysis occurs during the course of cheesemaking; hence, the loss of peptides in whey is very low. This unusually low level of non-specific proteolysis during cheesemaking (in comparison to other milk coagulants) is the main reason why chymosin is regarded as such an ideal milk coagulant (95).

While most of the chymosin added to milk in cheesemaking is lost in the whey, some adsorbs onto the caseins and is incorporated into the cheese curd; in addition, some is retained in the serum phase (whey) within the cheese (96). Along with plasmin, chymosin is one of the most significant agents during the early stages of ripening of many cheese varieties, hydrolyzing the caseins to large polypeptides that are further degraded by starter bacterial proteinases and peptidases. Chymosin hydrolyzes α_{s1}- and β-caseins quite readily (95). The hydrolysis of β-casein at pH 6.5 is strongly inhibited by increasing salt concentration, due to hydrophobic interactions, which shield chymosin-sensitive peptide bonds; this inhibitory effect is reduced at lower pH values. Chymosin principally hydrolyzes α_{s1}-casein at the Phe_{23}-Phe_{24} bond, yielding the peptides α_{s1}-CN (f1-23) and α_{s1}-CN (f24-199; sometimes known as α_{s1}-I-casein); this cleavage reaction plays a role in the initial softening of cheese texture during ripening (97). However, several other bonds in α_{s1}-casein are also cleaved by chymosin in cheese. α_{s2}-Casein is relatively resistant to hydrolysis by chymosin (95).

The activity of chymosin is generally evaluated by activity tests which measure the ability of an extract or preparation containing the enzyme to coagulate milk under controlled conditions (temperature, pH, etc.). More recently, a more sensitive and objective method was developed in the authors' laboratory; this test uses reversed-phase high-performance liquid chromatography (RP-HPLC) to measure the hydrolysis of a synthetic heptapeptide substrate by chymosin (98).

The optimum temperature for the coagulation of milk by chymosin is 45°C, but at temperatures above 50°C the enzyme is rapidly inactivated (99). This inactivation is responsible for the low chymosin activity in Swiss-type cheese, which is cooked during manufacture at around 55°C; the resultant lack of primary proteolysis of α_{s1}-casein in these cheeses during ripening contributes to their rubbery and elastic texture. Pasteurization of whey almost completely inactivates the enzyme, facilitating further processing of this by-product of cheese manufacture.

In the 1970s, the availability of calf stomachs became limited due to increased demand for rennets and reduction in the number of calves slaughtered, leading to an intense search for novel milk coagulants. An ideal alternative to chymosin as a coagulant for milk would:

- Be an acid proteinase capable of hydrolyzing κ-casein at approximately the same position as chymosin
- Possess a similar ratio of MCA to overall proteolytic activity
- Have an MCA that is not very pH dependent in the region 6.5–6.9
- Have thermostability comparable to that of calf rennet at the pH values and temperatures used during cheesemaking

- Have low thermostability during whey processing
- Possess the ability to produce desired flavor, body and texture characteristics in the finished cheese (100)

One result of this search was the identification of a number of microbial coagulants, as will be discussed below; the other was the application of the developing discipline of biotechnology to the production of pure chymosin (fermentation-produced chymosin, FPC) from genetically manipulated microorganisms, such as *E. coli*, *Aspergillus niger* and *Kluyveromyces lactis* (101, 102). More recent public concerns over bovine-related health issues (such as BSE and foot-and-mouth disease) have further increased demand for FPC and other alternatives to traditional rennets.

Among the principal advantages of FPC today are:

- Constant, controlled activity of a very pure enzyme
- Guaranteed supply
- Suitability for vegetarian, Kosher or Halal cheese

FPCs are identical in amino acid sequence to calf chymosin, and differences from the latter enzyme may occur only due to differing degrees of glycosylation by the host microorganism; such changes, however, have not been found to influence the properties of the enzyme. FPCs have been intensively studied in cheesemaking trials and generally found to give very satisfactory results (103), and are now widely used commercially in many countries.

Substitutes for chymosin used as coagulants include pepsins (bovine, porcine and to a lesser extent, chicken) and microbial proteinases from *Rhizomucor miehei*, *R. pusillus* and *Cryphonectria parasitica*. However, the fungal rennet substitutes are now used most commonly. Interestingly, *C. parasitica* proteinase cleaves κ-casein at Ser_{104}-Phe_{105} rather than at the Phe_{105}-Met_{106} bond, which is cleaved by chymosin, pepsins and the other fungal proteinases. *C. parasitica* proteinase has relatively high heat stability. The use of coagulants more heat stable than calf rennet should be avoided; otherwise, excess proteolytic activity may remain in the curd and may result in excessive proteolysis and bitterness unless ripening times and/or cooking temperatures are changed to compensate for the more rapid rate of proteolysis (96).

Plant rennets have a long history; the use of fig rennet was mentioned in Homer's *Iliad*. However, most plant coagulants are too proteolytic relative to their MCA, resulting in a reduced yield of curd and the development of bitterness during ripening. An exception is a protease from dried flowers of the cardoon thistle, *Cynara cardunculus*, which contain two enzymes, cardosins A and B, and which have been used successfully for many centuries in the Iberian Peninsula for the manufacture of some traditional cheeses, e.g., Serra da Estrela, La Serena, Los Pedroches (104).

Commercial rennet extracts are free from lipolytic activity. However rennet paste, which does contain lipolytic activity, is used in the manufacture of some hard Italian varieties (e.g., Provolone, Pecorino Romano and many Pecorino cheeses). Rennet pastes are prepared from the abomasa of calves, kids or lambs slaughtered after suckling. The abomasum and contents are partially dried and ground into a paste, which is slurried in milk before being added to the milk from which cheese is to be made. Rennet paste contains a lipase, pregastric esterase (PGE), which is highly specific for short-chain acids esterified at the *sn*-3 position. Suckling stimulates the secretion of PGE by glands at the base of the tongue, and it is washed into the abomasum with the milk. Due to concerns regarding the hygienic quality of rennet pastes, research has been focused on exogenous lipases which could be blended with rennet extracts to produce substitutes for rennet pastes; certain fungal lipases may be acceptable alternatives, as are semi-pure preparations of PGE (100).

B. Acceleration of Cheese Ripening and Enzyme-Modified Cheeses

In addition to their use as coagulants, exogenous enzymes have been investigated as possible agents to accelerate the ripening process of cheese. Cheese ripening is a slow, and consequently expensive, process in which the bland-flavored immature curd develops the flavor and texture characteristic of the mature cheese. Although soft (high moisture) varieties ripen quickly, the ripening period of hard cheeses is quite long (e.g., 6–24 months for Cheddar). A number of strategies have been investigated to reduce this ripening period, including the use of an elevated temperature, exogenous enzymes, slurry systems, adjunct cultures and high pressure treatment (105–108).

Proteinases, peptidases and lipases have been added individually, or in various combinations, to cheese with the objective of accelerating ripening. However, the use of exogenous enzymes to accelerate ripening suffers from a number of drawbacks, which have limited the commercial use of this approach. Probably the most serious limitation of the use of exogenous enzymes to accelerate ripening is that cheese flavor is the result of a wide range of sapid compounds produced by a number of enzyme-catalyzed pathways. Thus, addition of specific enzymes will not accelerate all pathways simultaneously and equally and thus can result in unbalanced flavor. In the case of exogenous proteinases, reduction in yield, textural problems and the development of bitterness have been reported (although the last defect can be ameliorated by the use of selected peptidase preparations). A second major

drawback to the use of exogenous enzymes is that most of the enzyme added to the cheesemilk is lost in the whey. Enzymes can be added more efficiently to varieties such as Cheddar by mixing with the dry salt, but problems with uniform distribution of enzyme have been reported. Encapsulation of enzymes (e.g., in milk fat or liposomes) has been used in attempts to overcome some of these problems, but with limited success (106).

Enzyme-modified cheeses (EMCs) are concentrated cheese flavors produced by the enzyme-catalyzed hydrolysis of cheese curd or other ingredients (109, 110). EMCs are produced by adding exogenous enzymes, e.g., exogenous proteinase, peptidase and/or lipase preparations, to a pasteurized slurry of emulsified cheese curd and incubating under controlled conditions (typically 30–45°C for 24–72 h). The product is then heat treated (70–85°C) to inactivate the added enzymes. EMCs are sold as pastes (40–60% moisture) or, after drying, as powders. EMCs may be manufactured using one-step or component approaches; in the latter approach, several different flavor fractions (e.g., produced by lipolysis or proteolysis) are then blended to give the final product.

Flavor generation in EMCs is principally *via* lipolysis and proteolysis of the base material using exogenous enzymes. EMCs contain high levels of free fatty acids, peptides and amino acids, far in excess of those of natural cheese. The extensive proteolysis of the caseins during the manufacture of EMCs often leads to bitterness unless proteolytic enzymes are carefully selected or other debittering strategies are adopted. The flavor of EMCs may be augmented by the addition of flavor enhancers such as monosodium glutamate, yeast extract, NaCl, organic acids or starter distillates.

A wide range of exogenous lipases, proteinases (e.g., from *Bacillus* or *Aspergillus* spp.) and peptidases (e.g., from *Aspergillus*, *Rhizomucor* or *Lactococcus* spp.) are used in the manufacture of EMCs. Most lipases used are derived from animal or microbial sources; the most commonly used animal lipase is PGE. PGE preferentially liberates strongly flavored fatty acids. A range of microbial lipases is also available; they tend to be cheaper than animal lipases and may have broader specificity. In addition, microbial lipases have vegetarian status and are free from amylase activity, which otherwise may cause problems in foods to which EMCs are added, many of which may contain starch.

Proteinases used in the manufacture of EMCs are generally derived from microbial sources (e.g., *Bacillus* spp. or *Aspergillus* spp.) and are used to develop rapidly an intense savory background flavor. Peptidase preparations, derived from fungal or bacterial sources, are used to enhance flavor and/or to control bitterness. Peptidase preparations contain a range of enzymes, including endopeptidases, aminopeptidases and proline-specific peptidases.

EMCs have the advantages over other sources of cheese flavors in the intensity and range of flavors available, reduced production costs and extended shelf-life. Because of their high flavor intensity, only small amounts of EMCs (ca. 0.1%, w/w) are needed to impart a cheese flavor to products in which they are used (e.g., processed cheese, cheese analogues, cheese spreads, snack foods, soups, sauces, cookies, dips and pet foods).

C. β-Galactosidase

Hydrolysis of the milk sugar, the disaccharide lactose (4-*O*-β-D-galactopyranosyl-D-glucopyranose), yields two monosaccharides, D-glucose and D-galactose (111). Hydrolysis of lactose may be achieved either chemically, by acidification to low pH values, or enzymatically. The enzymes capable of catalyzing the latter hydrolysis reaction are collectively known as β-galactosidases or, more simply, lactases (although, strictly speaking, many β-galactosidases, especially those of plant origin, cannot degrade lactose) (112, 113).

A large proportion of the world's population suffers from lactose intolerance, leading to varying degrees of gastrointestinal distress if dairy products are consumed. The two products of the hydrolysis of lactose, however, are more readily metabolized; glucose and galactose are also sweeter than the parent sugar.

Lactose also has a number of other properties that cause difficulty in the processing of dairy products. Among these is its tendency to form large crystals on cooling of concentrated solutions of the sugar; galactose and, to an even greater extent, glucose, are more soluble than lactose (112). Thus, for example, hydrolysis of whey concentrates offers the possibility of preserving such products through increasing osmotic pressure while maintaining physical stability. Industrial applications of lactose hydrolysis have, in fact, focused to a large extent on treatment of whey to produce lactose-hydrolyzed whey concentrates or syrups (112).

Other applications of lactose hydrolysis include production of low-lactose market milk (114); this may even be achieved domestically by addition of a commercial preparation of β-galactosidase to fresh milk and incubation in the refrigerator. For long shelf-life products (such as UHT milk), β-galactosidase may be added to the package at a very low level and allowed to work slowly during storage. Lactose hydrolysis also has applications in ice cream manufacture, where it can reduce the incidence of sandiness (due to lactose crystallization) during storage and, due to the enhanced sweetness, permit the reduction of sugar content. Use of lactose-hydrolyzed milk can also accelerate the acidification of yoghurt (112).

Several sources of β-galactosidase (including yeasts, fungi and bacteria) have been identified, including *E. coli, Aspergillus niger, A. oryzae* and *Kluyveromyces lactis*

(111–113). The enzyme from the latter yeast is active at 4°C, which raises interesting possibilities in dairy processing (for example, it could be added to milk before cold storage in silos, removing the need for holding at a higher temperature with concomitant problems of microbial control). There is also much current interest in the use of β-galactosidase from thermophilic bacteria, which could permit operation of reactors at a high temperature, resulting in high rates of hydrolysis without the risk of growth of contaminating microorganisms (115). The principal criterion for acceptability of a microbial β-galactosidase is that the source should be safe and acceptable to regulatory authorities; genes for some microbial β-galactosidases have been cloned into safe hosts for expression and recovery for this reason.

The activity of β-galactosidase is generally monitored either by measuring disappearance of lactose or production of galactose and glucose (measurement of product monosaccharides is easier and more common, e.g., by HPLC or commercial enzymatic assay kits) (112). Synthetic substrates may also be used for assays of activity. In milk, simple and rapid estimation of hydrolysis of lactose may be achieved by monitoring the freezing point: freezing point; depression is linearly correlated with the degree of hydrolysis. However, many assay methods are complicated in cases where production of side-products (oligosaccharides) is significant.

For hydrolysis of lactose in milk, β-galactosidase may simply be added in free solution, allowed sufficient time to react typically, for most enzymes, at a temperature from 10 to 35°C, and inactivated by heat-treatment of the product. In an attempt to control the reaction and prevent uneconomical single-use of the enzyme, immobilized enzyme technologies have been studied widely (116, 117). In such systems, β-galactosidase may be immobilized on inorganic supports (which can change its kinetic properties) or entrapped within gels or fibers, such as those of cellulose acetate. One of the earliest systems, developed by the Corning Glass Company in the U.S., used covalent enzyme attachment to microporous silica beads (112). In entrapment-based systems, the porosity of fibers allows inward and outward diffusion of reaction products, but does not allow the enzyme to escape. The enzyme is, in effect, in solution within the fibers, and its enzymatic characteristics are not affected. Batchwise systems based on cellulose acetate membranes capable of processing 10,000 L milk per day have been developed. Overall, however, few immobilized systems for lactose hydrolysis are used commercially, the main limitations being the poor mechanical properties of supports and other technological problems with the process.

In an alternative approach, after hydrolysis of lactose, β-galactosidase may be recovered from milk or whey by ultrafiltration and reused, which combines the kinetic advantages of using the soluble enzyme with the economical benefits of recycling of the enzyme.

A new technique with potential for application in lactose hydrolysis processes is the use of permeabilized cells of bacteria or yeast (e.g., *Kluyveromyces lactis*) with β-galactosidase activity (118). These cells are treated, e.g., with ethanol, to allow diffusion of substrate and reaction products across the damaged cell membrane; the cell itself becomes the immobilization matrix and the enzyme is active in its natural cytoplasmic environment. Permeabilization may provide a crude but convenient and inexpensive enzyme utilization strategy.

Lactose hydrolysis reactions rarely lead to complete conversion of lactose to monosaccharides, for two reasons (112). Firstly, the galactose produced in the reaction can inhibit the enzyme in a feedback inhibition mechanism. Secondly, side-reactions (such as transferase reactions) often occur, resulting in the production of isomers of lactose and oligosaccharides. While initially thought to be an undesirable by-product of lactose hydrolysis, galactooligosaccharides, it is now recognized, may actually act as bifidogenic factors, enhancing the growth of desirable probiotic bacteria in the intestines of consumers and depressing the growth of harmful anaerobic colonic bacteria.

Overall, despite considerable interest, industrial use of lactose hydrolysis by β-galactosidases has not been widely adopted (119).

D. Transglutaminase

Transglutaminase (TGase) can modify the properties of many proteins through the formation of new cross-links, incorporation of an amine or deamidation of glutamine residues (120). To create protein cross-links, TGase catalyzes an acyl-group transfer reaction between the γ-carboxyamide group of peptide-bound glutamine residues and the primary amino group of a variety of amine compounds, including lysine residues in proteins. TGase (protein-glutamine: amine γ-glutamyl-transferase) type-enzymes are widespread in nature. For example, blood factor XIIIa, or fibrinoligase, is a TGase-type enzyme, and TGase-mediated cross-linking is involved in cellular and physiological phenomena such as cell growth and differentiation, as well as blood clotting and wound healing. TGase enzymes have been identified in animals, plants, fish and microbes (e.g., *Streptoverticillium mobaraense*); the latter is the source of much of the TGase used in food studies. TGase from different sources may either be calcium-independent (most microbial enzymes) or calcium-dependent (typical for mammalian enzymes) in mode of action.

TGase-catalysed cross-linking can alter the solubility, hydration, gelation, rheological, emulsifying, rennetability and heat stability properties of a variety of food proteins. Not all proteins are similarly affected by the action

of TGase; the structure of individual proteins determines whether cross-linking by TGase is possible.

Perhaps not surprisingly, in recent years a number of studies have explored the potential applications of TGase in dairy protein systems. The caseins are good substrates for TGase, due to their open structure (121, 122). Treatment of casein micelles with TGase stabilizes them to the action of dissociating agents, such as calcium chelators or urea. In contrast, the whey proteins, due to their globular structure, require modification, for example heat-induced denaturation, to allow cross-linking.

A number of studies have shown clear effects of TGase treatment on the properties of milk and dairy products (123, 124). For example, TGase treatment of fresh raw milk increases its heat stability (125); however, if milk is pre-heated under conditions where whey protein denaturation occurs prior to TGase treatment, the increases in heat stability are even more marked. This is probably due to the formation of cross-links between the caseins and unfolded denatured whey proteins, brought into close proximity by formation of disulphide bridges between β-lactoglobulin and micellar κ-casein. When the whey proteins in milk are in the native state, the principal cross-linking reactions involve the caseins; heat-induced denaturation renders the whey proteins susceptible to cross-linking, both to each other and to casein molecules.

There has been considerable interest in the effects of TGase treatment on the cheesemaking properties of milk, in part due to the potential for increasing cheese yield. Some commercial reports have indicated that treatment, either of milk before renneting, or of curd if TGase is added during the cheesemaking process itself, can achieve this effect. However, a number of recently published studies (124, 126) have indicated that the rennet coagulation properties of milk and syneretic properties of TGase-crosslinked rennetted milk gels, as well as the proteolytic digestibility of casein, are impaired by cross-linking of proteins, which may alter cheese manufacture and ripening. Further studies are required to evaluate whether limited, targeted cross-linking may give desirable effects.

Other potential benefits of TGase treatment of dairy proteins include physical stabilization and structural modification of products such as yoghurt, cream and liquid milk products, particularly in formulations with a reduced fat content, and the production of protein products, such as caseinates or whey protein products, with modified or engineered functional properties (127–129).

Overall, it appears clear that TGase may have commercial applications in modifying the functional characteristics of milk and dairy products. However, some issues remain to be clarified; for example, control of the reaction in milk, to fix the exact extent of cross-linking of proteins to achieve desired properties, requires understanding of the heat inactivation kinetics of TGase in milk, which have not been reported. Further research is also required on the effect of variables such as temperature, pH and other operating conditions on the nature and rate of cross-linking reactions. Finally, a clear commercial advantage of using TGase over other methods of manipulating the structure and texture of dairy products (such as addition of proteins or hydrocolloids) must be established definitively.

E. Miscellaneous Exogenous Enzymes

There are also some additional enzymes that may be added exogenously to milk (130), although their commercial application is limited. These are summarized below.

(i) Since human milk contains significantly more indigenous lysozyme than bovine milk, the supplementation of milk-based infant formulae with lysozyme has been proposed. It has been claimed that supplementation of such formulae with egg-white lysozyme gives beneficial results, especially with premature infants, but results are equivocal. Lysozyme is effective at killing *Clostridium* cells and preventing the outgrowth of their spores and thus it also has been studied as an alternative to nitrate for preventing the growth of *C. tyrobutyricum* in cheese and the butyric acid fermentation which leads to late-gas blowing. Lysozyme has also been shown to be quite effective against *Listeria monocytogenes* and other bacteria involved in food-borne illness and spoilage (130).

(ii) Glucose oxidase (GO) catalyzes the oxidation of glucose to gluconate *via* gluconic acid-δ-lactone (Figure 27.1). Glucose oxidase has four principal uses in the food industry, viz, removal of trace levels of glucose, removal of trace levels of O_2, generation of H_2O_2 *in situ* and production of gluconic acid *in situ*. However, GO is not commercially very significant, particularly in the dairy industry (131).

(iii) Superoxide dismutase (SOD) catalyzes the reduction of superoxide anions to H_2O_2 and O_2. It has been suggested that SOD together with catalase may be useful as an antioxidant in dairy products, although as far as we know, it is not used commercially for this purpose (130).

(iv) Sulphydryl oxidase, which catalyzes the oxidation of sulphydryl groups to disulphides

$$\text{i.e., } 2RSH + O_2 \rightarrow RSSR + H_2O$$

has been shown to ameliorate the cooked flavor of UHT milk, although, as far as we know, the enzyme is not used commercially for this purpose (132).

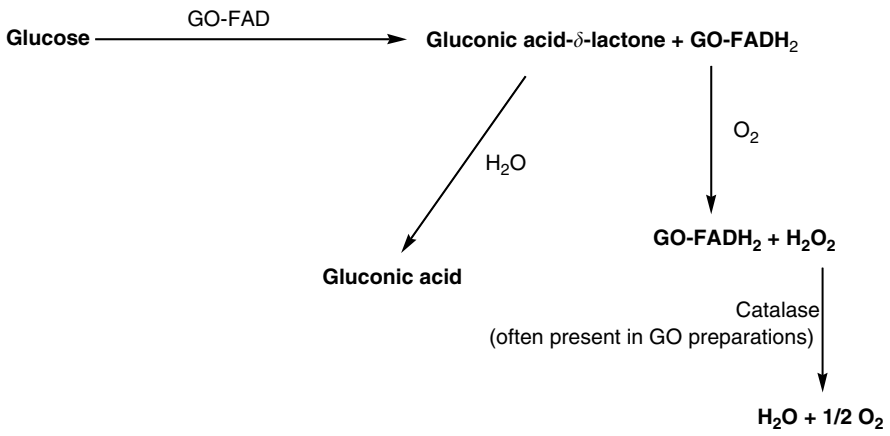

FIGURE 27.1 Reactions catalysed by glucose oxidase (GO).

(v) Catalase catalyzes the decomposition of H_2O_2 to H_2O and O_2. Produced H_2O_2 may be used for the cold-sterilization of milk and excess H_2O_2 may be destroyed by the use of exogenous catalase (130).

(vi) Exogenous β-lactamase, which degrades β-lactam antibiotics (e.g., penicillin), has been shown to be able to render milk contaminated with penicillin suitable for cheese manufacture (133).

IV. CONCLUSIONS

In summary, the two classes of enzymes considered in this chapter, i.e., indigenous and exogenous enzymes, are of great significance to the dairy industry, and an area of ongoing research and study, for two major reasons.

Firstly, milk is not an enzymatically inert raw material; on the contrary, it possesses a heterogeneous and highly variable complement of enzymes of many different types, the exact definition of which remains unclear, as does the significance of many of these enzymes for dairy product quality.

Secondly, the dairy industry is and remains a significant consumer of large quantities of commercially produced enzymes (e.g., the world market of commercial rennet is ~ 30×10^6 liters per annum, representing one of the largest commodity enzymes in use today). Identification of novel sources of enzymes (e.g., the search for more thermostable β-galactosidases, which would allow operation at temperatures which would inhibit microbial growth), and optimization of the application and control of the activity of existing enzymes remain key food biotechnological goals. In parallel, demand for new dairy products drives the study of novel enzymatic reactions that can be harnessed to manipulate the flavor, texture or other characteristics of milk and dairy products.

28 Meat: Chemistry and Biochemistry

Fidel Toldrá
Instituto de Agroquímica y Tecnología de Alimentos (CSIC)

CONTENTS

I. INTRODUCTION

Meat quality is very important for all segments of the industry from producers to consumers. There are many aspects such as source, cost, ethical factors, religion, production systems and safety that affect meat acceptability by consumers. Other quality factors perceived by consumers are related to sensory characteristics (i.e., color, tenderness and flavor), nutritional properties (i.e., calories, vitamins content, fatty acids profile, etc.) and appearance (i.e., exudation, marbling, amount of fat, etc.). One of the major concerns for consumers is the variability in meat quality; this constitutes a problem to solve within the meat industry. The composition, structure and metabolic status of the muscle have a great influence on numerous chemical and biochemical changes affecting meat quality characteristics such as tenderness in beef or exudation in pork and poultry. This chapter summarizes the chemistry and biochemistry of meat, taking into account how all these factors interact during postmortem stages and thus how they affect the final meat quality. A better understanding of these reactions and changes is essential for the standardization and improvement of production processes to obtain a high quality meat.

II. MUSCLE STRUCTURE

Skeletal, smooth and cardiac constitute the main types of muscles. However, from the point of view of meat, skeletal muscle is the most important because it represents a high percentage of the total body weight. Skeletal muscle is voluntary (the organism can contract it voluntarily), striated (cross striations may be observed under the microscope due to the alternance of dark and light bands) and multinucleated (several nuclei located peripherally in the cell). The muscle is covered by a sheath of connective tissue, the epimysium. There are several bundles of fibers inside the muscle which are covered by thin connective tissue layers, the perimysium, and each individual fiber is wrapped by thin collagen, the endomysium (see Figure 28.1). Each muscle fiber may contain about 1,000

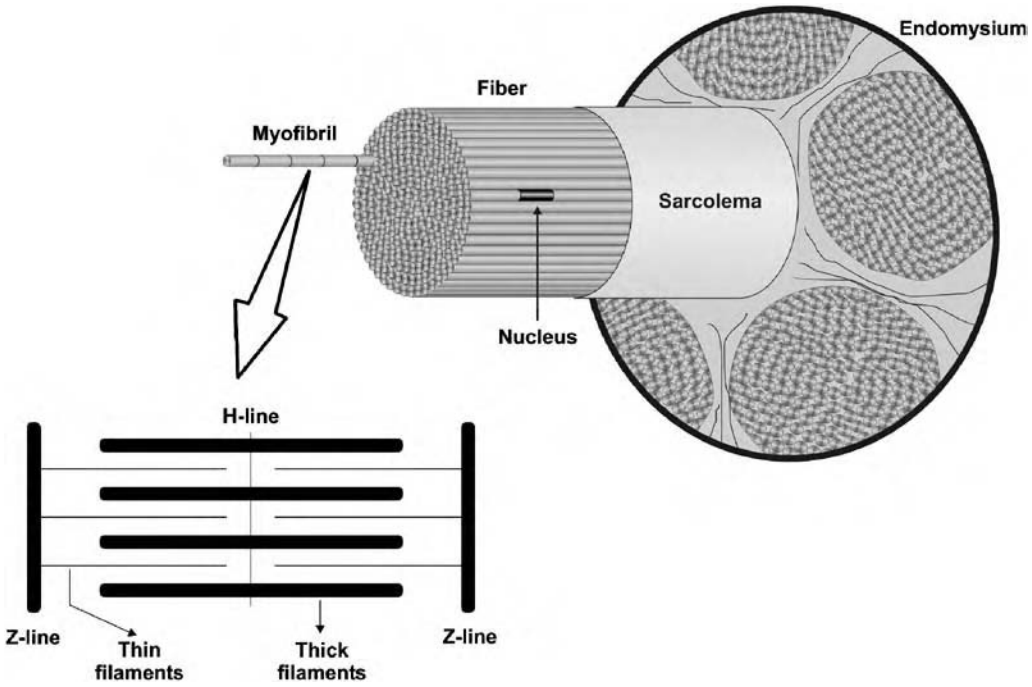

FIGURE 28.1 Scheme of the organization and structure of skeletal muscle.

myofibrils, which are arranged in a parallel way, and are responsible for the contraction of the muscle (1). Fibers have an approximate diameter of around 50 μm and may vary in length from a few milimeters up to several centimeters (2). They contain myofibrils, composed of thick and thin filaments arranged in an array and responsible for muscle contraction and relaxation, giving rise to alternating dark (A) and light (I) bands. The Z and M lines bisect each I and A band, respectively (see Figure 28.1). The M lines connect the center of the thick filaments to keep the structure (3). The Z line appears as a zigzag structure and has diverse properties such as resistance to physical forces but, on the other hand, it is susceptible to protease action (4). The sarcomere, usually in the range of 2–3 μm in length, is defined as the distance between two consecutive Z lines. The thick and thin filaments are composed of myofibrillar proteins (see Table 28.1). Actin filaments extend into Z lines at one end and extend between thick filaments at the other end (5). Thick filaments are mainly composed of myosin with minor presence of other proteins. The fibers are embebbed in a liquid or cytoplasm, also known as sarcoplasm, that contains mitochondria, lysosomes, enzymes, lipids, glycogen, myoglobin, ATP and creatine. As most of these proteins are soluble in water and are present in the sarcoplasm, they are known as sarcoplasmic proteins. The scanning electron microscopy of skeletal muscle reveals details of the muscle fiber structure in a three-dimensional image. An example of a micrograph from the scanning electron micro-scope is shown in Figure 28.2.

Muscles present different appearances and have been traditionally classified as red or white based on the color properties that are dependent on the proportion of the muscle fiber types. Other classifications based on the amount of released water have not been used widely. The red color is related to the content in myoglobin, naturally present in the muscle, and hemoglobin from remaining blood. Differences between red and white muscles are especially evident in pork and poultry while differences in color are relatively masked in beef due to its higher content in myoglobin. Based on histochemical properties, muscle fibers have been classified as red, intermediate and white (6). Red fibers contain higher amounts of myoglobin, are better capillarized, are oxidative in metabolism, and can function over a long period of time but are slower contracting than white fibers that are mainly glycolytic (7). Intermediate fibers have oxidative and glycolytic activity. Thus, red muscles contain a higher proportion of red fibers and are mostly related to locomotion while white muscles have a higher proportion of white fibers and are mostly related to support tasks (8). Other classifications of muscle fibers are based on the contraction speed (9): slow twitch oxidative (type I), fast twitch oxidative type (IIA) and fast twitch glycolytic type (IIB). So, the response of slow twitch muscles to a stimulus is slower and once the stimulus is finished the relax is also slower than fast twitch muscles.

Differences between red and white muscles are also significant during meat processing because large variations are found in sensory properties such as tenderness, juiciness, flavor (10) as well as physicochemical (11) and

TABLE 28.1
Location and Functions of Major Meat Proteins (Adapted from Refs. 2, 9, 24, 151)

Protein	Type	Function
Myosin	Myofibrillar	Major contractile
Actin	Myofibrillar	Major contractile
Tropomyosin	Myofibrillar	Regulatory
Troponins T, C, I	Myofibrillar	Regulatory
α and β actinin	Myofibrillar	Regulatory
Titin	Myofibrillar	Cytoskeletal
Nebulin	Myofibrillar	Cytoskeletal
Filamin,synemin, vinculin, zeugmatin, Z nin	Myofibrillar	Z-line
C, H, X, F, I proteins	Myofibrillar	Thick filaments
Desmin	Myofibrillar	Myofibrils union at Z-line level
Creatin kinase	Myofibrillar	M-line
Myomesin	Myofibrillar	M-line
M protein	Myofibrillar	M-line
Mithocondrial enzymes	Sarcoplasmic	Respiration
Lysosomal enzymes	Sarcoplasmic	Intracellular digestion
Other cytosolic enzymes	Sarcoplasmic	Glycolysis, gluconeogenesis, citric acid cycle, neutral proteolysis
Myoglobin	Sarcoplasmic	Natural pigment
Hemoglobin	Sarcoplasmic	Pigment from residual blood
Cytochrome	Sarcoplasmic	Respiratory pigment
Collagen	Connective	Structure resistance
Reticulin	Connective	Elasticity
Elastin	Connective	Structure resistance
Proteoglycans and glycoproteins	Connective	Ground substance

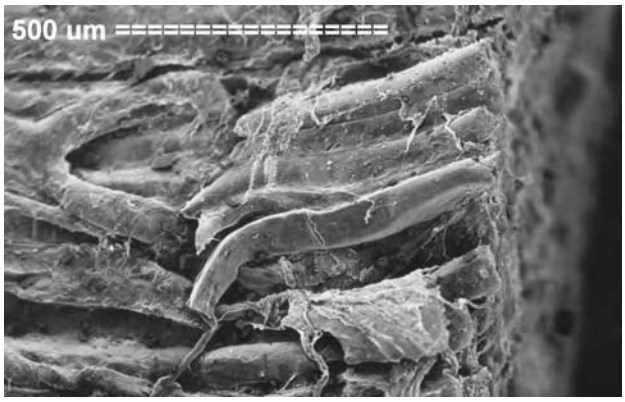

FIGURE 28.2 Scanning electron micrograph of porcine muscle fibers in porcine muscle (Toldrá and Voyle, 1987, unpublished).

biochemical characteristics like enzyme activity (12, 13), lipid composition (14, 15) and content in free amino acids and dipeptides (16–18). These variations may be attributed to certain differences in the biochemical and functional properties of myofibrillar proteins associated with the type of fiber (9, 19).

III. MEAT COMPOSITION

Meat presents a complex structure with water, proteins and lipids present in higher amounts. Water is the most abundant compound in meat (within the range of 65–80%) and has an important influence on juiciness, color, texture and surface appearance. The rest of the composition of meat can be divided into nitrogenous and non-nitrogenous compounds. Nitrogenous compounds are mainly composed of proteins (myofibrillar, sarcoplasmic and connective), peptides (carnosine, anserine and balenine), free amino acids, nucleotides/nucleosides (ATP-derived compounds) and water-soluble vitamins (group B vitamins). In addition to water, non-nitrogenous compounds include lipids (triacylglycerols, phospholipids and cholesterol), minerals (iron, phosphorus, sodium, potassium, etc.), trace elements (zinc, selenium, etc.), carbohydrates (glycogen, glucose, etc.) and fat-soluble vitamins (vitamins A, D, E and K). The main groups of compounds are described below.

A. PROTEINS

After water, protein is the major component of meat, in the range of approximately 15–22 g/100 g. Proteins are very important in postmortem conversion of muscle to meat, in changes affecting tenderness during meat processing and for the nutritional quality of the diet. Meat proteins are considered of high biological value because they provide relatively high percentages of all the essential amino acids (20). There are three categories in meat: myofibrillar, sarcoplasmic and connective (listed in

Table 28.1), in an approximate ratio 60/30/10, with each category having specific roles (7).

Myofibrillar proteins are the main constituents of the structure of the myofibrils. They are soluble in high ionic strength buffers and its content is around 9.5 g/100 g. Myosin and actin provide the structural backbone of the myofibril. Myosin is the major myofibrillar protein and, in fact, is the predominat protein of thick filaments. It is a large molecule composed of two heavy chains of 220 kDa and four light chains within the range of 16–22 kDa (9). The actin monomer, G-actin, has a globular shape and, in the presence of ATP, polymerizes to form filamentous F-actin. The thin filaments ensure by the helical arrangement of F-actin molecules twisted around each other (21). Two extremely large proteins, titin and nebulin, also known as gap filaments, ensure the longitudinal continuity and integrity of the structure (22, 23). Proteins in the Z-line area are involved in the linkage of thin filaments of adjacent sarcomeres while desmin connects adjacent myofibrils at the level of the Z-line. Regulatory proteins like tropomyosin and troponin, which has three subunits (Tn-T, Tn-C and Tn-I), are involved in the muscle contraction mechanism (9).

Sarcoplasmic proteins, around 9 g/100 g, constitute a varied group consisting of proteins soluble in low ionic strength buffers or even water. Myoglobin is the major sarcoplasmic protein responsible for the red color of meat. Myoglobin content in meat is variable, depending on the animal species (high in beef or lamb, low in pork and very low in poultry) and age (increases with the age of the animal). More or less hemoglobin may remain in meat depending on the efficiency of blood draining from muscle during bleeding. The rest of sarcoplasmic proteins consist of metabolic enzymes located in mitochondrias, lysosomes, microsomes, and nucleus and free in the cytosol.

Connective proteins, around 3 g/100 g consisting basically of collagen and elastin, are insoluble and contribute to the skeletal framework (strength, support and shape) of the muscle but also to certain toughness of the meat when consumed. In fact, collagen becomes tougher with the age of animal due to the progressive increase in the number of cross-links. Collagen is rich in hydroxyproline, a low biological value amino acid. There are different types of collagen (8). Type I is found in tendons, type II in cartilages and type III in skin and vascular tissues. Types IV and V form fine networks in the basement membranes around the muscle (24). Elastin is more elastic and is mainly involved in tissues requiring a certain degree of flexibility such as skin, tendons, ligaments, muscle and the walls of large arteries (24).

B. Lipids

The lipids content of muscle is variable (in the range of 1.5–17 g/100 g) and mainly depends on the degree of fattening and amount of adipose tissue. The main classes of lipids are non-hydrolyzable lipids (fatty acids, aldehydes, aliphatic hydrocarbons, sterols), neutral fats (mono, di and triacylglycerols and sterol esters) and phospholipids. The relative proportion varies depending on the species, the developmental stage and physiological status of the animal (8). Main locations of lipids are intramuscular, intermuscular and in adipose tissue. Intramuscular lipids are mainly composed of triacylglycerols, stored in fat cells, and phospholipids, located in cell membranes. Cholesterol is the only sterol found in meat; the cholesterol ester comprises about 90% of the total cholesterol content (25). Intermuscular and adipose tissue lipids are mainly composed of triacylglycerols and contain a small amount of cholesterol (below 60 mg/100 g).

Triacylglycerols are major constituents of reserve fats and have fatty acid composition that varies widely with species and diet. There are three possible pathways for the biosynthesis of triacylglycerols: the glycerol-3-phosphate, the dihydroxyacetone phosphate and the monoacylglycerol pathway (8). The type and fatty acid composition of feeds has a strong influence on the fatty acids profiles of fats, especially in monogastric animals (26, 27). Thus, the effects of different feeds on fatty acid composition of pork and poultry fats have been extensively reported in the literature (27–32) following consumer demands for higher unsaturated fats (26). In the case of ruminants, fat hydrolysis and hydrogenation of unsaturated fatty acids by the microbial population of the rumen somehow tend to standardize the final composition in fatty acids and certain changes in the diet fed to cattle may also change the content of the fat in the meat. For instance, dietary full-fat canola or even full-fat soybeans have been reported to alter the fatty acid composition of intramuscular and subcutaneous lipids of beef (33). The type of diet may have important consequences for the sensory quality of meat, especially its flavor (34). So, changes in the fatty acid composition of phospholipids have been reported to give significant differences in flavor characteristics of forage and grain-fed beef (35). It must be pointed out that meat from ruminants represents a major dietary source of conjugated linoleic acids (CLA), a group of C18 isomers of linoleic acid with conjugated double bonds in the cis or trans configurations at positions 10 and 12 or 9 and 11 (36). CLA content in meat is in the range of 3–6 mg/g of fat. CLA have been reported to have some health-promoting biological activity such as inhibition of tumor growth and reduction of atherosclerotic risk (36, 37). The composition in fatty acids determines main fats properties. So, fats with excessive polyunsaturated fatty acids, like linoleic (typical of feeds rich in corn, for instance) and linolenic acids, tend to be softer, have an oily appearance and are more susceptible to oxidation. This is the reason why meats with a high percentage of polyunsaturated fatty acids are not preferred for further meat processing.

Phospholipids are present in minor amounts but due to their particular fatty acid composition, which is richer in polyunsaturated fatty acids, they have an important role in flavor development and oxidation in postmortem meat. Major constituents are phosphatidylcholine (lecithine) and phosphatidylethanolamine while phosphatidylserine and sphingomyelin are present in minor amounts. Some variability in phospholipids has been reported depending on the genetic type of the animal and anatomical location of the muscle (38). For instance, the amount of phopholipids tends to be higher in red oxidative muscles than in white glycolytic muscles (15).

C. Minor Compounds

Meat constitutes a good source of group B vitamins that, although present in low concentrations, contribute significantly to the daily intake requirements (39, 40). Pork meat is particularly rich in thiamin. However, the amount of fat-soluble vitamins in meat is rather poor or even almost negligible. Only vitamin E is significant in those animals with specific supplementation in the diet. Feed enrichment with vitamin E, at levels above dietary requirements (i.e., 200 mg/kg feed), is a relatively new practice, expanded in recent years, to protect unsaturated lipids from oxidation and obtain other benefits like better color stability of fresh beef (41, 42) and improved water retention in pork meat (43). The content in carbohydrates is rather poor, around 1.5 g/100 g, although it depends on the previous exercise of the animal prior to slaughtering. Meat also constitutes a good source of dietary iron, with the additional advantage that a good percentage is in the absorbable form of heme iron (44), and trace elements like zinc, selenium, magnesium, manganesum, etc. (40, 45–48). The mineral content is around 1 g/100 g.

IV. THE MEAT ENZYME SYSTEMS INVOLVED IN MAJOR BIOCHEMICAL CHANGES

Skeletal muscle contains a wide variety of enzymes involved in multiple metabolic pathways. Some of the most important, shown in Figure 28.3, are related to carbohydrate metabolism (glycolytic enzymes), protein breakdown (endo-peptidases), generation of small peptides (tri and dipeptidylpeptidases) and free amino acids (aminopeptidases and carboxypeptidases), hydrolysis of triacylglycerols and phospholipids (lipases and phospholipases) and transformation of ATP into numerous derived compounds. Most of these enzymes remain active in postmortem muscle, playing important roles in glycolysis, proteolysis, lipolysis and transformation of nucleotides that are essential for the development of meat quality. The location of these enzymes may vary. Some are located in organules like lysosomes while others are bound to membranes or free in the cytosol (49). A brief description of the proteolytic and lipolytic enzymes that play an important role in meat quality is given below.

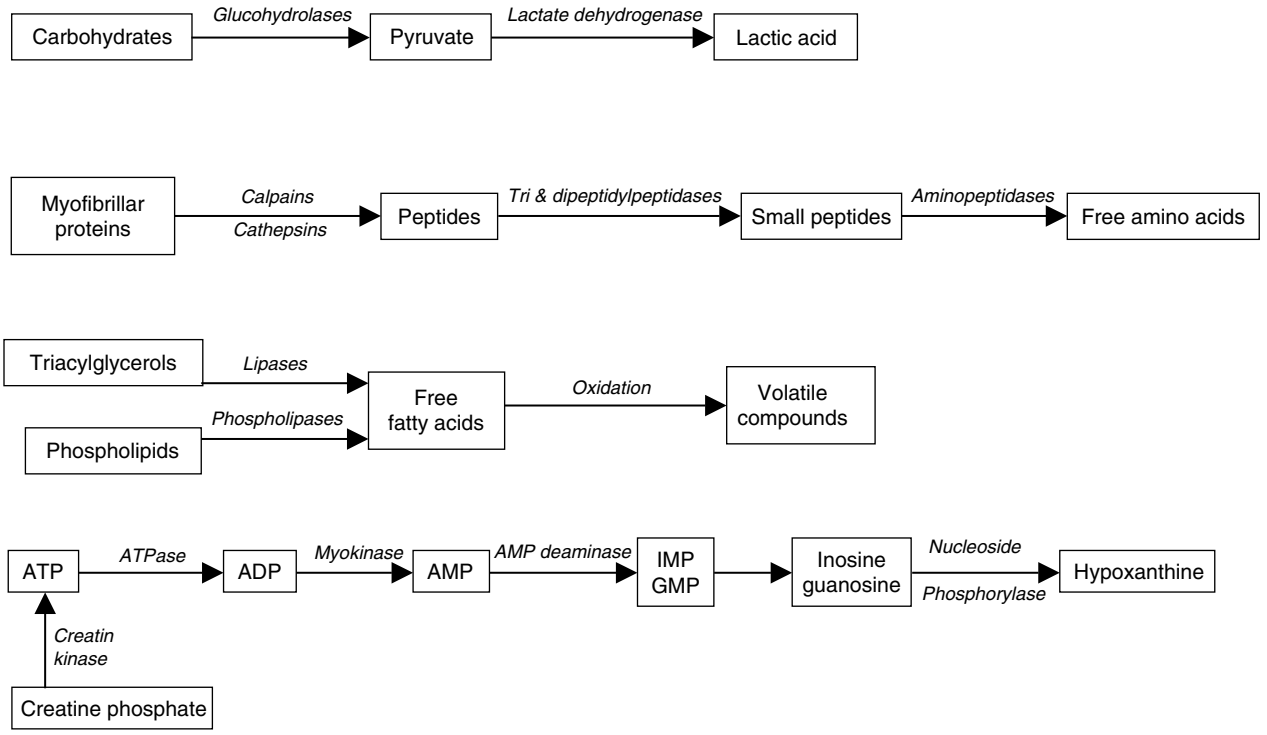

FIGURE 28.3 Scheme showing some of the most important enzymatic reactions affecting meat quality.

A. Proteases

Lysosomes are organules containing a large number of hydrolytic enzymes, including proteases. Cathepsins B, H and L, which are cysteine proteinases, and cathepsin D, an aspartate proteinase, are the main lysosomal proteinases. In general, these enzymes are small, 20–40 kDa (see Table 28.2), which allow their penetration into the myofibrillar structure. However, although the anaerobic glycolysis in postmortem muscle generates the adequate environment, such as pH drop, for cathepsin activity (50), the enzymes probably play a minor role in meat texture development during meat ageing as there is little or no degradation of myosin and actin, two important proteins very sensitive to cathepsins (51).

Cathepsins D and L are able to degrade myosin heavy chains, titin, M and C proteins, tropomyosin and troponins T and I (52–54). Cathepsin L is very active on both titin and nebulin. Cathepsin D may be quite inactive at refrigeration tenperatures (53) but can act during cooking because of its thermostability (55). On the other hand, cathepsin B is able to degrade myosin heavy chains, actin and even collagen but has no effect on myosin light chains and troponin C (56, 57), and cathepsin H shows both endo and aminopeptidase activity, being classified as an aminoendopeptidase (58). Cathepsin activity is regulated by cystatins, a family of cysteine peptidase inhibitors which are predominantly extracellular and have been isolated from different animal species (59, 60). Four families of cystatins have been reported in the literature based on their primary structure (51). Optimal pH for cathepsin D is acid (in the range of 3.0–5.0), slightly acid for cathepsins B and L (around 6.0) and near neutrality (6.8) for cathepsin H (61–64).

Calpains, a group of cystein endopeptidases, are located in the cytosol especially in the Z-line area. They have different names in the literature such as calcium-activated neutral proteinase, calcium-dependent protease or

TABLE 28.2
Main Characteristics of Meat Proteolytic Enzymes (Adapted from Refs. 51–84)

Enzyme	Classification	Location	Substrates	Optimal pH
Cathepsin B (EC 3.4.22.1.)	Cystein	Lysosome	Myosin, actin, collagen	5.5–6.0
Cathepsin D (EC 3.4.23.5.)	Aspartyl	Lysosome	Myofibrillar proteins	4.0
Cathepsin H (EC 3.4.22.16.)	Cystein	Lysosome	Myofibrillar proteins	6.8
Cathepsin L (EC 3.4.22.15.)	Cystein	Lysosome	Myofibrillar proteins, collagen	5.5–6.0
μ-Calpain (EC 3.4.22.17.)	Cystein/metallo	Z-line	Myofibrillar proteins	7.5
m-Calpain (EC 3.4.22.17.)	Cystein/metallo	Z-line	Myofibrillar proteins	7.5
20S proteasome	Ntn-hydrolase	Cytosol	Myofibrillar proteins	7.0–7.5
DPP I (EC 3.4.14.1)	Cystein	Lysosome	Polypeptides	5.5
DPP II (EC 3.4.14.2.)	Serin	Lysosome	Polypeptides	5.5
DPP III (EC 3.4.14.4.)	Serin	Cytosol	Polypeptides	8.0
DPP IV (EC 3.4.14.5.)	Serin	Membrane	Polypeptides	7.5–8.0
TPP I (EC 3.4.14.9.)	Serin	Lysosome	Polypeptides	4.0
TPP II (EC 3.4.14.10.)	Serin	Cytosol	Polypeptides	6.5–7.5
Alanyl aminopeptidase (EC 3.4.11.14.)	Cystein/metallo	Cytosol	Amino terminus of peptides	6.5
Arginyl aminopeptidase (EC 3.4.11.6.)	Cystein/metallo	Cytosol	Amino terminus of peptides	6.5
Methionyl aminopeptidase (EC 3.4.11.18.)	Cystein	Cytosol	Amino terminus of peptides	7.5
Leucyl aminopeptidase (EC 3.4.11.1.)	Metallo	Cytosol	Amino terminus of peptides	9.0
Pyroglutamyl aminopeptidase (EC 3.4.19.3.)	Cystein	Cytosol	Amino terminus of peptides	8.5
Carboxypeptidase A (EC 3.4.16.1.)	Serin	Lysosome	Carboxy terminus of peptides	5.2–5.5
Carboxypeptidase B (EC 3.4.18.1.)	Cystein	Lysosome	Carboxy terminus of peptides	5.0

calcium-activated factor. Calpain I or μ-calpain requires 50–70 μM of Ca^{2+} for activation and calpain II or m-calpain requires 1–5 mM of Ca^{2+}. Optimal pH for calpain activity is 7.5 (see Table 28.2) but poor activity is observed below pH 6.0, reaching negligible activity at pH 5.5 (65). Calpains are heterodimers of 110 KDa composed of an 80 KDa catalytic subunit responsible for the peptidase activity and a 30 KDa regulatory subunit which is common for both enzymes (66). Calpain I can be autolyzed in the presence of Ca^{2+} and usually shows a poor stability in meat while calpain II may be stable for a few weeks (67). Calpains have shown ability to degrade titin, nebulin, troponins T and I, tropomyosin, C-protein, filamin, desmin and vinculin but cannot degrade myosin, actin, α-actinin and troponin C (68, 69). The endogenous inhibitor calpastatin regulates calpain activity in postmortem muscle. Calpastatin is destroyed by autolysis after a few days postmortem (67).

The proteasome complex is a large protease with multiple catalytic sites such as a chymotrypsin-like activity, a trypsin-like activity and a peptidyl-glutamyl hydrolyzing activity (70, 71). The proteasome 20S can be associated with large regulatory complexes, like one or two 19S complexes, or one or two 11S activator complexes or even other activator complexes like PA700 or PA28 (51). The 20S proteasome can degrade myofibrils and affect M and Z lines, especially in high pH meats and slow-twitch oxidative muscles and thus could have a role in tenderness in those specific muscles (72, 73).

Peptidases constitute a large group of proteases. The most important found in meat are tripeptidylpeptidases (TPP) and dipeptidylpeptidases (DPP). TPP I, a lysosomal enzyme, shows optimal activity at acid pH and TPP II is most active at neutral pH. Both enzymes are able to hydrolyze different tripeptides from the amino termini of peptides, like Gly-Pro-Phe and Ala-Ala-Phe, respectively (74, 75). DPP I and II are located in the lysosomes and have optimal acid pH. DPP I has special preference for hydrolyzing dipeptides Ala-Arg and Gly-Arg from the amino termini of peptides and DPP II for Gly-Pro. DPP III is found in the cytosol and DPP IV is linked to the plasm membrane, both enzymes having optimal pH in the range of 7.8–8.0 (76–79). DPP III has a preference for hydrolyzing dipeptides Arg-Arg and Ala-Arg and DPP IV for Gly-Pro. Dipeptidases catalyze the hydrolysis of dipeptides and their names vary depending on the preference for certain amino acids. For instance, cysteinylglycine dipeptidase is specific for the dipeptide Cys-Gly and arginin dipeptidase has a special preference for basic amino acids (80).

Aminopeptidases constitute a group of exopeptidases able to release a free amino acid from the amino termini of peptides and proteins. They have a large molecular mass and a complex structure (62). Major aminopeptidases in skeletal muscle are: arginyl, alanyl, pyroglutamyl, leucyl and methionyl aminopeptidases. All of them are active at neutral or basic pH (see Table 28.2) and their names are related to the preference or requirement for a specific N-terminal amino acid although they can hydrolyze other amino acids at slower rates. Alanyl aminopeptidase, which mainly hydrolyzes alanine, is considered the major aminopeptidase in postmortem muscle. This enzyme is able to hydrolyze a wide spectrum of amino acids such as aromatic, aliphatic and basic aminoacyl-bonds (81). Arginyl aminopeptidase, also known as aminopeptidase B, hydrolyzes basic amino acids such as arginine or lysine (82). Methionyl aminopeptidase, a calcium-activated enzyme, has a wide spectrum of activity with preference for methionine, alanine, lysine and leucine (83). Leucyl and pyroglutamyl aminopeptidases are active at basic pH and play a minor role in meat (84). Carboxypeptidases are lysosomal enzymes with optimal activity at acid pH and able to generate free amino acids from the carboxy termini of peptides and proteins. Carboxypeptidase A has a preference for hydrophobic amino acids while carboxypeptidase B has a wider spectrum of activity (80).

B. Lipases

Major lipolytic enzymes in muscle are lysosomal acid lipase and phospholipase A (see Table 28.3). Both enzymes

TABLE 28.3
Main Characteristics of Meat Lipolytic Enzymes (Adapted from Refs. 61, 62, 86, 88, 89, 92)

Enzyme	Location	Substrate	Optimal pH
Lysosomal acid lipase	Lysosome	Long chain tri and diacylglycerols	5.0
Neutral lipase	Membrane	Long chain tri and diacylglycerols	7.5
Phospholipase A	Lysosome	Phospholipids	5.0
Muscle acid esterase	Lysosome	Short chain tri and diacylglycerols	5.0
Muscle neutral esterase	Cytosol	Short chain tri and diacylglycerols	7.5
Hormone-sensitive lipase	Adipose tissue	Long chain tri, di and monoacylglycerols	7.0
Monoacylglycerol lipase	Adipose tissue	Long chain monoacylglycerols	7.0
Lipopotein lipase	Adipose tissue	Lipoproteins	8.5
Acid esterase	Adipose tissue	Short chain tri and diacylglycerols	5.0
Neutral esterase	Adipose tissue	Short chain tri and diacylglycerols	7.5

are located in the lysosomes and are responsible for the generation of long chain free fatty acids in meat. Lysosomal acid lipase hydrolyzes primary ester bonds of tryacylglycerols at acid pH (4.5–5.5). This enzyme can also hydrolyze di and monoacylglycerols although at a slower rate (85, 86). Phospholipase A hydrolyzes phospholipids, at positions 1 or 2. The order of preference for fatty acids, especially polyunsaturated C18, esterified to phospholipids as a result of *in vitro* assays, is as follows: Linoleic acid > Oleic acid > Linolenic acid > Palmitic acid > Stearic acid > Arachidonic acid. The activity of lipases, phospholipase A and lysophospholipases is quite a bit higher in oxidative than in glycolytic muscles (15, 87). Acid and neutral esterases, able to hydrolyze short chain fatty acids from tri, di and mono acylglycerols, have been identified in the lysosomes and cytosol, respectively (88). In general, lipases prefer long chain fatty acids while esterases are especially active against short chain fatty acids.

There are three lipases in adipose tissue (see Table 28.3): hormone-sensitive lipase, monoacylglycerol lipase and lipoprotein lipase with optimal pH in the neutral/basic range (62, 89). The hormone-sensitive lipase (HSL) has a high specificity for the hydrolysis of diacylglycerols. The triacylglycerol hydrolysis by this enzyme is the rate-controlling step in the lipolysis phenomena in adipose tissue (90). The monoacylglycerol lipase (MGL) hydrolyzes 1 or 2 monoacylglycerols with no positional specificity, releasing medium and long chain monoacylglycerols (91). Lipoprotein lipase is located in the capillary endothelium and hydrolyzes the acylglycerol components at the luminal surface of the endothelium (92). This enzyme has a preference for fatty acids at position 1 over those at position 3 (93, 94). Acid and neutral esterases are also present in adipose tissue (62, 88).

V. CHEMISTRY OF THE CONVERSION OF MUSCLE TO MEAT

Multiple reactions involved at the early postmortem are briefly summarised in Figure 28.4. It is important to emphasize that not all muscles, or even parts within the same muscle, change in an uniform way because these changes will depend on the respective ratios of white and red fibers. Additionally, the rate of these changes also depends on the temperature achieved within each muscle. Twelve moles of ATP are produced per mole of glucose under aerobic conditions like those usually found in living muscle. The first important change in the muscle following death consists of its inability to synthesize or to remove certain metabolites (see Figure 28.5). The supply of oxygen is cut off once the blood circulation ceases and then there is a progressive decrease in oxygen concentration in the muscle cell and a reduction of the redox potential towards anaerobic values (95). The lack of available oxygen stops the activity of the mitochondria system and cell respiration is progressively stopped. Once in anaerobic

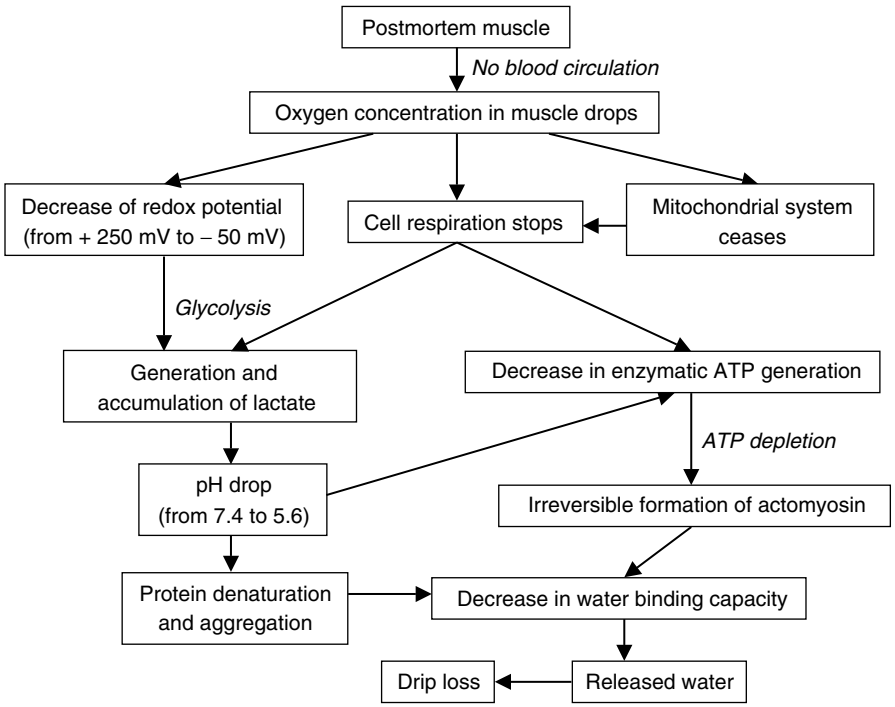

FIGURE 28.4 Scheme summarizing early post-mortem changes in muscle. From Toldrá, "Muscle foods:Water, structure and functionality," Food Sci Tech Int 9, 173–177, 2003.

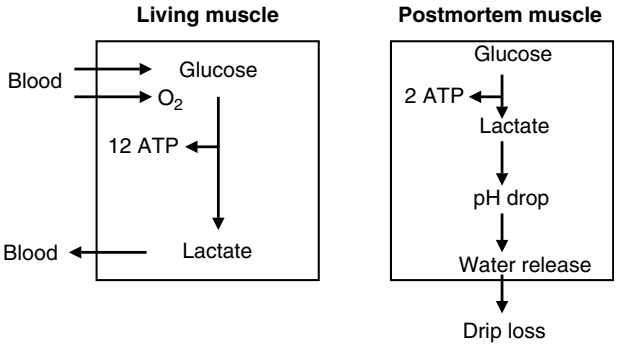

FIGURE 28.5 Main differences between living and postmortem muscle. From Toldrá, "Muscle foods:Water, structure and functionality." Food Sci Tech Int 9, 173–177, 2003.

conditions, lactic acid is produced from glucose through glycolysis, but the efficiency is lower than under aerobic conditions because only 2 moles of ATP are produced per mole of glucose. The generation of ATP is necessary in the muscle to provide the required energy to drive the Na/K pump of the membranes, to drive the calcium pump in the sarcoplasmic reticulum and to provide energy for muscle contraction. ATP may also be formed from ADP and creatine phosphate through the action of the enzyme phosphocreatin kinase (96). ATP is also necessary for muscle contraction-relaxation where it acts as a lubricant but, once ATP is fully exhausted, the muscle remains contracted (rigor mortis). This is related to the formation of actomyosin and the loss of extensibility (97).

An important consequence of lactic acid accumulation is the pH drop to acid values (5.6 to 5.9) within a few hours postmortem. The pH drop rate depends on the metabolic status of the muscle and glycogen availability. As pH approaches the isoelectric point of myofibrillar proteins (pH values around 5.0), their charges move towards neutrality and water binding decreases rapidly, the structure tightens and myofibrillar proteins are partially denatured (98). Thus, the water binding depends on the ultimate pH in the muscle and the amount of released water, lost as dripping, increases when the ultimate pH is lower (99). Important muscle soluble compounds like myoglobin, lysosomal enzymes, nucleotides and nucleosides, free amino acids, vitamins and minerals are partly lost in the drip, affecting the final quality. Pork carcasses during early postmortem are shown in Figure 28.6.

There are many and relevant biochemical changes during early postmortem and ageing of meat with important consequences for quality. Most of these changes are enzymatic in nature either affecting meat tenderness due to structural protein breakdown or generating a substantial number of new compounds with direct influence on taste and/or aroma. The trend towards rapid lean growth in cattle, pigs and poultry increases the relative proportion of meat quality defects, mainly related to color and water-holding capacity (100).

A. Glycolysis

Main reactions for glycolysis are schematized in Figure 28.3. Key enzymes in the glycolytic chain are phosphorylase, phosphofructokinase and pyruvic kinase. Lactate dehydrogenase is involved in the last step, consisting of the conversion of pyruvic acid into lactic acid. The generation and accumulation of lactic acid in the meat causes the pH to drop from neutral (pH around 7.2) to acid values (below 5.8). If the reserves of glycogen are rather poor prior to slaughter, the final pH will not experience such an intense drop and will remain above 6.0. The pH limit for the DFD pork meat condition (dark, firm and dry) is considered around 5.9 at 24 h. The ultimate pH depends on the type of muscle, animal species and physiological state. The rate of glycolysis also depends on the temperature. Minimum pH drop is observed at 10–12°C but if temperature decreases down to 0°C too early, there is a release of calcium ions into the myofibrillar space that activates ATPase. Under these circumstances and if there is still some available ATP, an extra contraction of actomyosin is

produced, resulting in a tight structure phenomenon known as cold shortening (97, 101). Cold shortening is mainly observed in beef, lamb and turkey, and with less intensity in pork (102). Prevention of cold shortening may be achieved by keeping carcasses above 15°C until the pH reaches 6.0. Another important alteration, known as thaw rigor or thaw shortening, is produced when thawing meat that was frozen in the prerigor state (still keeping a substantial amount of ATP). Under these circumstances, calcium is released and moves is into the intracellular spaces, causing an extensive contraction (101).

Exudation constitutes one of the major problems in pork quality. This condition, is known as pale, soft and exudative (PSE), is characterized by its pale color, soft texture and high drip loss (103). Another type of exudative meat, known as red, soft and exudative (RSE), is characterized by similar defects although this meat keeps its normal color (104), making it difficult to differentiate from normal meats (105). Finally, another defective meat with lower incidence is known as dark, firm and dry (DFD) due to its darker color, firm texture and dry appearance on the external surface. Pork meat classification is usually based on pH, color and drip loss (106, 107). Exudative (PSE and RSE) meats are characterized by a low pH value at early postmortem (i.e., pH below 5.8 at 2 h), a pale color reflected in a L value higher than 50 (only for PSE) and drip loss higher than 6%. Figure 28.7 shows a typical pH drop profile for normal, DFD and PSE pork meats. The negative effects of exudative meats may be reduced significantly with some preventive measures such as appropiate pre-transport handling, lairage, stunning, postmortem temperature and chilling rate. The incidence of exudative pork meat is still significant. For instance, a 1992 survey of the pork supply in the U.S. revealed that 16% was PSE and 10% was DFD (108). Only 16% was considered to be of ideal quality (RFN) while the remainder was found to be of somewhat questionable quality (RSE), indicating very little progress in the elimination or minimization of the problem (108).

B. Nucleotide Breakdown

ATP is the main source of energy for the biochemical reactions in postmortem muscle. However, its content rapidly decreases from an initial 5–8 μmol/g muscle to final negligible values (rigor state). Initially, some ATP may be formed through creatin kinase acting on creatin phosphate and through anaerobic glycolysis (96) but, once creatin phosphate and glycogen are exhausted or the involved enzymes inactivated, ATP drops in a few hours to near zero values through conversion into ADP, AMP and other derived compounds (see Figure 28.10 for an example on pork meat). The concentrations of ADP and AMP decrease to negligible values after 24–48 hours postmortem. 5′-inosin-monophosphate (IMP) is formed from AMP deamination by the action of AMP deaminase, an enzyme very active at pH near 6.2. Some IDP, generated from ADP, may be temporarily detected although it is depleted in a few days. IMP can be further degraded into inosine and hypoxanthine, both compounds experiencing a substantial increase as meat is aged (see Figure 28.8). Similar reactions, although at minor concentrations, are also observed for 5′-guanosin monophosphate (GMP). The rate for all these reactions varies depending on the metabolic status of the animal prior to slaughter as well as the pH and temperature of the meat (109, 110).

C. Proteolysis

Proteolysis consists of the progressive enzymatic degradation of major meat proteins, especially myofibrillar

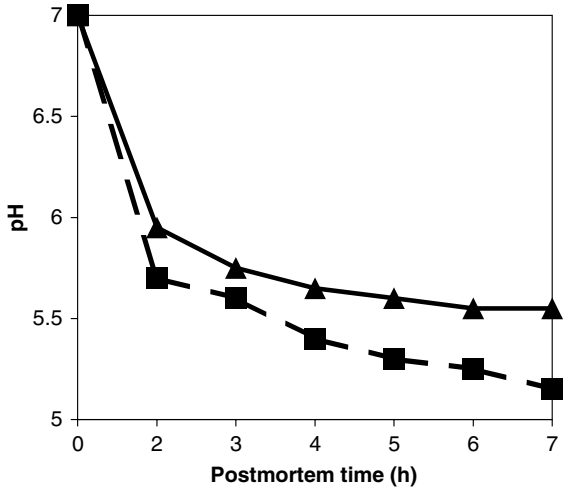

FIGURE 28.7 Example of pH fall of normal (—■—) and pale, soft, exudative (PSE) (▲) pork meat (Toldrá, 2000, unpublished).

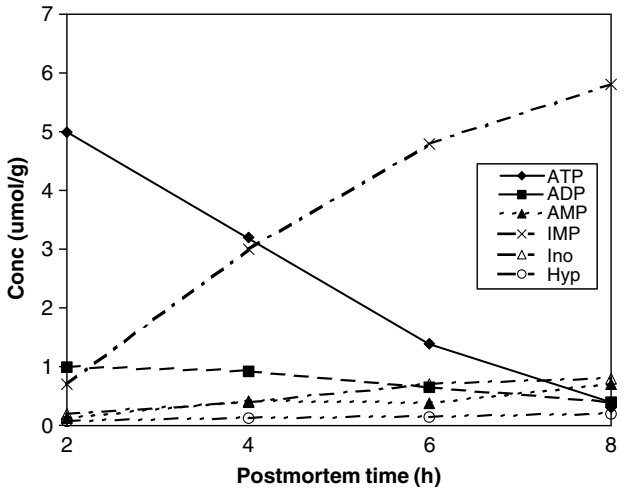

FIGURE 28.8 ATP depletion and evolution of ATP-derived compounds in aged pork meat (adapted from Ref. 109).

proteins, and the subsequent generation of peptides and free amino acids. The breakdown of structural proteins results in a weakening of the myofibrillar network and a sensible improvement in meat tenderness. There are many muscle endopeptidases (mostly calpains and cathepsins) and exopeptidases (mostly tri and dipeptidylpeptidases and aminopeptidases) involved in proteolysis (see Figure 28.3). Main properties of these enzymes have been described above (see Table 28.2). The extent of proteolysis and thus the tenderness and generation of taste compounds depend on many factors (111). The activity of endogenous muscle enzymes may vary depending on the genetics (112, 113) and the age of the animals (114, 115). Furthermore, the action of these enzymes also depend on the processing technology. For instance, major or minor action of the enzymes may be expected depending on the temperature and time of ageing. These enzymes are also regulated by certain agents like salt (63, 64, 116, 117).

In general, the amount of peptides increases during meat ageing as reported for beef, pork, chicken and rabbit (118). Some characteristic peptides have been described in postmortem meat and some of them are related to meat tenderness or have flavor properties, for instance, the 30 kDa peptide originating from troponin T through the action of calpain (119) which is related to meat tenderization (120–124), a 110 kDa polypeptide from C protein (125) and some peptides corresponding to 1282.8 Da from the sarcoplasmic protein glyceraldehyde 3-phosphate dehydrogenase, 1734.8 Da from troponin T and 5712.9 Da from creatine kinase (125). Recently, a 32 kDa peptide derived from troponin T has been reported to increase during 20 days of ageing (111). Several small peptides were also isolated from pork meat and some of them were proposed as predictors of pork meat quality (126–128). The generation of these peptides may be depressed if some salt, which inhibits muscle peptidases, is added (62). The activity of endogenous muscle aminopeptidases is quite relevant and, in fact, a significant amount of released free amino acids that contribute to meat taste may be found after several days of meat ageing (129–132).

D. Lipolysis

Lipolysis consists of the breakdown of triacylglycerols by lipases and phospholipids by phospholipases resulting in the generation of free fatty acids (see Figure 28.3). Some of these fatty acids may contribute to taste but, most important, unsaturated fatty acids may contribute to the generation of aroma compounds through further oxidative reactions. Main lipolytic enzymes, located in muscle and adipose tissue and involved in these phenomena, are listed in Table 28.3. These enzymes show good stability and, although their activity depends on pH, salt concentration and water activity, the conditions during meat ageing favor their action (88, 133). The generation rate of free fatty acids increases with length of ageing. In the case of intramuscular lipids, most of the released fatty acids proceed from phospholipid degradation while in adipose tissue they proceed almost exclusively from triacylglycerols (134, 135).

The generated mono and polyunsaturated fatty acids are susceptible to further oxidative reactions to give volatile compounds (136). The beginning of lipid oxidation is correlated with flavor development but an excess of oxidation may lead to off-flavors, one of the main mechanisms responsible for quality deterioration in meat and meat products. Warmed-over flavor (WOF) is recognized as a sensory defect that has been described as the rapid onset of off-notes developed in cooked meat after refrigeration storage (137). WOF is characterized by a decrease in fresh meatiness and the development of cardboard and rancid/painty notes in beef, pork and chicken, that may be detected even after 48 hours (137).

The beginning of lipid oxidation consists of the formation of free radicals, reactions catalyzed by muscle oxidative enzymes, like peroxydases and ciclooxygenases, external light, heating and the presence of moisture and/or metallic cations. The next step in oxidation is the formation of peroxide radicals (propagation), by reaction of free radicals with oxygen. The hydroxyperoxides (primary oxidation products) formed are flavorless but very reactive (136) giving secondary oxidation products that contribute to flavor (138). The oxidation is finished when free radicals react with each other. Unsaturated fatty acids, especially those of phospholipids, are prone to oxidation. The oxidation rate depends on the level of unsaturated fatty acids and number of unsaturations. For instance, arachiconid acid (C20:4) is oxidized faster than linolenic acid (C18:3), and this faster than linoleic acid (C18:2) and oleic acid (C18:1). An example of the evolution of oxidation during refrigerated storage of pork meat is shown in Figure 28.9. Typical volatile compounds resulting from lipid oxidation (139) are aliphatic hydrocarbons (poor contribution to flavor), alcohols (high odor threshold), aldehydes (low odor threshold) and ketones.

VI. DEVELOPMENT OF SENSORY QUALITY

The chemical and biochemical changes taking place during the refrigerated storage of meat are intimately linked to the development of specific sensory properties of meat like color, texture and flavor which are basic to quality. An example of meat conditioning is shown in Figure 28.10.

A. Color

The protein myoglobin constitutes the major pigment in meat, from 50 to 80% of the total pigment content (Miller, 1994). Myoglobin is composed of globin, a protein moiety,

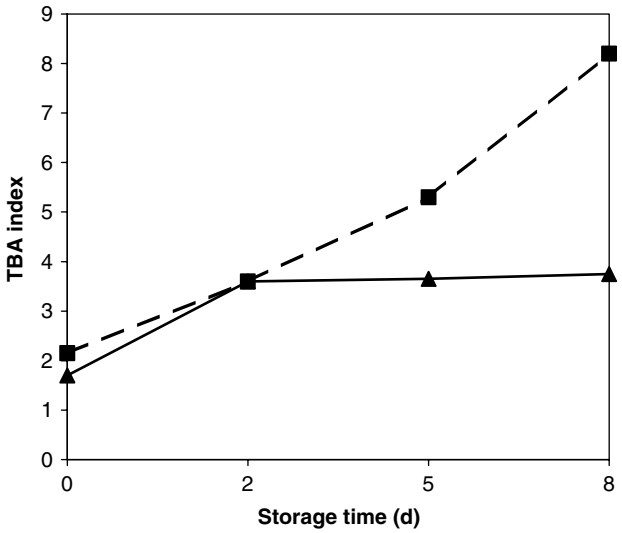

FIGURE 28.9 Example of lipid oxidation, measured through the thiobarbituric acid (TBA) index, during the refrigerated storage of pork meat (▲) and adipose tissue (—■—) (Toldrá, 2000, unpublished).

and an iron-containing heme group. When the heme iron exists in a reduced ferrous form, it is called deoxymyoglobin and gives a purplish-red color (140). When oxygen occupies the sixth ligand by oxygenation under high oxygen tension, it is called oxymyoglobin, and gives a cherry-red color. These two myoglobin forms may be oxidixed to metmyoglobin, which gives an undesirable brownish-red color (140). Metmyoglobin may be formed at high temperature, low pH and under exposure to UV light. Some bacteria may also favor its formation (97) while some lactic acid bacteria have shown ability to reduce metmyoglobin to myoglobin (141). When oxygen tension is low, oxygen dissociates from the heme and gives myoglobin. The content in myoglobin varies depending on the species. So, beef meat (containing about 5 mg of myoglobin per g of muscle) has the darkest color, followed by lamb (about 2.5 mg/g) and pork (about 1 mg/g) (142). Myoglobin content also varies depending on the physiological role (muscles with higher content of red fibers are darker) and age (myoglobin content increases with age) (16). In general, a better red color may be found in meats from mature animals than in meats from younger animals.

Color stability is very important for fresh meat marketability. Color may be influenced by drop in pH rate and is more stable at relatively higher ultimate pH values. The oxidation of myoglobin is accelerated by increases in temperature. The partial oxygen pressure is very important to the balance between the three myoglobin forms. Finally, light may produce meat discoloration as well as bacterial contamination (140).

B. Texture

Calpains play an important role in proteolysis and tenderness development during early postmortem while cathepsins play a minor role (143). Calpains are activated in postmortem meat by the increased calcium concentration as a consequence of calcium release from the sarcoplasmic reticulum and mitochondria and cause an intense breakdown of the myofibrillar structure, especially around the Z-line area. Further evidence has been obtained by addition of specific cathepsin inhibitors, observing a similar degree of meat tenderization and myofibrillar fragmentation (144) or even acceleration of the tenderization rate when calcium salts are added (145). The need for increased tenderness and optimized ageing processes prompted the development of tenderization models based on the activity of calpains (146). However, other factors must be considered when comparing proteolytical enzyme levels in different species (beef, pork, lamb and poultry) and respective rates of tenderization (147). Even non-enzymatic mechanisms regarding depolymerization of intermediate filaments under non-physiological conditions have been proposed for meat tenderization (148). Calpastatin and cystatins regulate the activity of calpains and cathepsins, respectively, and their content varies with species. For instance, pork muscle has lower calpastatin level (149) and lower calpain II activity than beef and lamb but at 1 day postmortem pork meat was the most tender (150). Thus, calpastatin and cystatins, or even the enzyme/inhibitor ratios, appear to be better predictors of meat quality than the assays of enzyme activity alone (151).

Changes in rate of tenderization may be due to different ultimate pH values (value at 24 h postmortem). So, preslaughter stress and consequent glycogen depletion may raise the ultimate pH to intermediate values (around 6.0) and give tougher meat at first day postmortem while lower and higher ultimate pH give tender meat (152). Myofibrillar protein extractability is lower in PSE pork meat than in normal meat and this may change the susceptibility of myofibrils to proteolysis (153). In fact, major changes by calpains are observed in DFD and normal meats while the action of cathepsins remains similar in both normal and PSE types of meats (154). Proteolysis and ultrastructural breakdown has been reported to be faster in fast glycolyzing muscles. Higher calpain I activity and lower calpastatin activity (high enzyme/inhibitor ratio) confirms that calpain I has an important role in tenderness even in meats with lower pH values (155).

C. Flavor

Raw meat has little aroma but meat flavor is developed as a consequence of a good number of compounds produced in postmortem muscle. The most important nonvolatile compounds with taste properties are free amino acids, peptides, inosine and hypoxanthine, lactic and succinic and other acids, sugars, and the sodium salts of glutamic and aspartic acids (156). Flavor enhancers such as 5′-inosin- and 5′-guanosin-monophosphate, glutamic acid and monosodium glutamate are also important for the final flavor of meat (157, 158). Free amino acids contributing to meat taste have been reported in beef, rabbit and pork (130, 131, 159, 160). Peptides generated in aged meat also make an important contribution to taste. An octapeptide, Lys-Gly-Asp-Glu-Glu-Ser-Leu-Ala, was isolated from beef after digestion with papain (161, 162). This peptide was named the beefy meaty peptide (BMP) or delicious peptide because of its taste-enhancing properties. This octapeptide exhibits sourness and astringency at pH 3.5 and umami at pH 6.5 which is enhanced in the presence of salt and monosodium glutamate (163). Other tripeptides like Ala-Asp-Glu, Ala-Asp-Glu, Asp-Glu-Glu and Ser-Pro-Glu and dipeptides like Glu-Glu and Glu-Val, with taste-enhancing properties, have been isolated from chicken meat treated with bromelain (164). The production of peptides with desirable flavors is favored within the pH range 5.0–6.0 in beef (165). The division of generated peptides in aged beef into three fractions revealed that those with molecular mass of 500–1000 kDa and higher than 10,000 kDa had a negligible effect on taste while those within the range 1,000–10,000 kDa suppressed sourness, probably by inhibition of the binding of lactic acid to membranes, and enhanced umami taste (118). In a similar way, small peptides in the range 2,700 to 4,500 Da or even below 2,700 Da, have been detected in postmortem pork meat and some of them gave characteristic brothy and umami tastes (166).

Volatile compounds are generated with aroma properties belonging to the following groups: aldehydes, ketones, esters, hydrocarbons, acids, alcohols, lactones, furanes, pyrroles, pyridines, pyrazines, non-heterocyclic sulphur compounds, thiophenes and thiazoles (167). Further generation of these taste and aroma compounds and interactions among them take place during meat processing and cooking (157, 168). For instance, the optimal flavor quality of aged top round beef meat was found after 4 days of ageing (165). The main reactions involved during cooking are: pyrolysis of amino acids and peptides, carbohydrate degradation, Maillard reactions, Strecker degradations,

degradation of thiamin and lipid degradation (157). Depending on the balance and relative intensity of all these reactions, the flavor may change. For instance, some pyrazines, thiophenes and thiazoles are responsible for the roasted flavor. Thus, the different flavors for different meats depend on the balance of the non-volatile and volatile compounds and the way they interact (167, 169).

In summary, the chemistry and biochemistry of meat are quite complex and involve numerous chemical reactions (i.e., lipid oxidation, Maillard reactions, Strecker degradations, etc.) and biochemical reactions related to indigenous enzymes (i.e., glycohydrolases, proteases, lipases, etc.). Knowledge of these reactions is very important in order to obtain standardized high quality meats because all related chemical and biochemical changes have a strong effect on final quality and consumer acceptability.

29 Chemical Composition of Red Meat

Baowu Wang
Department of Food and Nutritional Sciences, Tuskegee University

CONTENTS

I. INTRODUCTION

Red meat refers to the meat from mammalian skeletal muscle tissue with distinctive red color including beef, pork, and lamb. Although muscle and meat are used interchangeably on many occasions, there are differences between the two terms. Muscle refers to a tissue responsible for contraction and movement in live animals, while meat is a broad term referring to edible tissues from animals consisting of muscle, adipose, and other connective tissues (1). The major components of meat include water, proteins, lipids, carbohydrates, minerals, soluble non-protein substances, vitamins, and some incidental compounds such as feed additives or contaminants (Table 29.1). The composition of meat is dependent on the species, breed, sex, age, activity, the anatomical location of the cut, the relative proportions of tissues in the retail cut, and other factors. However, the composition of lean meat is fairly consistent even across different species (Table 29.2). Hence, in later discussions, the chemical composition of red meat is not separated into species.

II. WATER IN MEAT

Generally, water is the most abundant component in lean meat, ranging from 65% to 80%. However, if the meat contains excessive adipose tissue, fat may be the predominant component (Table 29.3). Water is not randomly distributed in meat. At the time of slaughter, approximately 85% water in muscle is located intracellularly. The remaining 15% water is located in the extracellular spaces. The water in the muscle is withheld through different mechanisms, less than 15% tightly bound to proteins, another 15% loosely bound to proteins, and the remaining 70% by capillary forces (6). Since most of the water is distributed in the spaces among myofibrils, swelling or shrinkage of myfibrils alters the distribution of water within the muscle but does not necessarily affect the muscle volume as a whole (7).

The level of water in meat has a direct impact on cooking yield as well as on tenderness and juiciness of meat products. Hence, it is desirable to improve water binding capacity of meat through breeding, slaughtering, post mortem handling, formulation, and further processing such as mixing, tumbling, and other procedures.

TABLE 29.1
Composition of Typical Mammalian Muscle*

Component	Wet %
Water	75.0
Protein	19.0
Lipids	2.5
Carbohydrates	1.2
Non-protein nitrogenous compounds	1.65
Inorganic	0.65
Vitamins and other minor components	Minimal

* Compiled from Ref. 2.

TABLE 29.3
Composition of Red Meat with Adipose Tissues (%)

	Water	Protein	Lipids	Ash
Beef	60	18	20	1
Pork	42	12	43	1
Lamb	62	17	18	1

Compiled from Refs. 3–5.

III. MEAT PROTEINS

For lean meat, proteins constitute 16% to 22% of the meat mass. Meat proteins can be divided into three groups based on their solubility: sarcoplasmic proteins (soluble in aqueous solutions with an ionic strength of 0.15 or less), myofibrillar proteins (soluble in aqueous solutions with an ionic strength of sodium or potassium ions at least 0.3), and stromal proteins (insoluble even in high ionic strength solutions of sodium or potassium ions) (2).

A. Sarcoplasmic Proteins

The sarcoplasmic proteins contribute to about 30% of the total protein, corresponding to 5.5% of lean meat. The sarcoplasmic proteins include a mixture of about 50 components. The major components are glycolytic enzymes, myoglobin, cytochromes, and flavoproteins (2). It should be noted that glycolytic enzymes are not randomly suspended in the sarcoplasm. Instead, they are bound to the myofibrillar protein (actin). This feature may assist in the muscular metabolism and physiological function. In addition, the proportion of the bound glycolytic enzymes increases in electrically stimulated glycolysis and decreases when the stimulation stopped (2). Glycolytic enzymes also bind to other sites in muscle cell, including the sarcolemma, the sarcoplasmic reticulum, and the membranes of nuclei and mitochondria. These glycolytic enzymes play a critical role during post mortem glycolysis. The myoglobin, and to a lesser extent, hemoglobin, are responsible for the typical red color of meat. The amount of myoglobin is determined by the metabolic characteristics of the muscle. For instance, red meat contains high levels of myogolbin to provide more oxygen for the synthesis of ATP. In contrast, white meat contains low levels of myoglobin because its energy is generated primarily through glycolysis. Generally, sarcoplasmic proteins have limited functionalities in water-binding, gel-forming, and emulsifying capacity.

B. Myofibrillar Proteins

Myofibrillar proteins constitute about 60% of total muscle proteins, corresponding to about 11.5% of lean meat. Myofibrillar proteins can be further divided into three subgroups including contractile proteins, regulatory proteins, and cytoskeletal proteins (Table 29.4). The major contractible proteins are myosin and actin. The major regulatory proteins are tropomyosin, troponin, actinins, and other minor regulatory proteins. Cytoskeletal proteins include a diverse group of proteins such as titin, nebulin, desmin, filamin, vinculin, and synemin. The myofibrillar proteins construct the thick filament, thin filament, Z-line, and M-line which can be observed under the microscope or electron microscope.

1. Myosin

Myosin is the most abundant myofibrillar protein, contributing to abut 40% of the total myofibrillar protein or about 5.5% of lean meat. Myosin contains six subunits with two identical heavy chains and four light chains (2). There are three kinds of light chains, i.e., DTNB light chain (MW 18,000 D), alkaline light chain 1 (MW 25,000 D), and alkaline light chain 2 (MW 16,000 D). The names of the light chains come from the reagents used to release them from myosin, either sulfhydryl agent 5,5-dithiobis(2-nitrobenzoic acid) (DTNB) or alkaline solution. One myosin molecule contains two identical DTNB light chains and two identical alkaline light chains (either 1 or 2). The six subunits form two identical units which form a complete myosin molecule with a length of 1500 Å (2). A whole myosin molecule looks like a golf club with the N-terminus in the head region. The four light chains and ATPase activity are located at the head. Many myosin molecules aggregate at the tail to form myosin filament (thick filament) which in turn forms myofibrils with other proteins (2, 9). Another protein component for thick filament, titin, will be discussed later.

TABLE 29.4
Some Characteristics of Myofibrillar Proteins from Vertebrate Skeletal Muscle

Protein	MW (KD)	%*	Location	Function
Contractile				
Myosin	500	43	Thick filament	Contraction
Heavy chain	220		(A-band)	
Light chain	16/18/25			
Actin (G-form)	42	22	Thin filament (I-band)	Contraction
Regulatory				
Tropomyosin	70	8	Thin filament	Regulates contraction
α-chain	34			
β-chain	36			
Troponin	74	5	Thin filament	
Troponin-C	18			Ca^{2+}-binding
Troponin-I	21			Inhibits myosin-actin interaction
Troponin-T	35			Binds to tropomyosin
α-actinin	95	2	Z-disk	Fastens thin filaments to Z-disk
β-actinin	130	0.1	Thin filament	Regulates thin filament length
γ-actinin	35	0.1	Thin filament	Inhibits G-actin
Eu-actinin	42	0.3	Z-disk	Density
C-protein	140	2	Thick filament	Adheres to thick filament
M-protein	165	2	M-line	Binds to myosin
X-protein	152	0.2	Thick filament	Binds to myosin
H-protein	69	0.18	Thick filament	Adheres to C-protein & myosin
Paratropomyosin	35	0.15	Edges of A-band	Involving postmortem changes
Creatine kinase	42	0.1	M-line	Binds to M-protein
Cytoskeletal				
Titin	>1000	8	Entire scaromere	Holds thick filaments & links them to Z-disks
Nebulin	600	3	N-line	Binds & holds thin filaments
Desmin	550	0.18	Z-disk	Links neighboring Z-disks
Filamin	230	0.1	Z-disk	Binds & holds titin
Vimentin	58	0.1	Z-disk	Links Z-disk in periphery
Synemin	220	0.1	Z-disk	Binds to desmin & vimentin
Zeugmatin	550	0.1	Z-disk	Links thin filaments to Z-disk

*Percentage of total myofibrillar protein
Compiled from Ref. 8.

2. Actin

The other important contractile protein is actin, contributing to about 20% of total myofibrillar proteins or about 2.5% of lean meat (Table 29.4). Actin contains a single polypeptide chain. Each actin molecule forms a globe that is called G-actin. A series of G-actin aggregate linearly to form a fibrous structure that is called F-actin. F-actin has a double stranded right-handed helical structure with a half pitch consisting of 13 monomers (10). The polymerization of G-actin to F-actin (G-F transformation) is thought to be similar to the process of crystallization (11). It occurs only above a critical concentration of actin at which F-actin is in equilibrium with G-actin. F-actin, tropomyosin, troponin, and nebulin are the major components for the thin filaments in myofibrils.

3. Tropomyosin

Tropomysoin contributes to about 8% of myofibrillar proteins. It is an α-helical molecule approximately 41 nm long. It is so named because its amino acid composition is similar to that of myosin (12). Tropomyosin consists of two subunits with a molecular weight of approximately 37,000 daltons. The two subunits are α and β which can be separated by sodium docecyl sulfate gel electrophoresis or by ion-exchange chromatography.

4. Troponin

Troponin is a protein of MW 80,000 consisting of three subunits that are named I, T, and C. Troponin C is an acidic protein that can bind Ca^{++} with four calcium

binding sites on each troponin C (13). Troponin I is a basic protein that inhibits the actin-myosin interaction in the presence of ATP. The presence of tropomyosin greatly enhances this inhibition (14). Troponin T binds strongly to tropomyosin periodically at 40 nm intervals along the entire length of the thin filament (15). Since each troponin molecule must regulate seven actin molecules, it is believed that this must be mediated via a dislocation of the filamentous tropomyosin molecule along the groove of actin filaments (16).

5. Actinins

Actinins are proteins that play a role in regulating the physical state of actin. Four classes of actinins are known, α-actinin, β-actinin, γ-actinin, and eu-actinin. α-actinin is the major actinin found in skeletal muscle, contributing to about 1–2% of myofibrillar proteins. It is an acidic protein located in Z-lines, probably participating in cementing the components of the Z-line (17). Mild treatment of myofibrils with proteases results in a marked decrease in the density of Z-lines with a release of intact α-actinin. The decrease in Z-line density and the loss of register of Z-lines in adjacent myofibrils are characteristic of postmortem muscle. It is believed that the release of α-actinin contributes to the tenderness of postmortem meat (18). β-actinin is a protein contributing to less than 0.01% of myofibrillar proteins. β-actinin is present at the free end of actin filaments to prevent actin from binding to another actin filament (19). γ-Actinin is a protein contributing to less than 0.01% of myofibrillar proteins. It inhibits the polymerization of G-actin. Eu-actinin contributes to about 0.3% of myfibrillar proteins. It is located at Z-lines to interact with both α-actinin and actin.

6. Other Regulatory Proteins

Other regulatory proteins include M-protein, C-protein, and F-protein, among other minor components. M-protein contributes to about 0.5% of myfibrillar proteins. It is located at the M-line of the thick filaments. Other proteins found at the M-line include myomesin and creatine kinase (20–22). C-protein comprises 2% of the myofibrillar protein with a relatively high proline content. C-protein copolymerizes with myosin filaments. F-protein binds to myosin filament. I-protein is located at the A-band. It is suggested that I-protein inhibits the unnecessary splitting of ATP in relaxed muscle (9).

C. Cytoskeletal Proteins

Cytoskeletal proteins include titin (connectin), nebulin, desmin (skeletin), and other minor components. Titin is the largest protein molecule with a MW of over 1,000,000. Titin contributes to about 10% of myofibrillar proteins. It seems that titin forms a three-dimensional net of very thin filaments to link the neighboring Z-lines (23). It extends longitudinally in each half sarcomere from the M-line to the Z-disk as a third filament of the myofibril. Titin and C-protein bind to the outside shaft of the thick filament. They encircle and stabilize the thick filament and hence should be considered components of thick filament. It is believed that titin is responsible for the resting tension associated with each sarcomere. Nebulin constitutes approximately 4% of myofibrillar proteins. It is located close and parallel to the thin filament. Nebulin extends longitudinally along the entire length of the thin filament from the A-band to the Z-disk. In mature muscle, it serves as a template for assembly and/or scaffold for stability of thin filaments. It may also help to anchor thin filaments to Z-disks (1). Desmin contributes to less than 0.2% myofibrillar proteins. It is located at the periphery of the Z-disk and also in the filaments that link neighboring Z-disks. Other minor proteins contributing to the cytoskeleton include filamin, vimentin, synemin, and paranemin (1).

D. Stromal or Connective Tissue Proteins

Stomal proteins include collagen, elastin, and other insoluble proteins. Connective tissue proteins play an important role in physiological functions as well as in determining the eating quality of meat. Their physiological functions include covering the body, protecting the body from damage, and connecting muscles, organs, and other structures to the skeleton and to each other (24).

Collagen is a major structural component of all connective tissues including tendon, bone, cartilage, skin, vascular tissues, and basement membranes. It is the most abundant protein in animal bodies constituting 20–25% of the total protein. Different tissues have different types of collagens (Table 29.5). Distribution of collagen is not uniform among skeletal muscles with the amount generally paralleling physical activity of the muscle. Hence, muscles of limbs contain more collagen than those around the spinal column. Consequently, the former are tougher than the latter. At a level of 33%, glycine is the most abundant amino acid in collagen, followed by proline and hydroxyproline comprising another one-third of the amino acids of collagen. Since hyroxyproline is a relatively constant component of collagen (13–14%) and does not occur to a significant extent in other animal proteins, chemical analysis of hydroxyproline is commonly used to determine the amount of collagen in tissues. In addition, collagen is a glycoprotein in that it contains a small quantity of galactose and glucose (24).

Tropocollagen is the structural unit of the collagen fibril. Tropocollagen molecules are composed of three α-chains that form a triple helix, with each α-chain forming a left-handed helix and three of the left-handed α-chains form a right-handed supercoil. Following synthesis of tropocollagen in fibroblasts, they are secreted

into the intercellular matrix where they are assembled into collagen fibrils. During fibril assembly, tropocollagen molecules are aligned longitudinally end to end and laterally in a slightly less than one-fourth overlapping stagger. The overlapping stagger gives rise to the unique striated appearance of collagen fibrils. It should be pointed out that only type I and type III collagen fibrils can form collagen fibers. Type I collagen forms large fibers while type III collagen forms fine fibers. In fibrous collagens, cross-linkages are formed via intermolecular or intramolecular cross-links. The number of cross-links depends on the load and stress of the muscle and also on the age of the animal. Limb muscle and aged animals generally have more crosss-links, resulting in tougher meat than meat from loin or young animals. The cross-links result from covalent bonding of hydroxyprolines, deaminated lysine, hydroxylysine, or sulfhydryl groups. The enzymes responsible for the modification of proline and lysine are located in fibroblasts and the modifications occur post-translation of the polypeptides.

Elastin is a much less abundant connective tissue protein than collagen. Its ultrastructural characteristics are not well known. Elastin is a rubbery protein present throughout the body in ligaments and arterial walls, as well as in the framework of a number of organs including muscle. Elastin fibers can be easily stretched and, when tension is released, return to their original length. Elastin contains eight amino acid residues with glycine being the most abundant. There are two unique amino acid residues in elastin, desmosine and isodesmosine. Elastin is highly resistant to digestive enzymes and cooking has little solubilizing effect on it. Thus, elastin contributes little to the nutritive value of meat (1).

IV. LIPIDS

Lipids is the component with the highest variability for meat, ranging from 1.5% to 13.0% (28), but lipids content can be as high as 43% if the meat contains excessive adipose tissue (3–5). The variability of lipids arises primarily from the differences in neutral fat, or triacylglycerides. Other lipid components such as phospholipids, cerebrosides, and cholesterol are fairly constant among different meat cuts. The differences in triacylglycerides reside in the fatty acids. The common fatty acids found in meat include stearic, palmitic, oleic, and linolenic (Table 29.6). Feed has an impact on the composition of fatty acids in meat. This is particularly obvious for pork. Bacon and other meat products from hogs that have ingested flax seed or fishy residue may develop painty or fishy flavors. Dietary fatty acids have less impact on the fatty acid profile of ruminant animals because the ruminant bacteria convert unsaturated fatty acids to saturated fatty acids through hydrogenation (28).

The level of phospholipids in muscle tissues is generally in the range of 0.5–1%. Most of the phospholipids are phosphoglycerides, i.e., phosphotidylcholine, phosphotidylethanolamine, and phosphotidylserine. Since phospholipids contain relatively high levels of polyunsaturated fatty acids, they tend to be oxidized to generate off-flavor. Meat also contains a small amount of cholesterol, generally in the range of 100 mg/100 g (3–5).

V. CARBOHYDRATES

Carbohydrates and related compounds contribute to about 1.0% of meat weight (22). The major components are glycogen and glucose. Other components such as triose

TABLE 29.6

phosphates and lactic acid arise from the metabolism of glucose or glycogen. The level and metabolism of carbohydrates determine, to a great extent, the eating quality of meat because during postmortem glycolysis, glucose is converted to lactic acid and ATP, both of which have significant impact on postmortem changes. Other important carbohydrates are bound to proteins which are called proteoglycans (protein accounting for 5–15% and carbohydrate accounting for 85–95%) and glycoproteins (protein being the major component and carbohydrate being the minor component).

VI. OTHER COMPONENTS

The mineral content in meat is generally low, with potassium 0.355%, sodium 0.07%, and phosphorus 0.19% (Table 29.7). However, meat provides some essential trace elements (Fe, Zn, Cu, etc.) that have higher absorption than food of plant origins.

Non-protein nitrogenous (NPN) substances contribute to about 1.5% of meat weight. These substances include creatine, creatine phosphate, nucleotides, free amino acids, peptides, creatinine, etc. The level of NPN may have a significant impact on the flavor of meat. Meat also contains significant amount of vitamins, especially vitamin B1 and niacin (Table 29.8).

30 Meat Species Identification

Y.-H. Peggy Hsieh
Department of Nutrition, Food and Exercise Sciences, Florida State University

CONTENTS

I. INTRODUCTION

Meat species identification has been an active area of research for the past three decades. Identification of the animal origin is important for fair trade, for ensuring compliance with labeling regulations, and for other issues such as wild life management and conservation. Initially, method development for species identification was mainly for the legal enforcement of regulations governing the import of raw meats at ports of entry, since species substitutions, such as the substitution of horse or kangaroo meat for beef (1, 2), and pork for beef or sheep meat (3), had been reported in several countries. Methods that give a clear qualitative result, verifying and identifying the species of origin, were sufficient at the time. However, as processed meat and prepared ready-to-eat products have become increasingly available to consumers, the possibility of fraudulent adulteration and substitution of the expected species with other meats has also increased. Widespread problems due to mixing undeclared meat species have been documented among fresh and processed ground meat products in retail markets as either a consequence of improper handling or economic fraud (4, 5). Whether this is due to accidental contamination of low levels of undeclared meat or intentional adulteration involving significant amounts and/or multiple species, such practices pose a substantial concern to consumers in terms of economic loss, food allergies, religious observance, loss of traceability, and food safety (6). It has been observed that the adulteration problem occurs more frequently in precooked meats than in fresh meat, possibly due to the lack of reliable and economical analytical methods for cooked meats (7). Wherever the law enforcement is inadequate with regard to meat species monitoring programs, the rate of adulteration increases substantially. Therefore, the recent focus of species detection has been on the content of various processed and precooked ground and comminuted meat products. The development of

reliable analytical methods that can sensitively identify and quantify the unknown species in processed and composite mixtures has thus become more important and, at the same time, more complicated. Research efforts have concentrated on searching for species markers that are not only unaffected by the processing conditions, such as cooking temperature, but can also be used to quantitatively assess the proportion of the target tissue present in meat samples (6).

Recently, an emerging issue concerning the transmission of the fatal neurodegenerative disease, Bovine Spongiform Encephalopathy (BSE, commonly known as mad cow disease), has made the science of species detection even more demanding and challenging. Most scientists agree that the BSE epidemic originated from the practice of feeding cattle with rendered animal protein derived from scrapie-infected sheep tissue, and the disease is further spread by recycling meat and bones from infected animals back into cattle feed (8). Etiologically linked to BSE, the recent occurrence of a new variant of Creutzfeldt Jakob Disease (nv CJD) in humans is believed to result from consumption of beef from BSE-infected cattle (9). Ultimately, food safety is the threshold issue for consumers' fear of BSE. To prevent the spread of the disease in animals and reduce the potential risk of BSE transmission to humans, stringent feed control is essential. The use of rendered protein supplement derived from ruminants was banned in ruminant feed in the European Union (EU) in 1994 (10) and in the U.S. in 1997 (11). Since 1996 the World Health Organization (WHO) has recommended that all countries ban the use of ruminant tissue in ruminant feed (12). The EU has introduced a total ban on the feeding of processed animal protein to all animals which are for human consumption under the new processed Animal Protein Regulations, while blood, milk and gelatin are exempt from the feed ban (13). This total feed ban has been in force since 2000. While the practice of adding rendered animal by-products, such as meat and bone meal (MBM) as a protein supplement to non-ruminant animal feed and pet food continues in many BSE-free countries, different regulatory emphases are placed on specific animal species and the materials that are permissible for use or prohibited. Therefore, methods that can reliably detect prohibited animal species in MBM and feedstuffs are crucial for effective implementation and enforcement of the preventive measures for BSE, as well as other Transmissible Spongiform Encephal-opathies. The requirement of adequate sensitivity and reliability of the assay to not only detect prohibited species but also differentiate the prohibited tissues from allowed animal materials, such as blood, milk and gelatin of the same species, and without cross reaction with plant materials in severely heat-processed and highly complex feed samples has greatly increased the level of the challenge involved in method development.

In this chapter, the author presents a brief overview of the techniques that are currently used to identify meat species and/or quantify the species content. These methods are summarized in Figure 30.1 and the currently available commercial assays for meat species identification are listed in Table 30.1. The term "meat species" is used in this chapter to refer to a broad range of animal species including mammalian, avian and marine animals. The intent is not to provide an exhaustive review of the analytical methods in this area but to describe the trend of method development and to discuss the principles, usefulness and limitations of the most commonly used techniques illustrated by using exemplary studies. More detailed reviews of the methods used for meat species identification in food or feed products at various developmental stages can be found in a number of articles in the literature (6, 14–22). The classic methods such as electrophoresis, chromatography and immunodiffusion usually depend on the stability of the soluble proteins and are generally applied to raw meat products, although some have also been applied to cooked meat with limited success. Since the recent development of new techniques has centered on protein-based enzyme immunoassay and DNA-based Polymerase Chain Reaction (PCR) analyses in heat-processed products, essential factors and considerations important to their assay development are discussed. An overall comparison between these two approaches is made in terms of specificity, sensitivity, quantitative measure and convenience of the assay.

II. CURRENTLY AVAILABLE METHODS

A. ELECTROPHORESIS

Electrophoresis is a powerful technique for the separation of soluble proteins into distinctive banding patterns. In general, most electrophoretic methods use sarcoplasmic proteins for species identification in raw meat, because heat denatures and insolubilizes most of the native sarcoplasma proteins, protein extracts of heat-processed meat result in only a few faint bands. Analysis of meat samples by electrophoretic methods must be made by comparing the patterns obtained to those of authentic samples run simultaneously. Usually, the complex protein banding fingerprint makes electrophoresis unsuitable for the analysis of meat mixtures. Several electrophoretic techniques are described below. They are commonly used to differentiate animal species, mostly in raw samples, although a few heat-processed sample treatments are also included.

1. Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

SDS-PAGE is the most widely used technique for the separation of soluble proteins based on their molecular sizes.

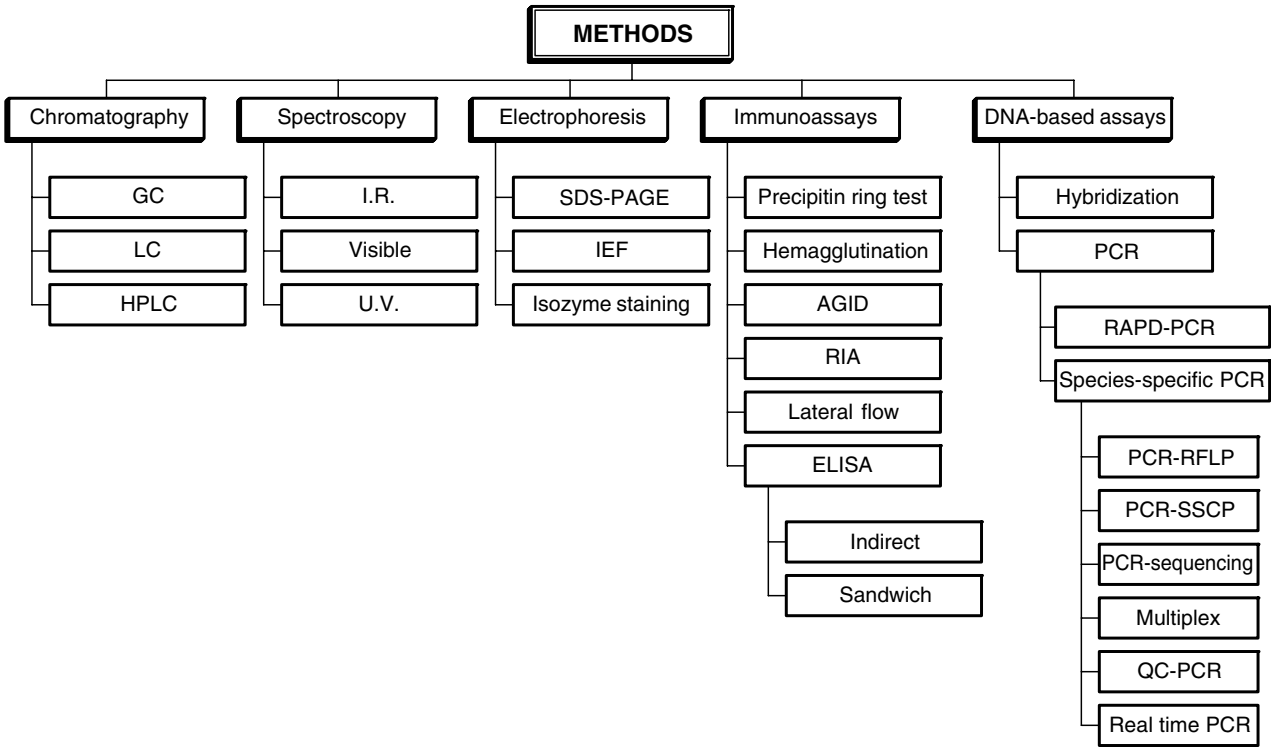

FIGURE 30.1 Current methods for meat species identification.

This technique has been successfully used to detect differences in native and heat-treated muscle proteins of various animals (23–25). Separation of different muscle proteins by SDS-PAGE usually results in relatively uniform patterns, therefore, this method is less reliable for meat species identification (26–28). Using more sensitive silver staining for visualization of the SDS-PAGE protein bands, Zerifi et al. (29) reported that this method detected species adulteration in cooked meat at concentrations of 10% (w/w) in a binary meat mixture. However, many factors other than the animal species, such as the amount of protein loaded on the gel, the freshness of the meat, the age and sex of the animal, the residual blood content, the degree of heat processing and the staining techniques, may all affect the protein-banding patterns. Thus, the lack of sensitivity and reproducibility of the assay and the difficulty of the gel interpretation are the main drawbacks limiting the use of SDS-PAGE for meat species identification.

2. Isoelectric Focusing (IEF)

IEF separates proteins into characteristic patterns based on differences in the isoelectric points of their protein bands. IEF was first used by Tinbergen and Olsman (30) for species identification. It has since been extensively used and officially recommended for the identification of fish species (31–34). The IEF protein banding profiles for many species are available from the U.S. Food and Drug Administration (http://vm.cfscan.fda.gov). It is also used in identifying animal species in either raw or cooked meats (35–39). Although the resolution is better than SDS-PAGE, the patterns of the total protein profiles obtained by IEF are much more complicated and less consistent (40). The technique may be useful for identifying individual species within families or genera, but the large number of protein bands makes the interpretation of the results impossible in meat mixtures or in uncommon meat samples.

3. Isozyme Staining

Another possible approach is to use isozyme staining to improve the sensitivity of electrophoretic assays in raw meat. Isozymes are different enzyme proteins that catalyze the same reaction. After electrophoretic separation of meat protein extracts, the gel is stained for a particular enzymatic reaction. The staining makes the isozymes catalyze the formation of colored compounds via a set of coupled reactions. For most meat extracts, isozyme staining will lead to several different protein bands on the gel at different positions, which correspond to the different enzyme proteins that are capable of catalyzing the same enzymatic reaction. The relative positions of the isozyme markers are characteristic of the species. Several staining systems using isozymes, such as esterase (41, 42), phosphoglucomutase (43), creatine kinase (44, 45), lactate dehydrogenase (40, 46) and peroxidase (47) have been employed for species

identification of meat after electrophoresis. Although isozyme patterns are essentially the same for all members within a species, there are distinctive patterns between each species (40) and some variations within species age and sex groups may also occur (41). Since the proteins must retain their activity for the staining process, it is essential that the isozyme markers do not denature during extraction and electrophoresis (43, 46). As a result, this method is less reliable due to the difficulty of controlling the enzyme activity of the unknown samples and its application is thus limited to the identification of species in raw meat.

4. Capillary Electrophoresis (CE)

Capillary electrophoresis is a sensitive separation technique that combines the electrophoresis principle with chromatographic methods for protein analysis. A sodium dodecyl sulfate polymer-filled capillary gel electrophoresis (CE-SDS) method was developed by Cota-Rivas and Vallejo-Cordoba (48) for species identification of raw beef, pork and turkey meat. The CE-SDS sarcoplasmic protein profiles that resulted were specific for each animal species both qualitatively and quantitatively. The same authors (49) later developed a pattern recognition statistical model that utilized linear discrimination analysis to interpret the CE-SDS meat protein profiles. This method is sensitive enough to differentiate between mechanically recovered chicken meat and hand-deboned chicken breast meat based on the difference in their hemoglobin (50). In general, however, this level of sensitivity is not desirable for routine meat species identification but only serves to complicate the results. Although fast separation, automation and on-line data analysis are major advantages of the technique, investment in an expensive instrument is required. It is also extremely difficult to interpret the results, especially when mixtures of multiple species or protein additives are involved.

B. Chromatography

Chromatographic methods such as gas chromatography (GC), liquid chromatography (LC) and high performance liquid chromatography (HPLC) have been applied to identify species in meat samples based on an examination of their fatty acid composition (51), histidine dipeptides (52, 53) or protein profiles (54, 55). Among these techniques, HPLC has been the most frequently used method by researchers. For example, a reverse phase high-performance liquid chromatography (RP-HPLC) method has been used to identify several animal species in raw and heated meat based on species-dependent histidine peptides, specifically the ratio of carnosine to serine (C/A) (53). In another study a size-exclusion HPLC column was used to examine differences in the myofibrillar protein profiles of fresh meat samples (55). Although the chromatographic patterns were similar for different muscles within species, there were several unique proteins and the percentage area under several protein peaks varied (54, 55), which may present difficulties for data interpretation. Based on the rationale that fat is not affected by heating, an LC method was developed for the detection of pork and lard in fresh and heat-processed meats based on the increased ratio of the triglyceride containing saturated fatty acid to the triglyceride containing unsaturated fatty acid at the C-2 position after derivatization (56). However, since the fat content in meat products varies widely, it is difficult to quantify meat adulteration from the fat profiling methods alone. As with electrophoretic methods, chromatographic methods may be capable of differentiating between individual meat species, but they are less effective in detecting adulterated species in meat mixtures or cooked meat because of the increased complexity of the chromatographic patterns. In addition, the requirements of expensive instruments and laborious sample preparation procedures have restricted their use for regulatory purposes.

C. Spectroscopy

Spectroscopic methods are based on the light absorption at selective wavelength of the electromagnetic spectrum by the molecules in the samples. Spectroscopies using mid-infrared (2000–800 cm^{-1}), near-infrared (750–2498 nm) and visible (400–750 nm) reflectance spectra of meat samples for both discrimination and quantification of species content have been reported (57, 58). These spectral ranges can be used alone and in combination. Data in each spectral region are related but not identical and their combination may provide a synergistic advantage to spectroscopic analysis (59). A near-infrared spectroscopic technique was developed to distinguish between beef and kangaroo meat (60) and detect beef hamburgers adulterated with 5–25% mutton, pork, skim milk powder or wheat flour with an accuracy of up to 92.7% (61). A feasibility study on the application of mid-infrared spectroscopy has been used for quantification of chicken/turkey blends (62). A combined visible and near-infrared spectroscopy has been applied to identify species in raw homogenized meats (63) and to detect MBM in fish meal (64). When an adulterant is detected, the adulteration level can be predicted by using calibration equations for each adulterant. However, the performance of the calibration equations may be affected by several factors, including spectral scatter, derivative treatment and even sample presentation methods. The position of the spectral peaks of absorption bands may shift not only due to adulteration with other meat, but also with different food additives, fat contents, residual blood and moisture levels and cooking methods (61). In addition, this spectroscopic technique requires advanced knowledge of using statistical models for data processing and different models may be required for each possible blend of meat (58). Thus, the application of this technique to identify

meat species in highly processed products presents serious difficulties and it is neither a common nor a convenient method for the routine analysis of meat origin.

D. Immunoassays

Ever since the beginning of the 20th century, immunological approaches based on specific antibody-antigen reactions have been applied in meat species identification (65). Classical immunological procedures that use antispecies antisera include the precipitin ring test (66), hemagglutination inhibition tests (67) and the agar gel immunodiffusion (AGID) technique (68). Advances in immunochemical techniques have led to new types of immunoassays, including radioimmunoassays, enzyme immunoassays and non-enzymatic chromatographic immunoassays (lateral flow), with greatly improved sensitivity and accuracy. Radioimmunoassay is commonly used only in clinical settings, as the hazardous radioactive materials involved and the requirement for expensive and delicate scintillation counting equipment have restricted its use in routine and field tests of meat species. Two immunoassays, agar gel immunodiffusion (AGID) and the more recent enzyme-linked immunosorbent assay (ELISA), both of which are widely used for meat identification, are described in more detail in the following sections.

1. Agar Gel Immunodiffusion

Agar gel immunodiffusion (AGID), a double immunodiffusion technique originally described by Ouchterlony (68), involves the diffusion of antigens and antibodies in a semisolid agar gel. After overnight incubation, a visible opaque band is formed at the point where the antibody and its correspondent antigen have met. The modification of this technique using stabilized reagent paper discs and pre-prepared agar plates has led to the development of convenient field test kits such as ORBIT (Overnight Rapid Bovine Identification Test, 69), PROFIT (Poultry Rapid Overnight Field Indentification Test, 70), PRIME (Porcine Rapid Overnight Field Identification Method, 71), SOFT (Serological Ovine Field Test, 72), REST (Rapid Equine Serological Test, 73), DRIFT (Deer Rapid Identification Field Test, 74) and MULTI-SIFT (MultiSpecies Identification Field Test) for meat speciation by USDA-FSIS meat inspectors (75). These field tests are mainly based on the detection of serum proteins and are suitable for testing intact pieces of raw meat. Antisera against plasma proteins for raw meat species identification are available commercially. The detection limit of the assay for the target species in a meat admixture relies on the quality of the antispecies antisera. With traditional AGID, the detection limit of the assay is usually in the region of 3–10% (17, 76). In most cases, standardization of the commercial antisera against each type of sample is required. Although AGID is relatively simple to perform, it requires a substantial amount of antisera and the variable sensitivity, possible interferences by non-meat ingredients and the requirement for overnight incubation have restricted AGID to qualitative assays of whole pieces of fresh meat.

2. Enzyme-Linked Immunosorbent Assay (ELISA)

ELISA has gained widespread acceptance for meat speciation applications due to its simplicity, specificity and sensitivity and is now recognized as a suitable analytical method for quality control and enforcement of muscle food safety and labeling regulations. It can be used for assaying various analytes in complex mixtures with minimal sample preparation requirements. ELISA does not need major scientific equipment, is easy to perform, uses only small quantities of immunoreagents, and has large-scale screening and field test capacity. However, the success of the assay primarily relies on the quality of the detecting antibodies that capture the target protein antigen in a sample extract. Both polyclonal (Pabs) and monoclonal (Mabs) antibodies have been employed in various formats of ELISA for the detection of species adulteration. Traditionally, Pabs obtained from the antisera of immunized animals have been used in ELISA. More recently, however, several Mabs against muscle proteins have been developed for the identification of raw meat (77–81) and for heat-processed meats and feedstuffs (6, 28, 82–85). A comprehensive review of studies published up to 1998 of ELISAs that utilize Pabs and Mabs for species identification of raw and cooked meat is provided in Hsieh et al. (6).

The two ELISA formats most commonly used for meat speciation are indirect ELISA and double sandwich ELISA. Indirect ELISA involves the adsorption of a fixed amount of meat proteins that may or may not contain the antigen molecules of a target species onto a microtiter plate. An antispecies antibody is then used to bind the antigen to the solid phase. The immunoreaction between the bound antigen and the antibody can be detected by a secondary anti-immunoglobulin enzyme conjugate, and subsequently color is developed by the addition of the enzyme substrate. The color intensity is proportional to the amount of antigen present in the protein extract. Indirect ELISA is often used to determine the titers and specificity of an antibody reagent. However, it is neither a convenient nor a reliable assay format for the routine analysis of unknown samples because the protein concentration for each meat extract must be determined before the sample can be properly diluted and coated on the microtiter plate. The dilution and composition of the meat extract affects the antibody binding, and thus the ELISA results. Sandwich ELISA employs an antibody immobilized on the solid phase as the capture antibody

and another antibody as the detecting antibody to form a sandwich with the antigen in the middle and two antibodies attached on the different epitopes of the antigen molecule. This is a more user-friendly format that is widely used for commercial test kits because properly diluted sample extracts can be directly added to the assay plates which are pre-coated with the first capturing antibody reagent. To develop a sandwich ELISA, if Pabs are used in the assay, the same Pab reagent can be used for both the capturing and detecting antibodies due to its heterogenous nature. If Mabs are used, however, two different antibodies with similar specificity and affinity that bind to different epitopes are required. A combination of Pab and Mab is also commonly used in a sandwich ELISA.

3. Factors to Be Considered in Immunoassay Development

a. Species markers

To identify an animal species using an immunoassay, a suitable species marker must be chosen as the antigen for antibody development. For most raw meat identification, serum proteins have been used as antigens to develop the immunoassays (2, 86–88). Serum proteins are water soluble and easy to extract, thus the sample preparation is simple. However, the presence of serum proteins may not necessarily denote the presence of muscle tissues due to variations in the residual blood content of the muscle tissues. Such assays would not be reliable for quantifying adulteration levels of extraneous muscle tissues (89). Moreover, serum proteins are susceptible to heat denaturation; the reliability of using serum proteins for detecting species origin would be greatly reduced in cooked meats (90). Any antigens used for cooked meat identification must either be able to withstand cooking or maintain their antigenicity after heating.

Assays based on the detection of heat-resistant, species-specific muscle proteins are more indicative for a quantitative measure of lean meat, as well as supporting the assay in both raw and cooked meat mixtures (77, 82). Several researchers have attempted to resolve the thermal-stable components of different meat species. Milgrom and Witebsky (91) described antigens from the adrenal gland that are suitable for species identification. Those antigens, designated as BE, retained their immunogenic properties even after being subjected to boiling and autoclaving, and can be precipitated with ethanol. Hayden (92) developed polyclonal antisera to adrenal BE antigens for species identification using an immunodiffusion assay, which enabled the detection of meat from different species at 5–10% levels in cooked beef sausages. Using isoelectric focusing, Jones and Mortimer (37) demonstrated that for the thermal-stable muscle proteins (TSMP) eluted in a low pH range (3.5–6.5), the characteristic pattern of thermal-stable proteins from different species were not notably different. Sherikar et al. (93) later reported that "troponin T," with a molecular weight of 36 kD, was the specific antigenic fraction of the TSMPs. Assays based on these TSMP markers showed more or less cross-reactivity to certain non-specific proteins. ELISA protocols currently used by the USDA-FSIS for the identification of cooked meats utilize Pabs against heat-resistant muscle glycoproteins (94, 95). Several commercial sandwich ELISA kits for cooked meat speciation have also been produced based on the detection of the glycoproteins (Table 30.1). These commercial kits are able to analyze meats cooked under normal conditions, although the ELISA signal decreases rapidly when the meat is cooked above 100°C.

Antisera raised against crude thermal-stable muscle proteins according to the method of Kang'ethe and Gathuma (96) have been used to detect ruminant proteins in rendered animal materials heated to >130°C (97). However, the ELISA based on these antisera requires a lengthy procedure to remove gelatin, which interferes with the measurement, and to concentrate sample proteins in order to boost the assay sensitivity. The assays also exhibit cross-reactivity with plant protein present in the feedstuff (98, 99). In our own laboratory, troponin I (TnI), a subunit of troponin which is a contractile regulatory protein in the muscle thin filament, has been identified as a suitable species-specific and thermal-stable biomarker for meat species identification in raw, cooked and autoclaved meats (100, 101). Mabs developed against TnI could detect and quantify muscle protein heated up to 132°C for 2 hours without compromising any of the reaction signals (85). An indirect ELISA based on the Mabs raised against porcine TnI was developed to quantify pork skeletal muscle tissue in a meat admixture, with a detection limit of 0.5% (w/w) (28). Sandwich ELISAs based on TnI-specific Mabs have also been developed for the detection of prohibited animal proteins, such as ruminant, mammalian and all animal species, in rendered MBM and/or in feeds with a detection limit of 5 ng/ml of TnI, or at least 0.05% of the adulteration meat species in feed (102). In addition, the abundance of TnI in muscle tissue and its excellent extractability, even after severe heating, offers advantages for a sensitive detection method with a simple sample extraction procedure. The lateral flow strip test kits marketed by a U.S. company (Table 30.1) are based on the detection of the ruminant TnI antigen, and are currently being used internationally for BSE surveillance.

b. Antibodies

Once a suitable antigen has been selected, the most important criterion for the successful development of enzyme immunoassays for meat speciation is the production of species-specific antibodies raised against the antigen. The antibodies are the key immunoreagents that differentiate individual species. The performance of ELISA depends on the nature, quality and availability of the antibody used

and both Pabs and Mabs have been used in immunoassays for species identification. Pabs are antibodies obtained from the antiserum produced by an immunized animal in response to an antigen. They are relatively quick and easy to develop and are heterogeneous in nature, with subpopulations binding to either species-specific or non-species-specific epitopes; hence cross-reactivity of the antisera with closely related species is commonly observed (103). However, the preparation of species-specific antisera requires immunoaffinity adsorption of cross-reactivity, which is a costly and time-consuming procedure. Moreover, variations in specificity and affinity between batches of antisera are the major concerns when developing standardized procedures (15). In contrast, Mabs are produced by a chemical fusion of antibody-producing cells (B-lymphocytes) and myeloma cells. They offer advantages over Pabs due to their homogeneous nature and biologically well-defined characteristics. Although the initial development costs of Mabs are higher than for Pabs, the use of Mabs in immunoassays ensures a continuous supply of a uniform immunoreagent and will eventually reduce the cost of the analysis (6, 77). Since every Mab has unique binding properties, ELISA procedures for each Mab must be optimized individually to achieve the most accurate analysis and the lowest detection limit.

Usually, IgG is the class of Mabs that is preferred for use in immunoassays, as it has been reported that IgM Mabs frequently participate in unexpected cross-reactions (104). IgM Mabs that are high-molecular-weight molecules are also more difficult to purify and store than IgGs (105). The most convenient way to avoid obtaining IgMs is to screen hybridoma clones with detection antibodies specific to the IgG γ-chain.

4. Specificity

Immunoassays for species identification are typically developed for a specific animal species and cross-reactivity of the antibody reagent to closely related species is often a major concern. As mentioned previously, the preparation of species-specific Pab reagents requires immunoaffinity absorption of the cross reactive components. Usually, pure antigen is required to immunize animals in order to increase the chance of producing more specific Pabs in the antiserum. Developing Mabs does not require the use of a pure antigen and crude antigens could theoretically be used for the production of species-specific Mabs. However, we found this to be ineffective, as the chance of selecting a specific clone by immunizing and screening with crude antigen is remote. The development of mono-specific Mabs is much more difficult than that of group-specific Mabs. This is mainly because species-specific antigenic determinants on the crude protein antigens are much rarer than those determinants shared by zoologically related species. The use of a pure antigen with known species-specific antigenic determinants substantially increases the chances of eliciting specific antibodies.

Developing antibodies with broad specificity is also important for the initial screening of samples for the detection of species adulteration or substitution in meat products. Currently available commercial ELISA kits for meat species identification are designed for qualitative tests of a single species at a time. For regulatory purposes, it is very expensive and time-consuming to test a large number of samples for multiple species using these ELISA kits, and it would be much more cost- and labor-effective for a single screening to be used to distinguish between different classes of meat. Mabs developed to recognize common mammalian species in cooked poultry products (83) and to detect poultry meat in cooked mammalian meat (84) have been reported. More recently, Chen et al. (85, 102) developed ruminant-specific, mammalian-specific and all animal-specific Mab-based immunoassays for the detection of ruminant, mammalian and animal proteins, respectively, in feedstuffs. These assays do not differentiate between individual species within the group but detect the presence of animal proteins of the target group.

The specificity requirement of an assay to differentiate allowed animal proteins from prohibited tissue proteins to ensure compliance with the BSE surveillance regulations presents fresh challenges for the development of species identification immunoassays. Specificity of the antibodies to muscle proteins seems to be a prerequisite for the development of such assays. Immunoassays using skeletal-muscle-specific Mabs that are able to detect severely heat-treated target meat with no cross-reactivity to blood and food proteins, including milk proteins, egg albumin, soy proteins and gelatin, have been reported (102, 106). The muscle-specificity of the assay is also important for food testing because food proteins are frequently used as additives in commercially prepared meat products.

E. DNA-Based Assays

Immunoassays have been extensively used for authentication of animal species in raw meat for decades, but the non-availability of antibodies or cross-reactions of the antibodies to proteins from closely related animal species in highly processed and heat-treated meat is the major reason behind recent efforts to develop nucleic acid-based methods as a alternative approach. In general, DNA is both more stable and more heat-resistant than proteins and the information content of DNA is greater than that of proteins due to the degeneracy of the genetic code. For these reasons, DNA-based methods are now being developed to counter the challenges that currently limit immunoassay techniques. DNA hybridization and polymerase chain reactions (PCR) are the two major DNA-based analytical approaches to meat species identification. DNA hybridization techniques are generally time-consuming and complicated. In contrast,

the more recent PCR techniques, which easily amplify target regions of template DNA with or without prior knowledge of the genetic information, have proved to be more sensitive and rapid than DNA-based techniques for meat species identification. Lockley and Bardsly (20) have reviewed DNA-based methods for food authentication.

1. Hybridization

The initial studies using DNA for meat speciation were based on hybridization of labeled DNA probes to samples. Either genomic DNA or cloned DNA was hybridized with target genomic DNA that had been covalently attached to nylon membranes in a slot- or dot-blot format and detected by color development or autoradiography (107–111). This had the advantage that preparation of probes from genomic DNA did not require prior knowledge of the DNA sequences. Utilizing hybridization based on a total genomic probe, a cross-reaction between cattle, sheep and goats was observed, reflecting some degree of homology in the sequences of the satellite DNA in these closely related species (109). Modified DNA hybridization for reducing cross-reaction by the addition of unlabeled DNA from the cross-hybridizing species enabled differentiation between sheep and goat with about a 10% detection limit (111). Improved assay specificity was also achieved by using probes derived from published satellite sequence information. Wintero et al. (108) compared a probe based on a 2.7 kb porcine specific satellite fragment (112) with labeled total genomic DNA, and found the former to be more specific. The use of species-specific satellite DNA probes for the unequivocal identification of raw meat from pigs, cattle, deer, chickens, turkeys, rabbits, sheep and goats has been reported (113–115). As the species-specific probes tend to be relatively short oligonucleotides of less than 100 bases, hybridization is possible even after DNA degradation has occurred. These methods are specific and useful for the identification of cooked meat species, but the procedure is complex, time-consuming and inadequate for complex sample matrices or for quantification of adulteration levels.

2. Polymerase Chain Reaction (PCR)

PCR methods have gained tremendous popularity in recent years because the amplification power of the PCR technique enables the detection of target DNA sequences when sample quantity is limited. A wide variety of PCR-based methods for the identification of meat species in food and feed products have been developed in the past decade. All of these PCR methods can be categorized into two approaches, Random Amplified Polymorphic DNA (RAPD) and species-specific PCR. RAPD amplifies multiple unidentified sequences using non-specific primers, leading to species-specific fingerprints of PCR products visualized by gel electrophoresis. No prior knowledge of the DNA sequences is required. Species-specific PCR uses either conserved or specific oligonucleotide primer pairs targeting species-distinguishing sequences in genomic or mitochondrial DNA. The prior knowledge on the DNA sequences is required for primer design. The amplified PCR products can then be discriminated according to their sizes, sequencing or further analyses such as Restriction Fragment Length Polymorphism (RFLP) or Single Strand Conformational Polymorphism (SSCP). Advances in modern PCR techniques have emphasized improving the efficiency, reproducibility and speed of detection.

a. Random Amplified Polymorphic DNA (RAPD)

Using arbitrary primers based on short oligonucleotide sequences, the RAPD method amplifies numerous unidentified sequences simultaneously. After gel electrophoresis, the PCR products generate fingerprint patterns that contain features unique to a particular species. The discriminating ability of the RAPD-PCR is virtually unlimited because there is an unlimited choice of arbitrary primers. However, not all random primers can adequately distinguish between species. A careful screening and selection of the primer used is important for the successful application of the technique (116). RAPD has been employed to differentiate species in domestic animals (117), various meat and meat products (116, 118) and feedstuffs (119). RAPD has also been shown to produce clear fingerprints from processed products in which DNA has been slightly degraded, such as smoked or salted fish products (120). Although the technique generates informative fingerprints in a relatively short time, the reproducibility of the patterns is unpredictable due to various factors, such as changes in cycling conditions or intra-species polymorphisms. Use of longer primers and higher stringency amplification conditions may improve the assay reproducibility and resolution (121). Therefore, RAPD assay protocols must be optimized for each application and must be stringently followed to ensure assay repeatability. The DNA molecules are usually degraded into smaller fragments in severely processed products; RAPD analysis thus cannot reliably be used to analyze canned or sterilized samples. In addition, RAPD may not be practical for identifying species of origin in products containing 50–50% mixtures of species that can be interbred, because the pattern of a 50–50% meat mixture cannot be distinguished from that of a hybrid (120). Thus, RAPD is useful as a rapid, qualitative method for meat speciation, but known standards must be run simultaneously each time a sample is tested (117). A review of the principles and applications of RAPD assay for genetic analysis of livestock species was published by Cushwa and Medrano (16).

b. Species-specific PCR

Species-specific PCR for species identification has been developed to target a DNA segment with sufficient species-specific variation. The forward and reverse primers are designed to be specific to each species based

on the alignment of available DNA sequences from selected genes. Under stringently defined reaction conditions, such primers generate an amplicon only in the presence of DNA from a given species. Complete sequence information permits the size of the product to be predicted, so that the identification can be confirmed if an appropriately sized amplicon appears on the gel. Mitochondrial genes such as the ATPase subunit 8 and subunit 6 (122, 123), D-loop (124) and cytochrome b (Cyt b) genes (125–129), satellite DNA (130), actin genes (131, 132), Art2 short and CR1 long interspersed repetitive elements in genomic genes (133) and growth hormone gene (134) have been studied for the purpose of identifying animal species, with most of the methods concentrating on the Cyt b gene as a target sequence. The specificity of PCR primer pairs that encoded the Cyt b gene sequence has permitted the amplification of degraded tuna DNA for the identification of cooked and canned tuna fish species in commercial preparations (135). Tartaglia et al. (122) developed a bovine-specific PCR assay using bovine-specific mitochondrial DNA sequence, which allowed the detection of bovine meat and bone meal in feedstuffs at the 0.125% level. By amplifying the satellite DNA using a bovine-specific primer pair, Guoli et al. (130) was able to identify raw, cooked (100°C, 30 min) and autoclaved (120°C, 30 min) beef without cross-amplification with other animal species tested. Multiplex PCR allows simultaneous identification of multiple species with one PCR by using one universal primer from a conserved DNA sequence in the gene paired with multiple primers target to hybridize on species-specific sequences for each species (127, 136). All these species-specific PCR products were obtained without the need to adopt other secondary associated techniques such as, RFLP, SSCP or DNA sequencing.

More recently, several real-time PCR methods have been developed in order to shorten the assay time by eliminating the need for post-PCR processing, such as electrophoresis associated with conventional PCR. For real-time PCR using TaqMan™ technology (137), one of the primer probes is labeled with a reporter fluorescence dye and a quencher dye. When both dyes are attached to the probe, the fluorescence is quenched by the quencher dye so that negligible fluorescence from the reporter dye's emission is observed. Once the PCR amplification begins, DNA polymerase cleaves the labeled probe and the reporter dye is released from the probe. The separation of the reporter dye from the quencher dye during each amplification cycle generates a sequence-specific fluorescent signal. The signal increases in real time as the PCR cycles progress, as the intensity of the fluorescence is a function of the number of cycles. Real-time PCR, therefore, can be used to monitor the PCR product accumulation as the amplification cycle proceeds, allowing the detection of the target sequence with a high sensitivity. Since the analysis and detection take place in a closed reaction vessel, this has the advantage of minimizing carry-over contamination and reducing the incidence of false-positive results. TaqMan™ technology amplifying species-specific primers has been developed for the detection of beef or pork in foods with a detection limit of 0.1% to 0.01% of the adulteration level (138–140). An alternative real-time PCR system using LightCycler™ technology has been used for the detection of trace amounts of tiger bone, with a detecting power of 10 substrate molecules (141). In this system, fluorescence is emitted when labeled probes are hybridized to newly synthesized DNA (142).

3. Factors to Be Considered in the Development of PCR Methods

a. DNA probes

The specific interaction between the sequence of the DNA probe and the complementary sequence in the DNA segment of interest determines the assay outcome. PCR allows a particular sequence of DNA in samples to be targeted by primers and amplified. Selection of the primer sequence for PCR amplification depends on the sequence variation in primers that subsequently and adequately produce amplicons unique to each animal species. Primers used will affect the sensitivity and accuracy of the PCR assay. Total genomic probes can be used to identify distantly related species, but tailored oligonucleotide probes need to be designed for differentiation of closely related species (17). Most strategies to date have targeted the Cyt b gene in the mitochondrial DNA sequences because of the high number of copies per cell in animal tissues (143), inherent variability (144) and the difference in its gene arrangement between plants and animals (145). It has been shown that each cell may contain up to 1000 copies of Cyt b locus and Cyt b sequences differ by at least a few nucleotides even in very closely related species (146). PCR assays based on the amplification of Cyt b have the advantage of increased sensitivity compared to single or low copy nuclear DNA targets (147). The repetitive sequence in genomes can also be markers for sensitive species identification because these repetitive elements are present in more copies than mitochondrial DNA. Using short and long interspersed nuclotide elements, Tajima et al. (133) reported a PCR assay with improved sensitivity. Their primers were able to detect DNA in feed containing 0.01 to 0.001% commercial MBM. However, the quantity of genomic DNA or mitochondrial DNA per gram present in different types of tissues varies (148), which may affect the detection limit of the assay or a quantitative estimation of the target species in a meat mixture (136). For identification of hybridized animals, assays based on the maternally transmitted mitochondrial DNA are invalid because only the maternal lineage can be identified. Species origin of a hybrid animal can only be verified by analysis of nuclear DNA (149).

Although DNA is more heat stable than most proteins, DNA is also degraded by heat or the action of radicals. Severe heat treatment or prolonged processing of the meat product will increase the degradation of DNA; thus the recovery of analyzable DNA can be difficult or uneven from different species (127). The fragment sizes of DNA from meat heated to 100°C is reduced from ~1100 bp to ~300 bp (110), while the DNA extracted from canned tuna meat was degraded to an average size of ~100 bp. In order to confirm the utility of the PCR method for analyzing heat-processed tissues, the amplification should be carried out on DNA derived from larger portions that were subject to longer heating times (147). In other words, the length of the DNA fragments should be long enough to distinguish species variation and at the same time short enough to allow amplification of highly degraded DNA. RAPD analysis does not seem to be reliable for analyzing canned or sterilized samples. The specie-specific oligonucleotide probes which recognize relatively short sequences of DNA with adequate sequence variation between species, on the other hand, are able to accommodate a considerable amount of DNA degradation without influencing assay specificity. In addition, PCR fragments generated from mitochondrial DNA seem to be more successful than nuclear DNA for speciation of heat-processed samples because mitochondrial DNA, being circular in shape, is more resistant to heat disintegration (150). Most recently developed PCR methods (123, 138, 151–154) for the detection of bovine tissue in feedstuffs are based on the amplification of the ATPase subunits 8 and 6 of the bovine mitochondrial DNA sequences, which was firstly described by Tartaglia et al. (122).

b. Secondary analyses of PCR products

For species identification, several secondary analyses have been applied to PCR amplified products of which each targets a conserved region of the DNA sequence. These methods vary in their complexity, utility and cost due to the nature of each assay.

1. PCR-RFLP

PCR analysis with subsequent restriction fragment length polymorphism is the most widely used method of identifying meat and fish species (19). PCR-RFLP allows the genetic variation between species to be distinguished by digesting PCR amplified fragments from a conserved region of DNA with restriction enzymes, which act on DNA at specific sites. Based on the sequence variability among species, these enzyme-digested products can be visualized by agarose or polyacrylamide gel electrophoresis as a DNA fingerprint unique to each species. The banding pattern varies when different restriction enzymes are employed. It is important to use appropriate restriction enzymes and to ensure the complete digestion of all the DNA fragments analyzed. The enzymes selected should be available commercially, economically priced, reasonably active in the PCR mix and able to maximally differentiate between the species analyzed. PCR-RFLP has been extensively used for meat species identification in food and feed samples (149, 154–160). Partis et al. (147) evaluated this DNA fingerprinting method for determining the species origin of raw and cooked meats by amplifying a fragment within the Cyt b gene, and concluded that although the PCR-RFLP is a suitable method for identifying species in raw and cooked pure animal tissues, the assay is not suitable for analyzing mixtures since the results may not be representative of the true components present in the mixture due to differential template amplification. The general applicability of RFLP may also be hampered by intraspecies DNA sequence polymorphism or point mutations that affecting the typical RFLP pattern of a species. To overcome this drawback, the use of two restriction enzymes for the identification of an unknown sample may be sufficient because no individual identified as having two different RFLP patterns compared to other individuals of the same species has been observed (156).

2. Sequencing

If information on the DNA sequence is available from databases, individual species may be identified through a given sequence of digestions with specific restriction enzymes (155). Direct sequencing of the PCR products is an ideal confirmation test and allows an assignment to a species even if there is no reference material available. Comparing Cyt b sequences from the database Brodmann et al. (5) reported that vertebrates of different classes showed correspondence of at the most 80%, and animals of the same genus showed correspondence above 94%. Correspondences of more than 99% generally indicate the same species. Traditionally, sequencing has been considered to be time-consuming and expensive and to require data handling skills, but due to recent advances in the nucleotide sequencing process, this method is nowadays relatively simple and fast. Since sequencing PCR fragments has become a standard procedure in laboratories working with recombinant DNA technologies, it has been suggested that a DNA sequence database for unambiguous authentication of animal species should be constructed (19). However, it is still difficult to apply sequencing to mixtures of different species.

3. PCR-SSCP

In comparisons involving high homology DNA sequences, further analysis of PCR products may be accomplished using Single Strand Conformational polymorphism (SSCP), which can be used to analyze the polymorphism at single loci. The PCR-SSCP technique is based on the principle that single-stranded DNA molecules take on specific sequence-dependent secondary structure under non-denaturing conditions. After performing the PCR, the amplicons are denatured to single strands. Single-stranded molecules differing by as little as a single base substitution will form different conformers and migrate differently in a non-denaturing gel

electrophoresis (161). This technique has been applied to identify fish species (162–165) as well as differentiate between samples of species of pig and wild boar meat (166). Stringent conditions must be maintained for intrabase pairing, as this affects the electrophoretic mobility and reference material must be treated in the same way and run alongside the unknown sample. Intraspecies variability of single-strand DNA patterns may also cause some confusion in identifying an unknown sample. In such cases, different regions of the DNA probe can be used for SSCP, or use of RFLP analysis or sequencing of the amplicons (163).

F. Overall Comparison of Immunoassay and PCR Methods

Immunoassay systems are suitable for use in the laboratory for routine analyses or large-scale sample screening, as well as for development into convenient field test kits. These assays usually only require simple sample preparation and need no major instrumentation. The overall assay time can be as short as 30 minutes. However, immunological approaches depending on antibodies often suffer from loss of reactivity due to heat treatment of the sample and cross-reactions of proteins from closely related species. Availability of suitable antibody reagents is the major limiting factor for the application of immunoassay methods. Immunoassays based on the detection of serum proteins are limited to qualitative analysis only because the amount of residual blood does not parallel the quantity of meat tissue present in a sample. In order to achieve a quantitative analysis, the assay must target an abundant antigen with an even distribution in muscle tissues from different parts of the animal, so that the amount of antigen measured by the assay corresponds to the amount of the target muscle tissue in the sample, regardless of the location of the cut. Once developed, the antibodies can be applied in various immunoassays for maximum success.

It is a common belief that PCR-based techniques offer a high detection sensitivity and specificity. They can be applied in both raw and highly processed products even with extensive protein denaturation; thus most of the recently developed methods for meat species differentiation in feedstuffs are PCR-based techniques (see Table 30.2). Since DNA can potentially provide more information through the acquisition of sequence database, differentiation of closely related species is less difficult than in an immunoassay, which relies on the availability of specific antibodies. However, PCR-based methods are technically demanding and prone to contamination; they also require expensive instruments and dedicated facilities. Moreover, PCR based methods for quantification of the extent of sample adulteration are complex and the data interpretation is difficult. Current DNA-based techniques provide no satisfactory answer to the proportional amount of a particular species for the following reasons: 1) the difference in DNA quantity and extractability in different tissues (113); 2) differential template amplification resulted from primer mismatches (147); and 3) the ubiquity of DNA in all types of cells. Although quantitative PCR detection of porcine DNA has been reported (167, 168), the results only refer to the DNA content over a certain limited range, which cannot be translated into the content of fat or lean meat. DNA based methods are not able to distinguish between different tissues or materials (21). Therefore it is impossible to use DNA-based methods to differentiate prohibited animal tissue from the allowed blood or milk in feedstuffs. In addition, most PCR methods require the extraction of nucleic acids from the sample tissue, which limits its application for large-scale practice and the development of field testing kits. For all the above reasons, PCR-based techniques have not been adopted for routine analysis, while faster and more specific DNA-based technologies are developing rapidly. Accumulation of an extensive database of DNA sequences from different animal species will facilitate the design of primers, and thus the development and usefulness of PCR methods.

III. FINAL CONSIDERATIONS

Reliable analytical methods are indispensable for the accurate labeling of food and feed products. Detection of species adulteration requires an assay capable of working in complex and variable matrices. Hence, the challenges in developing antibody-based immunoassay or PCR methods for meat species identification lie in overcoming the potential cross-reactivity with other species and food additives. Usually, the judgment of the violation samples is limited to determining the minimum level that the method could achieve. For practical purposes, it is necessary to set a cutoff value for judging violations. Hsieh et al. (4, 7) applied 1% as their criterion for reporting the violation rate of species adulteration in official meat samples, because adulteration at such a low level would not confer any economic incentive. An assay capable of detecting down to the 1% adulteration level thus seems to be adequate for routine analysis. The assay sensitivity of both modern immunoassays and PCR methods are comparable, and either can achieve this generally acceptable detection limit of 1% or below for the adulteration level in food products. As the minimum safe level to prevent transmission of BSE in feedstuffs has not been established, no agreed sensitivity value of the assay has been established. A detection limit at a lower level than 1% is generally expected for safety reason. It is also crucial that the assay conditions are properly controlled in order to preclude incidences of false positive and false negative results.

It is necessary to optimize and standardize the conditions for protein or DNA extraction from a variety of samples. Due to the variation in sample composition, factors affecting the recoveries of antigen or DNA from samples,

TABLE 30.2
PCR and ELISA Methods Used to Identify Animal Species in Feedstuffs

References	Methods	Target Species	Probes	Detection Limit	Test of Industrial Samples No. Correctly Identified/No. Tested
159	PCR-RFLP	Dog or cat	Cyt b mt DNA	0.01% in rendered meat mixtures (121°C, 30 min)	
123	PCR	Bovine, ovine, swine or chicken	mtDNA*	0.01% in ref feedstuffs	
134	TaqMan™ real-time PCR	Mammal orbBovine (cross react w/*Cervidae*)	Growth hormone genes	0.02 ng or 0.01% DNA 1–5% in MBM	4/7 bovine in MBM 5/7 mammalian in MBM
158	PCR-RFLP	Cattle, sheep, goats, deer, elk	mtDNA	Not reported	
139	Real-time PCR	Cattle or pig	mtDNA	0.1–0.5% in feed	
168	PCR	Beef	Satellite DNA	1% bMBM (120°C, 30 min) in feed	
138	Real-time PCR	Bovine	mtDNA*	0.001% in LSR	4/6
133	PCR	Ruminants, pigs, chickens	Genomic DNA	0.01% in feed	
154	PCR-RFLP	Sheep, pork, poultry	mtDNA*	0.125% in LSR 1–5% in industrial MBM	3/7
157	PCR-RFLP	Ruminant or nonruminant	Cyt b mtDNA	Not reported	
153	PCR	Bovine	mtDNA*	0.125% in feed	False-negative 1.25% (3/240) False-positive 0.83%
152	PCR	Bovine, ovine or porcine	mtDNA*	0.3% (bovine/ovine) 1% (porcine) in LSR	Amplified 5/7 samples with accuracy of 72.5% and 60% for 2 extraction methods, failed to amplify 2/7 samples
151	PCR	Bovine	mtDNA	0.125% bMBM in feed	
122	PCR	Bovine	mtDNA*	0.125% bMBM in feed	
102	Sandwich ELISA	Ruminant	Tn I-specific Mabs	5 ng/ml TnI or 0.05% in feed	
85	Indirect ELISA	All animal, mammalian and ruminant species	Tn I-specific Mabs	0.1% (all animal) 0.3% (mammalian) 2% (ruminant) in feed	
98	Sandwich ELISA	Ruminant and porcine	Rabbit antisera	1250 ppm proteins after gelatin removal	
97	Sandwich ELISA	Ruminant	Rabbit antisera	166 ppm proteins after gelatin removal	

* Primer design according to Tartaglia et al., 1998 (Ref. 122)

bMBM: bovine meat and bone meal
Cyt b: cytochrome b
LSR: laboratory scale rendered samples
Mabs: monoclonal antibodies
MBM: meat and bone meal
mtDNA: mitochondrial DNA
PCR: polymerase chain reaction
RFLP: restriction fragment length polymorphism
TnI: troponin I

such as the extraction method, pH, salt content and heating conditions of the sample and sample matrices, need to be carefully controlled, studied and considered in interpretation of results. For validation of an assay, the lab-formulated meat mixtures might not sufficiently represent the vast variety of commercial products. Therefore, conducting trials on a variety of commercially available meat and feed products is important for assessing the validity of a new assay.

Ideal analytical methods for meat species identification and detection of species adulteration need to be specific, sensitive, rapid, affordable, of high throughput, able to analyze heat-processed as well as raw products and provide quantitative measures. No single method can meet all these requirements for all types of samples at all times. Selection of an assay depends on many factors, such as the purpose of the assay, nature of the sample, sample size and numbers, specificity and sensitivity required, turnaround time, cost, availability of facilities and equipment, etc. Although many challenges have yet to be fully met by any laboratory or diagnostic service, most assays mentioned in this chapter may be used complementarily to each other. To safeguard consumers, the integrity of the food chain is non-negotiable. As the problems and trends of species adulteration change in the meat and/or feed industries, in order to ensure compliance with the corresponding regulations, our analytical skills will continue to face challenges in this area. New techniques emphasizing faster and more convenient assays, such as one-step assays, biosensors, microarray technology, and automated systems based on antibodies, DNA or both, will provide the weapons for the next generation's fight to protect consumers and safeguard our food supply.

CONTENTS

I. INTRODUCTION

The conversion of muscle into meat is a complex process that involves an understanding of muscle components as well as metabolic reactions. This chapter will focus on the chemical components of the live muscle and chemical and biochemical reactions leading to the conversion of muscle into meat.

II. COMPOSITION AND CHEMISTRY

A. Water

One of the most abundant and important components of meat is water. Poultry meat contains approximately 75% water by weight. Water has several functions within meat, one of which is a medium for transportation of nutrients, hormones, metabolites, and waste to and from cells. It also provides a medium for chemical reactions and metabolic processes. Three states of water exist in muscle: bound, immobilized, and free. Bound water is very tightly bound to proteins and can only be removed by ashing. Immobilized water has weaker interactions than the bound water and is associated with ions and proteins. This water, held by ionic interactions, may be released during cooking or heat application. Free water is loosely held in the cell, and is susceptible to loss known as drip or purge.

B. Carbohydrates

Skeletal muscle does not have an abundant supply of carbohydrates. Glycogen, the storage form of glucose, is the major carbohydrate found in muscle and can be up to 0.5 to 1.3% of the weight of the muscle (1). It is important in providing energy for metabolism, contraction, and relaxation. Other carbohydrates include intermediate substances and products of cell metabolism.

C. Lipids

Poultry muscle contains several types of fatty acids including saturated, unsaturated, acylglycerols or neutral lipids, and phospholipids. The neutral lipids are the most abundant. These fats are composed of fatty acids and a glycerol backbone. They consist of mono-, di-, and triglycerides, depending upon how many fatty acids are bound to the glycerol backbone. Phospholipids are mainly found in the cell membranes and contain both hydrophobic and hydrophilic sites. Lipids have many functions including providing energy for the muscle cell, metabolic functions, and cell membrane structure and function.

D. Proteins

Protein constitutes approximately 16% to 22% of the muscle, second in abundance only to water (1). Muscle contains several classes of proteins including myofibrillar, sarcoplasmic, and connective tissue proteins. The myofibrillar proteins are long, fibrous, charged, and are salt soluble in elevated ionic concentrations of 0.3 M or greater (<1.5% NaCl) (2). These myofibrillar proteins are responsible not only for contraction and relaxation, but also water holding capacity and protein functionality. The myofibrillar proteins can be further divided into three functional categories: contractile (myosin, actin), regulatory (tropomyosin, troponin) and cytoskeletal proteins (titin, connectin, C-protein, and desmin). Of these proteins, myosin and actin are considered to be the most abundant and the most functional, especially in food complexes.

Sarcoplasmic proteins are mainly globular and function as enzymes and cofactors involved in energy metabolism. Many of these proteins share common properties such as high isoelectric points, globular structures, and low molecular weights. With these properties, the sacroplasmic proteins are water soluble and can be extracted in low salt solutions with an ionic strength of less than 0.15 M.

Connective tissue proteins provide strength and support for the muscle in such ways as tendons and ligaments. Within the interstitial space of the muscle, the connective tissues consist of collagen, reticulin, and elastin along with other supporting proteins termed ground substance. Connective tissue proteins are very fibrous and insoluble in high ionic strength solutions.

E. Inorganic Substances

Most of the inorganic constituents consist of cations and anions used in muscle metabolism, contraction, and relaxation. Calcium is required for contraction to occur and is stored within the muscle cells. Other inorganic substances are potassium, sodium, magnesium, chloride, and iron.

III. SKELETAL MUSCLE

A. Ultrastructure

Skeletal muscle is a complex structure that is a major component of the body and has been reviewed by several authors (3–7). The muscle is surrounded by a thick connective tissue sheath known as the epimysium which is continuous with the tendon (Figure 31.1). The muscle is then divided into bundles of fibers surrounded by the perimysium. The connective tissue surrounding individual muscle fibers is the endomysium.

Avian skeletal muscle fibers are long, unbranched, narrow, and multinucleated cells (4–6). These fibers can vary in length from several millimeters to more than 30 cm and have a diameter of 10 μm to 100 μm. Surrounding the muscle fiber is the sarcolemma, an elastic plasma membrane composed mainly of proteins and lipids. The sarcolemma not only surrounds the contractile units of the muscle, but also regulates uptake and release of molecules by the cell. The most distinguishing feature of the sarcolemma is its ability to depolarize during a nerve impulse. Invaginations of the sarcolemma form a network of tubules known as the transverse tubule (t-tubule) system. When an action potential reaches the myoneural junction, the t-tubule system aids in the progression of this impulse longitudinally along the sarcolemma in both directions along the entire length of the fiber.

The sarcoplasmic reticulum (SR) is an intracellular membrane structure separate from the sarcolemma and t-tubule system. The SR is responsible for the release and sequestration of calcium involved in contraction (3). Small structures called “feet” bridge the gap between the t-tubules and the SR. When the muscle cell is stimulated, the action potential reaches the sarcoplasmic reticulum through the t-tubule system causing the release of stored Ca^{+2} for muscle contraction initiation (4).

The basic contractile unit of the muscle is the sarcomere which is mainly composed of the myofibrillar proteins myosin and actin (Figure 31.2). These proteins are arranged parallel to the muscle fiber and overlap in certain regions. This overlap accounts for the banding pattern of the myofibril. The protein-dense bands where actin and myosin overlap are referred to as the A bands because they are anisotropic in polarized light. The less dense area is known as the I band since it is isotropic in polarized light.

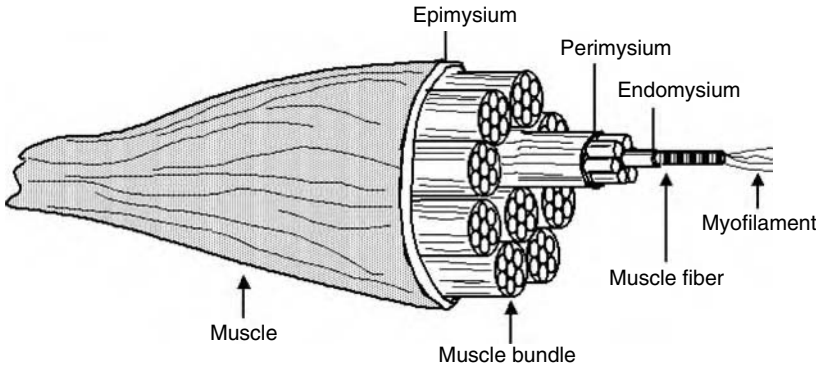

FIGURE 31.1 Diagram of gross muscle structure indicating muscle and connective tissue components. (Modified from Bechtel, 1986, and Gualt, 1992.)

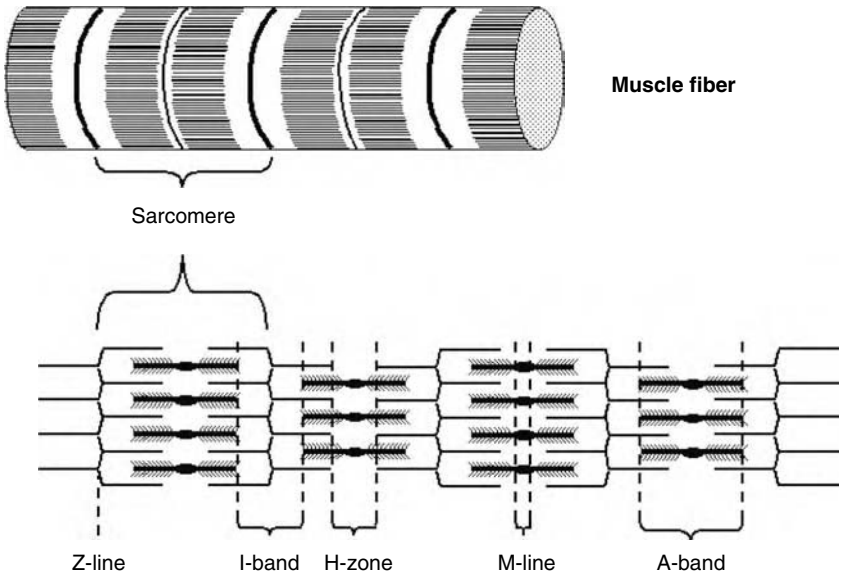

FIGURE 31.2 Diagram of the striated muscle fiber and the structure of the sarcomere.

B. Muscle Proteins

The muscle is made up of three major types of proteins: myofibrillar (or contractile), sarcoplasmic, and stromal (or connective). The myofibrillar proteins make up approximately 50–60% of total muscle protein and include proteins that are involved in the contraction-relaxation process (5, 6, 9). Sarcoplasmic proteins comprise approximately 30–35% of the muscle proteins and include the enzymes involved in muscle metabolism (5, 9). Connective tissue is made of stromal proteins and comprises approximately 3–6% of total muscle protein (9).

1. Thick Filament

Myosin is a globular and filamentous protein, which is the basis for the thick myofilament. Myosin makes up approximately 45–50% of total myofibrillar protein (6, 10). It is also one of most important proteins, along with actin, that is involved in muscle contraction. The protein consists of two globular heads attached to a long α-helical-like filamentous tail (Figure 31.3). Myosin is a large molecule of approximately 520 kD and is made up of six subunits. There are two heavy chains, approximately 220 kD, that make up the fibrous portion of the molecule, and two sets of light chains, approximately 17–22 kD, that are found in the globular regions of the molecules (5). Furthermore, the myosin molecule can be divided into two sections: heavy meromyosin (HMM) and light meromyosin (LMM). The globular heads, located in HMM, contain the adenosine triphosphate (ATP)-binding site and the actin-binding region, which are necessary for muscle contraction. The HMM section also contains a portion of the fibrous myosin. The LMM section, a portion of the fibrous myosin, is the area of the molecule that is packed into the thick filament. It is thought that the myosin molecule has two hinge points, one between

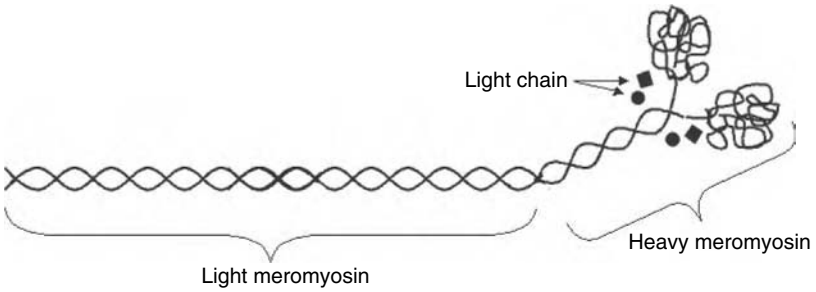

FIGURE 31.3 Diagram of myosin, a component of the thick filament. (Modified from Vander et al., 2001.)

HMM and LMM and the other between the fibrous myosin and globular myosin, so that it can function properly and effectively in the contraction-relaxation process. Approximately 200 myosin molecules aggregate along with other structural proteins to form the thick myofilament (7, 8). During aggregation, the myosin heads point toward the Z-lines and the tails toward the M-line. The thick filament is approximately 1.5 μm in length and 14–16 nm in diameter (4). The primary structural proteins are called C-proteins and M-proteins. The C-proteins are thought to hold the myosin filament together by wrapping around the myosin filament (11). There are seven bands of C-protein around the thick filament on each side of the H-zone (4, 5). The M-protein and myomesium are thought to adjoin the two myosin filaments at the tail region of myosin in the center of the sarcomere, or at the M-line (3). At the M-line, creatine kinase is also present, but its role in the structure of the thick filament is not known (3, 11). Creatine kinase is important to muscle metabolism. It is used in the formation of ATP from creatine, which is a short term energy supply for the muscle. Other proteins are also associated with the thick filament including F-protein, H-protein, and I-protein although their role in structural integrity of the thick filament is not known. It is thought that the I-protein inhibits myosin ATP-ase activity, an enzyme involved in ATP hydrolysis (11).

2. Thin Filament

The actin protein is made up of globular molecules, approximately 42 kD, that form a filamentous protein which is the basis for the thin filament (Figure 31.4). Actin comprises approximately 20% of the total myofibrillar proteins and is essential to the muscle contraction process (5). Approximately 200 globular molecules, G-actin, are bound together by ionic and hydrophobic bonds to form each filamentous actin, or F-actin. Two strands of F-actin along with two strands of filamentous tropomyosin and associated troponin (globular) are twisted together to form the thin (actin) filament. There are approximately 13 G-actin molecules per strand per twist of F-actin. The tropomyosin protein is made up of two α-helical polypeptide chains that twist around each other forming a filamentous rope-like structure. Tropomyosin, approximately 41 nm in length and 71 kD, lies near the groove of the F-actin filament (11). In conjuction with tropomyosin is the globular protein, troponin, which appears every seven G-actin molecules. Troponin is made up of three subunits: troponin I (21 kD), troponin T (37 kD), and troponin C (15 kD). Each subunit has a different function that is important in the contraction process. Troponin-T binds to tropomyosin, troponin-I inhibits actomyosin interactions by binding to actin, and troponin-C binds to calcium. These functions will be discussed later in this chapter. The thin filament, made of actin and the tropomyosin-troponin complex, is approximately 6–8 nm in diameter and extends approximately 1 μm from the Z-line toward the thick filament where a portion of the thin filament overlaps with the thick filament at the A band. The I band of the sarcomere consists of the thin filament alone.

In addition to actin, tropomyosin, and troponin, there are other proteins also present that are associated with the thin filament. γ-Actinin and β-actinin are present along the thin filament and at the end of the filament, respectively. It is thought that these proteins aid in regulating the length of the thin filament, thereby stabilizing the structure. Furthermore, β-actinin may inhibit interfilament intereactions thereby allowing it to smoothly slide during contraction and relaxation (5).

3. Z-Line and Gap Filaments

Each sarcomere is made up of thick filaments, thin filaments, and other proteins located near or at the Z-line and either as an integral part or on the periphery, the beginning and end of each sarcomere. Some of the Z-line proteins include desmin, vimentin, synemin, α-actinin, Eu-actinin, vinculin and zeugmatin (5, 10). Nebulin is also present near the Z-line in the N-line. Other myofibrillar proteins that are present include Z-protein and tensin, located in the integral, and filamin, plectin, spectrin, and ankyrin, located in the periphery; however, the role of these proteins in muscle is not fully understood.

Desmin is generally located around the periphery of the Z-line, running transversely, indicating that this protein acts

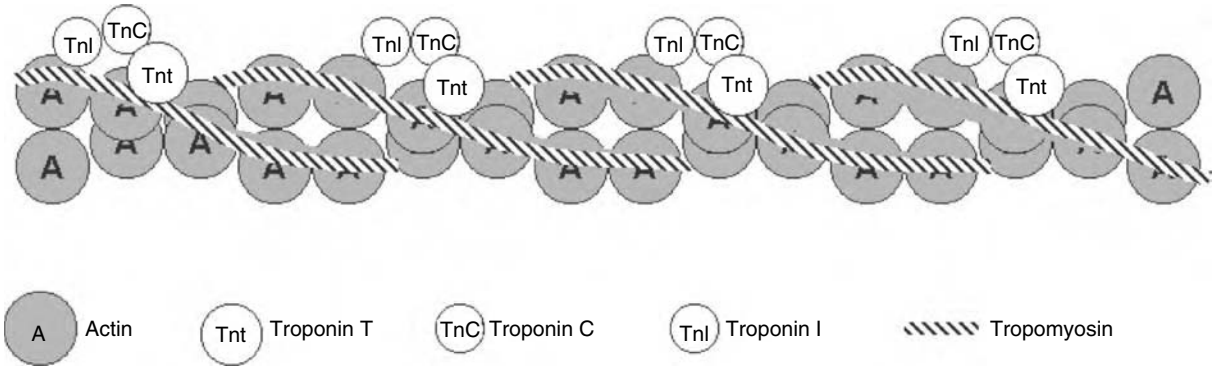

FIGURE 31.4 Diagram of thin filament. Actin, tropomyosin, and troponin make up the thin filament (Drawn by E. M. Hirschler; Modified from Cohen, 1975).

to tie the adjacent myofibrils together by forming a filamentous network. Furthermore, desmin may also link myofibrils to subcellular organelles, nuclei and mitochondria, and to the cellular membrane (10). Vimentin and synemin, like desmin, are also involved in forming a network around and between adjacent myofibrils. The role of these proteins is to provide structural integrity to not only the single myofibril, but also to a group of myofibrils, or muscle fiber. α-Actinin is a protein that ties actin into the Z-line, or Z-disk. This protein is an integral component of the Z-disk and is located in the interior. In addition to its role in structural integrity, α-actinin is thought to play a role in the formation of actin (i.e., direction of forming filament, length of filament). Although not well understood, zeugmatin and Eu-actinin are thought to link actin to the Z-disk (5). Vinculin is thought to attach the myofibrils to the sarcolemma; however, its function is not fully understood (5, 11). Nebulin was previously thought to be associated with the N-lines within the sarcomere and to control the geometric organization of the thin filament (12). However, more recent evidence suggests that nebulin is an elongated filamentous protein that runs parallel to the thin filament binding to both F-actin and α-actinin, thereby suggesting that nebulin aids in stabilizing the thin filament (10, 12, 13). Nebulin is also thought to serve as a template for the thin filament during formation. In addition to these proteins, there is another major protein present in the muscle that aids in structural integrity known as titin. Titin, a gap filament, is the third most abundant protein in the muscle, comprising approximately 8% of the myofibrillar proteins. Titin is a highly elastic filamentous protein that is located throughout the sarcomere, extending longitudinally from the Z-line to the M-line (10). Titin is thought to serve as a template for the formation of thick and thin filaments. It also serves to keep the thick filaments aligned in striated muscle (5, 10).

4. Stromal Proteins (Connective Tissue)

There are two types of connective tissue found in the body: connective tissue proper and supportive connective tissue. While these types differ in their function, they are very similar in composition. Connective tissue that covers the muscle, muscle bundle, and muscle fiber (epimysium, perimysium, and endomysium, respectively) is known as connective tissue proper (4). It is this type of connective tissue that can influence the tenderness of meat. In contrast, connective tissue in bones and cartilage provides structural support; therefore this type is known as supportive connective tissue. Connective tissue is made up of a non-structured ground substance which contains carbohydrates, proteins, and lipids (14). There is also an extracellular matrix which is fibrous in structure and made up of a class of proteins called stromal proteins (5). The stromal proteins consist primarily of collagen and elastin, and aggregation of these proteins make up the extracellular fibers that are embedded in the ground substance. Unlike any other aggregation of proteins, these have high tensile strength once a fiber is formed. Several authors have compiled a comprehensive review of connective tissue (5, 15, 16).

5. Collagen

Collagen makes up the majority of the stromal proteins and is considered the most abundant protein in the body, comprising up to one third of the total body protein (3, 14). It is not only found in muscle, but also in bone, skin, tendons, cartilage, and the vascular system (4, 14). Collagen has a unique structure. The collagen molecule is made up of three polypeptide chains that form into a triple helix known as *tropocollagen,* the structural unit of a collagen fibril (Figure 31.5). Globular domains also exist on the collagen molecule and are referred to as non-triple helical domains (15). These domains are important in the association of multiple collagen molecules. The polypeptide chains are made up of repeating amino acid sequences of Gly-X-Y, where X and

FIGURE 31.5 Diagram of tropocollagen, the collagen molecule made up of three polypeptide chains that form a triple helix.

Y can be any amino acid except tryptophan. Most often the X and Y are proline and hydroxyproline, respectively (5, 15). The amino acid glycine comprises one third of the amino acids found in collagen. Hydroxyproline and hydroxylysine are also present in high proportions within collagen, and are generally only found in collagen. There can be at least 19 variations of the polypeptide chains. Fifteen identified types of collagen can form from various combinations of the individual polypeptide chains that make up the tropocollagen molecules (16). Types I, III, IV, V, and VII are associated with connective tissue in skeletal muscle (4, 14). Type I collagen is located in the epimysium and perimysium, type III in the perimysium and endomysium, and types IV and V in the endomysium (16). It is thought that type III collagen plays a major role in meat tenderness when connective tissue is a factor (14).

Tropocollagen molecules, 300 nm in length, are bound together to form *collagen fibrils* with a striated appearance in types I, II, III, V, and XI. Fibrils are assembled by the tropocollagen molecules aligning adjacently end to end. The molecules align in a quarter-stagger parallel pattern with an end overlap of 25 nm, and are stabilized by ionic and hydrophobic interactions (5, 16). This quarter-stagger and overlapping pattern that repeats every 67 nm results in the striated appearance of the *collagen fiber* (Figure 31.6). The collagen fibers have a distinctive crimp (fold) that is observed once the fiber is formed; however, the crimp disappears when the muscle is under tension (Figure 31.7). It is thought that this *planar crimping* serves as a shock absorber to take up strain before tension is applied to the muscle (15, 16).

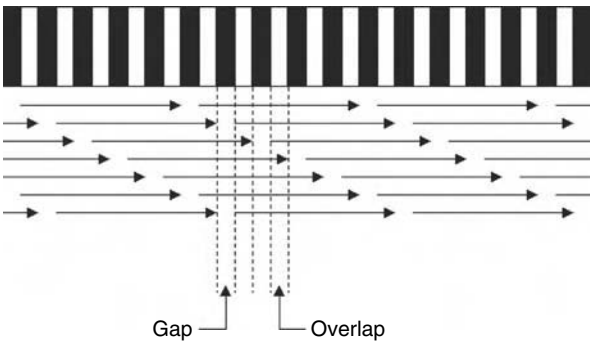

FIGURE 31.6 Diagram of collagen fibril where the light segments represent overlapping collagen molecules and the dark segments represent areas where a gap is present. (Modified from Sims and Bailey, 1992.)

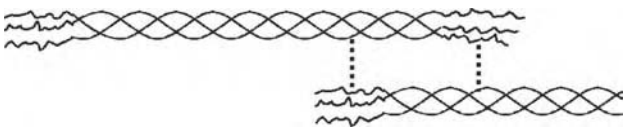

FIGURE 31.7 Diagram of intermolecular crosslinking between two collagen molecules. (Modified from Bailey and Light, 1989.)

The fibrous structure of collagen has high tensile strength due to its enzyme-induced intermolecular (between molecules) crosslinks (Figure 31.7). These crosslinks are covalent bonds that can occur in the carboxy- and amino-terminal ends of the tropocollagen, depending on the collagen type. Because type III collagen is the predominant collagen type that can play a role in meat quality, only the crosslinks of this type will be discussed. However, the crosslinking mechanism is similar in other collagen types.

Three types of crosslinks can occur in the formation of stable collagen fibers. First, disulfide bonds are formed in type III and IV collagen. These types of collagen contain the amino acid, cysteine, whereas the remaining types do not. The disulfide bonds are formed near the carboxy-terminal end of a tropocollogen molecule and can occur both intra- (within molecule) or intermolecularly between α-chains of tropocollagen. Secondly, lysine-derived reducible divalent crosslinks can be formed during fiber synthesis, both intra- and intermolecularly. The third type of crosslink that can occur in collagen is a trivalent crosslink that forms as the animal ages. This type of crosslink is usually referred to as *mature crosslinks*. Mature crosslinks are heat stable and are the cause of toughness due to connective tissue associated with mature animals. In the latter two types of crosslinks, the enzyme lysyl oxidase plays a major role in the crosslink formation.

Lysyl oxidase binds to α-chains in the tropocollagen molecule in either the amino- or carboxy-terminal end. Lysyl oxidase reacts with and converts the lysyl group into an aldehyde group. Two aldehyde groups can further react to form either an intramolecular crosslink, known as an aldol, or the aldehyde can react with hydroxylysine to form an aldimine or oxo-imine (or keto-imine) bond (15). The aldimine bond is heat labile while the oxo-imine is heat stable. Both of these bonds form intermolecularly at either the amino- or carboxy-terminal end of the tropocollagen molecule. As the animal ages, nonreducible trivalent bonds can form from these existing divalent bonds. There is much less information available on the mechanism of mature crosslink formation. However, it is known that the trivalent bonds increase the tensile strength of collagen. Furthermore, the mature crosslinks are heat stable. Therefore, upon cooking of meat from a mature animal, the crosslinks will not break and the network of connective tissue remains intact resulting in decreased tenderness of the meat.

The tropocollagen molecules found in type IV collagen do not form collagen fibrils, but form a more open network of tropocollagen that is hexagonal in shape, resembling chicken wire. The molecules found in type IV collagen are 400 nm in length and, due to the location of the glycine residues and the charge profile, the molecules are more flexible and form a thin open structure upon aggregation (16). Type IV collagen is often found in basement membranes. In skeletal muscle, it is one of the types of collagen found in the endomysium.

6. Elastin

In addition to collagen, elastin also makes up the stromal proteins of connective tissue. However, elastin is much less abundant than collagen and plays less of a role in meat quality except in instances where elastin content is high in certain muscles. Elastin is generally found in arterial walls and ligaments in the body. It is a rubbery protein that is insoluble in water or salt solutions, is very heat stable, and is resistant to digestive enzymes.

C. Contraction/Relaxation

Contraction and relaxation of the muscle are both active processes which have been reviewed by several authors (4–6, 17, 18). The act of contraction begins when an action potential received from a motor neuron at the motor end plate depolarizes the sarcolemma, allowing a rapid influx of Na^+ and efflux of K^+, and causing a membrane polarity reversal. When a threshold of -70 mV is reached, this action potential is propagated in both directions along the sarcolemma down the length of the entire muscle, finally reaching the sarcoplasmic reticulum through the t-tubule system. Once the action potential reaches the sarcoplasmic reticulum, the sequestered Ca^{+2} is released into the sarcoplasmic fluid. This release increases the free Ca^{+2} concentration from 10^{-7} moles/L normally present within the muscle to 10^{-6} or 10^{-5} moles/L (4). The free Ca^{+2} then binds to the regulatory protein troponin-C causing a change in configuration of the troponin-I subunit, which releases the inhibition of tropomyosin, exposing the actin-binding site to myosin. This release of tropomyosin allows myosin to bind to actin and form actomyosin crossbridges. The myosin ATPase is then activated and hydrolyzes ATP into ADP and inorganic phosphates, thereby releasing the energy required to tilt the myosin head (Figure 31.8). This action pulls the actin filament toward the center of the sarcomere, resulting in a shortened sarcomere (Z-lines are closer together). During the resulting contraction, actomyosin crossbridges are continually broken and formed to allow for sliding of the filaments. In cases of severe muscle contraction, the actin filaments may overlap. However, it is important to note that during contraction, the actual length of the myosin and actin filaments do not change.

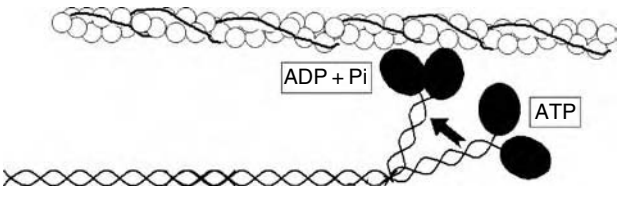

FIGURE 31.8 Diagram of myosin heads coupling with actin and ratcheting releasing ADP and Pi.

Relaxation is measured by a decrease in muscle tension (4). In order for relaxation to occur, the membranes must become repolarized, Ca^{+2} must be resequestered within the sarcoplasmic reticulum, and ATP must be regenerated through a series of reactions. Membrane repolarization is due to the Na^+/K^+ ATPase pump re-establishing a resting membrane potential of -90 mV through the active transport of Na^+ out of the cell and K^+ into the cell (17). The resequestration of Ca^{+2} is accomplished by activation of an ATPase, which aids in pumping Ca^{+2} back into the sarcoplasmic reticulum.

Both muscle contraction and relaxation require energy in the form of ATP for re-establishment of the electrochemical gradient through the Na^+/K^+ pump, for breaking and forming actomyosin bonds, and for pumping Ca^{+2} into the sarcoplasmic reticulum (4). Normally, muscle contains approximately 2 to 4 mM of ATP (18). Due to the fact that muscle cannot store a sufficient amount of ATP for the above conditions to occur, a rapid source and an efficient method of rephosphorylating ADP to ATP must be available.

D. Energy Metabolism

The synthesis of ATP required for these processes to occur has been reviewed by several authors (3, 4, 6). The most rapid source of energy is through phosphocreatine, a sarcoplasmic component, which, when combined with ADP, is converted to ATP and creatine by the catalytic enzyme creatine kinase. During extensive use of ATP within the muscle, creatine is depleted and must be regenerated at the mitochondrial membrane during rest.

$$\text{ADP} + \text{Phosphocreatine} \xrightarrow[\text{Creatine Kinase}]{} \text{ATP} + \text{Creatine}$$

Aerobic metabolism is the method that generates the most ATP (Figure 31.9). This series of reactions utilizes carbohydrates, proteins, and lipids, which are degraded to carbon dioxide and water while releasing energy as ATP. Glucose is broken down into pyruvate through glycolysis, netting three ATP molecules per molecule of glucose. In the presence of oxygen, pyruvate then enters the tricarboxylic acid cycle (TCA) in the mitochondria, releasing hydrogen ions. These ions then enter into the electron transport chain and through oxidative phosphorylation net 34 ATP molecules per molecule of glucose (4). Therefore a total of 37 ATP molecules are produced during aerobic metabolism.

Anaerobic glycolysis is a less efficient method of producing ATP, with three molecules of ATP produced per glucose molecule. In anaerobic metabolism, there is a lack of oxygen and pyruvate cannot enter into the TCA cycle. Instead, the combination of pyruvic acid and H^+, both by-products of glycolysis, form lactic acid. In a normal functioning homeostatic system, lactic acid is removed

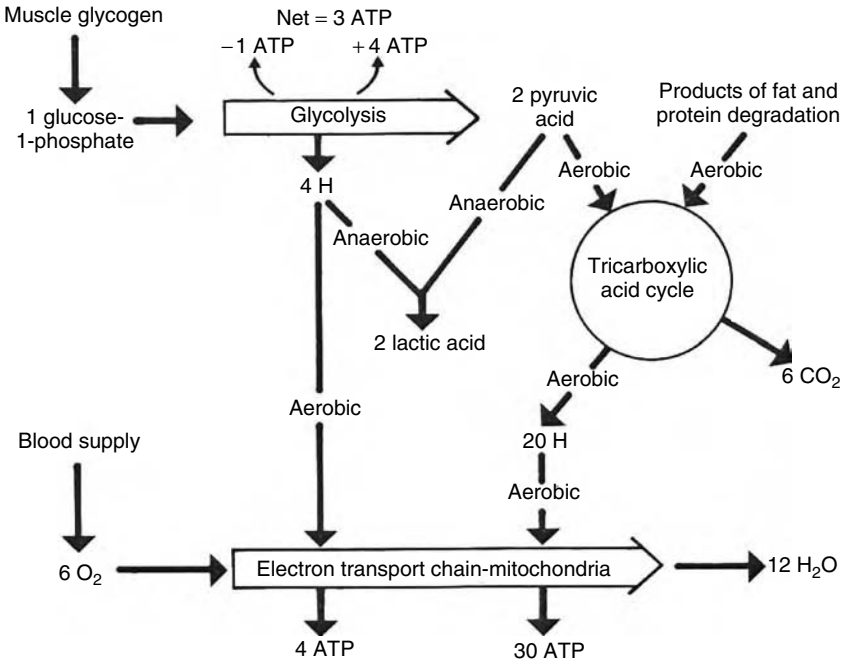

FIGURE 31.9 Pathways that supply energy for muscle function. One molecule of glucose 1 – phosphate is split from glycogen and is degraded to CO_2 and H_2O in the aerobic pathway (sarcoplasm). Then energy yield in terms of ATP is indicated at each step. When oxygen is limited, energy is supplied by glycolysis and conversion of pyruvic acid to lactic acid. (Courtesy of W. H. Freeman and Company.)

through the blood stream. However, during poultry processing, exsanguination, occurs, leading to a build-up of lactic acid in the muscle. This increase in lactic acid postmortem is important in the development of rigor mortis as will be discussed later.

E. Glycogen Catabolism

Homeostasis can be defined as the state of equilibrium in an organism. Homeostasis is maintained by the cyclic nature of providing energy to the muscle cells as well as removal of waste (Figure 31.10). Glucose is absorbed by the gastrointestinal tract into the blood stream where it is either absorbed by the liver for storage as glycogen or carried to the muscle cell for utilization or storage as glycogen. Glycogen is the major storage form of glucose in the muscle and can be 0.5 to 1.3% of the weight of the muscle (4).

In times of high muscle activity, liver glycogen can be hydrolyzed into glucose and transported via the blood for utilization by the muscle cell (Figure 31.10). The regulation of glycogen breakdown into glucose in the muscle cell is controlled through phosphorylase (19, 20). Phosphorylase is the enzyme controlling the conversion of glycogen into glucose-1-phosphate for ATP generation in glycolysis. In resting muscle, phosphorylase activity is low. However, in an active muscle, phosphorylase is activated through a process of phosphorylation to allow breakdown of glycogen for ATP production.

There are several different control mechanisms for phosphorylase, including external regulators, hormones and calcium concentration. Phosphorylase can be activated by an increased amount of ATP breakdown products (inorganic phosphate, AMP, and IMP) which are indicative of an active muscle. Hormones such as epinephrine and adrenaline can also activate this cascade. During stress, glycogen breakdown is required for generation of ATP for the "fight or flight" response.

Calcium concentrations can also stimulate glycogen catabolism. Calcium is required for muscle contraction. When the muscle receives a nervous impulse, Ca^{+2} is released from the sarcoplasmic reticulum increasing the cellular concentration to 10^{-6} M. This concentration is required not only for contraction via myofibrillar ATPase activity, but is also the same concentration required for activation of phosphorylase. Therefore, both nervous and hormonal changes aid in concert to increase the breakdown of glycogen to ATP for energy.

Once glycogen has been catabolized into glucose, the muscle cell utilizes glucose to form ATP. Glycolysis yields 3 ATP, pyruvate and two molecules of lactic acid. Pyruvate can then enter the TCA cycle in the mitochondria and yield CO_2 and H^+. The H^+ then enters into the mitochondrial electron transport chain yielding water, oxygen, 34 ATP, and heat.

Metabolic waste such as lactic acid, heat, CO_2, and water are removed from the cell by the circulatory system

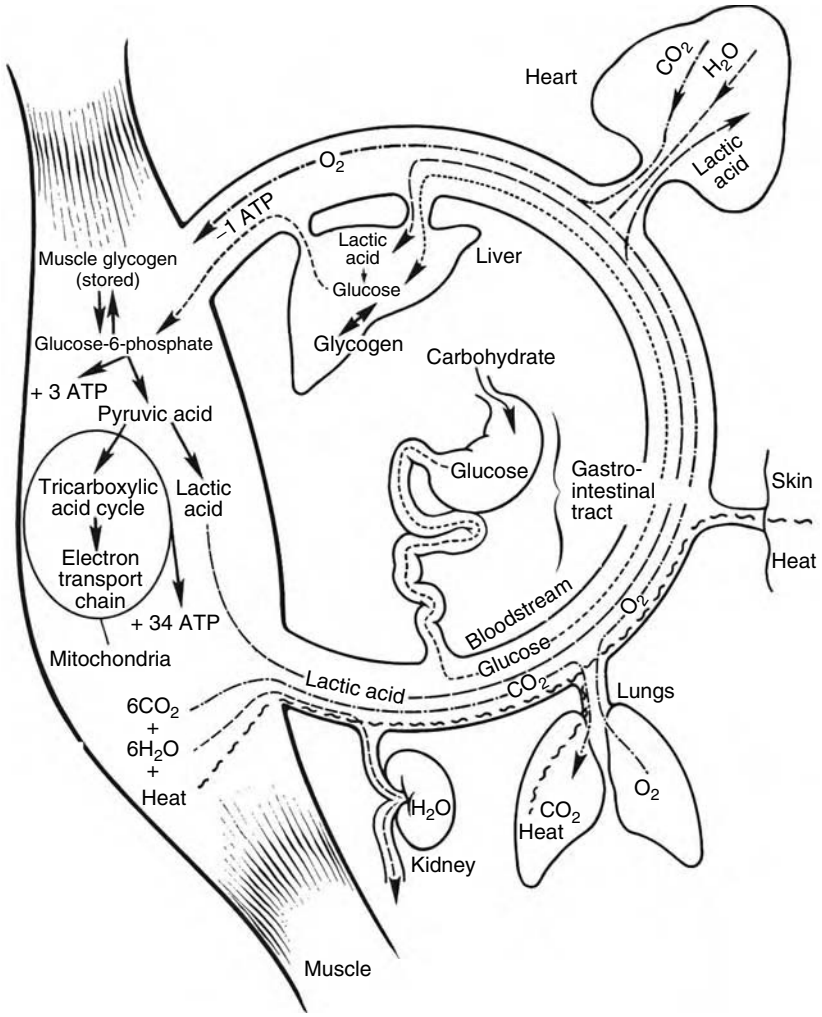

FIGURE 31.10 Cyclic pathways that provide energy for muscle contraction and relaxation. (Courtesy of W. H. Freeman and Company.)

and removed from the body via the lungs and kidneys. Lactic acid can be metabolized into CO_2 and water by the liver or it can be re-synthesized into glucose for storage. During times of increased activity, a build-up of lactic acid can occur and can cause acidosis. However, following a rest period, the lactic acid is removed via the blood and the muscle can return to its resting state.

F. Rigor Mortis

Rigor mortis or "stiffness of death" is the process of converting muscle into meat through a series of biochemical, physical, and structural changes. These changes begin with exanguination at which time there is a loss of both oxygen transportation to the muscle and a removal of metabolic waste such as lactic acid from the muscle. When stores of creatine phosphate have been depleted, glycogen stores are used for further phosphorylation of ADP. Aerobic metabolism continues until oxygen is depleted. Anaerobic metabolism is then utilized for the production of ATP until lactic acid accumulates and pH decreases to a level (approximately pH 5.9) that prevents glycolysis. However, ATP is still present within the muscle cell. Therefore, any stimulation to the muscle such as deboning prior to the completion of rigor mortis will increase actomyosin bond formation and sarcomere shortening, resulting in decreased tenderness. Due to this objectionable toughness associated with early deboning, poultry carcasses must be aged for 4–6 hours to allow for rigor mortis development (21, 22). This phase of oxygen depletion and muscle extensibility is referred to as the onset of rigor mortis (Figure 31.11).

Reduced extensibility begins the onset phase and continues until the muscle is completely inextensible and rigor mortis is complete. During the completion phase, 90% or more available actomyosin bonds are formed compared with only 20% in the living muscle (4). An ATP concentration of 1 μM/g is required for muscle function to occur. When the concentration of ATP decreases to below 1 μM/g, the muscle is no longer extensible (Figure 31.12).

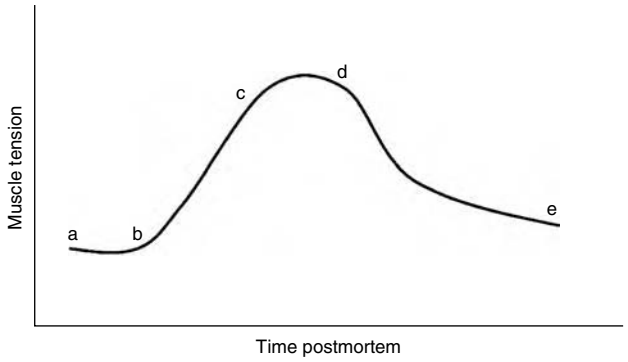

FIGURE 31.11 Phases of rigor mortis development. a–b delay phase; b–c development of rigor; c–d completion phase; d–e resolution phase. (Reprinted with permission from S. Barbut, Poultry Processing Products, An Industry Guide. Boca Raton, FL: CRC Press, 2002, p. 58.)

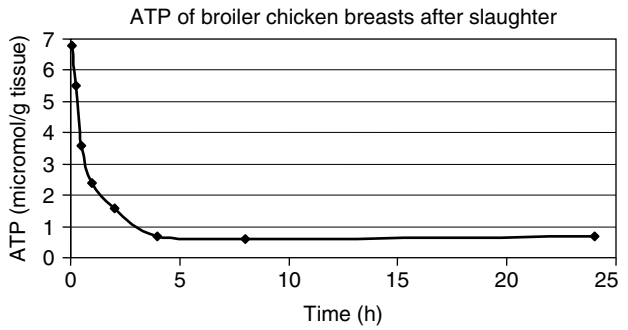

FIGURE 31.12 ATP concentration in broiler muscle during rigor mortis development.

The final stage of rigor, resolution, is characterized by a decrease in structural integrity of the muscle during postmortem storage. This decrease in structural integrity is due to proteolytic degradation of certain myofibrillar Z disk proteins such as desmin, titin, and nebulin by proteases such as calpain. Calpains improve meat tenderness by degrading Z disk proteins, thus increasing myofibrillar fragmentation. Also, ionic interactions may affect the postmortem tenderization of meat. Ionic strength increases in postmortem muscle due to the release of Ca^{+2} from the sarcoplasmic reticulum and the accumulation of phosphate from ATP degradation. This increased ionic strength decreases the sphere of charge surrounding each protein and weakens the structural integrity of the myofibrils, resulting in decreased toughness (23).

G. Metabolic Differences between Red and White Fibers

Muscle fiber types differ among species and also among muscles within a single animal due to genetic expression, function, and stage of growth. The four basic fiber types include: slow-twitch oxidative (type I, red), fast-twitch oxidative and glycolytic (type IIA, red), fast-twitch glycolytic (type IIB, white), and intermediate (type IIC). Broiler pectoralis muscles, for example, contain 100% white fibers, while Pekin duck pectoralis contain around 84% red fibers (24–26). Intermediate muscles contain a mixture of both red and white fibers.

Red fibers contain more myoglobin, are more vascularized, and are able to utilize oxidative metabolism as a source of energy, while white fibers mainly utilize glycolytic enzymes (Table 31.1) (5, 27). As a result of the increased oxidative metabolism in the red fibers, they contain not only more but larger mitochondria. When comparing red muscles of the broiler leg to white muscles of the broiler breast during rigor development, the white muscles have an increased accumulation of lactic acid due to their ability to use stored muscle glycogen in the glycolytic pathway for energy (Figure 31.13). Without oxygen, the red fibers cannot utilize the oxidative pathways and energy replenishment decreases.

White fibers are able to contract more rapidly and in short bursts since they mainly utilize glycogen rather than fat stores and have a more developed sarcoplasmic reticulum and t-tubule system (6). White fibers are also more easily fatigued compared to red fibers, which contract slower and for a longer duration without fatigue (27).

Red fibers develop rigor mortis at a faster rate compared to white fibers. No biochemical changes occurred after 2 hours postmortem in red muscles; however, the white muscle fibers display metabolic changes up to 8 hours postmortem. The red muscle fibers of the duck pectoralis have a faster rate of pH decline than the white muscle fibers of the broiler pectoralis, indicating a more rapid onset of rigor mortis (24). Red fibers are generally smaller in diameter when compared to white fibers, and have

TABLE 31.1
Relative Comparisons of Red and White Fibers in Poultry Muscle

Parameter	White	Red
Myoglobin	Low	High
Color	White	Red
Contraction Speed	Fast	Slow
Fatigue Resistance	Low	High
Contractile Action	Phasic	Tonic
Capillary Density	Low	High
Energy Source	Glycolytic	Oxidative
Mitochondrial Size	Small	Large
Mitochondria Number	Low	High
SR and T-tubules	More Developed	Less Developed
Fiber Diameter	Larger	Smaller
Connective Tissue	More	Less
Rigor Development	Slow	Fast
Glycogen Content	High	Low
Lipid Content	Low	High

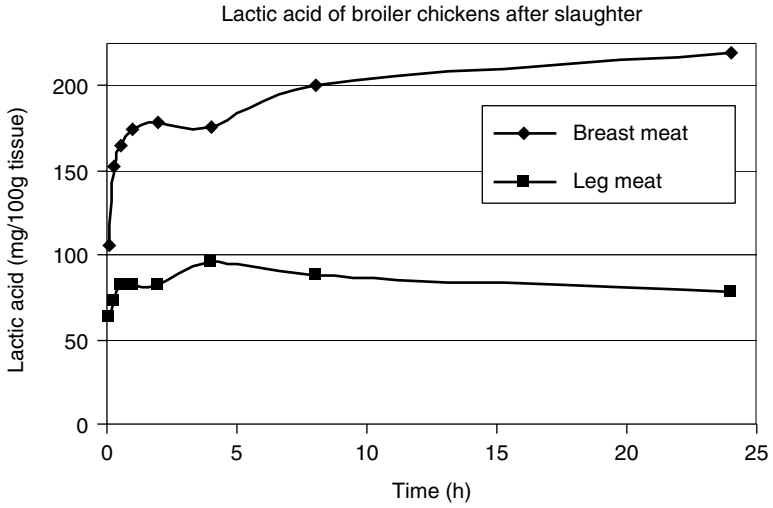

FIGURE 31.13 Comparison of lactic acid accumulation in red- and white-fibered muscles in broilers during rigor development.

proportionally more connective tissue surrounding each fiber as compared to white fibers (5). Thus, tenderness decreases with an increase in red fiber content within specific muscle groups.

IV. MEAT QUALITY CHARACTERISTICS

The inability of the muscle cells to rid themselves of metabolic by-products such as lactic acid causes several postmortem metabolic and structural changes within the muscle, the most important of which is a decrease in pH (28). This decrease in pH is the most significant postmortem change and can affect important meat quality attributes such as color, water holding capacity, and texture (29, 30). These three attributes are used to evaluate meat quality by both processors and consumers. Two conditions caused by the rate of pH decline include dark, firm, and dry (DFD) and pale, soft, and exudative (PSE) meat.

Dark, firm, and dry meat develops when muscle glycogen is depleted prior to slaughter, resulting in high muscle pH from reduced postmortem glycolysis (4, 6, 31). Dark, firm, and dry meat is characterized as having a high water holding capacity, even though the meat appears dry (5).

Pale, soft, and exudative meat is characterized as having a pale color, soft texture when cooked, and a low water holding capacity. This condition develops due to an accelerated postmortem metabolism which leads to a rapid decline in postmortem muscle pH (4–6). Rapid postmortem glycolysis has been observed in both swine and turkeys in which pH of PSE muscles was less than 5.8 within 45 min postmortem in swine and 15 min postmortem in turkeys. This would be compared to normal muscle pH at this postmortem time of greater than 6.0 (32, 33). This rapid decline in pH occurring while muscle temperatures are still elevated denatures proteins and causes a decrease in solubility and enzymatic activity (34, 35). Porcine muscles with pH values below 6.0 at 45 min postmortem had a higher ATPase activity, indicating a more rapid glycolytic rate, and were found to produce poor meat quality (36). Authors have reported that rabbit muscle kept at 37°C for 6 hours postmortem resulted in a rapid pH decline to below 5.8 and a loss of half Mg-ATPase activity compared to muscles incubated at 34°C (37).

A. Color

Color is an important quality attribute as consumers are often willing to pay more for poultry products based on color. Several factors can influence meat color including pH, myoglobin concentration, and nitrites (4). Even though myoglobin has been shown to be important in determining raw meat color, it is less important in broiler and turkey breast meat meat simply because there is less myoglobin than in other meats (beef, pork).

Pinking is an important problem in turkey and broiler meat. Pinking can result from several factors such as undercooking meat, contamination with nitrites, addition of ingredients such as peppers, improper stunning, and several antemortem stressors. There are several problems that can arise from pinking such as food safety issues with undercooked meat, consumer complaints, and a decreased purchasing of poultry products by consumers. Probably one of the main reasons for pinking in white poultry meat is the addition of nitrite. Nitrite is an ingredient that is normally added to cured products and produces a characteristic pink cured color upon heating. Normally, nitrite is not added to products made with white meat but can inadvertently be added through contamination from water sources or human error.

In cooked products, several pigments have been linked to pinking in poultry white meat. Myoglobin facilitates the

transfer of oxygen and waste to and from muscles from the blood. Denaturation of myoglobin is related to pH, time, and cooking temperature. Undenatured myoglobin due to improper heating of high pH that prevent denaturation at adequate cooking temperatures can reault in pinking of white meat. This is especially true in turkey breast meat, which has a higher concentration of myoglobin than broiler white meat. Cytochrome c is another important pigment in meat which can lead to undesired pinking since it has a higher denatutaion point that myoglobin. Cytochrome c is a heme protein responsible for transport of electrons in the mitochondria. Levels of this protein have been elevated in stressed animals.

B. Water Holding Capacity

The state of water in striated muscle has been reviewed by several people (3, 4, 38). Striated muscle contains approximately 75% water, which exists as three forms in the muscle: bound, immobilized and free. Since water is a polar compound, it can bind with other water molecules as well as charged protein groups. Bound or constitutional water is less than 1% of muscle water and is located within the protein molecules. This water has such a strong protein-water interaction that it cannot be lost except during ashing of the meat. The second form of water is immobilized or interfacial water and is approximately 10–15% of water in meat. Immobilized water is attracted to the bound water layer, creating multilayers of water each more loosely bound as the distance from the bound water increases. Due to the strong water-water and water-protein interactions, immobilized water is typically lost with cooking. Free water accounts for the remaining portion of water in meat tissues and is associated with the extracellular space. Free water is held loosely through capillary forces and can be lost easily through mechanical actions such as cutting, grinding, cooking, and storage of meat.

Water binding capacity of meat is altered in two ways: by the net charge effect and the steric effect. As a polar molecule, water can bind to other charged amino acid side groups. The amount and type of charge on a protein changes with pH. As pH decreases, the number of reactive groups available for water binding decreases. The point at which water binding is minimal on a protein is referred to as the isoelectric point or pI. Since actin and myosin are the most predominant proteins in the muscle and since they are most responsible for water holding capacity, their pI is the pH at which the meat's water holding capacity is the least. The pI of muscle is approximately 5.1 where the number of positive charges equals the number of negative charges resulting in a net zero charge or the pH at which the meat's water holding capacity is minimal (17).

The steric effect or degree of contraction has the greatest effect on the water holding capacity of meat. As the amount of space between the muscle protein structures decreases with contraction, less space is available for water around the proteins. Contractile state and pH of the muscle can influence the amount of interstitial space. If the muscle is in a contracted state, there is less space within the muscle to hold water intracellularly due to the shortening of the sarcomeres. Therefore, water is expelled into the extracellular space.

Muscle pH can also affect the amount of space to bind water molecules. If repulsion between charged groups is increased, as occurs in higher pH muscle, the protein network is enlarged and allows an increased amount of water holding capacity. In PSE meat, when the pH is closer to the pI of the myofibrillar proteins, attraction between charged groups increases and the protein network shrinks. Therefore, part of the immobilized water becomes free water, which may be lost as drip (39).

Myofibrillar proteins such as myosin, the predominant muscle protein, have a large amount of water holding capacity. Any changes to this protein can decrease the ability of the muscle to retain water. Denaturation of myosin has been found to decrease water holding capacity (35, 40). In PSE muscle the myosin head shrinks from 19 nm in normal muscle to 17 nm (40). This shrinkage of the protein lattice causes expulsion of intracellular water into the extracellular space and decreases water holding capacity. The extent of myosin shrinkage is also dependent upon the rate of pH decline, ultimate pH, and temperature during chilling with the faster rate of decline and higher temperatures early postmortem, leading to increased denaturation and shrinkage.

C. Texture

Protein gels are formed by intermolecular crosslinks resulting in an ordered three-dimensional network of proteins. The two primary steps involved in thermal gelation are denaturation of native myosin and aggregation of the partially unfolded myosin molecules to form the protein gel. Myosin denaturation can decrease the strength of heat-induced gelation. There are two transition temperatures (T_m) of myosin that are important in gel formation. Chicken breast myosin Tm_1 at 47.5°C is associated with the aggregation of the globular heads through disulfide bond formation while Tm_2 at 54°C is more associated with the network formation by the unfolding of the helical tail portion (41). However, turkey breast myosin is more temperature sensitive with the Tm_1 in turkey breast being only 40°C at pH 6–12 (42). These researchers also found that there was full reversibility of turkey breast myosin denaturation when heated for 5–30 min at 40°C and 5 min at 50°C followed by incubation at 4°C for 24 hours.

Gel strength is negatively correlated with cook loss and meat color, with higher cook loss and paler meat resulting in decreased gel strength. This negative correlation is probably due to the decreased solubility of myosin in PSE meat as well as fewer charges available for water-

water and protein-protein interactions. Extraction of salt soluble proteins from PSE meat is decreased compared to that of normal meat and gel strength is significantly less from product made with PSE meat. It has been postulated that the precipitation of phosphorylase onto the myofibrils at the Z line and A band results in a decreased solubility of myosin (43).

V. CONCLUSION

Muscle is a complex and highly specialized tissue that is able to convert chemical energy into mechanical energy for locomotion. The biochemical reactions that allow the muscle to complete these highly specialized tasks are the same reactions which cause the conversion of muscle into meat. The loss of the circulatory system is responsible for the anoxic conditions and allows the build-up of lactic acid which begins the process of rigor development. Meat quality characteristics can be affected by the rate of rigor mortis development. Once rigor mortis is complete, the muscle has been converted into meat.

32 Chemical Composition of Poultry Meat

Tomasz Lesiów
Department of Quality Analysis, University of Economics

CONTENTS

Poultry, especially chicken broilers and turkey, is one of the most widely consumed muscle foods in the world. It is an important source of dietary energy and nutrients, such as high quality proteins, essential fatty acids, vitamins and highly bio-available minerals [1]. In south-east and east Asia, as well as in eastern and western Europe, ducks and geese also play an important role because of their tasty meat. The world consumption of poultry meat in the year 2001 exceeded 69 949 thousand tons, ranked between production of beef and veal (56 647 thousand tons) and pig meat (91 188 thousand tons) [2]. The increase in muscle proportion and the reduction in carcass fat content by selection and careful restriction are major attempts to improve carcass quality of poultry and the nutritional value of meat [3–7]. However, concern has been raised over its high consumption and the fat content, in particular saturated fatty acids, which can greatly increase the risk of cardiovascular diseases and some type of cancer [8,9].

The chemical properties of poultry meat (or muscle) have been studied intensely. These studies were primarily carried out on whole poultry carcasses and/or specific muscles and included the examination of variables such as breed (genetics), diet formulations, age, gender, housing (live bird production) and general management practices (short-term antemortem stress) on composition, nutritive value, and quality of meat [10–13]. The present review will focus on the impact of muscle type on the nutritional value of poultry meat.

I. CHEMICAL COMPOSITION

Information about body composition can be important for those producing and selling animal products and nutritionists. Producers need information about body composition to produce leaner meat animals, sellers need information to determine how much of the energy that an animal eats is captured as growth or other forms of production [10].

The chemical composition of poultry breast (B) and thigh/leg (T/L) muscles is presented in Tables 32.1 through 32.3. The richest in protein were breast muscles of turkeys, broilers, geese, and ducks. The T/L muscles of

M = male, F = female, * = drumstick, ** = white, dark muscles.

all kinds of poultry contained approximately 0.4–3.8% less protein (Table 32.1). Some authors found higher differences in protein content between breast and thigh muscles of broilers (23.80 vs. 18.30% [16]), 22 wk male turkeys (24.51 vs. 19.60% [22]), 16 wk female turkeys (25.24 vs. 21.29% [43] or 23.96 vs. 18.92% [45]) (Table 32.3), and 14 wk geese (23.02 and 19.39% [46]).

The fat content of breast muscles, in ascending order, was turkey females, Pekin and Muscovy ducks, broilers, hens, turkey males, Mule ducks, and geese; for T/L muscle, it was Pekin, mule, and Muscovy ducks, hens, turkey (Table 32.1). The fat content for the breast muscles from all poultry types was lower than for the L/T muscles.

Moisture content for Pekin and Muscovy ducks was greater than for other kinds of poultry. Moisture was comparable for turkey and geese and it was lower than in broilers, hens, and Mule ducks. Broilers, Pekin ducks, and goose breast muscles had higher percentage of moisture than the T/L muscles. The higher content of moisture in broiler breast muscles than in thigh muscle (73.74 vs. 73.22%) was also found by Gornowicz and Dziadek [15] but it was not significantly different (Table 32.3). However, Biliński et al. [38] found about 1% lower moisture content in 17 wk goose breast muscle compared to thigh muscle (72.31 vs. 73.54%).

The content of ash in breast muscle of chickens, Pekin ducks, and geese was higher than in thigh muscles while it was comparable both brest & thigh muscles for hens, turkeys and Mule ducks.

A. Chemical Composition—Age, Sex, Strain

The influence of age and sex on chemical composition of poultry meat is presented in Tables 32.2 and 32.3. In earlier studies as the broiler increased in age from 6 to 8 wk protein content in light male and female meat increased by 0.52 and 0.80% and fat in male white and dark meat increased by 1.32 and 1.66% [47]. The protein content increased with age to the detriment of water content in 12 vs. 14 wk female turkey breast and thigh muscles (23.60 vs. 24.80% and 20.70 vs. 22.40% [41]) and Pekin and Mule duck breast muscles [4,26] (Table 32.2). In 16–18 wk female turkey muscles the protein (breast) and moisture (breast and thigh) contents were comparable, while in thigh muscles protein content decreased after 16 wk [41]. During the growth from 2 to 5 wk Pekin duck breast muscles decreased in protein content from 21.5 to 20.0% and then after 7 wk increased to 21.9% while the leg muscle protein content was not influenced by age [25]. With advancing age increased fat content was observed in turkey breast muscle [40]; female turkey

thigh muscle [41]; Pekin breast [6]; Pekin thigh muscles [26]; and Mule duck breast and thigh muscles [4,6]. However, less fat content was found in 15 vs. 10.5 wk Muscovy ducks [6] and 24 vs. 15 wk geese [42]. According to Bieliński et al. [38] the protein and fat content in goose breast and thigh muscles increased with age from 10 to 17 wk, remained comparable between 17 and 25 wk, and after 33 wk protein content decreased and fat content increased, respectively. Moreover, in muscles of 10 wk geese the moisture content was the highest and the ash content was the lowest and they did not change with age (Table 32.2). Friend et al. [48] found no effect of age on geese breast muscles protein and fat contents.

The differences in chemical composition between males (M) and females (F) were found for broilers, turkeys, and ducks (Table 32.3). Evans et al. [47] found that fat content was higher in male broiler light (white, breast) meat than in light females (16.18 vs. 14.66%) and the protein content of dark meat of males compared with females was higher (18.32 vs. 17.60%) but the moisture (64.37 vs. 66.62%) and fat (11.85 vs. 13.99%) contents were lower. Gornowicz and Dziadek [15] found only a higher content of moisture and ash in broiler male muscles compared to female muscles (Table 32.3). The breast muscles of 22/24 wk male turkeys contained less moisture [22,23,45] and more fat than those of 15/16 wk females [21–23,43,45]. However, Faruga et al. [43] noticed higher amounts of moisture in 24 wk turkey males both in breast and thigh muscles than in 16 wk females. Lower moisture content and higher fat content were also observed in male Mule duck breast compared with females [4]. The reverse trend, i.e., higher moisture and lower lipid content, was found for male and female breast muscles of Pekin ducks [28]. Muscovy duck [28] and goose [36,44] male breast muscles were characterized by higher fat content than females. The thigh muscles of turkey and male Pekin duck had lower lipid levels than female thigh muscle [22,23,27,43,45] (Table 32.3). At the same age (14 wk) male turkeys deposited in breast and thigh muscles less total lipid content than females, i.e., 0.96 vs. 1.32% and 2.26 vs. 2.88%, respectively [49]; this was in line with lower fat content in male turkey thigh muscles than female at different ages (22/24 vs. 15/16 wk). Male Turkeys had higher ash content in the breast muscles compared to females (1.11 vs. 0.93% [40]).

Other authors found no differences in moisture, fat, and protein contents based on sex for broiler muscles [15] and Pekin duck [25] and goose [48] breast and/or leg muscle protein and fat; broiler breast [14], turkey breast [40] and Muscovy duck [29] and 12/16 wk goose [50]

muscles; turkey thigh [22,23,45] and goose [36] breast muscle protein and moisture; and Mule duck breast muscle [4] mineral content.

Differences in the moisture, protein, and fat content of pullet and cockerel breast and thigh muscles or broiler breast muscles were associated with strain crosses [13,15]. Strain also influenced the protein percentage and fat in broiler thigh muscles but no strain-related differences were found in moisture content. The small differences in muscle chemical composition among strain crosses may slightly alter the nutritional value of broiler meat [13]. Puchajda et al. [22,45] found that turkey medium-heavies' genetic lines influenced the differences in breast protein content of 22 wk males and in thigh muscle fat content of 15/16 wk females. However, another survey found no influence of genetic lines of heavies turkey males (22 wk) on muscle protein and fat content [23]. Filus et al. [21] did not show any significant indication of the dependency of hybrid turkey heavies and medium-heavies on the chemical composition of meat.

Górska and Górski [26] reported differences among duck crossbreds in breast and thigh muscle moisture and protein contents with no apparent species-fat content relationship in the case of both muscles. Nutritive values of breast and thigh muscles of SW (Small White), Synta (Pekin) ducks and their reciprocal crosses showed a tendency of paternal effect on protein and fat contents in breast and thigh muscles; in ash this was only evident in thigh muscles [27]. The strain had also a significant impact on the protein [39,50], moisture, and/or ash content in goose breast and leg muscles [39]. According to Friend et al. [48] strain influenced the fat content in goose breast muscles but had no influence on protein content.

II. AMINOACIDS AND COLLAGEN

Poultry meat is an important source of high biological value proteins providing all of the indispensable (essential) amino acids [44,51,52]. On average, 40% of the amino acids present in meat are indispensable for human health [9]. Dietary proteins are the only source of amino acids that we need. Our bodies require nine essential amino acids that animal protein contains in the best "proportion" [1]. The high lysine content of meat protein is important nutritionally because it counter-balances the low lysine content of cereal proteins when they are eaten together in a mixed diet [9].

The content, type, and cross-links in collagen influence nutritional and dietetic values of meat and its tenderness [53,54]. Poultry breast muscle was found to contain less collagen than thigh muscle (Table 32.4). The same trend was observed when collagen was expressed in relation to total protein content in the particular kind of poultry meat with the exception of 8 week Pekin ducks for which breast protein contained 1% more collagen than thigh muscle protein. As a protein of lower value collagen was the lowest in turkey and geese, and higher in broiler an Pekin duck muscles.

III. HEME PIGMENTS

Primary heme pigments in poultry meat include myoglobin, hemoglobin, and cytochrome c. The quantity of myoglobin greatly influences the appearance of poultry meat. Hemoglobin is another pigment of importance since about 20 to 30% remains in the carcass of a well-bled bird, thus influencing final carcass coloration [57]. Heme pigment content and "free iron ions" were associated with occurrence of lipid oxidation [19,58].

Table 32.5 shows total heme and heme pigments in poultry muscles. Goose and duck breast muscles contained considerably more heme pigments than the breast muscles of turkeys, hens, and broilers. The same trend was observed in T/L muscle; however, differences in heme pigment content (except for young and adult layer) were less pronounced among different poultry types. Nishida et al. [62] found different amounts of myoglobin in adult layer leg muscles, i.e., from 4.44 to 5.82 mg/g in adductores, 2.53 mg/g in sartorius, and 0.57 mg/g in biceps femoris, which was greater than for young layer, amounted to 0.33 mg/g of myoglobin in biceps femoris. The broiler, hen, and turkey breast muscles had from 1.4 to 6.4 times lower concentration of heme pigments, hemoglobin, myoglobin, and cytochrome (broilers) than those for T/L muscles (Table 32.5). These differences were smallest broilers and greatest for hens. In duck and goose breast muscles the heme pigments content was 14 to 79% greater than that in the leg muscles. However, total pigment concentration in Muscovy ducks and hemoglobin content in Pekin ducks were not significantly different in both muscles.

The mg of total pigment per gram of muscle increased in the following order: broiler breast, hen breast, turkey breast, broiler thigh/leg, hen leg, turkey leg, duck leg, goose leg, duck breast, and goose breast.

A. Heme Pigments—Age, Sex, and Strain

With advancing age (18 vs. 28 wk) myoglobin concentration significantly increased in male turkey breast muscles

TABLE 32.4

and male and female thigh muscles with no changes in the breast muscles from female turkeys [63].

Male turkeys exhibited significantly higher myoglobin concentration than females [63] and male Muscovy ducks had higher total heme pigment concentration than females (Table 32.5) [29].

IV. VITAMINS

Poultry meat is rich in niacin (PP), an essential vitamin that plays a role in many metabolic cycles. Moreover, it is also an important source of vitamins from the B group, like thiamine (B_1) and riboflavin (B_2), both important in energy metabolism, and B_{12}, which is necessary to the nervous system and exclusively present in foods of animal origin (not available in plants) [1]. Depending on the kind of diet, broiler and turkey muscles, hens, ducks, and goose meat can be also a supplementary source of vitamins diluted in lipids, i.e., vitamins A, D, and E [64,65].

The content of vitamins in poultry muscles is presented in Table 32.6. Thiamine content (B_1) was the highest in duck flesh and substantially lower, 2.79 times, in goose flesh, 5.1 times in broiler breast, and 5.6 times in turkey white meat [52]. The content of vitamin B_1 was comparable in broiler breast and T/L muscles and turkey white and dark meat, respectively. The increasing order of the amount of riboflavin (B_2) in poultry meat was as follows: broiler breast, turkey white, turkey breast, hen breast, broiler leg, turkey dark, duck and goose flesh. The broiler muscles had two times more niacin (PP) than turkey light and dark meat and 2–3 times more than hen, duck, and goose flesh. The richest in vitamin B_6 were broilers, then geese and turkey, while duck content of this vitamin was the lowest.

A. Vitamins—Age, Sex, and Strain

Riboflavin (B_2) content in breast broiler muscles decreased with age from 7 to 12 wk (0.093 vs. 0.086 mg/100 g) with no changes in niacin (PP) and vitamin B_6 [66]. In contrast, Singh and Essary [67] reported that with advancing age of broilers from 8 to 10 wk the content of thiamine (B_1) and riboflavin (B_2) increased in breast (0.032 vs. 0.045 and 0.040 vs. 0.050 mg/100 g) and thigh (0.059 vs. 0.066 and 0.096 vs. 0.113 mg/100 g) while the amount of niacin (PP) decreased in thigh muscles (6 vs. 5.6 mg/100 g) and did not change in breast muscles (10.4 vs. 10.2 mg/100 g).

Ang and Hamm [14] stated no significant differences due to sex in riboflavin (B_2), niacin (PP), and vitamin B_6 in the breast of 7 wk broilers. It was in line with results of Singh and Assary [67] who found that only male broiler thigh contained significantly more thiamine (B_1) and riboflavin (B_2) than female thigh muscles, i.e., 0.065 vs. 0.060 and 0.111 vs. 0.101 mg/100 g, respectively.

V. MINERALS

Minerals influence palatability, acidity of meat, biological activity of different enzymes, and osmolarity of meat. Iron is an important nutrient for human beings because it plays a part in the process of oxygen transport from lungs to various tissues by means of hemoglobin to which it is linked. Iron functions as a catalyst in many metabolic reactions. Its absence provokes anaemia [1]. Preponderance of haem

iron in meat, which is absent from plant sources, makes the iron from meat more bioavailable [9]. Zinc is important because it is involved in several metabolic reactions and meat is its main source. Its deficiency reduces the immunological defenses of the organism [1,68].

Table 32.7 shows the mineral content in poultry meat. The broiler breast muscles contained more Mg, K, P, and Li (18.2 vs. 5.8 μg/g [69]), less Cu, Fe, Zn, and Na, and a comparable level of Ca than T/L muscles. Goluch-Koniuszy et al. [70,71] found no difference in Cu and Mg content between broiler breast and leg muscles and Kunachowicz et al. [65] found lower Ca content in broiler breast than thigh muscles. Turkey breast muscles were characterized by higher content of K and P and lower content of remaining minerals when compared with thigh muscles [41]. However, Posati [52] showed higher Mg content in light than in dark turkey muscles. Goose breast muscles had a higher content of Fe and lower Ca than thigh muscles. The higher content of Fe in broiler and turkey T/L muscles as well as in goose breast muscle was related to their greater content of myoglobin and hemoglobin than in corresponding breast and thigh muscles, respectively (Table 32.5). Higher content of Zn in T/L muscles can be explained by their greater metabolic activity.

The iron content in goose muscles was substantially higher than in broiler and turkey muscles and in hen, duck, and goose flesh (Table 32.7). The richest in zinc were turkey thigh muscles. The average zinc content was in duck flesh and broiler T/L muscles, and the lowest was in turkey and broiler breast muscles. The Mg content was rather uniformly distributed in broiler and turkey muscles and its content in duck, hen, and goose flesh was between that of broilers and turkeys. It was difficult to estimate the order of Na, K, and P contents in poultry meat on the basis of different author results presented in Table 32.7.

A. Minerals—Age, Sex, and Strain

In broiler breast and thigh muscles sex influenced Fe, Zn, and Na levels. Fe content was lower in breast and thigh muscles of broiler males than females while Zn content was higher in males than females, but differences were not so high as for Fe content [16]. According to Goluch-Koniuszy et al. [71], sodium content was higher in female breast muscles and in male leg muscles, respectively. Other authors found no sex influence on the level of nutrients (Cu, Fe, Zn, Mg, Ca, Na, K, P, and Li) in broiler cockerels and pullets [69,70].

Strain influenced the level of Mg, Ca, and K [16] as well as Ca and Li levels [69] in broiler breast and thigh muscles.

VI. LIPID FRACTIONS CONTENT

Lipids play a key role in many quality traits of meat products including nutritional value and sensory properties, mainly flavor because they are both solvent and precursors of aroma compounds. Intramuscular lipids refer to lipids contained in both intramuscular adipose tissue and muscle fibers. The intramuscular adipose tissue comprises cells located along the fibers and in the interfascicular area. The fat cells contain almost exclusively triacylglycerols (TAG). The lipids of the fibers consist of cytosolic droplets of TAGs and membrane lipids, phospholopids (PL), and cholesterol. The amount of TAGs in the fibers only accounts for a small part of the total intramuscular TAGs [74].

Landaise Goose (24 wk)			3.88		0.98		0.04		[80]

M = male, F = Female, * = TAG (triacylglycerols), ** = PL (phospholipids).

Table 32.8 shows that the TAG content was the lowest in broiler breast, average in turkey and Muscovy duck breast, highers in male mule duck, and the highest in goose breast muscles. The PL content in broiler and turkey breast muscles was lower by nearly half of its level in duck and goose breast muscles.

Broiler, hen [81], and turkey breast muscles contained less total lipids, TAGs, and PL than thigh muscles. The high level of PL is characteristic of red, oxidative muscles. Therefore breast, glicolytic muscles of broilers and turkeys contained less PL than T/L contra partners as well as breast muscles of ducks and geese which mainly comprised red fibers [12,82–84]. Surprisingly, some authors found that PL was higher in the lipids of broiler breast than thigh muscle lipids [76,77]. In both broiler and turkey muscle types, free fatty acids were present in only trace amounts. The FFA concentration was higher in broiler leg muscles by 37% [85] and turkey thigh muscles by 73% [79] compared to corresponding breast muscles.

Broiler muscle lipid fraction contained more FFA amounts than turkey muscles. The broiler and Muscovy and 10 wk Mule duck breast muscles contained more PL than TAG. The reverse was true for goose breast and 12 wk male Mule duck muscles while in turkey breast and 12 wk mule female duck the level of the main components of lipids was comparable. On the other hand, in broiler and turkey T/L muscles PL content was lower than the TAG content.

The fatty acid composition of the different lipid classes of broiler and turkey muscles is shown in Tables 32.9 and 32.10. There were only small differences between broiler and turkey breast and leg TAG fatty acid composition (Table 32.9). According to Pikul et al. [78] in broiler muscles palmitic (C16:0), oleic (C18:1), linoleic (C18:2n6), and linolenic (C18:3n3) acids in TAG accounted for about 26%, 37%, 22%, and 1%, respectively. Ahn et al. [85] and Sklan and Tenne [75] found that broiler breast TAG contained less oleic acid (C18:1) and more linoleic acid (C18:2n6) and linolenic acid (C18:3n3) than leg muscles. Sklan and Tenne [79] found lower content of palmitic acid (C16:0) and higher content of linoleic acid (C18:2n6) in turkey breast TAG than in turkey thigh TAG. There were no arachidonic acid (C20:4n6) and polyunsaturated PUFA n-3 in turkey muscle TAGs fraction. The decreasing percentage of the fatty acid groups in TAGs was monounsaturated fatty acids (MUFA), saturated fatty acids (SFA), and PUFA for broiler muscles [64,75,78,85] and SFA, MUFA, and PUFA for turkey muscles [79].

The PL fatty acid composition of broiler and turkey breast muscles was different from T/L muscles (Table 32.10). The PL fraction of broiler and turkey breast contained more palmitic acid (C16:0) and oleic acid (C18:1) and less stearic acid (C18:0) and linoleic acid (C18:2n6) than PL from T/L muscles [64,75,78]. The above pattern was also valid for phosphatidyl choline (one apart phosphatidyl ethanolamine major PL) with the one exception of similar or higher values of linoleic acid (C18:2n6) in breast and T/L broiler muscles [75,85]. The broiler breast and T/L muscles contained a higher level of arachidonic acid (C20:4n6) in PL fraction than corresponding turkey muscles by 6.5 and 7.0%, respectively. The relative percentage of PUFA was the same in the PL from broiler breast and leg muscles while for turkey PL the percentage of PUFA was lower in breast than thigh muscles. Compared to phosphatidyl choline (PC) phosphatidyl ethanolamine (PE) in broilers contained more PUFAs. Turkey muscles lacked PUFA n-3 in the PL fraction, likewise in the TAGs fraction.

n-3		1.46	1.25		0.87	1.24		
n-6/n-3		12.03	17.84		15.30	18.97		

The decreasing percentage of the fatty acids groups in PL for broiler muscles, i.e., PUFA, SFA, and MUFA (The reverse when compared with TAGs) differed from turkey muscles: SFA, PUFA, and MUFA [64,75,78].

The fatty acid composition of TAGs was different from the fatty acid composition of PL (Tables 32.9 and 32.10). The PL fraction from broiler and turkey muscles contained more PUFA and SFA and less MUFA than the TAGs fraction. The arachidonic acid content in broiler breast and leg muscles was substantially higher in PL than in TAG. The broiler breast and leg PUFA n-6/n-3 ratio in PL was two times lower than in TAG (2.04 and 2.11) [78].

A. Lipid Fractions Content—Age, Sex, and Strain

The TAG content of Mule duck increased with age and this correlated with the increase in lipid content (Table 32.7) [4].

There was no change in the content or class composition of the lipids with sex of broilers [77]. At any given age, the TAG content was higher in male Mule duck breast compared with the females but this difference was not significant [4].

VII. CHOLESTEROL

Determination of cholesterol in food is important for consumer health [86]. High dietary cholesterol intake is considered to be one of the risk factors for human atherogenesis [87]. The higher cholesterol concentration reduces membrane fluidity, lowers Ca^{+}-ATPase activity, and regulates contraction and relaxation rates [88]. Cholesterol content in chicken tissue is possible to be influenced by fatty acid composition of the diet [3] or by the dietary garlic and copper content [88].

Table 32.11 presents cholesterol content expressed in mg/100 g of poultry meat. The cholesterol content in poultry breast white muscles, in ascending order, was as follows: broilers, hens and turkeys, Muscovy ducks, goose, Pekin and Mule ducks, and ranged from 41.0 to 123 mg/100 g. The cholesterol content in different poultry T/L muscles was on similar level with one exception of higher content in hen dark meat, and ranged from 64.0 to 101 mg/100 g. Cholesterol is solely a membrane lipid in meat, and is also found in cell membranes of adipose tissue and fatty tissue [91]. Cholesterol is usually associated with adipose tissue, which is more abundant in thigh than in broiler and turkey breast muscles (Table 32.1). Moreover,

* = PE (phosphatidyl ethanolamine), ** = PC (phosphatidyl choline).

slow-twitch fibers of thigh muscles have many more mitochondria, their mitochondria are bigger, and the metabolic rate in muscles is faster in comparison to the fast-twitch fibers of breast muscles [88]. Therefore, the cholesterol content in T/L or dark meat was higher by 17.0–48.3% in broilers, by 50.2% in hens and by 20.3–37.3% in turkeys (range from 63.7 to 78.9 mg/100 g) compared to breast or white meat (range from 40.9 to 58.2 mg/100 g). In contrast, the cholesterol level in goose breast muscles was higher by 15.3% than in thigh muscles.

The cholesterol content expressed as a percentage of total lipids in broiler breast muscles (2–2.7%) was two to three times higher than in thigh muscles (1.0%) [17,77]. In contrast, the cholesterol concentration in total lipids of turkey male breast and thigh muscles was not significantly different (4.07 vs. 3.10%) [90]. Irrespective of the differences between muscles, cholesterol concentration was substantially higher in total lipids of turkey muscles than in chicken muscles. This can be explained by lower total lipid content in turkey breast and thigh muscles (1.47 and 2.45%) (Table 32.1) than in breast and thigh broiler muscles (1.80 and 7.30%) [17,90].

A. Cholesterol—Age, Sex, and Strain

The cholesterol content decreased with age: in 7 vs. 9 wk broiler breast muscle by 33.30% [66], in 5 vs. 13 wk broiler breast muscle by 8.40%, and in thigh muscle by 23.57% [92], in 10 vs. 25 wk male turkey breast muscles by 20.97%, and in thigh muscles by 23.76% [49], and in

10 vs. 12 wk male Mule duck breast muscles of males by 13.22% and females by 13.68% [4]. In 9–11 wk broiler breast muscles there was no age dependency on cholesterol content and after 12 wk its content increased to the level of 7 wk broiler breast muscle [66]. The cholesterol content in breast and thigh muscles of female turkeys (10 vs. 18 wk) was entirely independent of age [49].

At the comparable age (14 wk) male turkeys had higher cholesterol content than females in breast and thigh muscles (Table 32.11) [49]. The same trend was observed for goose and male and female Mule duck breast muscles but differences were not significant [4].

VIII. FFA

To prevent serious chronic diseases of humans, it is necessary to consider both the balance intake of fatty acids [8,93] and the intake of cholesterol [86] in poultry meat. A substantial reduction in carcass fats and cholesterol and improvement of the fatty acid make-up in poultry muscles, such as omega-3 fatty acids, bring about nutritional and economic benefits to consumers and producers alike [3]. Fat deposition is controlled by the calorie: protein ratio of the diet, and the fatty acid composition is controlled by type and amount of dietary fat by adding linoleic (LA, C18:2n6) and linolenic (LNA, C18:3n3) acids, vegetable oils, fish meal, fish oils, beef tallow and marine algae [3,8,85,87,94–99]. For example, the composition of fatty acids in chicken carcass can be modified through feeding because in the digestive system of chickens, lipids are absorbed and deposited in tissue in unchanged form. The concentration of fatty acids in tissue is closely correlated with their dietary content, in contrast to SFA and MUFA acids which can be synthesisted de novo from simple precursors such as glucose or amino acids [5,8,94,100]. Linoleic acid (C18:2n6) and α-linolenic acid (C18:3n3), the precursors of the n-6 and n-3 family of fatty acids, respectively, are essential fatty acids and have to be supplied by the diet [100].

Average	84.35 (5.16)	70.00	

M = male, F = female, * = white, dark muscles.

The fatty acid composition of muscle tissue plays a major role in lipid stability and product quality. Lipid oxidation is one of the main causes of deterioration in the quality of meat during storage and processing. Lipid oxidation is a major problem in poultry meat due to the high content of polyunsaturated fatty acids (PUFA) and low level of natural antioxidants such as tocopherol [8,64,85,94,101]. However, introducing antioxidants to the diet, especially vitamin E, efficiently protects the carcass from this process [102,103].

Okuyama et al. [104] recommended the decrease of polyunsaturated (PUFA) n-6/n-3 ratio in diet and the separate evaluation of the content of α-linolenic acid (LNA, C18:3n3; the basic fatty acid and precursor of PUFA n-3 family), arachidonic acid (AA, C20:4n6; a key metabolite in the PUFA n-6 family), eicosapentaenoic acid (EPA, C20:5n3), and docosahexaenoic acid (DHA, C22:6n3) in foods, because the physiological activity of EPA+DHA is five times higher in comparison with LNA. Another dietary factor influencing the risk of atherosclerosis in humans is the ratio of saturated (SFA), monounsaturated (MUFA), and polyunsaturated (PUFA) fatty acids [8].

Some long chain PUFAs (i.e., dihomo-α-linolenic acid, AA and EPA) are precursors of eicosanoids — important metabolites in the control of cell metabolism [105]. In contrast to PUFA n-6 arachidonic acid (C20:4n6), dietary PUFA n-3 decrease production of pro-inflammatory eicosanoids and have a positive effect on cardiovascular–coronary heart disease, autoimmune, and other chronic diseases, including cancer [8,100,106]. The incidence of coronary heart disease has been said to be dependent upon two different processes – atherosclerosis and trombosis – where atherosclerosis relates to the thickening of the arterial wall and trombosis relates to formation of a clot that occludes the artery, causing heart attack [8,107]. The DHA has an important role in the development of the central nervous system of the newborn while the EPA is involved in blood clotting and the inflammatory response [9]. In view of physiological effects of arachidonic acid (AA), i.e., an increased synthesis of pro-inflammatory prostaglandins,

leukotrienes and platelet-activating factor which is connected with cancer and autoimmune diseases, the decrease of its intakes is recommended [108–110]. Generally, high intakes of EPA+DHA and AA are considered important positive and negative aspects for human nutrition, respectively [49,87,109,110].

The percentage representation of fatty acids in lipids from poultry breast and T/L muscles is presented in Tables 32.12–32.15. The main SFA fatty acids in poultry breast and T/L muscles were palmitic acid (C16:0) and stearic acid (C18:0), with minor quantity of myristic acid (C14:0), and for duck and goose breast muscles also lauric acid (C12:0). The stearic acid (C18:0) is not thought to raise blood cholesterol level while the myristic acid (C14:0), appears the most atherogenic and has four times the cholesterol-raising effect of palmitic acid [107]. Kelly [115] showed that stearic acid (C18:0) in the diet had beneficial effects on thrombogenic and atherogenic risk factors in males. The predominant MUFA fatty acids in the poultry for both muscles were oleic acid (C 18:1) and palmitoleic acid (C16:1). In the PUFA fatty acids group linoleic acid (C18:2n6) dominated followed by arachidonic acid (C20:4n6), α-linolenic acid (C18:3n3) and DHA (C22:6n3, except duck muscles and goose leg muscles). In all tissues the principal fatty acid was oleic (C18:1), followed by palmitic acid (C16:0) and/or linoleic acid (C18:2n6).

Broiler, hen and goose breast, or white muscle lipids contained more SFA, PUFA n-6, and PUFA n-3, and total PUFA but less MUFA than T/L or dark muscle lipids (Tables 32.12, 32.13, and 32.15). However, some authors found in broiler breast muscles, when compared with T/L muscles, less PUFA n-6 by 2.16% [111] or almost the same percentage of SFA [3,17,105], MUFA, and PUFA n-3 [105]. The nutritionally significant PUFA n-6/PUFA n-3 ratio was lower (more favorable) in broiler breast muscle (5.35) compared with thigh muscle (6.33). For hens the ratio of PUFA n-6/PUFA n-3 was slightly higher (by 0.32%) in white than in dark smuscles.

Broiler, hen, duck and goose breast muscles were characterized by a higher proportion of stearic acid (C18:0) and lower proportion of oleic acid (C18:1) than thigh muscles. Lipids associated with broiler or hen breast meat contained less linoleic acid (C18:2n6) and linolenic acid (C18:3n3), but more arachidonic acid (C20:4n6) and eicosapentaenoic EPA (C20:5n3—no difference in hens), docosapentaenoic DPA (C22:5n3) and docosahexaenoic DHA (C22:6n3) than lipids associated with T/L muscles. The level of EPA, DPA, and DHA in broiler breast lipids was at least one and a half that of thigh muscles lipids and DHA exceeded EPA in both breast and thigh muscles lipids by a factor of two and a half. Kralik and Ivankovic [111] found higher content of EPA, DPA, DHA, and total n-3 fatty acids but less n-6 fatty acids in broiler breast muscles compared with thigh muscles which indicated that the percentage of PUFA in both kinds of muscles was comparable. Others found no difference in linoleic acids (C18:2n6) [3,17] or in fatty acid profiles between broiler white and dark muscles [105]. The level of DPA and DHA in hen breast muscles was 2.8 times higher than in thigh muscles [20]. In goose breast muscles, likewise in broilers and hens, the proportion of linolenic acid (C18:3n3) was lower than in leg muscles [42]. In contrast, goose breast muscle lipids were characterized by the presence of higher levels of linoleic acid (C18:2n6) and the same values of arachidonic acid (C20:4n6) as in leg muscles, and according to Biesiada-Drzazga et al. [42], by the absence of EPA, DPA, and DHA in both muscles. The proportion of linoleic acid (C18:2n6) in Pekin [6,12] and in Muscovy duck [6,32] breast muscles compared with thigh muscle was higher and lower, respectively.

Breast and thigh muscle lipids of 20 wk male turkeys were comparable in total values of the main fatty acids fractions [49] or were different in fatty acid composition [90]. Therefore, turkey breast muscles were characterized by a higher proportion of linolenic acid (C18:3n3) and lower proportions of SFA, linoleic acid (C18:2n6), and arachidonic acid (C20:4n6) compared to thigh muscles [49,79] which was in accordance with data for chicken and hen only for linoleic acid (C18:2n6). According to Komprda et al. [90], turkey breast muscles had slightly higher arachidonic acid (C20:4n6) and DHA (C22:6n3) percentages than thigh muscles which corresponded with broilers. However, higher or

M = male, F = female, * = intensive system, ** = semi-intensive system.

the same MUFA percentage and lower or the same PUFA percentage in male turkey breast than thigh muscles were not in line with broilers and hens. The PUFA n-6/n-3 ratio was comparable in turkey muscles and hens. A comparison of fatty acid composition in male turkeys and broiler breast and thigh muscles revealed that in turkey muscles the ratio of SFA was higher by 5.06/6.59%; MUFA was lower by 10.28/14.08%; PUFA was higher by 4.60/7.49%; and arachidonic acid (C20:4n6) was higher by 2.05/2.69% [17,90]. Therefore, turkey meat provided substantially less MUFA (a desirable fraction from the viewpoint of human nutrition) and more arachidonic acid (undesirable fraction) compared to broiler meat.

Duck breast muscles contained more SFA than other kinds of poultry and less PUFAs than broilers, hens, and turkeys. The fatty acid contents of duck and goose muscles were very similar and contained approximately 50% SFA, 33% MUFA, and 16% PUFA (Tables 32.12–32.15).

The interpretation of fatty acid composition in poultry meat depends on the presentation method. As a percentage of total fatty acids, broiler thigh SFA were not different (30.60 vs. 31.27%), MUFA was higher (49.06 vs. 43.31%), and PUFA was lower (15.51 vs. 18.87%) than breast muscles of the corresponding fatty acid groups [58]. In contrast, when fatty acid content was expressed in mg/100 g of muscles, broiler thigh muscles contained more SFA (1530 vs. 300 mg/100 g), MUFA (2460 vs. 410 mg/100 g) and PUFA (780 vs. 180 mg/100 g). Likewise, in turkey thigh muscles the sum of SFA, MUFA (725 vs. 441 mg/100 g), PUFA, and EPA and DHA (18.2 and 14.6 mg/100 g) and arachidonic acid (C20:4n6) (72.7 vs. 50.3 mg/100 g) was substantially higher than in breast muscles, due to the higher total lipid content in thigh compared to breast muscles (2.45 vs. 1.47%) [90]. These values differ from that expressed as a percentage of total fatty acids for turkey muscles as shown in Table 32.12. Turkey breast muscles contained 5% less SFA, nearly 40% less MUFA, and approximately the same amount of PUFA compared to broiler breast muscles [17,90]. The EPA+DHA values for turkey and chicken breast muscles

were similar. However, turkey thigh muscles contained less EPA+DHA than broiler thigh muscles (18.2 vs. 31 mg/100 g) due to the substantially lower total lipid content, i.e., 2.45 vs. 7.30%, respectively. The content of arachidonic acid (C20:4n6) in turkey breast muscles (50.3 mg/100 g) was higher by nearly 60% in comparison to chicken breast muscles (32.1 mg/100 g).

A. FFA—Age, Sex, and Strain

Fatty acid composition of broilers, turkeys, ducks, and geese was affected by age and sex. A comparison of 13 wk fast growing broilers with 5 wk broilers showed that older birds had significantly lower MUFA content in breast muscles, and the levels of PUFA and arachidonic acid (C20:4n6) were higher in breast muscles and lower in thigh muscles, respectively [92]. Advancing age of male and female turkey was accompanied by increased MUFA and decreased PUFA percentage in breast and thigh muscles while the percentage of SFA decreased in breast muscles and increased in thigh muscles, respectively (Table 32.13) [49]. Moreover, with increasing age the content of sum of EPA+DHA decreased in both male muscles, but did not differ in female muscles. The arachidonic acid (C20:4n6) content decreased with age in breast muscles of turkeys of both sexes, but not in thigh meat. With age duck thigh muscle lipids had a lower level of MUFA and higher levels of PUFA and linoleic acid (C18:2n6). Age had no influence on SFA content in Pekin duck thigh muscles, but in Muscovy and Mule duck the SFA level decreased with age (Table 32.13). During the time of rearing of geese from 6–30 wk the fat of male and female breast, muscles decreased gradually with the content of SFA by 3.0–3.4% and stearic acid (C18:0) by 4.9%. The share of MUFA and palmitoleic acid (C16:1) increased by 1.1–3.0% and by 1.1%, respectively (Table 32.14) [114]. However, the PUFA, linoleic acid (C18:2n6), and arachidonic acid (C20:4n6) were not influenced by age. Friend et al. [48] found no differences due to age in goose fatty acid composition.

The male broiler breast muscles concentration of total PUFA and PUFA n-3 was lower than in female breast muscles while the male thigh muscle concentration of MUFA was lower and total PUFA and PUFA n-3 were higher than in female thigh muscles. The level of arachidonic acid (C20:4n6) in male broiler muscles was higher than for female muscles [77]. At the same age, male turkey breast muscles were characterized by lower MUFA content and thigh muscles had lower contents of both MUFA and PUFA than corresponding female muscles [49].

The breast muscle lipids of 16 wk male geese males were characterized by more favorable composition of fatty acids compared to females due to the higher share of MUFA and lower level of SFA (Table 32.14) [114].

Geese strains influenced the composition of the following fatty acids: palmitic (C16:0), palmitoleic (C16:1), stearic (C18:0), oleic (C18:1), linoleic (C18:2n6), and arachidonic (C20:4n6) [48]. Batura et al. [50] also found geese strain dependent on differences in the level of myristic acid (C14:0), linoleic acid (C18:2n6), and arachidonic acid, (C20:4n6).

IX. CONCLUSIONS

Muscles highest in protein content were turkey, broiler and goose breast muscles while the lowest in fat were breast muscles of turkeys, broilers, and Pekin-Muscovy ducks. The best proportion of protein to fat was in the duck thigh muscles. Goose and turkey muscles had the lowest moisture content.

The broiler muscles were the highest in niacin. Duck and goose flesh were the best sources of thiamine (B_1) and riboflavin (B_2). The broiler and turkey thigh/leg or dark muscles contained more riboflavin (B_2) and less niacin (PP) and vitamin B_6 than breast/light muscles. Poultry meat is also an important source of several minerals, especially iron (goose muscles, turkey dark), zinc (turkey dark), potassium and phosphorus (goose flesh), and other trace elements such as copper.

Lipids of white poultry meat (broilers, hens, geese) were richer in SFA and PUFA and the lipids of red meat were richer in MUFA. Therefore, poultry consumption, especially breast muscle, could provide an important additional source of nutritionally important unsaturated fatty acids (PUFA).

Poultry breast muscles have higher nutritional and dietetic values than thigh muscles (lower lipid and collagen content and higher protein content).

33 Poultry Processing Quality

Christine Z. Alvarado
Department of Animal and Food Sciences, Texas Tech University

CONTENTS

I. INTRODUCTION

Per capita consumption of poultry has increased dramatically during the last 40 years with poultry meat ranking as the most consumed muscle food per capita in the United States. This increased consumption in poultry compared to other meats can be attributed to vertical integration, an increase in value-added product offerings, and nutritional quality. In vertically integrated companies, the same company owns several or even all of the process from live production through slaughter, and distribution to retail or foodservice. Vertical integration has improved product uniformity and increased profit margins for the poultry industry compared to other meat industries. The poultry industry has also increased the production of value-added poultry products to meet consumer demands for convenience, versatility, and variety. Also, nutritionally, the fat in both chicken and turkey meat is easily removed compared to other meats, enabling consumers to adopt a more low-fat type of meat into their diets. The process of converting the live animal into meat is complex. Many steps are implemented to ensure uniformity and high quality for the consumer. This chapter will detail the steps required to convert a live bird into a convenient and versatile product for consumers.

II. SLAUGHTER

Poultry slaughter involves six primary unit operations: preslaughter, immobilization, feather removal, evisceration, chilling, and further processing. In each of these processes, bird uniformity and automation can affect both quality and efficiency (yield). Normally, plants process birds at 70–140 birds per minute depending on the inspection system used, the type of birds (broilers versus turkeys), and the uniformity of the birds.

A. PRESLAUGHTER

The United States Department of Agriculture (USDA) has a "Zero Tolerance" for fecal contamination of poultry

carcasses in the Pathogen Reduction/Hazard Analysis and Critical Control Point System (HACCP) (1). Therefore, birds are removed from feed, but allowed access to water 8–12 hours prior to slaughter to allow for clearing of the intestinal tract (2). This time for clearing of the gastrointestinal tract helps prevent some fecal contamination of carcasses due to intestinal rupture by the automated evisceration/processing equipment. Feed withdrawal fewer than eight hours can result in fecal contamination and full crops, which can lead to contamination of the carcass during evisceration and possible condemnations (3). Feed withdrawal greater than 12 hours prior to slaughter can result in loose feces, green gizzards, and bloated intestines, which leads to downgrades and meat yield loss for processors. Also, the longer the feed withdrawal period, the more water weight is lost, resulting in a decreased yield for processors. Therefore, feed withdrawal should be within the 8–12 hours prior to slaughter to allow for the clearing of the intestinal tract, and to minimize yield losses (4).

Antemortem handling of the birds preslaughter can affect meat quality and consumer acceptability of the product. The largest meat quality determinants at this antemortem stage are handling and stress to the bird. Improper handling can result in bruises, broken and dislocated bones, and variation in breast meat color, all resulting in decreased yield for the processor through carcass downgrading. The areas most frequently bruised are the breast, wings, and legs (5). An estimate of 90–95% of all bruises found on broiler carcasses occurs during the final 12 hours prior to slaughter (6). This period is normally when the birds are caught, cooped, transported to the plant, and unloaded for slaughter. Ages of bruises are easily determined and can be used at the plant to determine problem areas either at the farm or during catching, transportation, or unloading. During the initial formation of a bruise, the area appears bright red, followed by purple, yellow, green, and orange before returning to the normal color of the tissue (7, 8).

Increased stress due to catching and transportation may also lead to poor meat quality and reduced yield. Most birds are usually caught and cooped during the evening to early morning hours to ensure cooler temperatures and to reduce stress. Several broiler companies use automated methods to catch birds. These machines "scoop" birds from the floor of the house into coops minimizing bruising and broken bones. However, most turkey facilities are still completely manual when catching birds due to their large size. Transportation of the birds may lead to increased stress and can result in poor meat quality. This will be discussed in more detail later in the chapter.

B. Immobilization – Stunning, Exsanguination

Following arrival at the processing plant, the birds are unloaded from the transportation trucks onto a conveyor line through an automated "dumping" mechanism. However, turkeys are normally unloaded from the trucks by hand. Both methods can cause bruising and broken bones if the animal is handled improperly. Once on the conveyor, the birds enter the plant and are hung on shackles prior to slaughter. The hanging room is usually a dark room with red or black lights to offer a calming effect on the birds to reduce stress. Once shackled, the birds are electrically stunned in a saline (approximately 1% NaCl) water bath to render the bird unconscious. Electrical stunning is the most common method of bird immobilization in the U.S. because it is inexpensive, convenient, and safe (9, 10).

Electrical stunning produces a uniform heartbeat for better bleeding, immobilizes the bird for slaughter, and relaxes the feather follicles for better picking. Normally, the birds are stunned for 10–12 seconds (10–20 mA per broiler; 20–40 mA per turkey) to produce a state of unconsciousness for 60–90 seconds (11). Stunning parameters with excessive amperage can cause downgrades, while too low of an amperage can cause poor bleeding, poor meat quality, and improperly killed birds. Therefore, proper stunning amperages are important determinants of good quality meat.

Stunning parameters and methods vary from country to country. For example, the European Economic Community requires birds to be irreversibly stunned by using saline bath electrical stunning methods that deliver approximately 100 mA per bird. This high amperage can cause broken clavicles, blood splash, rupture femoral arteries, and other downgrades (12). Brazil and some European countries have replaced high amperage electrical stunning with gas stunning. Gas stunning utilizes argon and carbon dioxide mixtures to displace oxygen and cause hypoxia in birds. Meat quality from gas stunned birds and low amperage stunned birds is better in comparison to high amperage electrical stunning because of the prevention of blood splash and broken bones (13, 14).

To reduce blood splash and ruptured arteries, bleed out must be performed within 10 seconds of low amperage electrical stunning. Exsanguination (or bleed out) is the period of blood removal which usually lasts 1.5 to 3 minutes. Following stunning, the head of the bird is guided through a set of bars for proper presentation to the cutting blade (Figure 33.1). Most of these automated cutting blade machines use a single unilateral neck cut which severs the right carotid artery and jugular vein. However, some processors use a rotating blade to sever both carotid arteries and jugular veins for a more complete bleeding efficiency. Either way, the blood volume lost is 30–50%, mainly from the major arteries and veins (11). This loss of blood volume causes brain failure and eventually death to the bird. Insufficient bleeding can result in poor meat quality and discoloration of the skin during scalding. Flavor is the most affected quality parameter associated with improper bleeding with the development of a gamey flavor due to the residual blood remaining in the muscles.

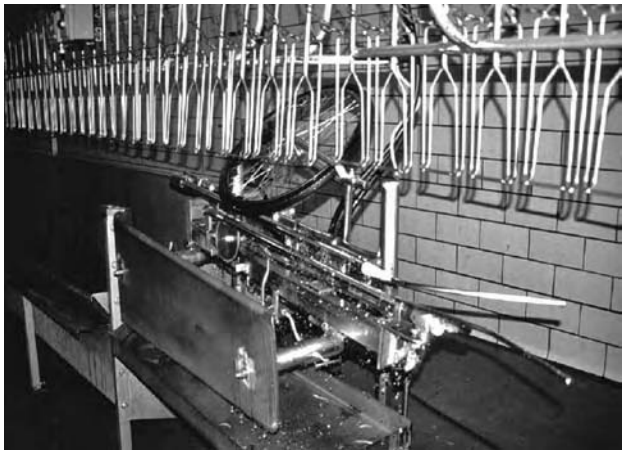

FIGURE 33.1 Killing machine indicating the bicycle wheel and guide bars used for alignment. Reprinted with permission from Poultry Meat Processing, 2002. Ed. AR Sams, Copyright CRC Press, Boca Raton, Florida.

C. Feather Removal – Scalding, Picking

Feather removal is a two-step process – scalding and picking. Scalding is time and temperature dependent with two variations, soft scald and hard scald, depending upon the intended use of the carcass or parts. Soft scald is immersion of the carcasses in 53.35°C (128°F) water for 120 seconds (11). Soft scalding loosens the feathers but does not disrupt the outer skin layer or the cuticle (waxy, yellow-pigmented outer layer). Thus, a yellowish coating is retained on the skin of the bird. Soft scalded birds can be difficult to pick because the feather follicle is not loosened fully. Also, a quality problem can exist in further processed products with soft scalded birds because the cuticle prevents coating adhesion on batter and breaded products.

A hard scald is immersion of the carcass in 61–63°C (140–145°F) water for 45 seconds. The cuticle layer is removed through this hard scald process. Feathers are also easier to remove compared to the soft scald. Also, there are fewer quality problems with hard scalding since coated products have better batter adhesion without the cuticle layer. However, appearance may be a problem for those consumers that prefer the "yellow" tinted soft scalded birds.

Feather removal (picking) is completed by rotating rubber fingers which grasp the feathers and remove them (Figure 33.2). Proper picking is dependent upon the time the carcass spends in the picker as well as the speed of the rotating fingers. Over picking may cause downgrades and mutilations (carcass that have no salvageable parts) while under picking may leave feathers on the carcass resulting in downgrading further down the processing line. Therefore, feather removal is important in maximizing quality and yield of the carcass.

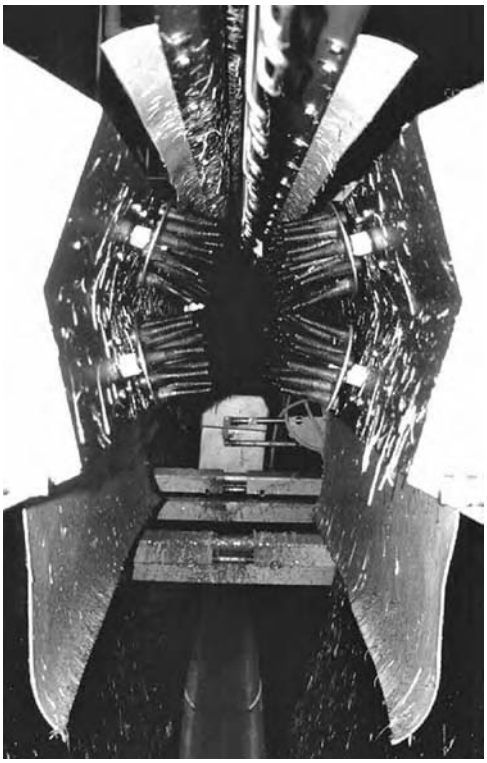

FIGURE 33.2 Picking cabinet with rubber fingers used to remove feathers. Reprinted with permission from Poultry Meat Processing, 2002. Ed. AR Sams, Copyright CRC Press, Boca Raton, Florida.

D. Evisceration – Viscera Removal, Inspection

Prior to actual evisceration, the head, feet, and preen gland (oil gland located at the base of the tail) are removed. Evisceration, or the process of removing viscera from the carcass, is normally automated in chicken plants but is still performed manually in most turkey plants. With either method, the viscera is exposed and removed from the internal body cavity. Once exposed, the USDA inspector examines the carcass for field or plant condemnations and fecal contamination. Condemned birds are usually those with obvious signs of disease as well as cadavers (birds that have died for reasons other than exsanguinations). These birds are disposed of and do not enter the production chain. Fecal contaminated birds must be reprocessed and or trimmed prior to re-entering the production chain. The inedible viscera is then removed from the carcass and discarded while the edible viscera (heart, liver, and gizzard) are collected, cleaned, chilled, and packaged for retail or fast food restaurants. Necks are removed from the birds and lungs are vacuumed out of the body cavity by automated machines. Birds without their viscera are then visually inspected (final inspection) by trained plant personnel for such things as surface lesions, tumors, and bruising. Any imperfections will be trimmed and washed prior to the bird re-entering production.

To ensure high quality of meat, the most important parameter in evisceration is dependent upon the uniformity of the birds and proper machine adjustment. Improperly adjusted machines or flocks with very little uniformity in size or shape can cause an increase in number of mutilations and downgrades. Both of these scenarios cause decreased yield and profit margins for the processor. For this reason, processors utilize specific genetic lines of broilers or turkeys to minimize size variation within the plant.

E. Chilling

Poultry meat must be chilled to 4.4°C within 4 hours of slaughter for 4 lb. broilers, 6–8 hours for 4 to 8 lb broilers and within 8 hours for broilers greater than 8 pounds and for turkeys. In order to accomplish this, two methods are utilized, immersion or air chilling. Air chilling is not the most common method in the United States for poultry carcasses; however, it is used extensively in Europe, South America, and Canada. With air chilling, the birds remain on the shackles following evisceration and enter a room with temperatures ranging from −7°C to 2°C (15). The carcasses remain in this room for 1–3 hours and may have a continual spray mist to help reduce temperatures of the carcass as well as prevent extra moisture loss and reduction in carcass yield. Even with misting, air chilled birds normally have a dry appearance to their skin which disappears during rehydration. However, air chilled birds normally have a lower pathogen load and have an increased shelf-life when compared to immersion chilled carcasses (16, 17).

Immersion chilling is the most common method of chilling poultry in the U.S. Carcasses are removed from the shackle following evisceration and are placed in staged water tanks for a period of about 80 minutes (sometimes longer for turkeys). During immersion chilling, the carcasses are moved through a continuous chilling system by paddles or an auger, through increasingly colder and cleaner water (counter-current flow system) (Figure 33.3). An air bubble agitation system is also employed that decreases the thermal layering effect cooling the carcasses at a faster rate (Figure 33.4). This counter-current flow method of chilling increases water uptake, increases heat exchange, and provides a method of cleaning the bird. Immersion chilled birds have a lower total microbial count than air chilled carcasses due to the washing effect of the immersion. However, there are an increased number of pathogen-positive birds due to cross-contamination issues related to tank sharing during the production day. It is important to note that antimicrobials are used during the chilling process to decrease bacteria, especially pathogens. Chlorine is the most common antimicrobial used in immersion chilling at a level of 20–50 ppm as allowed by FSIS.

FIGURE 33.4 Water immersion chilling tank showing air hoses used to agitate water. Reprinted with permission from Poultry Meat Processing, 2002. Ed. AR Sams, Copyright CRC Press, Boca Raton, Florida.

Immersion chilling involves three steps. The first stage is referred to as pre-chilling and can be a separate tank in some processing plants. This separate tank acts as a "bird wash" to decrease microbial load and debris in the subsequent tanks. The temperature of the pre-chill is around 12°C (55°F) while the other stages are 4–7°C (40–45°F) and finally 1°C (30–34°F) prior to exit of the birds from the chiller and into second processing. During the pre-chill stage, birds absorb some amount of water in their skin while the final stage allows pores in the skin to close trapping the water inside and increasing the weight of the bird.

Postmortem temperature is an important processing factor involved in determining meat quality. Improper chilling of the bird can cause color defects in the meat

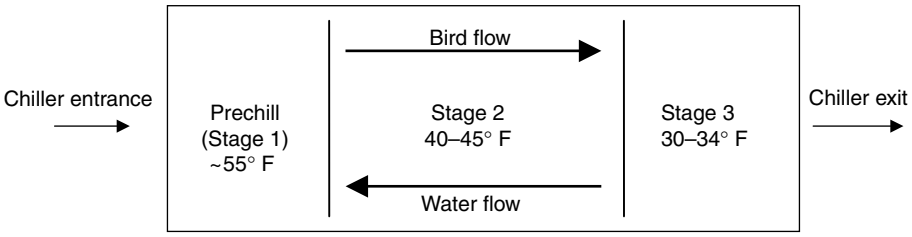

FIGURE 33.3 Immersion chiller system showing the counter-current flow of water and birds.

know as pale, soft, and exudative (PSE) meat. The development of PSE meat is caused by protein denaturation resulting from a rapid rate of pH decline while carcass temperatures are still elevated. The elevated carcass temperatures may have a more damaging effect when meat pH is below 6.2 (18). Carcasses with a normal pH decline may develop PSE meat if improperly chilled (19, 20). Rapid chilling decreases protein denaturation and can significantly reduce the development of PSE meat. Therefore, processors should chill carcasses rapidly early postmortem to prevent poor meat quality problems. Achieving a breast muscle temperature of less than 36°C (95°F) by 60 minutes postmortem and 28°C (82°F) by 90 minutes postmortem may reduce the PSE-like characteristics in turkeys (21).

A recent change in the poultry industry has occurred with a new regulation regarding moisture absorption and retention. The Food Safety Inspection Service has issued a final rule requiring that plants produce poultry products with either no retained water or only the minimum amount required to meet food safety requirements (22). The reasons for this rule deals with both complaints from consumer groups and inconsistencies with red meat processing. Consumer groups have long argued that retained water in poultry meat and subsequent leakage from the meat into packages could lead to spillage and contamination in the home. This increased contamination could result in an increase in food-borne illnesses from *Salmonella* and *Campylobacter.* The inconsistencies in meat processing have focused on the different methods of chilling carcasses. Meat carcasses (beef, pork, and lamb) are air chilled not immersion chilled so water is not retained in these meat products as in poultry carcasses. Actually, water (moisture) is reduced due to shrinking that occurs with air chilling these carcasses. Therefore, the red meat industry has argued that poultry meat is "adulterated" because water has been added to increase its bulk weight and therefore consumers are paying for water along with meat weight. If water is not regulated to be at a minimum uptake during chilling, then the product is not only adulterated but misbranded. Therefore, FSIS has proposed this regulation to help make the meat processing and poultry processing more consistent.

F. Second Processing

Following temperature reduction of the carcasses, the birds are hung on shackles and either packaged as whole birds or cut into parts through automated processes. Adding value to carcasses by cutting them into parts has revolutionized the poultry industry (Table 33.1). In 2000, the predominant form of chicken marketed in the United States was parts (11). This trend started more than 30 years ago when consumers demanded more versatility and variety in chicken meat. At this time, consumers were mostly made up of two income families and there was less time for preparation of meals and cutting up of whole birds. Therefore, as we have entered into the 21st century, this trend of increasing versatility and variety has continued. From a processor stand point, adding value by cutting whole carcasses into parts increases profit margins and consumers are willing to pay an increased price for convenience.

TABLE 33.1
Commonly Used Configurations for Parts of a Chicken Carcass in the U.S.

Part	Description
Half Carcass	Carcass split evenly into right and left halves
Breast Quarter	Anterior right or left quarter containing half of the spine, the ribs, the pectoralis muscles (major and minor), and the attached wing
Leg Quarter	Posterior right or left quarter containing half of the spine, the thigh, and the drumstick
Wing	The three segments of the wing with a variable amount of the breast meat (depending on the customer)
Breast	The major and minor pectoralis muscles with or without rib and sternum bones or skin
Thigh	The upper part of the leg containing the femur
Drumstick	The lower part of the leg containing the tibia and fibula
Drumette	The inner portion of the wing
Wing Portion	The middle section of the wing, with or without the outer "flipper or wing tip" portion still attached
Whole Breast	The anterior half of the carcass without wings, with both breasts still connected in front and with or without the spine connecting them in the back
Keel Piece	The pointed posterior tip of the whole breast before splitting (approximately one third of the whole breast)
Breast Piece	After the removal of the keel piece from the whole breast, the remaining part is split into right and left halves
Whole Leg	Drum and thigh with no spine
Back or Strip Back	Spine and pelvis, production of quarters puts the back as part of the respective quarters
Breast Half or Front Half	The entire, intact, anterior half of the carcass
Leg Half, Back Half, or Saddle	The entire, intact, posterior half of the carcass

G. Deboning

Following second processing, any birds not sold as whole carcasses or parts for retail are usually stored in tubs on ice in a 4°C cooler for 8–12 hours. This storage time allows for the development of rigor mortis and helps to decrease the toughness associated with early deboning. Once aged, the carcass can be either deboned manually or automatically by specialized equipment. Deboning method is the same for either automatic or manual operations: the breast fillet is stripped from the carcass. The wings are then sold as parts and the butterfly can either then be sold or split into two fillets as a less expensive part.

Deboned broiler beast meat is the most valued portion of the carcass and has the highest scrutiny from the consumer. Since this product is normally free of skin, all discolorations and blemishes (bruises) are evident and highly scrutinized by consumers. The three toughest challenges to the processor with deboned broiler breast fillets are portion control, uniformity, and toughness. Portion control is important in the food service industry (restaurants, hotels, etc.) where every consumer should receive the same amount of meat to allow for better cost estimation and meat ordering. In order to accomplish this portioning, scales are used in the deboning section of plants so all deboned broiler breast fillets are automatically weighed and sold based on uniformity of weight.

To ensure uniformity of size, the breast fillets can also be hand trimmed of excess fat, connective tissue, and even meat. Several restaurants require the meat to be a specific shape and size, so, either manually or by specialized equipment, the breast fillet is cut either horizontally or vertically to achieve the desired shape as defined by the customer. Automated equipment is now available to quickly create specific dimensions of the fillets by water knives. This specialized sizing is costly to the consumer because it is very labor intensive.

Uniform tenderness is a very challenging consumer concern for the poultry industry. Rigor mortis development is discussed in detail in other chapters. However, the development of rigor mortis takes 4–6 hours in broilers. Any stimulation to the muscle prior to the development of rigor mortis can cause an increase in toughness. For this reason, carcasses, or even front halves, are aged on the bone in a cooler for a minimum of 4 hours to overnight to prevent toughening. This aging time is expensive and labor intensive and can even cause a decrease in yield from water loss up to 2–3% (23).

To alleviate this toughness associated with early deboning, several plants have implemented electrical stimulation of the carcass following death or marination techniques following chilling. Electrical stimulation (ES) is different from stunning in that ES requires higher amperage and it is applied to the carcass immediately after death. When applied, electrical stimulation causes muscle contractions which uses energy stored in the muscle and allows rigor mortis to develop at a faster rate. Therefore, storing carcasses to prevent toughness associated with early deboning is no longer needed. Another method used to alleviate toughness is marination or the addition to salt and phosphates to increase juiciness of the meat. This increase in juiciness results in a more tender product. Marination will be discussed further in this chapter.

III. GRADING

A. Classification

Each species of poultry (chickens, ducks, geese, guineas, and pigeons) is divided into classes by their physical appearance mainly associated with age and sex. Based on these classes, quality grades are then established based on the quality of individual carcass and parts as will be discussed later in the chapter.

B. Standards for Grading

One way to add value other than cutting whole carcasses into parts is to grade carcasses or sort them by specific conditions and quality characteristics. The Agricultural Marketing Service (AMS) is a branch of the USDA responsible for poultry grading. Following mandatory inspection for wholesomeness (Figure 33.5), each bird is examined to determine eating quality and uniformity. Grading is voluntary, unlike inspection by FSIS. Therefore, the processing plant must pay for personnel from AMS to grade carcasses, thus increasing the price of the graded product for consumers. However, consumers are willing to pay for the added increase to ensure good eating quality and uniformity with tenderness, juiciness,

FIGURE 33.5 USDA inspection shield for wholesomeness.

color, and meatiness. Grading has become an industry standard and is almost expected from consumers.

Once graded by an authorized grader, the official USDA grade mark is used on packages and is easily identified by consumers (Figure 33.6). The highest quality grade is USDA Grade A, followed by USDA Grade B and then USDA Grade C. The standards for USDA Grade A, B, and C carcasses and bone in parts are listed in Table 33.2 (24). USDA Grade A is usually in retail packages and consumers are mostly familiar with this grade. Downgraded carcasses, USDA Grades B and C, are usually further processed because of some deformities or defects. One way to add value to downgraded carcasses is to cut them into parts for retail.

IV. QUALITY CHARACTERISTICS

Three main characteristics of poultry meat determine overall meat quality: tenderness (texture), water holding capacity, and color.

A. Tenderness

Tenderness is one of the most important meat quality characteristics. Several factors influence the tenderness of whole muscle meat products. These factors include the contractile state of the muscle, the amount of connective tissue, and juiciness. In market age broilers (6 weeks), probably the most important influence is the contractile state of the muscle. Most of the tenderness variation due to contractile state in meat from young broilers is related to the conversion of muscle to meat (rigor mortis development). During this conversion, which begins at the time of slaughter, muscle pH declines due to an accumulation of lactic acid in the muscle. In addition, ATP content declines as the muscle shifts from aerobic to anaerobic metabolism. This rigor mortis period takes approximately 4–6 hours in broilers (25, 26). If the muscle is stimulated by deboning or extreme cold temperatures (cold shortening) prior to rigor completion, the muscle can have some degree of contraction possibly without enough energy present for muscle relaxation (depending on what time the stimulation occurred). Therefore, the muscle would shorten thus altering the state of contraction; the denser the muscle, the tougher it will feel to consumers.

FIGURE 33.6 Grade mark from USDA Agricultural Marketing Service.

The connective tissue component of meat tenderness does not play a major role in young broilers. However, it does affect older animals (such as spent fowl) to a greater extent because as the animal ages, heat-stable crosslinks in the collagen form that will not melt during cooking. Juiciness is important in meat tenderness as well because it provides lubrication and mouth feel which are important from a consumer sensory perception. Cooking method is the primary factor impacting juiciness. For example, overcooking which can cause excess moisture loss can decrease tenderness or perceived tenderness by consumers. Any cooking method in which the product can lose excess moisture (example: uncovered grilling compared to covered baking) can decrease the juiciness and therefore decrease tenderness of the product.

B. Water Holding Capacity

Water holding capacity (WHC) is another important characteristic of meat quality. Water holding capacity can be defined as the ability to retain inherent water in the meat or added water (observed in further processed items). Water can be lost from meat through gravitational (storage, drip loss), mechanical (cutting), or thermal (cooking) forces. Differences in meat quality are directly related to how the meat can handle the application of these forces.

Water exists as three forms in the muscle: bound, immobilized, and free. Bound water is closely associated with the muscle proteins. Because water molecules are polar, they associate with the electrically charged reactive groups of the proteins. This water layer is so tightly bound that it can only be removed by incineration (high temperatures). The second form of water is known as immobilized. This water layer is attracted to the bound layer of water, but the attraction is much weaker. The attraction also decreases as the distance to the proteins increase. The third form of water is known as free water and accounts for the majority of the water in meat. Free water is loosely held by capillary forces and is easily lost during processing procedures such as cutting, grinding, storage (drip), and cooking.

Water holding capacity is affected by pH (net charge effect) and the amount of space between the muscle protein structures (steric effect). The postmortem decline in pH results in a loss of reactive groups to bind water due to reduced net protein charge and reduced protein solubility. As pH decreases in meat, it nears the isoelectric point (pI) of muscle proteins (approximately 5.1). The closer the pH is to the pI of the meat proteins, the number of charged sites on the proteins that normally bind water decreases. Examples of changes in WHC due to pH are pale, soft,

TABLE 33.2
Summary of Specifications for Grading A, B, and C Grade Carcasses

Ready-to-Cook Poultry — A Quality
Summary of Specifications for Standards of Quality for Individual Carcasses and Parts
Effective April 29, 1998 (Not All Inclusive — Minimum Requirements and Maximum Defects Permitted)

A Quality

Conformation:	Normal
Breastbone	Slight curve or dent
Back	Slight curve
Legs and Wings	Normal
Fleshing:	Well fleshed, considering kind and class
Fat Covering:	Well-developed layer — especially between heavy feathers tracts

Defeathering:	**Turkeys** (feathers less than 3/4 in.)		**Ducks and Geese**[1] (feathers less than 1/2 in.)		**All Other Poultry** (feathers less than 1/2 in.)	
Free of protruding feathers and hairs	**Carcass**	**Parts**	**Carcass**	**Parts**	**Carcass**	**Parts**
	4	2	8	4	4	2

Exposed Flesh:[2] Weight Range		**Carcass**		**Large Carcass Parts**[3] (halves, front and rear halves)		**Other Parts**[3]
Minimum	Maximum	Breast and Legs	Elsewhere	Breast and Legs	Elsewhere	
None	2 lbs.	1/4 in.	1 in.	1/4 in.	1/2 in.	1/4 in.
Over 2 lbs.	6 lbs.	1/4 in.	1 1/2 in.	1/4 in.	3/4 in.	1/4 in.
Over 6 lbs.	16 lbs.	1/2 in.	2 in.	1/2 in.	1 in.	1/2 in.
Over 16 lbs.	None	1/2 in.	3 in.	1/2 in.	1 1/2 in.	1/2 in.

Discolorations: Carcass		**Lightly Shaded**		**Moderately Shaded**[4]	
		Breast and Legs	Elsewhere	Hock of leg	Elsewhere
None	2 lbs.	3/4 in.	1 1/4 in.	1/4 in.	5/8 in.
Over 2 lbs.	6 lbs.	1 in.	2 in.	1/2 in.	1 in.
Over 6 lbs.	16 lbs.	1 1/2 in.	2 1/2 in.	3/4 in.	1 1/4 in.
Over 16 lbs.	None	2 in.	3 in.	1 in.	1 1/2 in.

Discolorations: Large Carcass Parts (halves, front and rear halves)		**Lightly Shaded**		**Moderately Shaded**[4]	
		Breast and Legs	Elsewhere	Hock of leg	Elsewhere
None	2 lbs.	1/2 in.	1 in.	1/4 in.	1/2 in.
Over 2 lbs.	6 lbs.	3/4 in.	1 1/2 in.	3/8 in.	3/4 in.
Over 6 lbs.	16 lbs.	1 in.	2 in.	1/2 in.	1 in.
Over 16 lbs.	None	1 1/4 in.	2 1/2 in.	5/8 in.	1 1/4 in.

Discolorations: Other Parts		**Lightly Shaded**	**Moderately Shaded**[4]
None	2 lbs.	1/2 in.	1/4 in.
Over 2 lbs.	6 lbs.	3/4 in.	3/8 in.
Over 6 lbs.	16 lbs.	1 in.	1/2 in.
Over 16 lbs.	None	1 1/4 in.	5/8 in.

Disjointed and Broken Bones:	Carcass—1 disjointed and no broken bones. Parts—Thighs with back portion, legs, or leg quarters may have femur disjointed from the hip joint. Other parts—none.
Missing Parts:	Wing tips and tail. In ducks and geese, the parts of the wing beyond the second joint may be removed if removed at the joint and both wings are so treated. Tail may be removed at the base.
Freezing Defects:	Slight darkening on back and drumstick. Overall bright appearance. Occasional pock-marks due to drying. Occasional small areas of clear, pinkish, or reddish-colored ice.

[1] Hair or down is permitted on the carcass or part, provided the hair or down is less than 3/16 inch in length, and is scattered so that the carcass or part has a clean appearance, especially on the breast and legs.

[2] Maximum aggregate area of all exposed flesh. In addition, the carcass or part may have cuts or tears that do not expand or significantly expose flesh, provided the aggregate length of all such cuts and tears does not exceed a length tolerance equal to the permitted dimensions listed above.

[3] For all parts, trimming of skin along the edge is allowed, provided at least 75 percent of the normal skin cover associated with the part remains attached, and the remaining skin uniformly covers the outer surface and does not detract from the appearance of the part.

[4] Moderately shaded discolorations and discolorations due to flesh bruising are free of clots and limited to areas other than the breast and legs except for the area adjacent to the hock.

TABLE 33.2 (*Continued*)

Ready-to-Cook Poultry — B Quality

Summary of Specifications for Standards of Quality for Individual Carcasses and Parts
Effective April 29, 1998 (Not All Inclusive — Minimum Requirements and Maximum Defects Permitted)

	B Quality
Conformation:	Moderate deformities
Breastbone	Moderately dented, curved, or crooked
Back	Moderately crooked
Legs and Wings	Moderately misshapen
Fleshing:	Moderately fleshed, considering kind and class
Fat Covering:	Sufficient fat layer—especially on breast and legs

Defeathering:	**Turkeys** (feathers less than 3/4 in.)		**Ducks and Geese**[1] (feathers less than 1/2 in.)		**All Other Poultry** (feathers less than 1/2 in.)	
A few scattered protruding feathers and hairs	**Carcass**	**Parts**	**Carcass**	**Parts**	**Carcass**	**Parts**
	6	3	10	5	6	3

Exposed Flesh: Weight Range			
Minimum:	Maximum:	**Carcass**	**Parts**
None	2 lbs.	No part on the carcass (wings, legs, entire back, or entire breast) has more than 1/3 of the flesh exposed	No more than 1/3 of the flesh normally covered by skin exposed
Over 2 lbs.	6 lbs.		
Over 6 lbs.	16 lbs		
Over 16 lbs.	None		

Discolorations:[2] **Carcass**		**Carcass** Lightly or Moderately Shaded Discolorations	
		Breast and Legs	Elsewhere
None	2 lbs.	1 1/4 in.	2 1/4 in.
Over 2 lbs.	6 lbs.	2 in.	3 in.
Over 6 lbs.	16 lbs.	2 1/2 in.	4 in.
Over 16 lbs.	None	3 in.	5 in.

Discolorations:[2] **Large: Carcass Parts** (halves, front and rear halves)		**Large Carcass Parts** Lightly or Moderately Shaded Discolorations	
		Breast and Legs	Elsewhere
None	2 lbs.	1 in.	1 1/4 in.
Over 2 lbs.	6 lbs.	1 1/2 in.	1 3/4 in.
Over 6 lbs.	16 lbs.	2 in.	2 1/2 in.
Over 16 lbs.	None	2 1/2 in.	3 in.

Discolorations:[2] **Other Parts**		**Other Parts** Lightly or Moderately Shaded Discolorations
		Breasts, Legs, and Parts
None	2 lbs.	3/4 in.
Over 2 lbs.	6 lbs.	1 in.
Over 6 lbs.	16 lbs.	1 1/2 in.
Over 16 lbs.	None	1 3/4 in.

Disjointed and Broken Bones:	Carcass—2 disjointed and no broken bones, or 1 disjointed and 1 non-protruding broken bone. Parts—may be disjointed, no broken bones; wing beyond second joint may be removed at a joint.	
Missing Parts:	Wing tips, 2nd wing joint, and tail.	
Trimming:	**Carcass**	**Parts**
	Slight trimming of the carcass is permitted provided the meat yield of any part on the carcass is not appreciably affected. The back may be trimmed in an area not wider than the base of the tail to the area halfway between the base of the tail and the hip joints.	A moderate amount of meat may be trimmed around the edge of a part to remove defects.
Freezing Defects:	May lack brightness. Few pockmarks due to drying. Moderate areas showing a layer of clear, pinkish, or reddish-colored ice.	

[1] Hair or down is permitted on the carcass or part, provided the hair or down is less than 3/16 inch in length, and is scattered so that the carcass or part has a clean appearance, especially on the breast and legs.

[2] Discolorations due to flesh bruising shall be free of clots and may not exceed one-half the total aggregate area of permitted discoloration.

TABLE 33.2 (*Continued*)

Ready-to-Cook Poultry — C Quality
Summary of Specifications for Standards of Quality for Individual Carcasses and Parts
Effective April 29, 1998 (Not All Inclusive) (Minimum Requirements and Maximum Defects Permitted)

	C Quality
Conformation:	Abnormal
Breastbone	Seriously curved or cooked
Back	Seriously crooked
Legs and Wings	Misshapen
Fleshing:	Poorly fleshed
Fat Covering:	Lacking in fat covering over all parts of carcass

Deathering:	**Turkeys**		**Ducks and Geese**[1]		**All Other Poultry**	
Scattering of protruding	(feathers less than 3/4 in.)		(feathers less than 1/2 in.)		(feathers less than 1/2 in.)	
feathers and hairs	**Carcass**	**Parts**	**Carcass**	**Parts**	**Carcass**	**Parts**
	8	4	12	6	8	4

Exposed Flesh: Weight Range			
Minimum:	Maximum:	**Carcass**	**Parts**
None	2 lbs.		
Over 2 lbs.	6 lbs.	No limit	
Over 6 lbs.	16 lbs		
Over 16 lbs.	None		

Discolorations:[2]		**Carcass**	
Carcass		Breast and Legs	Elsewhere
None	2 lbs.	No limit	
Over 2 lbs.	6 lbs.	on size, number of areas, or intensity of discolorations	
Over 6 lbs.	16 lbs	and flesh bruises if such areas do not render	
Over 16 lbs.	None	any part of the carcass unfit for food.	

Discolorations:[2]		**Parts**
Parts		Breasrs, Legs, and Parts
(includes large carcass parts)		
None	2 lbs.	No limit
Over 2 lbs.	6 lbs.	on size, number of areas, or intensity of
Over 6 lbs.	16 lbs.	discolorations and flesh bruises if such areas
Over 16 lbs.	None	do not render any part unfit for food.

Disjointed and Broken Bones:	No limit
Missing Parts:	Wing tips, wings, and tails. Backs shall include all meat and skin from pelvic bones, except that the meat contained in the ilium (oyster) may be removed. The vertebral ribs and scapula with meat and skin and the backbone located anterior (for ward) of ilia bones may also be removed (front half of back).
Trimming:	**Carcass** **Parts** Trimming of the breast and legs is permitted, but not to the extent that the normal meat yield is materially affected. The back may be trimmed in an area not wider than the base of the tail and extending from the tail to the area between the hip joints.
Freezing Defects:	Numerous pockmarks and large dried areas.

[1] Hair or down is permitted on the carcass or part, provided the hair or down is less than 3/16 inch in length, and is scattered so that the carcass or part has a clean appearance, especially on the breast and legs.

exudative (PSE) meat, and dark, firm, and dry (DFD) meat conditions. Because the pH of PSE meat is closer to pH 5.1, it will have lower water holding capacity partly due to its lower pH resulting in fewer charges to bind water; however, DFD has high water holding capacity because its high pH is further away from the pI. Meat with high pH has a pH that is further away from the pI of myofibrillar proteins increasing the number of charged groups; therefore, the proteins have more reactive groups available to hold water.

Water holding capacity is also affected by a steric effect, or the amount of interstitial space between muscle proteins. The amount of this space can be influenced by pH and contractile state of the muscle. At higher muscle pH, further away from the pI, there are more charged ions in the muscle. These charged ions separate muscle proteins by repulsive force which then allows more physical space available to hold water. The contractile state of the muscle can also affect this space. For example, if muscle is in a contracted state, there is less interstitial space available to hold water. Any factor contributing to muscle shortening in the prerigor state such as early deboning can affect WHC.

C. Color

Color is an important meat quality attribute that can be affected by several factors including myoglobin concentration, oxidation state of the iron within the myoglobin, and muscle pH. Pinking in poultry has become a problem in recent years because consumers seem to associate the "pink" color to a food safety problem (undercooking of the chicken or turkey meat). However, pinking can occur as a result of addition of ingredients such as nitrite, improper stunning causing petechial hemorrhaging, and undenaturated myosin following improper heating. Nitrites are normally added to further processed products to add color and for food safety measures. However, during heating, a characteristic pink color develops in the product, which can sometimes be confused with undercooking. Insufficient heating can also cause some undenatured myoglobin pigments to retain a "pinkish" color which could present a quality problem to consumers. Another common reason for pinking is contamination of the meat with nitric dioxide and carbon dioxide from oven gasses. These combinations can cause pinking in meat often leaving the consumer wondering if the product is fully cooked. Pinking in poultry meat can be avoided by cooking meat to an internal temperature of 71–73°C, adding compounds that scavenge undenatured myoglobin components that cause pinking, and keeping burners cleaned and running efficiently (27).

Another common quality problem with color in poultry meat is pale, soft, and exudative meat. Denaturation of proteins, specifically the sarcoplasmic proteins, can cause increased scattering of light in the muscle resulting in lighter (or paler) meat. Shrinkage of myofibrils at low muscle pH levels causes greater scattering of light at the myofibril surface. The transmittance of individual muscle fibers is decreased at low pH resulting in less light absorption and paler meat. Furthermore, myofibrils are birefringent, or have two refractive indices, which cause light to take two different paths as it travels through the myofibrils. Muscle pH strongly affects the difference between the two paths with increased light scattering at low pH levels.

D. Relationship between Color and Water Holding Capacity

Color is also related to water binding capacity of the meat. Color of meat is discussed further in Chapter 31, "Poultry: Chemistry and Biochemistry." In general, pale, soft, and exudative (PSE) meat has a low pH; therefore, water binding is low because more water is contained in the extracellular space rather than intracellular space. With more water in the extracellular space, light will be reflected rather than absorbed. In poultry, muscle pH is highly correlated with L* value, a measurement of lightness. In the case of dark, firm, and dry (DFD) meat, meat color is darker due to the high pH. The high pH causes the meat to bind more water, and because of the high water binding, more light is absorbed rather than reflected and results in a darker color.

V. MARINATION

The easiest way to improve quality for consumers and improve the profit margins for processors is to marinate poultry parts, especially breast fillets. Marination of poultry breast meat continues to grow as the demand for further processed products increases. Marinades can be incorporated into meat by tumbling, mixing, or massaging the meat at low temperatures, thereby facilitating tenderization through disintegration of the muscle fiber sheath and stretching of the myofibrils. Commercial methods used to marinate meat including tumbling, blending, and injection. Each method has its advantages and disadvantages. Tumbling promotes rapid and consistent pickup at controlled temperatures, the ability to marinate large quantities, and the capability to handle many different products and sizes. Blending allows for finer control of product mixing as compared to tumbling, and the ability to directly apply refrigerant. Injection marination is beneficial for its relative consistency of marinade application on large and complex products, and reduction of labor and speed of marination.

The two key ingredients in commercial poultry marinades are salt and phosphate. Marination with a variety of combinations of salt and phosphates has been used as means to improve taste, tenderness, and protein functionality of broiler breast fillets. Marination has also been used to improve protein functionality losses imparted by the PSE condition (28).

One of the most important properties of poultry meat is its water holding capacity (ability to bind and retain innate water, as well as added water during marination). Pale, soft and exudative meat has poor water holding capacity which results in an economic loss for processors, as well as a decrease in consumer acceptance. Marination has been used as a method to increase the water holding capacity, thereby improving the quality and increasing the

yield of the meat. This increase in functional property is due to the marinade solution maintaining a higher pH postmortem.

Myofibrillar proteins, such as actin, myosin, and the actomyosin complex, are primarily responsible for WHC and marinade pick-up and retention. The salt and sodium tripolyphosphates commonly used in poultry meat marination work synergistically to increase water binding by increasing pH and ionic strength, combined with the dissociation of actomyosin, exposing more water binding sites (29). Basically, the salt and phosphate marinade uptake causes the tissue fibers to swell, resulting in decreased cooking loss and increased juiciness and tenderness of the meat.

Salt can affect proteins in many ways. At a low concentration, salt increases the WHC of proteins due to hydrated salt ions binding to charged groups of proteins. This resultant increase in water binding can be attributed to the water associating with bound ions. When salt binds to proteins, electrostatic repulsion causes the protein structure to loosen and allow more water binding. Salt also increases marinade pick-up by solubilizing the actin and myosin proteins which increases the space between the thick and thin filaments to pick up and retain marinade solution. Phosphates also increase WHC by increasing the number of charged sites on the protein for water binding to bind. The most common phosphates used in the poultry industry are sodium tripolyphosphates. However, several other phosphates are available with differing solubility, pH, and functional properties. An increased WHC allows for better uptake and retention of the marinade solution itself, as well as increasing the retention of the meat's own moisture, consequently increasing yield in an inexpensive manner.

The effect of various polyphosphate and salt (NaCl) solutions on myofibril protein extraction has been studied (30). In the absence of phosphates, no significant swelling or any other changes were noted at salt concentrations of 0.4 M or less. When salt concentrations were increased to 0.5 M and 0.6 M, myofibrils started to enlarge transversely and protein extraction became significantly noticeable.

The addition of polyphosphates induces changes in the protein extraction pattern. It is thought that polyphosphates possess an ATP-like property that allows polyphosphates to extract myosin and disintegrate part of the myofibril (30). Actomyosin is formed during rigor mortis and creates a state of permanent muscle contraction that leads to tough meat. Polyphosphates have the ability to dissociate this actomyosin complex, enabling myofibril lattices to expand laterally, resulting in an increase in water uptake. Tripolyphosphates were also shown to have similar effects. The researchers concluded that both poly- and tripolyphosphates are ionic species that dissociate myofilaments, depolarize thick filaments, and remove the actomyosin structural barricade, thereby enhancing cooking yield and juiciness.

VI. CONCLUSION

The process of converting muscle into meat is highly complex. The poultry industry has reduced this complexity some by vertically integrating the production and processing stages. This integration has helped improve uniformity and quality in poultry meat. However, as discussed in this chapter, there are very intricate steps in the conversion of the live animal into meat for consumers and quality can be affected at each step.

34 Fats and Oils: Science and Applications

Jan Pokorný
Department of Food Chemistry and Analysis, Prague Institute of Chemical Technology

CONTENTS

I. DEFINITIONS OF FATS, OILS, AND LIPIDS

In the scientific and even professional literature, the term lipids is more and more widely used. Lipids are classes of fatty acid derivatives. Their nomenclature is defined by the joint IUPAC-IUB standard (1). Fatty acids (aliphatic monocarboxylic acids) of 4 and more carbon atoms are usually bound as esters in plant and animal tissues, and only rarely as amides or free acids. Triacylglycerols, waxes, phospholipids, glycolipids, mucolipids, and lipoproteins are the most important lipid representatives. For many authors, especially in medical or biological sciences, lipids are exclusively naturally occurring fatty acid derivatives, but this definition is not useful for food science and technology because many closely related compounds, such as hydrogenated oils, structured lipids, fatty acid methyl or ethyl esters, and many oleochemicals do not occur in nature, but have been produced industrially. Aliphatic fatty acids are not the only organic acids bound in lipids because alicyclic or even phenolic acids were detected in natural lipids.

Substances like psychosin or lysoplasmalogens are included as lipids even when they do not contain any fatty acids. Long-chain fatty alcohols naturally occur in the liposoluble fraction of foods. Their properties and chemical structures are close to those of fatty acids, and therefore they are often treated as lipids. The same is true of sterols, but it is preferable to classify steroes as terpenic derivatives or as a separate class of compounds. Sterols are often esterified with fatty acids so that sterol esters are formed. They are classified as lipids because they contain bound fatty acids. Ethyl or higher esters of fatty acids (4–12 carbon atoms) are often present as natural components in fruits or are produced by fermentation in alcoholic beverages. They have specific aromas. They are, however, not considered lipids. It is evident from this discussion no generally accepted definition of lipids exists.

Fats and oils are lipophilic products obtained by processing natural materials of both plant and animal origin. Fats are usually of animal origin, and most oils are of plant origin, but animal oils such as fish oils exist, too. Fats are solid at room temperature while oils are liquid. The classification depends on the ambient temperatures; some products of tropical trees, such as palm or coconut oils, are liquid in the country of origin, but are solid in a temperate climate. Some semisolid lipid products are called butters, such as cocoa butter or shea butter, because their consistency is similar to butter in the country of origin. Officially, only a product of milk fat may be called butter; butters of vegetable origin should be better called fats.

Fats and oils are not pure compounds because they consist of all liposoluble substances extracted during processing of biological materials. They mostly consist of triacylglycerols (more than 95%), which are lipids, but they are accompanied by other liposoluble nonlipidic products, such as sterols, hydrocarbons, or liposoluble vitamins. Essential oils may be present in traces, but they are not lipids as they mainly consist of terpenes. For this reason, it would be preferable to use the terms fats and oils only for industrial products, and to use the term lipids for classes of pure substances. Of course, professionals in English-speaking countries often are not very careful concerning terminology.

II. FATTY ACIDS

A. Definition

Fatty acids bound in lipids are mostly monocarboxylic acids with an aliphatic straight hydrocarbon chain. Branched fatty acids are rare, and are present almost exclusively as minor components. Odd carbon number fatty acids are also present only exceptionally. Fatty acids differ in the number of carbon atoms and double bonds. Some fatty acids are substituted by oxygen groups and even by other functional groups. Fatty acids with less than 4 carbon atoms have not been found in natural lipids.

B. Saturated Fatty Acids

Saturated fatty acids have no double bond in their hydrocarbon chain. They have both systematic and trivial names, usually reflecting their origin (Table 34.1). The most common saturated fatty acid is palmitic acid, present in all lipids, at least in a small amount. Even carbon-number saturated fatty acids are mostly present in natural lipids, while odd carbon-number acids are present only as traces or as no more than minor acids in some fats. Short chain acids (1–3 carbon atoms) occur in nature, but are not bound in natural lipids. They may be found in lipids from some industrial products. Medium chain saturated acids (4–10 carbon atoms) are liquid at room temperature. Higher saturated acids are solid with their melting points increasing with the increasing carbon number.

C. Monounsaturated Fatty Acids

Monounsaturated fatty acids contain a double bond in their hydrocarbon chain. They have both systematic and trivial names. In the case of unsaturated fatty acids, isomerism is possible. The double bond exists in *cis* (*Z*) or trans (*E*) configuration, and the double bond may be located at different carbon atoms (Table 34.2). Natural unsaturated fatty acids are mostly of the *cis*-configuration. Traces of trans-unsaturated fatty acids (0.04–0.05%) are detected even in cold-pressed edible oils (2). The position of double bonds is usually counted from carboxyl carbon, but in texts dealing with nutrition, calculation is often from the final methyl group. In such cases, they are defined, e.g., as an n-6 or ω-6 acid, if the double bond is located at the 6th carbon atom from the final methyl group. The most common unsaturated fatty acid is oleic acid (an n-9 fatty acid), which is present in nearly all lipids at least in small amounts. Monounsaturated acids

TABLE 34.1
The Most Important Saturated Fatty Acids (Compiled from Beilstein and Chemical Abstracts Data Bases)

Systematic Name	Trivial Name	Number of Carbon Atoms	Molecular Weight	Melting Point [°C]
Butyric	Butyric	4	88.1	−4.6
Hexanoic	Caproic	6	116.2	−1.5
Octanoic	Caprylic	8	144.2	16.3
Decanoic	Capric	10	172.3	32.4
Dodecanoic	Lauric	12	200.3	43.8

Tetracosanoic	Lignoceric	24	368.6	84.2
Hexacosanoic	Cerotic	26	396.7	87.7

TABLE 34.2
The Most Important Monounsaturated Fatty Acids (Compiled from Beilstein and Chemical Abstracts Data Bases)

Systematic Name	Trivial Name	Number of Carbon Atoms	Molecular Weight	Melting Point [°C]
9-*cis*-Hexadecenoic	Palmitoleic	16	254.4	34.5
6-*cis*-Octadecenoic	Petroselinic	18	282.5	31.5
9-*cis*-Octadecenoic	Oleic	18	282.5	16
9-*trans*-Octadecenoic	Elaidic	18	282.5	45.5
11-*trans*-Octadecenoic	Vaccenic	18	282.5	39
13-*cis*-Docosenoic	Erucic	22	338.6	33.5
13-*trans*-Docosenoic	Brassidic	22	338.6	60.6

containing a triple bond are very rare, and are found only in fats for nonedible uses.

Unsaturated fatty acids have lower melting points than the respective saturated fatty acids, and are better soluble in organic solvents. Trans unsaturated acids have higher melting points than the respective *cis* acids (Table 34.2).

D. Polyunsaturated Fatty Acids

Polyenoic unsaturated fatty acids contain 2–6 double bonds. Many isomers are possible, but only a few are really found in nature. The majority among them belong to essential fatty acids as they cannot be synthetized in the human body [3]. Most natural polyunsaturated fatty acids have trivial names, which are more widely used than the systematic names (Table 34.3). Melting points of polyenoic fatty acids are lower than 0°C; therefore, they are not given in Table 34.3. An exception is eleostearic acid – because of the presence of trans double bonds (α-eleostearic acid = 49°C, β-eleostearic acid = 71°C). The allylic (pentadienoic) configuration is most frequent, -CH=CH-CH_2-CH=CH-, where the double bonds are separated by a methylene group. Their structures (4) are shown in Figure 34.1. Both n-6 and n-3 polyunsaturated fatty acids belong to the essential fatty acids. They are enzymatically transformed into eicosanoids (5). The n-3 polyenoic acids are appreciated as they neutralize unfavorable effects of the excessive n-6 polyunsaturated fatty acid intake in modern diet of developed countries [6]. The balance between n-6 and n-3 polyunsaturated fatty acids should be maintained in the diet (7).

Conjugated unsaturated acids, -CH=CH-CH=CH- are rather rarely found, e.g., in milk fat or in some nonedible oils. In the most common fatty acids, the first double bond is located at the 9th or 6th carbon atoms (from the carboxyl group) or at the 3rd or 6th carbon atom (from the methyl group). Pentaenoic and hexaenoic n-3 fatty acids are typical for marine oils. They belong to the important essential fatty acids.

III. LIPIDS

A. Esters of Glycerol

Fatty acids are mostly bound as glycerol esters in natural material. Glycerol (propantriol, Figure 34.2.A) contains three hydroxyl groups, each of which could be esterified with a fatty acid residue. Monoacylglycerols (formerly monoglycerides) contain only one fatty acid residue in the molecule, and exist in two isomeric forms (Figure 34.2.B and 34.2.C). The former one is more stable. The 1-acyl isomer has an unsymmetrical carbon atom, so that two optical isomers exist. Diacylglycerols (formerly diglycerides) are formed by substitution of two hydroxyl groups with an acyl group (Figure 34.2.D and 34.2.E). The 1,2-isomer has an asymmetrical carbon atom. It is easily isomerized into its more stable 1,3-isomer. The most common glycerol esters are triacylglycerols (formerly triglycerides), where all hydroxyl groups of glycerol are substituted with fatty acids (Figure 34.2.F). Monoacyl and diacylglycerols are present only in small amounts as intermediary metabolic products.

In simple triacylglycerols, all hydroxyl groups may be substituted with the same fatty acid (Figure 34.2.F), but in most cases, mixed triacylglycerols exist in nature, where two or three different fatty acids are bound on the same

TABLE 34.3

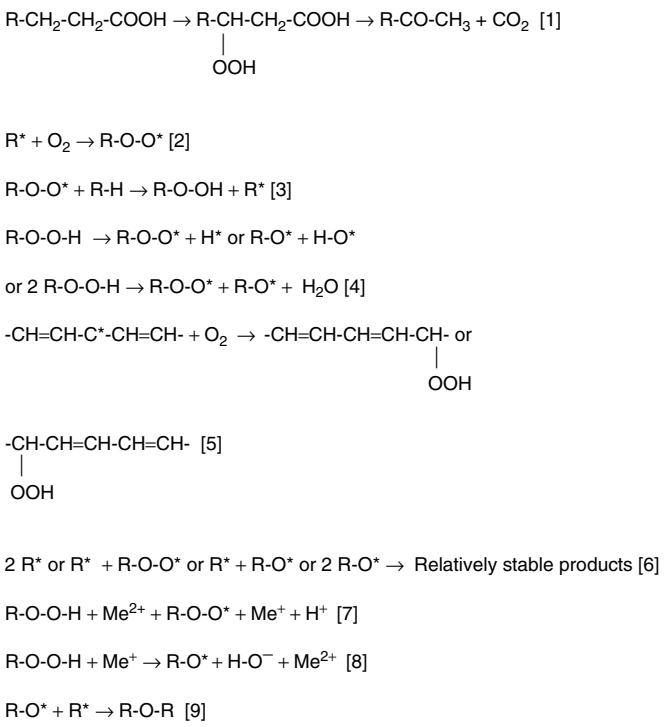

FIGURE 34.1 Chemical structures of polyenoic fatty acids.

glycerol molecule. If the carbon atoms 1 and 3 are occupied by different fatty acids, the carbon atom 2 becomes asymmetrical; if the stereospecificity has to be evident, it is expressed by means of the *sn* system. The carbon numbers of glycerol are numbered stereospecifically (1). The carbon atom that appears on top in that Fischer projection that shows a vertical carbon chain with the hydroxyl group at carbon-2 to the left is designated as C-1. To differentiate such numbering from the conventional numbering, the prefix *sn* is used, e.g., *sn*-1-palmitoyl, 2-linoleoyl, 3-oleoylglycerol. Physical properties of optical isomers are not very different.

The number of triacylglycerol isomers is theoretically very high, but it is usually substantially restricted in natural fats and oils. Triacylglycerols are formed in natural food raw materials by esterification of glycerol under catalytic action of lipases. Lipases possess certain selectivity so that in most natural vegetable fats and oils the carbon atom *sn*-1 is occupied by palmitic acid or other saturated acids, and the carbon atom *sn*-2 by linoleic acid or linolenic acid, less often by oleic acid. The carbon atom *sn*-3 may be substituted with any fatty acid, most often unsaturated fatty acids.

In some plant or animal raw materials fatty acids are bound to monohydroxylic aliphatic alcohols or sterols. They are called waxes (8). The most important wax is bees wax. Their importance in the human diet is low.

Fatty esters of sugars, e.g., sucrose, are produced as fat replacers [9] as they are not cleaved by natural lipases, and cannot thus be utilized as a source of energy by humans.

More information on physical and chemical characteristics of oils, fats, and waxes are obtained from the literature (10).

B. Phospholipids

Phospholipids consist not only of fatty acids and an alcohol, but also contain a phosphoryl group, usually ionized (1). The most common phospholipids are esters of glycerol; therefore, they are called glycerophospholipids. They are derivatives of 1,2-diacylglycerol, where the phosphoryl group is bound to the carbon atom *sn*-3. Such a derivative is called a phosphatidyl (Figure 34.3.A). If no other residue is bound to the phosphoryl group, phosphatidic acids are formed (Figure 34.3.B). They may exist as calcium or magnesium or other salts.

Very often, the aminoalcohol choline is bound to the phosphoryl group, and the resulting compound is phosphatidylcholine (earlier lecithin) (Figure 34.3.C), most often existing as an inner salt. The phospholipid containing another amino alcohol — ethanolamine — is called phosphatidylethanolamine — earlier known as colamine (Figure 34.3.D). Another important phospholipid class contains bound amino acid serine — phosphatidylserine (Figure 34.3.E). Other phospholipids may not contain any nitrogen, e.g., they contain bound myoinositol (hexahydroxycyclohexane); such phospholipids — phosphatidylinositols (Figure 34.3.F) — may be esterified by other phosphoryl residues. The phosphoryl group may be substituted by a glycerol (Figure 34.3.G) or a diacylglycerol (Figure 34.3.H).

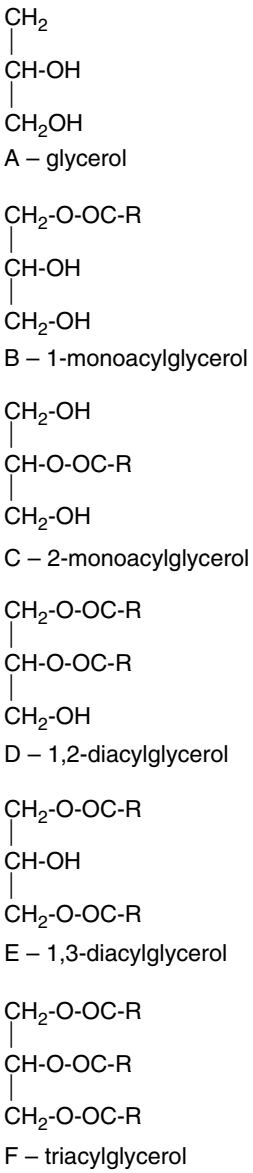

FIGURE 34.2 Chemical structure of glycerol and glycerol esters.

Phosphatidylinositols, among other functions, diminish the postprandial oxidation of triacylglycerols, thus increasing the feeling of satiety, and decreasing the weight gain (11).

In natural phospholipids the fatty acid residue in the position *sn*-2 may be cleaved off by action of phospholipases, and lysophospholipids are formed (Figure 34.3.J). Plasmalogens are phospholipids, where a fatty acid is replaced by an aldehyde in the form of a hemiacetal, usually in its dehydrated form as the respective 2-unsaturated alcohol (Figure 34.3.K).

Some phospholipids do not contain any bound glycerol. Fatty acids are bound to a long-chain alcohol, such as sphingosine in animal tissues (Figure 34.3.L) or phytosphingosine in plant tissues (Figure 34.3.M). They are not bound as esters but as amides, and the hydroxyl group is esterified by a molecule of phosphoric acid, which may contain bound choline or other compounds. Such lipids are called sphingolipids (Figure 34.3.N).

Phospholipids are present in all food materials at least in small amounts (12). Their content in oilseeds varies between 1–3% of the oil basis. The phospholipids fraction is present in crude oils obtained by extraction of oilseeds with nonpolar. It is precipitated from crude oils by action of water, or better by phosphoric or citric acid. The precipitate contains about 60% phospholipids. It is called lecithin. Lecithins of acceptable sensory properties, good functional properties, and reasonable availability are obtained only from soybeans or egg yolk, but the latter are more expensive. For most edible purposes, it is bleached and/or modified, e.g., by addition of free fatty acids. Lecithins enriched in phospholipids or phoshatidylcholine are available on the market. Lecithin is highly appreciated as an emulsifier or for many other purposes. Lower quality products are used for nonedible purposes. For more information about phospholipids see References 13–15.

C. Glycolipids

Glycolipids are fatty acid derivatives containing bound sugars, most often D-galactose or D-glucose. The simplest glycolipids are derived from 1,2-diacylglycerols by substitution of the remaining hydroxyl group with a galactosyl (Figure 34.4.A) or a digalactosyl (Figure 34.4.B) residue. More complicated derivatives were identified, e.g., in oat lipids (16).

Galactosyldiacylglycerols are present in plants as a part of membranes for storage of starch (17). Emulsions containing galactolipids are components of fat replacers as they evoke the sense of fullness.

Cerebrosides are glycosides derived from sphingosine amides — ceramides (Figure 34.4.C).

Glycolipids contain sulphuric acid, sometimes bound to the glycoside residue (Figure 34.4.D). Gangliosides are complex phospholipids containing bound sialic acid (Figure 34.4.E), and usually also one or several residues of bound sugars. They were earlier called mucolipids.

D. Lipoproteins

Lipids form macromolecular complexes with protein, where lipids are bound to proteins by multiple physical forces. They are present either as dispersible aggregates, soluble in water, or as membranes. Covalent bonds are found only exceptionally in natural lipoproteins, but may be formed by interactions of oxidized lipids with proteins.

In water-soluble lipoproteins, the lipid moiety is surrounded by a layer of hydrated proteins (Figure 34.5.A). The contact between the lipid and the protein moieties is effected by a layer of emulsifiers, chiefly sterols and phospholipids. The lipophilic, hydrophobic hydrocarbon chains of the emulsifiers are oriented inside the oil droplet while the hydrophilic parts are oriented towards the relatively polar and hydrophilic protein layer. The stability of

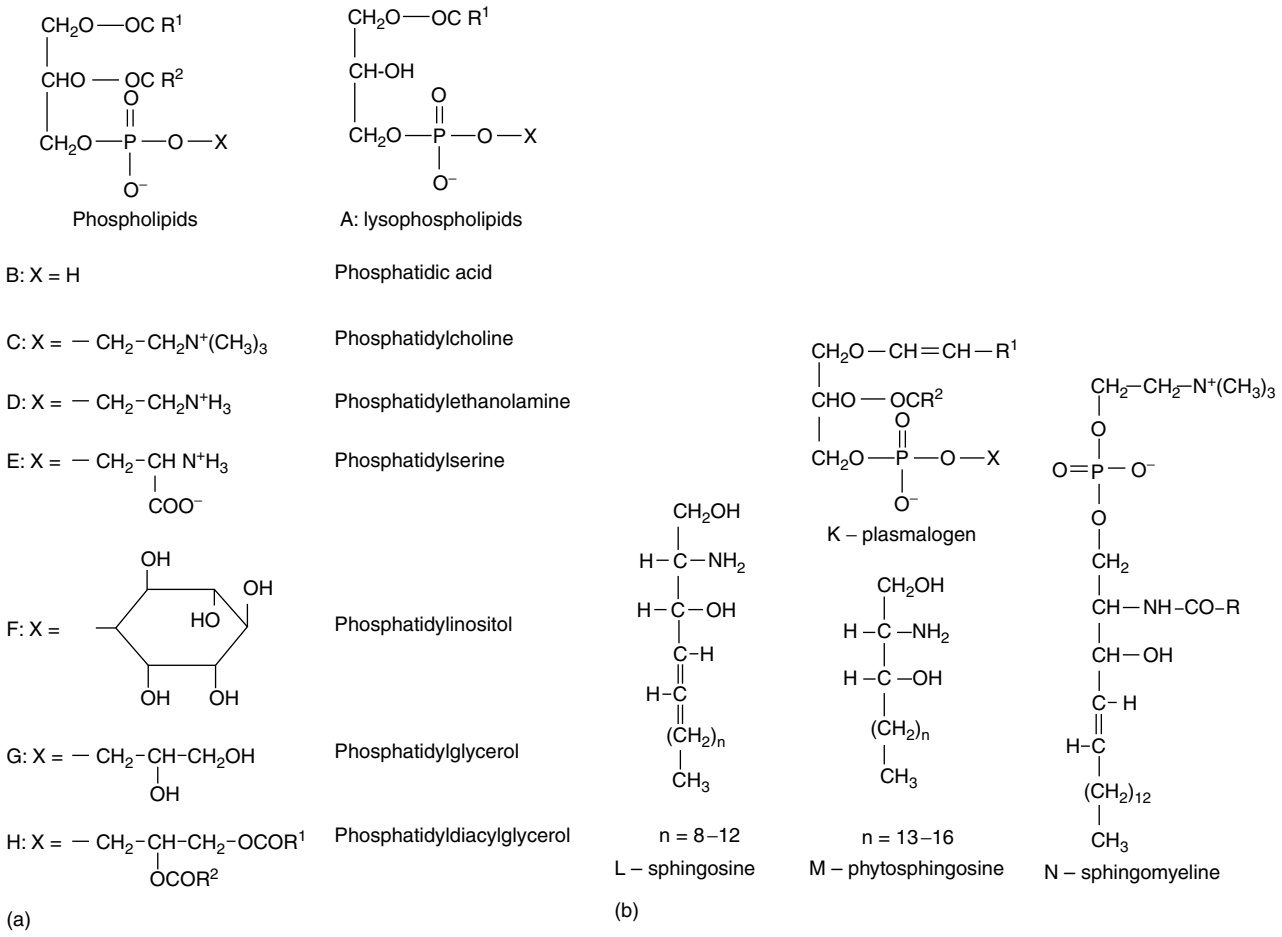

FIGURE 34.3 Chemical structures of phospholipids.

the dispersions of lipoproteins in water depends on the ratio of lipids:proteins. More information on lipoproteins is available from specialized literature (18, 19).

The most widely studied dispersed lipoproteins are those of blood plasma, which belong to the following classes according to their behavior under centrifugation, where they are separated on the basis of their density (specific gravity):

a. VLDL — very low density lipoproteins;
b. LDL — low density lipoproteins;
c. HDL — high density lipoproteins.

The content of hydrophilic components and the stability of lipoprotein dispersion increases with their increasing density.

Lipoproteins forming membranes regulate the permeation of water molecules into cells and subcellular particles. They mostly consist of a double layer of lipoproteins. The polar moieties are oriented towards the water phases on both sides of the membrane, while the non-polar moieties form multiple physical bonds between the two lipid layers of the membrane (Figure 34.4.B). Both phospholipids and sterols are important parts of membrane lipoproteins.

Lipids form complexes with starch and other macromolecular carbohydrates as well as with proteins (20). Three types of these interactions exist:

a. Complexes consisting of lipid inclusion compounds inside an amylose helix or short helices inside amylopectin straight-chain oligosaccharide branches.
b. Complexes, where lipids are sorbed on the surface of carbohydrate particles.
c. Complexes, where lipids are located in capillaries between carbohydrate particles.

IV. OCCURRENCE OF LIPIDS IN PLANT AND ANIMAL FOOD MATERIALS

Lipids are present in almost all food materials of both animal and plant origin (21). They are necessary for the existence of living tissues, even when mostly only in small amounts of 0.5 to 3.0%. These lipids are mainly located in

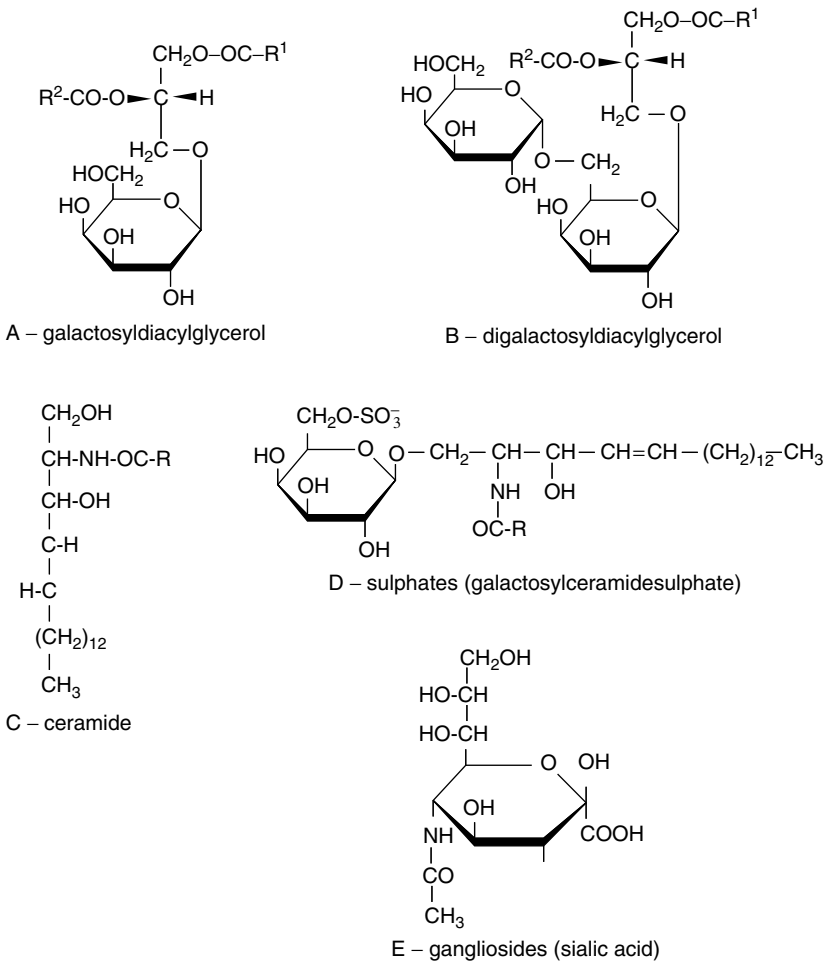

FIGURE 34.4 Chemical structures of glycolipids.

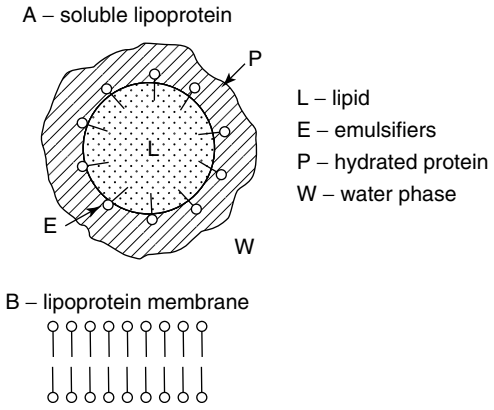

FIGURE 34.5 Chemical structures of lipoproteins.

cell membranes and in intracellular membranes, and mainly consist of phospholipids, glycolipids, and lipoproteins. The triacylglycerol fraction is relatively low in these tissues. The lipids are mostly bound to proteins and other hydrophilic components so that they are extractable only with solvent mixtures containing polar components, such as mixtures of chloroform and methanol or diethyl ether and ethanol.

In addition to their function in the metabolism of living organisms, lipids are deposited as energy reserves. The reserve lipids are very important raw materials in the food industry. They consist mostly of relatively non-polar triacylglycerols. Therefore, they are extractable with hydrocarbon solvents. Plant seeds contain either macromolecular carbohydrates or lipids as a source of energy for the germinating organism. In those plants, where the energy is stored in lipids, the content of seed lipids (called mostly oils) may be 30–60% dry weight (Table 34.4). In some plants, energy is stored both as lipids and as starch, such as in soybeans, where the lipid content is about 20%. In some seeds, lipids are stored also in the pericarp, e.g., in olives, avocado, or oil palm fruits. The fatty acid composition of storage lipids may be very different from that of membrane lipids.

Seed oils have different fatty acid composition from pericarp oils, e.g., palm oil has a fatty acid composition close to that of lard, while the palm kernel oil has the fatty acid composition similar to that of coconut oil (Table 34.5).

TABLE 34.4
Content of Plant Lipids (15)

Plant Name	Systematic Name	Lipid Source	Lipid Content [% Dry Weight]
Soya	*Soja hispida*	Beans	16–22
Sunflower	*Helianthus annuus*	Seed	42–62
Peanut	*Arachis hypogaea*	Seed	45–50
Rape	*Brassica napus*	Seed	40–48
Cocoa	*Theobroma cacao*	Seed	53–59
Almonds	*Prunus amygdalus*	Seed	60–65
Sesame	*Sesamum indicum*	Seed	50–55
Cotton	*Gossypium hirsutum*	Seed	20–24
Oil palm	*Elaeis guineensis*	Pericarp	30–40
Cocos palm	*Cocos nucifera*	Copra	63–70
Olive	*Olea europaea*	Pericarp	13–50
Rice	*Oryza sativa*	Bran	8–15
Wheat	*Triticum aestivum*	Germ	7–12
Corn	*Zea mays*	Germ	14–19

Examples of fatty acid composition of the most important fats and oils are shown in Table 34.5 (trace fatty acids are not included).

Even in plants using starch as a source of energy for germinating organism, at least the germ is rich in lipids so that it may be used for industrial processing, e.g., in the case of corn or wheat germs (Table 34.4). During the germination, oil is gradually used up as a source of energy, or it is converted into other compounds, chiefly cellulose.

Animal tissues also consist of two types of lipids. Lipid membranes and dispersible lipoproteins are present only in limited amounts of about 1–2% dry weight in the respective tissue. They consist mainly of phospholipids and glycolipids. Animals store energy in carbohydrates only in very small amounts; therefore, only energy reserves stored as triacylglycerols are important for the organism and in the industry. Surprisingly, in some tissues the amount of lipids may be much higher than the amounts of proteins. The fatty acid composition of reserve (depot) fat is different from the composition of polar lipids as polar lipids are rich in linoleic acid and more unsaturated polyenoic acids. The fatty acid composition of depot fat in farm animals depends partially on the composition of feed lipids, and similar relations exist in other animals. A typical example are lipids of fish and other aquatic animals as the fatty acid composition is influenced by that of algae and small crustaceans, which are their main source of nutrition. Polar lipids bound in membranes are not substantially affected by fatty acid composition of feed lipids.

The fatty acid composition of the triacylglycerol fraction of fats and oils is very different, and it is specific for each species. Examples of fatty acid composition of the most important fats and oils are shown in Table 34.5. (Trace fatty acids are not included and may be found in the original literature). The fatty acid composition of vegetable oils is very variable. In some species oleic acid prevails, in other it is linoleic acid, and in another group linolenic acid is present, too. In palm seed lipids the major fatty acids are lauric, myristic, and palmitic acids. Triacylglycerols of land animals mostly consist of palmitic, stearic, oleic, and linoleic acids while polyunsaturated fatty acids are major components of marine oils (22).

The traditional fatty acid composition may be substantially modified by breeding, genetic manipulations, or even climatic conditions. Modified soya cultivars yield oil with high saturated fatty acid content, suitable as trans-free replacers of hydrogenated oils, or canola oil with 40% lauric acid is suitable for nonedible uses (23). In animals it is affected by feed lipids. The novel modified oils usually have higher oleic acid content and lower polyunsaturated acid content so that they are more resistant against oxidation on heating or long storage.

V. CHEMICAL CHANGES DURING INDUSTRIAL FAT AND OIL EXTRACTION AND PROCESSING

A. Fat and Oil Extraction from Natural Sources

Oilseeds are the most important raw material for the production of edible oils. Soybeans, followed by palm fruits, are the chief oilseeds worldwide, but rapeseed and sunflower seed are also important in Europe, followed by olives and animal raw materials (24). Seeds are first crushed, and the resulting meal is heated by steam application. During the process, heat denaturation of the protein moiety destroys lipid membranes and other lipoproteins so that the yield of oil substantially increases in comparison to the cold extraction. This process is called conditioning.

Conditioned oilseed meals of oilseeds containing 40–60% oil are then fed to expeller presses, where oil is extracted from the meal under high pressure and temperatures up to 100°C. Crude oil is removed and collected in a tank, and the pressed material (cakes), still containing about 12–20% oil, is cooled to the ambient temperature. Soybeans have only about 20% oil so that the cake has a lower concentration of oil or is treated by solvent extraction before the previous expeller pressing. Rice brans or corn germs are not expeller pressed because of low oil content, but are treated directly with solvents. Olives are cold-pressed in special crushers at temperatures below 40°C with production of virgin olive oils (25, 26).

The cakes are then extracted using solvents, most often hexane, pentane, and their isomers, or other hydrocarbons of similar boiling temperatures. Continuous processes are mostly used, and the resulting extracted meal is then separated from the solution of oil in the extraction solvent (micella). Crude oil is then obtained by

TABLE 34.5
Fatty Acid Composition of Fats and Oils (66)

A. Linoleic Acid Oils

Fatty Acid Code	Sunflower Oil	Peanut Oil*	Safflower Oil	Sesame Oil	Cottonseed Oil**

distilling off the solvent. The last solvent residues are removed by distillation with steam. The resulting crude oil is stored in a separate tank or mixed with oil obtained by expeller pressing.

During the industrial extraction of fats and oils, other lipophilic substances, such as sterols or tocopherols, come into the extract, even when they may be originally not present in oil droplets of seed cells but in other parts of the seed (27).

The extracted meal from the solvent extraction is treated in a toaster at temperatures of about 100°C or higher to liberate the residual solvent, to deactivate enzymes, and to detoxicate extracted meal. The last solvent traces are removed by steaming. Meal is then cooled down and stored in elevators. The extracted meal is used for feeding purposes.

B. Crude Oil Refining

Crude vegetable oil contains various minor components, such as oxidation products of triacylglycerols and terpenes, polar lipids, trace metal derivatives, which deteriorate its sensory and functional properties. Therefore, it is processed by refining. Good detailed information on vegetable oil processing techniques for human nutrition is available (28–30). The first refining step is the degumming. Oil is treated with hot water, usually containing phosphoric or citric acid. Most phospholipids present in crude oil are hydrated and become insoluble in oil. Some phospholipids are not precipitated unless special procedures are used, such as superdegumming. The precipitate, containing coprecipitated components other than phospholipids and some oil, is removed, dried, and used as commercial lecithin. The membrane filtration is another approach to degumming (31).

The degummed product may be treated in two ways. If the free fatty acid content is high, it is alkali refined by a solution of sodium hydroxide or, less often, by sodium carbonate.

Free fatty acids are converted into water soluble sodium salts, which are washed out of oil with hot water. Natural pigments and other impurities are partially removed, too. After the alkali refining, oil is dried by heating at reduced pressure, and treated with bleaching earth or a mixure of bleaching each and with active carbon. In the process of bleaching, natural pigments (mainly carotenoids, pheophytins and chlorophylls) and the last traces of sodium salts are removed. Dimers of polyunsaturated fatty acids or sterols and trans-isomers may be formed in the course of bleaching (32). More information on bleaching is available (33).

Bleached oil is deodorized by treatment with overheated steam under reduced pressure in nitrogen at temperatures of 220–250°C. Volatile substances, formed by oxidation of unsaturated fatty acids during seed storage or seed processing, are removed during the process, and both the sensory value and the resistance against oxidative

sensory deterioration (called rancidity) are thus substantially improved. Other relatively volatile substances are also removed at least partially, such as sterols or tocopherols. The deodorized oil has a bland neutral flavor.

Crude oils containing less than about 1% free fatty acids may be refined in a simpler way, i.e., by physical refining (34). After degumming, crude oil is deodorized in a similar way as in the case of alkali refined oils to remove all relatively volatile components, including free fatty acids. The resulting oil is bleached. The alkali refining step is thus eliminated, which is advantageous from the environmental standpoint. The resulting refined oil is of about the same quality as alkali-refined oil, e.g., as in the case of rapeseed oil (35).

During the process of deodorization *cis,cis*-diunsaturated fatty acid bound in triacylglycerols is partially isomerized into *cis,trans* and *trans,cis*-dienoic isomers in the case of linoleic acid (36). Several other trienoic isomers are formed in oils containing linolenic acid, such as soybean or rapeseed oil. As the nutritional value of these isomers is doubtful, the deodorization temperature should be lower than 240°C to minimize the isomerization. The best results are obtained using thin-film deodorization. In this process the temperature may be lower and the heating time shorter (37).

Vapors removed during deodorization are collected as deodorization sludges. They contain free fatty acids, sterols, and tocopherols so that they can be used for the production of tocopherol concentrates suitable as antioxidants. Sterols may be isolated, too, and used either directly or after hydrogenation in stanols in margarines as an additive lowering blood pressure and decreasing the cholesterol content in blood plasma (38).

Refined oils are either used directly as salad oils or frying oils, or after emulsification as mayonnaise and salad dressings, or are added to margarines (39). If fresh fish oils are properly refined (40), they are acceptable for margarines even without hydrogenation (41), even when their oxidation stabiliity may still be a problem (40).

C. Production of Lecithin

Crude lecithin is obtained in the process of crude oil degumming (39) as explained in Section 34.V.B. It is mostly used for feed or other nonedible purposes; only soybean or egg lecithin are used for edible purposes. Typical properties of soybean lecithin are shown in Table 34.6. They are used as natural surface active agents for many purposes in the food industry (42). Lecithin may be modified in different ways (43). For use in light-colored food products, it is bleached by hydrogen peroxide. For some purposes concentrated phospholipids are necessary; therefore, oil is removed from commercial lecithin by membrane filtration or selective extraction, e.g., with acetone or propane, which is a more acceptable solvent for environmental reasons (44). The most important component of soy phospholipids is phosphatidylcholine. Soy phospholipid concentrate may be enriched to high levels of phosphatidylcholine by interesterification with choline in the presence of phospholipases (45). Fractions enriched with phosphatidylcholine and in phosphatidylinositol may be obtained from lecithin by fractionation with 90% aqueous ethanol (46).

D. Interesterifiction, Ester Interchange, and Saponification

Fats and oils are essentially mixtures of triacylglycerols. They may be converted into other esters by interesterification (47) with methanol or higher alcohols (Figure 34.6.A). The process is called alcoholysis, and is catalyzed by small amounts of alkaline hydroxides or alcoholates, produced *in situ* by dissolution of metallic sodium in alcohol. The conversion of triacylglycerols into methyl esters is used for analytical purposes and for diesel fuels.

The alcoholysis of triacylglycerols with glycerol — glycerolysis — is of technical importance. Solid fats, such as fully hydrogenated oils, are commonly used. They are heated with glycerol to high temperatures in the presence of small amounts of sodium hydroxide. A mixture of monoacylglycerols and diacylglycerols results (Figure 34.6.B), which are used as emulsifiers. They may be fractionated into the monoacylglycerol fraction and the diacylglycerol fraction using short space vacuum distillation. The monoacylglycerol fraction is particularly useful as an emulsifier for the production of margarines and other emulsified fats and oils.

Another procedure for production of partial glycerol esters is the treatment of triacylglycerols with water in the presence of lipases, most often immobilized on a solid support (45).

Tricylglycerols of natural fats and oils possess specific distribution of fatty acids. The distribution may be randomized by interesterification of the particular fat and oil or a mixture (ester interchange, Figure 34.6.C) or of a mixture of different tricylgycerols (Figure 34.6.D). The reaction is carried out again in the presence of sodium hydroxide, metallic sodium, or sodium methoxide as a catalyst. Immobilized lipases may be used as catalysts, too. The reaction proceeds at ambient or moderately increased temperatures. The resulting products may be tailored to specific properties, especially rherological properties (sensory texture or consistency). Low-caloric structured lipids are produced in this way, containing

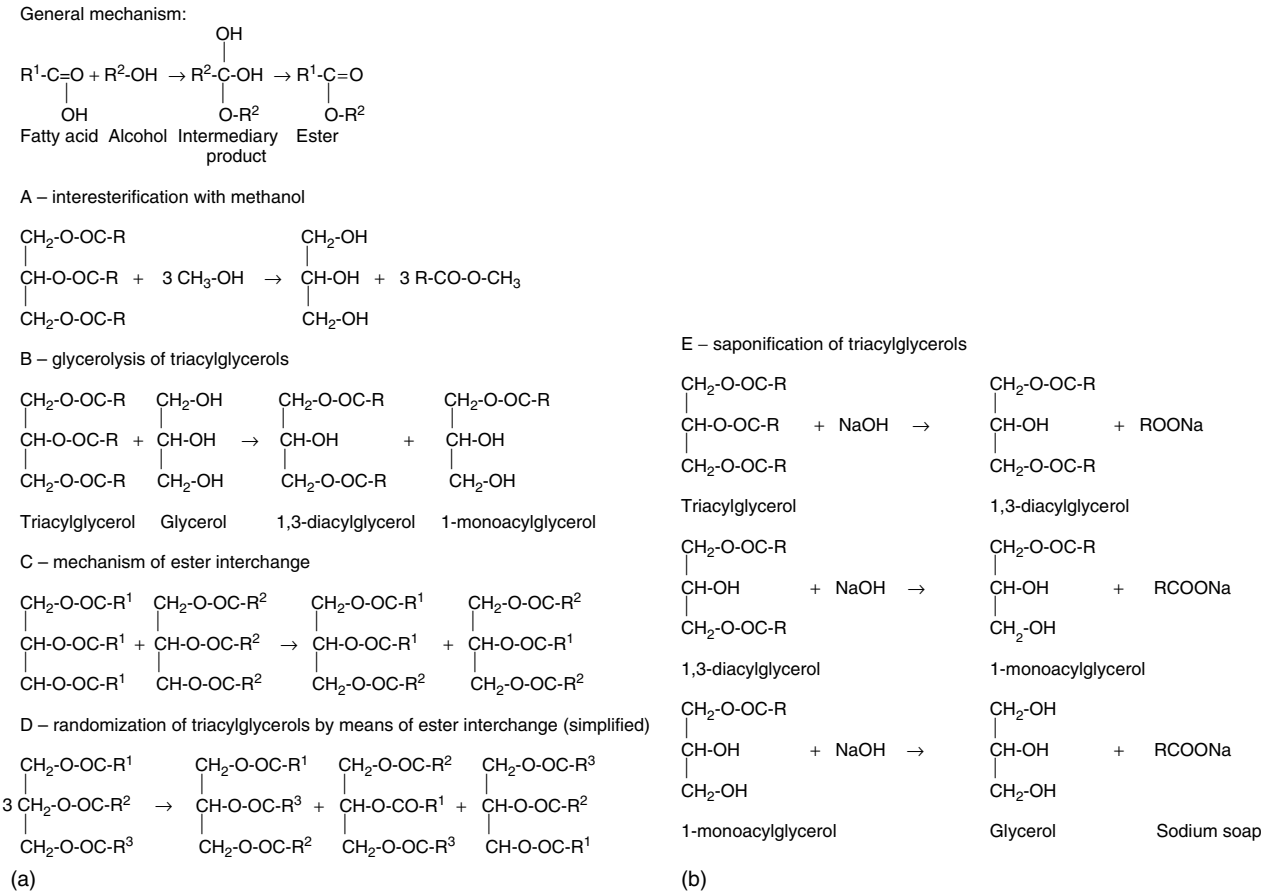

FIGURE 34.6 Esterification reaction of fats and oils.

long-chain, medium-chain, and short-chain fatty acids (48). In contrast, the stability against oxidative rancidity is often decreases (49).

Natural fats and oils may be fully hydrogenated and the resulting trisaturated triacylglycerols are then interesterified with non-hydrogenated oils (50). Plastic solid fats are thus produced, containing no *trans*-unsaturated fatty acids. The topic of structurally modified food fats has been reviewed (51).

As some consumers would like to decrease their energy consumption of fats without affecting the sensory properties of food and decreasing the agreeable fatty taste, some undigestible fat replacers have been introduced to the market, such as Olean, Salatrim, and Caprenin. In these products, esterified fatty acids cannot be split off by lipases (52).

Fats and oils are very rich sources of energy; therefore, their consumption may result in obesity. Fats with lower energy content are produced by interesterification of natural oils with stearic or behenic acid, which are not completely utilized in the metabolism, and medium-chain fatty acids, which have moderately lower energy content and are not deposited in the fatty tissues. These products are marketed as structured fats.

E. Hydrolysis of Fats and Oils

Triacylglycerols are hydrolyzed into fatty acids and glycerol. The reaction with sodium hydroxide was used to produce soap; therefore, the process is still called saponification (Figure 34.6.E). Saponification proceeds by mixing fat with a solution of sodium hydroxide at the boiling temperature. The first stage, i.e., the cleavage of a triacylglycerol molecule into a diglycerol and soap, is slow as the reactants are immiscible and the reaction proceeds only on the interphase. The reaction products act as emulsifiers so that the second stage of saponification is fast. After saponification, sodium chloride is added to the reaction mixture in order to decrease the solubility of soaps in the aqueous phase. The lower aqueous layer also contains glycerol, which is isolated, and distilled from impurities, especially water. The separation of soaps from the water phase containing glycerol by salting is still not complete.

Saponification is now carried out on the plant scale mostly by simply heating fats or oils with water under pressure to high temperature, sometimes in the presence of metallic oxides as catalysts. Fatty acids are gradually cleaved from the original glycerol esters. Free fatty are then purified by vacuum distillation. They are then used for soap

production, production of metallic soaps, or for other purposes. Glycerol obtained in this way is less contaminated than in the case of saponification with sodium hydroxide.

Lipids may be hydrolyzed with immobilized lipases, too (45). Depending on the origin of lipase, the reaction may be stereospecific.

F. Hydrogenation of Fats and Oils

At the beginning of the 20th century, there was an excess of oils on the market, but consumers required solid fats, similar to lard or butter. Hydrogenation was a suitable solution. The unsaturated fatty acids bound in triacylglycerols are converted into less unsaturated or even saturated fatty acids by the addition of hydrogen. Triacylglycerols of saturated fatty acids are solid, unlike triacylglycerols of unsaturated fatty acids. However, triacylglycerols containing three saturated fatty acids in the molecule have too high melting points (about 70°C). They remain solid at body temperature; therefore, they are not attacked by lipases, and their digestibility is only very low. They have a strong tallowy taste, and are thus unsuitable for human nutrition. Therefore, only one or two fatty acids in a triacylglycerol molecule should be converted into a saturated fatty acid. Solid fats with melting points corresponding to lard are thus obtained.

Prerefined edible vegetable oils or fish oils are used as raw material. They are heated to 160–180°C in the atmosphere of hydrogen using nickel as a catalyst. Nickel is deposited on the surface of kieselguhr or another suitable inert substrate; mixtures of nickel with nickel oxide are preferred. Other metals, such as palladium, rhodium, cobalt, or mixtures of nickel with copper also have catalytic qualities, but nickel is usually used. The pressure may be between 0.15–0.5 MPa. Free fatty acids, phospholipids, soap or other surface active compounds, and sulphur derivatives act as catalytic poisons, so they should be removed from oil before the reaction, usually by refining processes. More information is available on both the theory and practice of hydrogenation (53). Partially hydrogenated oils are chiefly solid; therefore, they can be used for the production of shortenings (cooking fats). Fluid shortenings are available on the market, mainly for use in the baking industry (54).

During the hydrogenation reaction polyunsaturated fatty acids are first converted into monounsaturated fatty acids (Figure 34.7.A). The formation of saturated fatty acids (Figure 34.7.B) is slower. The ratio of reaction rates k_1:k_2 is the selectivity of hydrogenation (55), which depends on the catalyst and the reaction conditions. The reaction rate constant k_1 defines the rate of hydrogenation of dienoic acids into monoenoic acids, while the constant k_2 defines the rate of hydrogenation of monoenoic fatty acids into saturated acids. Low hydrogen pressure, low temperature, and low catalyst content determine the selectivity. Because hydrogenation is an exothermic reaction, heat is produced and the reactor has to be cooled. The reaction is usually stopped at the stage when the melting point reaches the required value, usually between 30–45°C, depending on the purpose of the product.

An important side reaction takes place during hydrogenation, i.e., the isomerization of the original *cis* double bond into a *trans* double bond. The *trans* monounsaturated fatty acids have higher melting points than the corresponding *cis* fatty acids so that the desired melting point is already attained at a higher degree of unsaturation. The low hydrogen pressure, lower content of the catalyst, and higher temperature favor the formation of *trans* fatty acids. The *trans* fatty acids are now considered undersirable for human nutrition (36, 56). Therefore, hydrogenation conditions have to be adapted to obtain products with low content of *trans* fatty acids or hydrogenated oils are replaced with other solid fats. The *cis,trans* isomerization is accompanied by positional isomerization of double bonds.

Hydrogenated oils are cooled after the reaction, filtered to remove the catalyst, and refined to remove impurities. They may be used as shortenings or cooking fats, or added to emulsified fats, such as margarines. There is now a tendency to replace hydrogenated oils with palm oil fractions or other solid fats free of *trans* fatty acids.

Free fatty acids may be fully hydrogenated too, e.g., for the production of metallic and alkaline soaps or solid free fatty acids, but higher hydrogen pressure and higher content of catalyst are needed.

At very high hydrogen pressures of 20–50 MPa, higher temperature, and using special catalysts containing copper and chromium, not only double bonds, but also the carbonyl double bond in the carboxyl or ester group are hydrogenated, and fatty alcohols result which are useful for the production of surfactants.

G. Oxidation Reactions

Unsaturated fatty acids bound in lipids are oxidized on storage using several mechanisms (58). Different types of oxidation processes occur in unsaturated fats and oils (59). The spontaneous oxidation by air triplet oxygen is called autoxidation, and it is usually initiated by free radicals or by singlet oxygen. Singlet oxygen is produced in course of photooxidation of unsaturated lipids in the presence of photosensitizers. Several enzymes present in oilseeds or animal tissues, such as lipoxygenases, catalyze oxidation reactions.

The most important oxidation mechanisms are shown in Table 34.7. Enzyme-catalyzed oxidation occurs even in seeds or fruits and other edible parts of raw materials of both plant and animal origin. Lipoxygenases are the most important representatives of this group of enzymes (60). For this reason, even fresh edible oils contain at least minute traces of oxidation products. The oxidation occurring spontaneously in the presence of oxygen is autoxidation. In both cases unsaturated hydroperoxides are the primary reaction products.

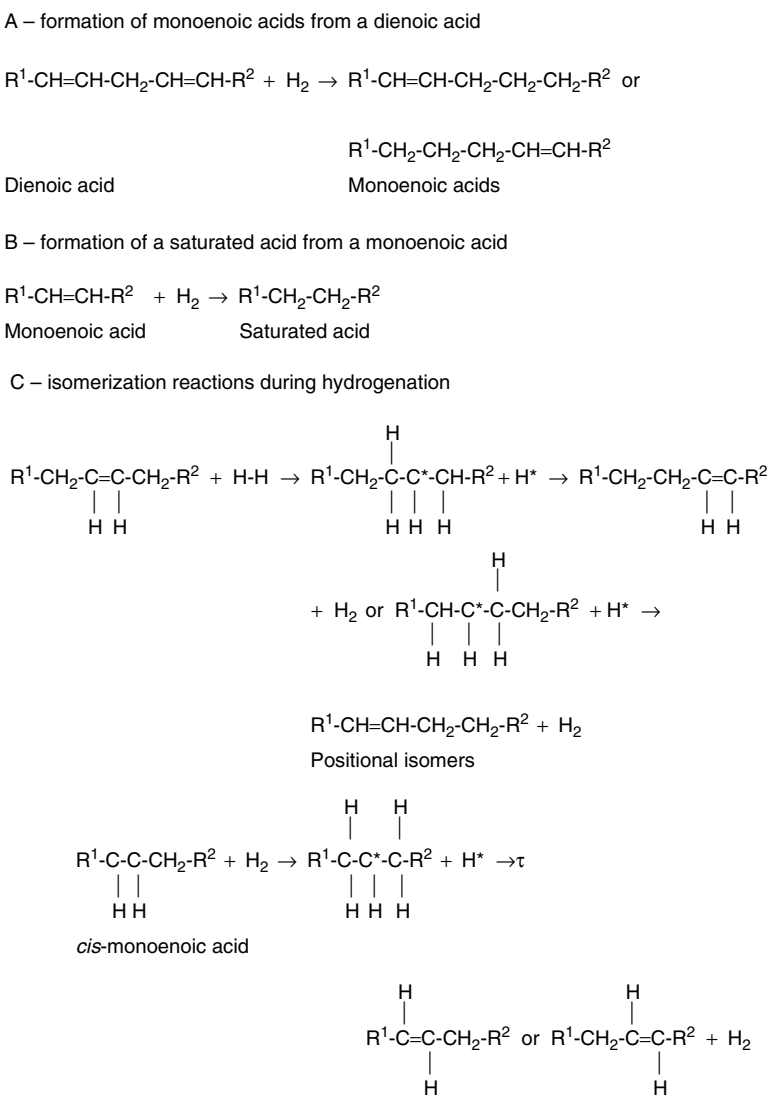

FIGURE 34.7 Hydrogenation of fats and oils.

TABLE 34.7
Mechanism of Lipid Oxidation

Type of Oxidation	Precursors	Primary Products
Lipoxygenase catalyzed	Linoleic, linolenic acids	Conjugated hydroperoxides
Autoxidation	Unsaturated fatty acids	Hydroperoxides
Photooxidation	Unsaturated fatty acids	Hydroperoxides
In vivo oxidation	Essential fatty acids	Eicosanoids
Hydrogen peroxide oxidation	Unsaturated fatty acids	Hydroxy acids

The oxidation is a free radical chain raction, proceeding after the following mechanism (Figure 34.8). The methylene groups adjacent to a double bond or located between two double bonds are the primary site of attack (Figure 34.8.A). Free radicals produced in this way add a molecule of oxygen with formation of free peroxy radicals (Figure 34.8.B).

These radicals can abstract hydrogen from another molecule of an unsaturated fatty acid with formation of a hydroperoxide and another free radical (Figure 34.8.C). Such a reaction chain can be repeated up to several hundred times before the reaction is stopped by a termination reaction (Figure 34.8.D). The reaction is efficiently terminated by interaction of free R-O* or R-OO* radicals with

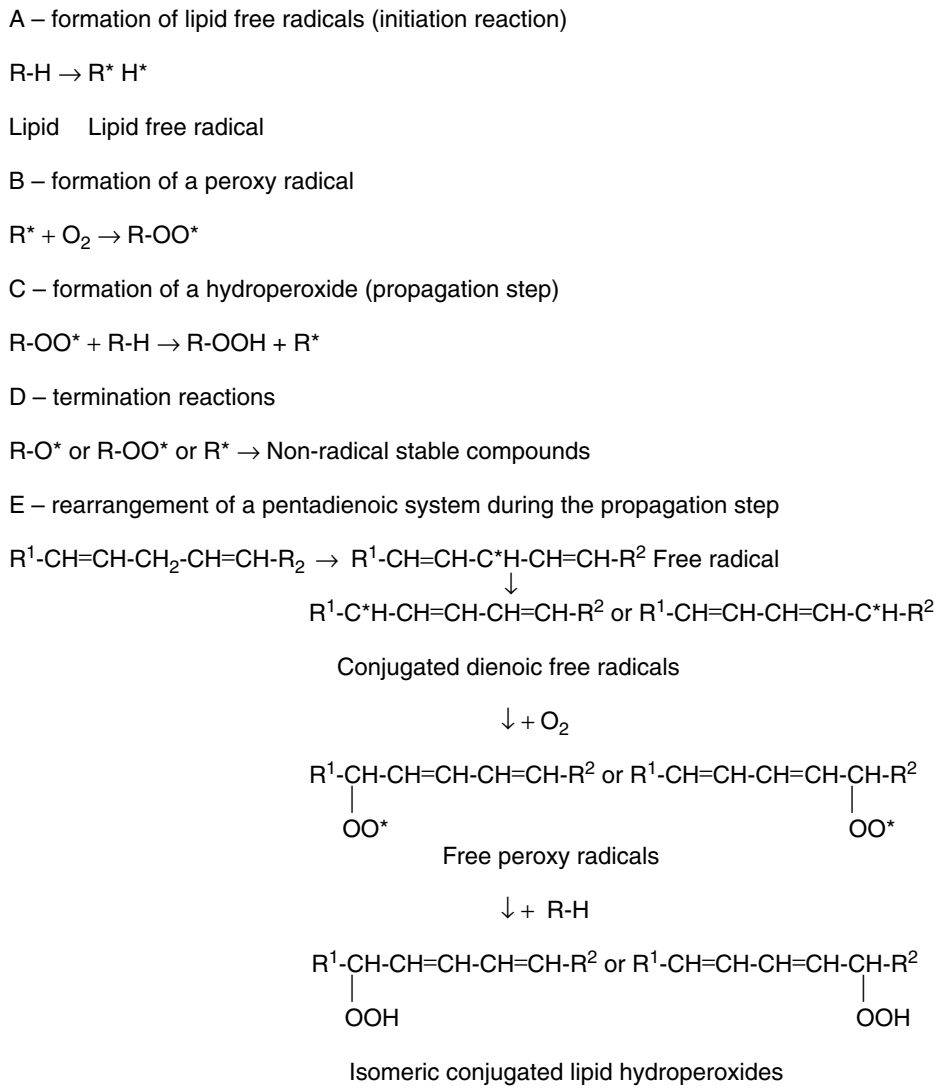

FIGURE 34.8 Mechanism of lipid autoxidation.

antioxidants (61), which are discussed in detail elsewhere in this book. Rearrangement of the double bond and the pentadienoic double bond systems (Figure 34.8.E) accompanies the formation of free radicals. Products with a conjugated double bond system are produced, which contain *trans* double bonds, at least partially. The reaction mixture consists of two to four isomers, the proportions of which depend on reaction conditions. In the case of enzyme-catalyzed reactions, selective oxidation takes place so that certain isomers prevail.

The autoxidation rate increases with increasing temperature. At room temperature linoleic and linolenic acids are oxidized at a much faster rate than monoenoic fatty acids, but at high temperatures, monoenoic fatty acids and even saturated fatty acids can be oxidized, especially in the presence of metallic catalysts. The relative reaction rates depend on the reactive system, e.g., the stability of fatty acids in bulk oils decreases with increasing degree of unsaturation. In contrast, the oxidation stability increases with the increasing degree of unsaturation in water micelles (62).

The lipid hydroperoxides can be oxidized into diperoxides of different structures, usually peroxohydroperoxides. Hydroperoxides are very unstable, particularly at higher temperatures, being dissociated after two mechanisms (Figure 34.9.A,B). The cleavage into alkoxy free radicals is more probable. The degradation is accelerated in the presence of heavy metal compounds with transient valency, such as copper or iron ions (Figure 34.9.C,D). During the reaction the metal ion is reduced into its lower valency state and oxidized again into its higher valency state (61). As the decomposition is again a chain reaction, one metal ion can catalyze the decomposition of many hydroperoxide

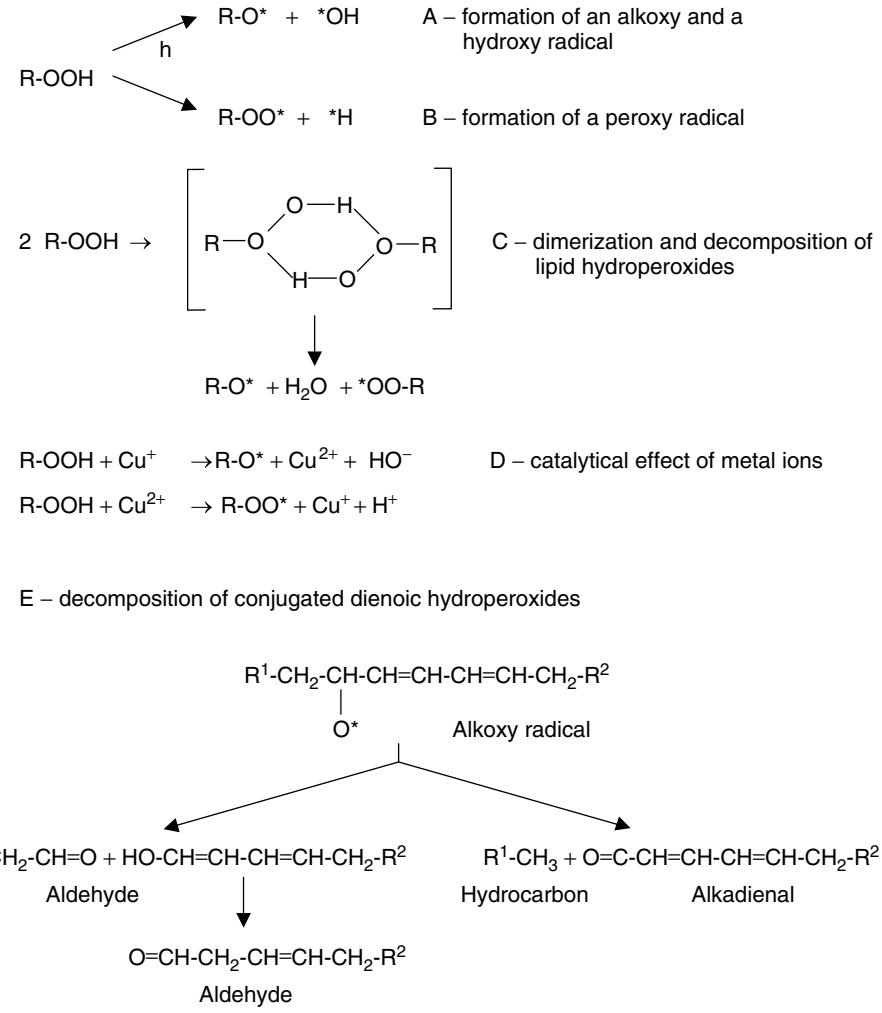

FIGURE 34.9 Decomposition of lipid hydroperoxides into nonvolatile compounds.

molecules. Each reaction produces two free radicals, initiating further oxidation chain reaction. Therefore, heavy metals are very efficient oxidation catalysts.

Free radicals are eliminated by reaction of two free radicals, e.g., with formation of a dimer (Figure 34.9.E), or by reaction with antioxidants, as explained in another Chapter. The dimeric compounds are transformed in free antioxidant radicals of very low reactivity. However, large excess of free radicals becomes harmful in biological systems (63).

Polymers produced during the autoxidation are mainly dimers, where the fatty acid chains are bound by C-C, C-O-C, or C-O-O-C bonds, their ratios depending on the access of oxygen during oxidation. Multiple bonds may be formed in case of polyenoic fatty acids so that lipids oxidized to an advanced degree always contain cyclic compounds. In addition to cyclic oligomers, cyclic monomers are also produced by oxidation (64). The amount of polymers may be high, up to 10%, in frying oils used for a repeated deep frying.

Another reaction of unsaturated lipid hydroperoxides is their decomposition by rearrangement and chain cleavage with formation of both volatile and non-volatile compounds, such as shown in Figure 34.10.A. Aldehydes, alcohols, hydrocarbons, and ketones are produced in this way. They are very sensory active, especially the unsaturated derivatives, and impart to fats and oils a characteristic off-flavor called a rancid flavor. Hexanal, 2-hexenal, 2-octenal, or 2,4-decadienal (Figure 34.10.C) are typical rancidity products.

Another type of oxidation proceeds on light in the presence of photosensitizers, such as chlorophylls or pheophytins. They convert the ordinary triplet oxygen present in air into singlet oxygen, which is several hundred times more reactive than triplet oxygen. It is added to double bonds with the formation of hydroperoxides. Edible oils and foods nearly always contain minute traces of chlorophyll pigments; therefore, the exposure of oils to light should be avoided. The concentration of chlorophylls is particularly high in virgin olive oil which is rather sensitive to singlet oxygen oxidation.

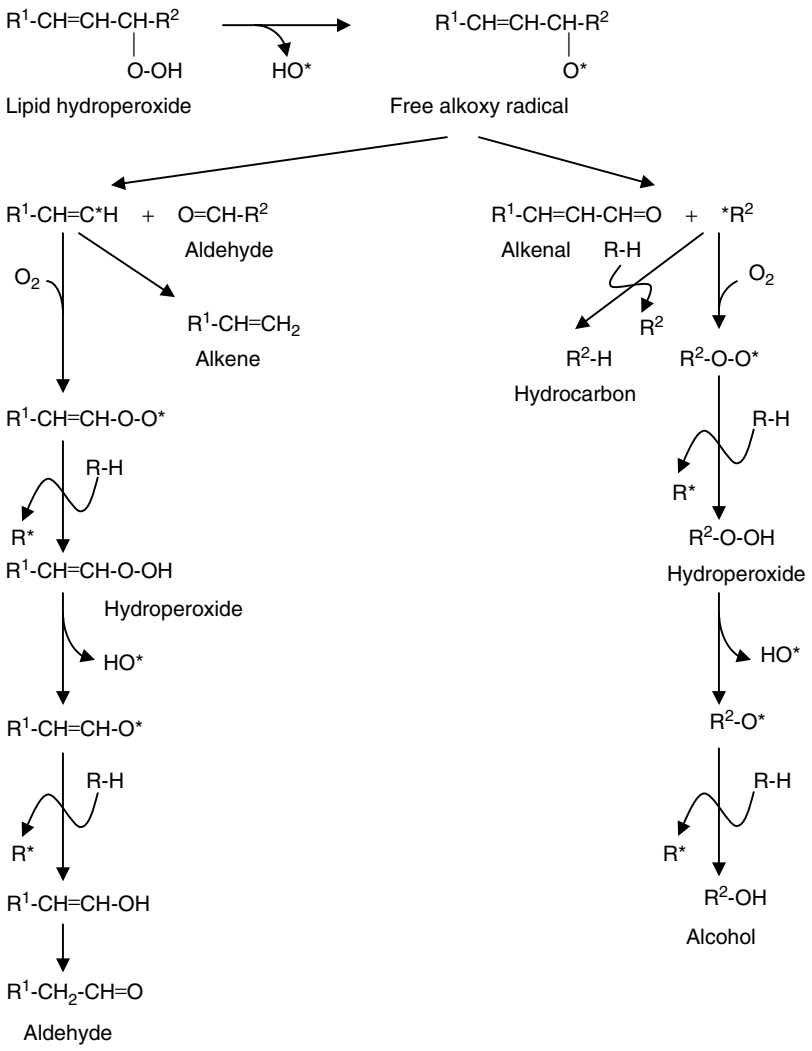

FIGURE 34.10 Cleavage of monoenoic lipid hydroperoxides into volatile compounds.

Oxidation reactions proceed rapidly at high temperatures, such as during deep fat frying (65, 66) or microwave heating (67).

Oxidation is desirable for some industrial purposes. Dry films are formed from thin layers of oil applied on a metallic or wooden surface. Such oils are called drying oils, e.g., linseed or tung oil belong to this group. In the formation of coatings containing linseed oil, and in artistic painting, metal salts are often added to hasten the drying reaction.

H. Chemical Changes in the Production of Oleochemicals from Fats and Oils

Lipids are important sources of oleochemicals. Alkaline soaps have been already mentioned. Salts of other metallic cations, such as calcium salts, are also produced for various purposes, and are called metallic soaps. They are usually produced from solutions of alkaline or ammonium salts of fatty acids by precipitation with metallic anions. Metallic soaps are used for many purposes. Aluminium or zinc stearates are used as lubricants, as paint thickeners, or in the cosmetic and pharmaceutical industries. Salts of heavy metals (such as manganese or cobalt) are used in paint dryers and as additives in plastic materials.

Fatty acids are used as raw materials in other products, mainly surfactants, such as copolymerates with ethylene oxide (Figure 34.11.A) or propylene oxide.

Very important intermediary products are fatty alcohols, produced by high pressure hydrogenation of fats or fatty acids (explained in Section 34.V.E). They may also form copolymers with ethylene or propylene oxides (Figure 34.11.B) or they are sulphated with sulphuric trioxide into sulphates. Alkaline salts of alkyl sulphates are used as detergents.

Fatty acids of fats can be converted into amides by reaction with amoniac (Figure 34.11.C). Amides are dehydrated into nitriles (Figure 34.11.D), which are hydrogenated into alkyl amines (Figure 34.11.E). Salts of

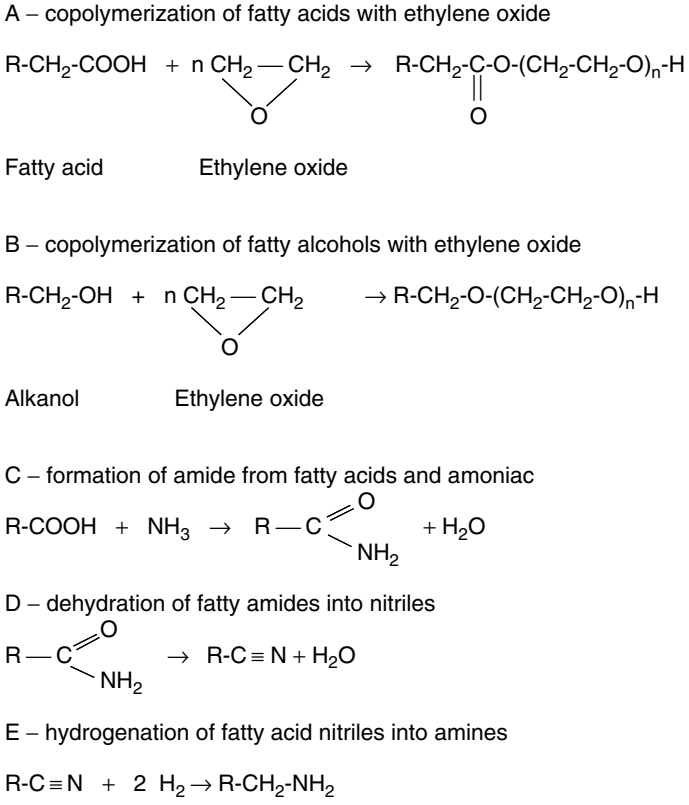

FIGURE 34.11 Formation of surfactants from fats, oils and fatty acids.

alkyl amines (usually alkylated) are technically important surface active agents — inversion salts. Quarternary ammonium salts are particularly useful.

Many other oleochemicals can be manufactured from fats and oils, but they are a topic for special monographs.

VI. PHYSICAL CHANGES OF FATS AND OILS

A. EMULSIFICATION

Fats and oils are insoluble in water, but may form emulsions. Two types of emulsions occur in foods: oil-in-water emulsions (O/W), where water is the continuous phase and oil is the dispersed phase, and water-in-oil emulsions (W/O), where water is the dispersed phase and oil is the continuous phase. Mayonnaise and cream belong to the O/W type, while butter and margarine belong to the W/O type. Mixed emulsions also exist (31), e.g., in margarines or cosmetic emulsions, where drops of the dispersed aqueous phase may contain dispersed tiny oily droplets.

Emulsions are unstable unless they are protected by emulsifiers. Emulsifiers are semipolar compounds, consisting of a polar group and a non-polar hydrocarbon chain. On the water and oil interface they are oriented towards the water phase with their polar groups and towards the oil phase with their hydrocarbon chains (Figure 34.12). The phases are thus protected against coalescence. Even stabilized emulsions are not equilibriated systems, and still have a tendency to partial coalescence, especially if the size of droplets of the dispersed phase is large (68).

The choice of suitable emulsifers is limited; they should be natural food components and harmless to human health. Phospholipids are natural emulsifiers as they act as emulsifiers in blood plasma and other tissues in the organism, and in cream or butter. However, the amount of phospholipids — mostly soybean lecithin — available on the market is not sufficient for the industrial production of food emulsions. Another choice are monoacylglycerols. They are natural metabolites of fats and oils easily produced by glycerolysis of fats and oils in the industry, and the reaction mixture may be used either directly or after fractionation into monoacylglycerols and diacylglycerols. Most margarines and bread spreads contain monoacylglycerols as emulsifiers. The amount of the emulsifier depends on the composition of the water and oil phases, on their ratio, and on the size of dispersed particles. The chemical structures of emulsifiers are similar, consisting of a polar functional group and a long nonpolar chain. The ratio of the polar and the nonpolar moieties indicates the emulsifying capacity, and is defined as the hydrophilic-lipophilic balance (HLB). A higher HLB

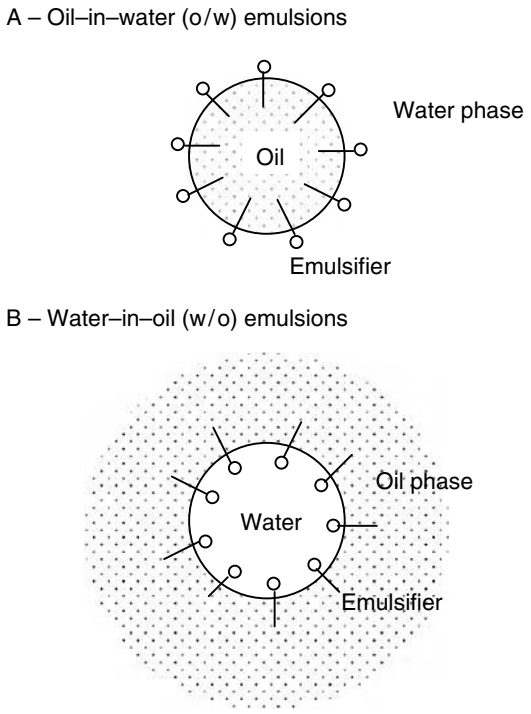

FIGURE 34.12 Role of emulsifiers in the stabilization of an emulsion.

value of an emulsifier enhances the formation of O/W emulsions. In low-fat emulsified products the emulsion stability may be enhanced by additions of ingredients increasing the viscosity of the aqueous phase, such as modified starches or carbohydrate gums. Other emulsifiers are manufactured for nonedible uses. More information may be obtained from specialized literature (69–71).

B. Fractionation of Fats and Oils

Physical properties, mostly the texture (formerly consistency), and the nutrition value, are changed by fractionation into a higher melting and a low melting (or even liquid) fraction. Either dry process or fractionation in the presence of emulsifiers may be used. The proper procedure of crystallization and the crystalline modifications obtained are of great importance (72). The process is used for the preparation of stearin and olein, fractionation of milk fat (73) or palm oil, e.g., for cocoa butter replacements (74). Palm stearin and palm olein are important ingredients for the production of margarines (75).

VII. CONCLUSIONS AND FUTURE TRENDS

New raw materials for edible and speciality fats and oils are constantly being sought, and other new oils are developed by conventional breeding or genetic manipulation from traditional oilseeds. They have fatty acid composition and properties tailored for specific uses. Another trend is to modify the fatty acid and triacylglycerol composition of conventional fats and oils or phospholipids by treatment with lipases or phospholipases or by ester interchange. Minor components may be removed from natural fats and oils by modern technologies, such as membrane filtration. New culinary equipment such as microwave heating affects fats and oils in ways not completely understood, and should be studied. The stability of fats and oils against oxidation is still a problem, and new methods of stabilization, especially new natural antioxidants, are being studied. Fats and oils may be stabilized against oxidation, too, by preventing the air access.

VIII. SUGGESTIONS FOR FURTHER STUDY OF FATS AND OILS

More systematic information on fats and oils may be obtained in general compendia on fats and oils (76–79), or in specialized monographs, such as on soybean processing (39), applications to functional foods (80), and lipid chemistry (81). Tables provide useful information about lipid analysis (82, 83). Data on fatty acid composition of natural lipids have been reviewed recently (21, 82, 84).

35 Fish Biology and Food Science

R. Malcolm Love
Consultant, East Silverburn, Kingswells

CONTENTS

I. INTRODUCTION

The science of fish as food usually concentrates on the deterioration that occurs after death. Even when packed in ice, the dead fish are still attacked by spoilage bacteria. If they are frozen immediately after catching and cold-stored, the texture of the thawed, cooked product gradually toughens with storage time, while the flavour will become rancid unless special precautions are taken.

While investigating cold-storage phenomena, the writer became aware that natural variations in the raw material could sometimes be more significant than the changes resulting from refrigeration, which had been the focal point of the study. This finding indicated a prior need for an investigation of 'variation,' the role of season and fishing ground, and ultimately their effects on the suitability of a batch of fish as a foodstuff.

Anecdotal evidence existed long before any systematic work had been undertaken in this field. For example, fishermen from the Moray Firth (north of Aberdeen, Scotland) used to risk damaging their nets by fishing as close as possible to stony ground, since experience had taught them that fish caught there were firm-fleshed. Those caught on a soft ground 'had a soft texture,' which precluded their being transported to Aberdeen because they decayed so rapidly. Similar conclusions were derived from the nature of the diet of the fish at the time. Cod (*Gadus morhua* L.) which were consuming soft and fatty sand-eels (*Ammodytes* spp.), 'became soft themselves,' while those with shellfish in their stomachs ('hard-feeding') were firmer.

These observations, based on a lifetime's experience at sea, were of course reliable; the interpretations were not. In fact, the basis for the observations was almost certainly the nutritional status of the fish. Most species starve during the winter, and those that spawn in late winter, developing gonads while starving, drain their resources further. Since they deplete their own body proteins, the flesh becomes soft. When feeding resumes, the fish cram themselves with whatever food has become available — in the case of cod, fatty sand-eels. However, at this point they have not yet recovered, and when the fishermen examine them, they are still soft. Additionally, digestive enzymes are found in abundance in stomachs full of food. If the fish are not sufficiently washed after gutting, some autodigestion could also take place, leading to further softening. Later in the summer, the fish become more choosey and prefer shrimps — and their flesh by now is firmer.

Nearly 50 years ago, a scientific report (1) hinted that the fishing grounds themselves might influence the quality of the fish. It was stated that cod caught in the Faroes kept better in melting ice than did those from other grounds. This is now known to be a pH effect, governed by the carbohydrate reserves of the fish, and will be fully described later.

In the following account, we shall describe some individual features of the fish and how or why they change with the seasons and the locality. Shulman (2) described them collectively as the 'syndrome' of the fish: it is the integrated features which govern the overall acceptability of the fish as food. The fish type used for study has mostly been the Atlantic cod along with lesser consideration of other gadoids, fatty fish, and salmonids. Observations made with one species do not necessarily apply to others.

II. FEATURES OF THE FISH

A. Skin Colour

The skin colour of many species of fish reflects that of the sea-bottom. Thus, cod from the north of Iceland, where the bottom is mostly of black volcanic ash, are the darkest of all that we have encountered. Cod from the fjords along the coast of Norway live amongst weeds and are often of a rich gold colour. Those from the Faroe Bank (60–53 N 08–20 W), which is composed of gleaming white shells, are extremely pale, as are all other species from that ground.

The fish change their colour according to stimuli received from their eyes, so if there is a black fish in a shoal of normally-coloured fish, that fish is blind. An experienced buyer on the fish-market can often pin-point where any batch was caught, so is able to choose those which he most favours.

There are so many variables involved in animal biology that apparently simple relationships do not necessarily apply at all times. In the present instance, the adaptability of fish skin colour to background colour is limited. When some pale-coloured cod from the Faroe Bank were brought back alive to Aberdeen (3) and placed in an aquarium together with darker-coloured cod from the Aberdeen Bank (57–05 N 01–15 W), the skins of the two groups of fish tended to change towards the intermediate colour of their new surroundings, *but not completely*. After as much as 16 weeks in the same environment, the two groups of fish could still easily be distinguished by colour, though not as strikingly as at first. This could indicate either a genetic difference between the two stocks, or different, limited ranges of colours being assigned to the two groups early in life as, for example, are the numbers of vertebrae in herrings (*Clupea harengus* L.), which become established in the young fry of a specific age according to the environmental temperature (4).

B. Flesh Colour

1. Non-Fatty Fish

Figure 35.1 shows the appearance of a cod with the skin removed. The lateral dark area represents 'red muscle,' the remainder 'white muscle.' The former is more fatty and more vascular than the latter and is rich in myoglobin and mitochondria, characteristics typical of very active muscle. Its metabolism is aerobic, and its purpose is to enable the fish to cruise for long periods without resting. The white muscle operates anaerobically and is used for a sudden dash in pursuit or escape; its poor vascularity and lack of haem pigments result in the need for a recovery period between bursts of activity to restore the energy

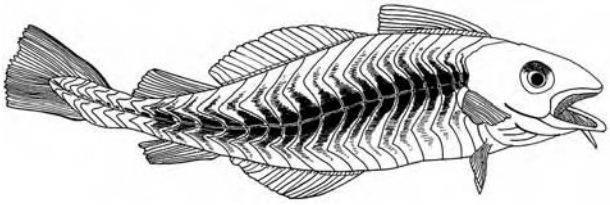

FIGURE 35.1 A cod with skin removed, showing the lateral red muscle. (Drawn by Eva Parsons. Crown copyright.)

compounds. The actual proportion of red muscle between different species of fish reflects their customary physical activity; flat fish which spend much of their time at rest have hardly any of it.

The most active species of the gadoid family is the saithe (*Pollachius virens* L.), so its musculature contains a greater proportion of red muscle than that of cod or whiting (*Merlangius merlangus* L). It can make the fillet look rather dirty, for which reason it fetches a lower price on the market. This can have important commercial consequences, as the following account shows.

A certain company bought the total catch of cod from a trawler, without prior inspection. When filleted, the flesh was found to be unacceptably dark for processing into the frozen cod fingers for which they had been purchased. It was realised that there would be complaints and possible litigation so, rather than scrap the whole batch, they made it into fish-cakes, a lower-priced product. The exact source of the fish was unknown, so an extensive survey of cod from different grounds was undertaken at Torry Research Station (5).

The actual *proportion* of red muscle was found to differ little between cod caught on different grounds, but the *intensity* of the red colour was greater in the fish from two localities at Svalbard, the most northerly grounds investigated. The Svalbard cod are unique in swimming great distances each year, from the Lofoten Islands off Norway, where they spawn in February, to Svalbard, where they arrive in summer to feed. Another feature which makes the Svalbard cod unique (Figure 35.2) is the distribution of red muscle colour between the individual fish of each sample. In the fish from grounds other than Svalbard, the distribution was Gaussian — a symmetrical shape, with values greater and less than the median tapering off in each direction. No such shape was seen in the samples from the two Svalbard grounds, where values ranged haphazardly from pale to intense. Examination of the same race during the spawning season off Lofoten again revealed deep chocolate-brown lateral muscle.

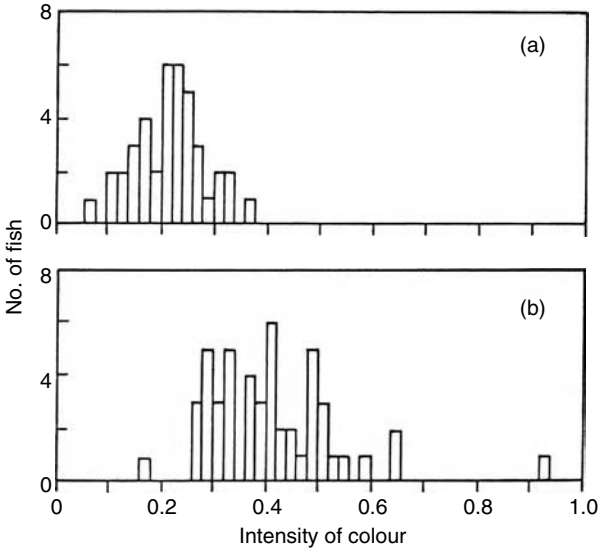

FIGURE 35.2 Distribution of intensity of red muscle colour in batches of 50 cod caught (a) on the Faroe Bank and (b) off West Svalbard. Faroe Bank fish are a stationary stock, Svalbard fish are migratory. The values on the abscissa are optical densities at 512 nm of a 4 cm light path of acid-acetone extracts. (Reference 5.)

The most reasonable interpretation of Figure 35.2 is that, while the red muscle in cod from Svalbard was on average darker than that from other grounds, the fish with the most intense colour had just arrived from their long journey, while the pale ones had reached Svalbard some time previously and were now less active. Subsequent experiments with cod caught near Aberdeen showed that after 28 days of activity, swimming round a circular tank (5), their red muscle had become significantly darker than that in fish from the same batch, which had been rested for the same period; during this resting time, the colour had faded appreciably. Thus, the intensity of colour in red muscle adapts to activity level, rather than being a fixed characteristic of a species.

In a seasonal survey of cod from Aberdeen Bank, the red muscle colour showed a smooth variation during the year (Figure 35.3), the minimum value in April being just 63% of the maximum in August. Since changes in pigmentation follow physical activity, a 'swimming activity curve' would probably lie somewhat to the left. Be that as it may, the more deeply pigmented cod must have been more energetic than usual, presumably because of increased feeding activity.

2. Fatty Fish

All species of fish carry triacyl glycerols as reserves of energy, but non-fatty fish, such as cod, carry virtually all of it in the liver, and fatty fish, such as herring (*Clupea* spp.) and salmonids, distribute it throughout the flesh. Since fatty species are active swimmers, their musculature is usually dark-coloured, but this fact does not actually worry the consumer. The point is that, because of its content of flavourous substances, the red-coloured muscle is more tasty than the white muscle anyway. In a trial at sea with two senior Japanese fishery scientists (6), European species of non-fatty fish were tasted, immediately after catching, as *O-Sashimi*, i.e., raw, with *Wasabi* sauce. The somewhat despised saithe was here considered the most desirable, better even than prime fish such as lemon sole (*Microstomus kitt* Walbaum).

The lipid content of the muscle of fatty fish is the major factor influencing quality. Since it decreases markedly at and following spawning, there is therefore a seasonal variation in the acceptability of these fish. When the proportion of lipid is low, the cut surface of the fillet is matt instead of

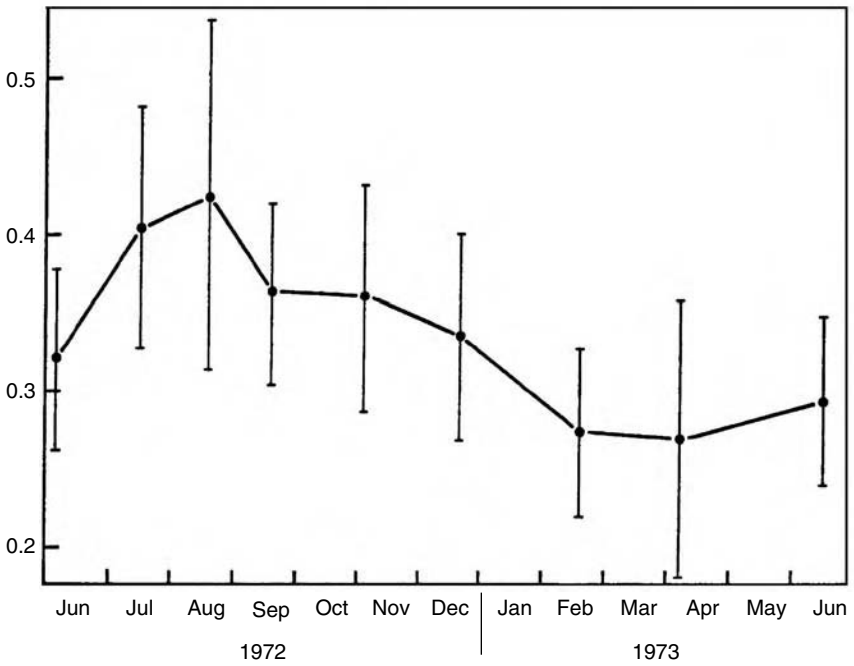

FIGURE 35.3 Changes in the concentrations of total haem pigments in the red muscle of cod over a 12-month period. Units as for abscissa in Figure 35.2. (Reference 5.)

glossy, it does not smoke satisfactorily, and the texture is 'dry' or fibrous in the mouth. The colour is not affected.

3. Salmonids

The pink colour of salmon and trout flesh reveals the presence of carotenoids, mostly astaxanthin and canthaxanthin. As far as the consumer is concerned, the colour is a desirable feature, but why is it present in these species and not in others? For a long time, carotenoids were considered to be a 'playful diversion of Nature' (7) of no real use to the fish except as precursors of vitamin A, but in salmonids they are closely tied to the reproductive cycle. The fish obtain them from their food, some being deposited unchanged while others are converted into other carotenoids before being laid down in the tissues (8). During the feeding season, they accumulate in the liver, flesh, skin, and fins, but accumulation in the flesh is negligible until maturation has definitely started (P.N. Lewtas, personal communication, 1977). As the gonads grow larger, their demand for carotenoids exceeds the dietary intake, and pigment is then increasingly transferred to them from the flesh. The process is induced by 17-methyl testosterone (9) and halted if the fish are castrated (10).

There is therefore a seasonal variation in the amount of pigment in salmonid flesh, which drains almost to zero around the spawning time. Figure 35.4 shows the changes in farmed rainbow trout (*Salmo gairdnerii* Richardson), which occur despite the fact that because the fish were farmed, they were receiving a continuous supply of

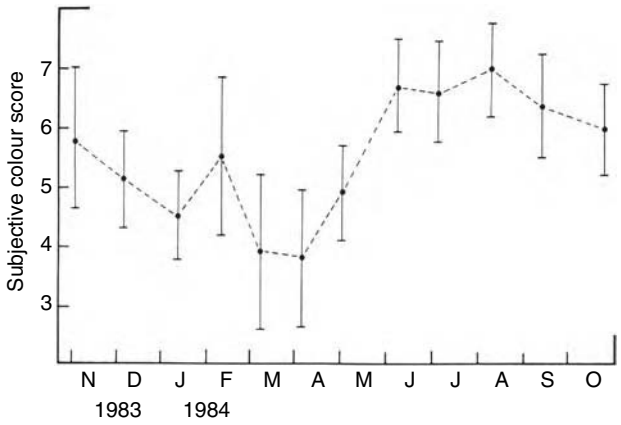

FIGURE 35.4 Seasonal variation in the flesh colour of rainbow trout from one farm, assessed by a panel on a subjective scale. (After Mochizuki and Love, unpublished. Crown copyright.)

canthaxanthin. Studies on chum salmon (*Oncorhynchus keta* Walbaum) during their spawning migration (11) showed that the carotenoid concentration in the blood serum ('in transit') rises steeply in the pre-spawning and near-spawning phases, but drops sharply when spawning actually starts.

A number of functions has been suggested for carotenoids in salmonids: as hormones and as assistants for fertility and embryonic development among other ideas. However, trout embryos with the orange oil droplet removed can develop normally (summarised 7). M. Hata

(personal communication, 1977) successfully reared rainbow trout embryos which were free from carotenoids. The main function of carotenoids may well be to protect the eggs from the harmful effects of sunlight, since salmonids lay them in shallow water.

C. Changes in the Main Constituents

1. Lipids

All mature fish undergo a regular cycle of depletion and restitution. This is the background to most of the phenomena, important in food science, described in the present account. It is based on the fact that ripe gonad tissue in most fish, particularly the females, occupies a relatively large part of the body cavity, and represents a huge synthesis of new protein and transfer of lipid. In most cases, the amount of food that the fish eats is quite inadequate to supply all this material plus the energy required for swimming, so the fish must perforce break down much of its own musculature ('endogenous feeding' - 12). As triacyl glycerols in the muscle of fatty fish are used up for gonad synthesis, the relative proportion of water in the tissue rises. This inverse relationship was called the 'fat-water line' by Brandes and Dietrich (13), who found that the percentage of muscle lipids in fatty fish could be assessed more conveniently just by measuring the water content.

In cod and similar low-fat fish, triacyl glycerols are virtually absent from the white muscle. The total lipid content is only between 0.5% and 0.6%, made up of 'structural' components, phospholipids and cholesterol and derivatives (14), the latter being about 10% of the total lipid. These membrane lipids are not available for mobilisation unless the muscle itself is broken down. Stored triacyl glycerols are removed from the liver instead.

There is some evidence that maturation, as distinct from simple starvation, mobilises polyunsaturated fatty acids selectively from the reserves for transfer to the gonads. An early report (15) stated that the lipids remaining in the bodies of herrings at maturity were less unsaturated than those from fish in the early stages of maturation. Studies on capelin (*Mallotus villosus* Müller) also showed (16) that polyunsaturated fatty acids tended to be mobilised from the body lipids and the more saturated fatty acids tended to be left behind. Neither study compared the changes in maturing fish with those which were not maturing under the same conditions. However, more fatty acid C22:6 (docosahexaenoic acid) has been found to be removed from the livers of starving cod which were actively maturing than from similar fish which had been castrated (17). This fatty acid is the most important one in the gonads of both sexes.

Some activities, such as maturation and migration which deplete the lipid levels in the fish, actually require a certain level of lipid reserves before they can take place. Thus, when young Atlantic salmon are starved on alternate weeks in the springtime, reducing their lipid stores, maturation is suppressed (18). Knowledge of this phenomenon can help the economics of fish farms, since the expensive fodder is directed towards profitable body growth, rather than to gonads which represent waste.

Anchovy (*Engraulis encrasicholus* L) overwinter by migrating from the Sea of Azov in September to warmer water, but must first accumulate a critical level of lipid. This 'triggers' migration at a particular range of water temperatures. Those which fail to exceed 14% lipid during their summer feeding do not migrate at all and die when this shallow sea freezes (19, 20).

2. Proteins

a. *Muscle Tissue*

In the muscle of non-fatty fish there is a significant 'protein-water line' (21), but in this case the water content is not just relative: extra water has entered the tissue. Figure 35.5

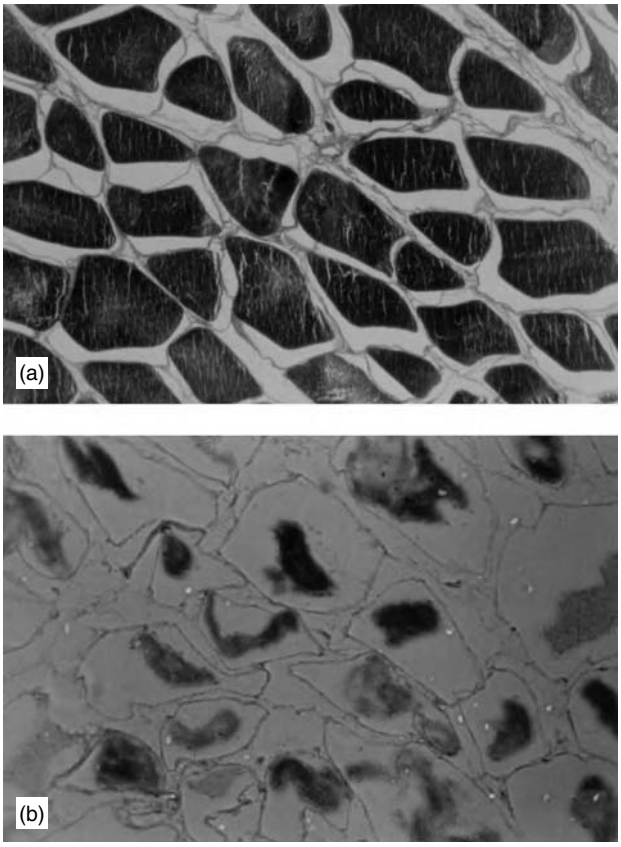

FIGURE 35.5 Cross sections of the white muscle of starving cod. (a) Moderate starvation, water content 83.3%. Some diminution of the solid contractile tissue can be seen, and the collagen sheath of each cell is separated from it by a layer of fluid. (b) Very severe starvation, water content 95.3%. The original outlines of the cells are still delineated by the thin lines of connective tissue but most of the contractile tissue has disappeared. Magnification: 120 times. (After Lavéty, unpublished. Crown copyright.)

shows a cross section of the muscle of a much-depleted cod, compared with a less-depleted counterpart. It will be seen that, while much of the contractile muscle tissue has been removed, the cells still retain roughly the same shape as before, the vacant space now being occupied by fluid.

This observation shows the main weakness of the classical 'condition factor,' used extensively at one time to assess the nutritional status of fish. The weights of fish of the same length were compared, using the formula (W/L^3), where W is the weight of the fish and L the length. Figure 35.5 shows that measuring the loss in weight during starvation or maturation under-estimates the actual loss of protein. In the case of extreme emaciation, cod do actually appear thinner (22) as seen in Figure 35.6, but the loss of protein in the earlier stages is not revealed. The concurrent loss of lipids from the liver can be seen in its diminishing size and its change of colour from creamy-yellow to red.

More than 40 years ago, a simple survey of the proportion of water in the white muscle of cod during the year (23) provided more information than expected (Figure 35.7). The water content of sexually immature cod was seen to increase in the spawning season, though to a lesser extent than in mature fish. This shows that the shortage of food in winter depletes every fish, not just those which synthesise gonads. In addition, fish which have spawned several times are more depleted than first-time spawners. In the author's laboratory (unpublished), it was later shown that the water content of the white muscle of cod held without food in an aquarium could increase to 86% in young fish before death ensued. That of large cod, however, could rise to as much as 96%, so it is clear that larger fish adapt to the greater drain on their resources. As fish grow, the proportion of gonads produced as a percentage of the body weight increases steadily. For example, the burden of spawning in hake (*Merluccius merluccius* L.) doubles for every 10 cm increase of body length (24). Eventually, the fish become so depleted that they cannot recover from spawning and die (25).

The relevance of these observations to food science is that while many species of fish go through a season of wateriness, which makes them unsuitable as food, small fish are less likely to be affected.

b. *Connective tissue*

The glistening sheets of material which bind individual muscle cells together and join blocks of muscle to the vertebral column are constructed of collagen, a protein rich in proline and hydroxyproline. It appears not to be mobilised to supply energy during starvation but, as described later, its physical properties change with the season.

3. Carbohydrates

a. *Their role and origins*

Carbohydrates are stored in the liver as glycogen, a 'polyglucose,' which is released into the blood as free glucose and transported to the muscle as required. On arrival, it is either used immediately to supply energy, or resynthesised into muscle glycogen for temporary storage. Although carbohydrates make up only a small percentage of the weight of the fish at any time, they are probably the most important of all constituents in the context of food science, since they are responsible for changes in the texture of the cooked product and in the way the fillets hold together. Their behaviour will therefore be described in some detail.

Carnivorous species of fish can acquire appreciable quantities of glycogen from the livers of their prey. Vegetarian fish on the other hand receive little or none of it in this manner, and indeed all species continually synthesise most or all of what they need from protein and lipid precursors ('gluconeogenesis'). They do, however, maintain certain levels of it which vary according to the general nutritional status of the fish, the glycogens of liver and muscle varying in tandem with each other (26). Figures 35.8 and 35.9 illustrate these relationships. There have been particular problems in studying the glycogen of white muscle. While there is enough of it in the liver to be measured by standard methods, this is not possible in white muscle because of the low levels present and their

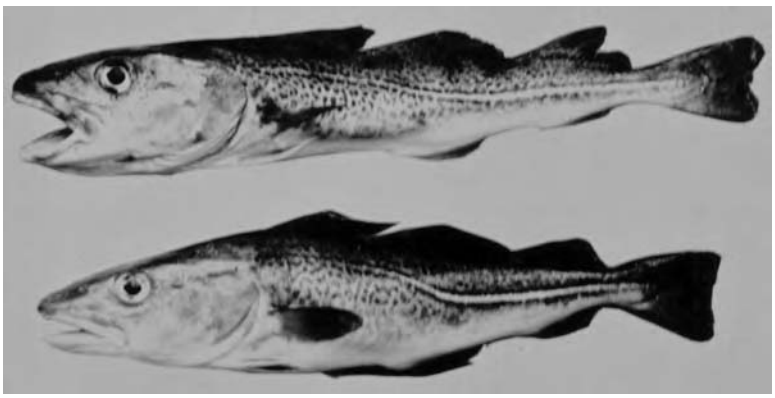

FIGURE 35.6 Severely starved cod (upper), showing overall change in shape compared with a fed specimen (lower). (Reference 21.)

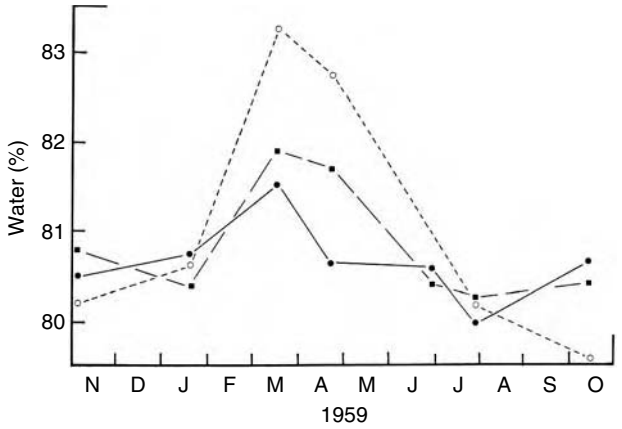

FIGURE 35.7 Changes in the water content of cod white muscle during a year in the wild. Solid circles: immature fish. Squares: first-time spawners. Hollow circles: spawned more than once. Large fish not available in June. (Reference 22, redrawn in Reference 41.)

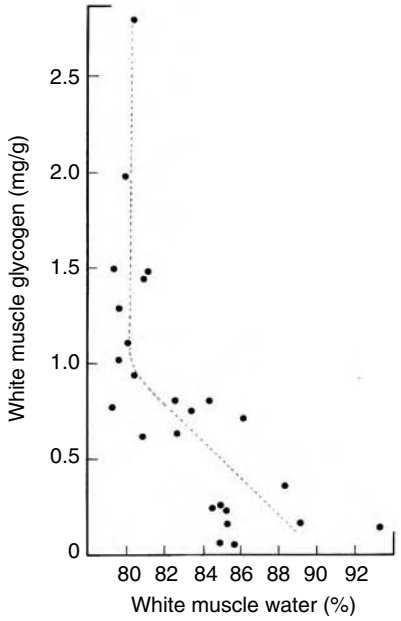

FIGURE 35.8 Relationship between the glycogen content of the white muscle of cod and its nutritional state as indicated by the water content. (Reference 25.)

ephemeral nature. Glycogen fuels all muscular activity, so it is rapidly consumed by the thrashing about which accompanies capture, and indeed its concentration in the muscle can be reduced by half after only 15 seconds of struggling (reviewed p 423 of Reference 8). Attempts to measure it in the muscle of newly-captured or frozen fish are therefore pointless.

The best that can be done in the way of direct assessment of glycogen in muscle is to stun rested fish by a blow on the head before they have had time to struggle. Small

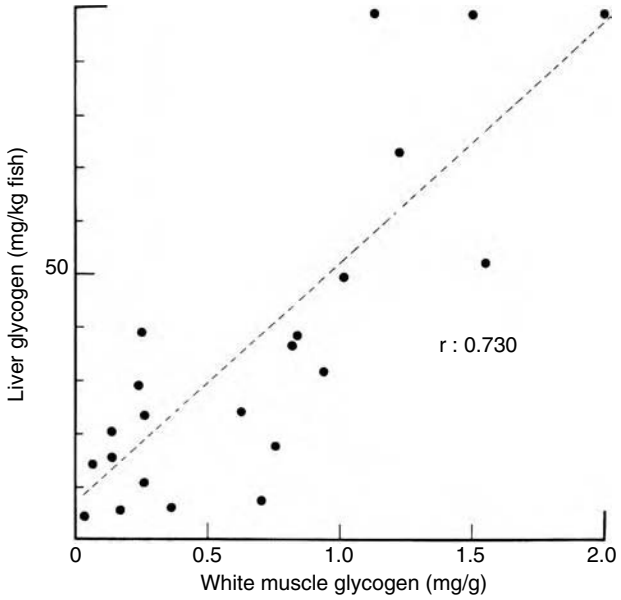

FIGURE 35.9 Relationships between the glycogen contents of liver and muscle in rested cod of various nutritional states. (Reference 25.)

samples of muscle are then rapidly excised and dropped into liquid air for subsequent analysis. As it is not possible even with these precautions to avoid all struggling, the levels as measured vary more than those from the liver.

b. The pH of muscle after death

i. Its derivation and measurement

As soon as a fish dies, oxygen no longer circulates to the muscle and glycogen breakdown stops at the lactic acid stage, through the Embden-Meyerhof-Parnas pathway. Some of it takes another path and is broken down into glucose by the action of an amylase present in the muscle (reviewed 27), so any variation in the proportion of the lactic acid and amylolytic pathways would affect the 'final' pH of the muscle (the pH after carbohydrate degradation is complete, usually measured 24 h after death), since lactic acid lowers it and glucose does not. It has been shown that the initial glycogen concentration strongly influences the 24 h post-mortem pH value of the white muscle of cod, whether fully fed, starved, or starved and refed. Possible effects of variations in the pathway therefore seem unimportant (28).

One question remains. Does the amount of struggling undergone by the fish at death influence the final pH? While the lactic acid formed during exercise is rapidly released into the blood system from the muscle of mammals (29), very little is released from fish muscle (30). The stress which accompanies some modes of exercise seems to cause the fish muscle to retain its lactic acid, probably under the influence of the catecholamine hormones (31). The lactic acid generated by violent exercise will therefore

supplement that generated spontaneously after death, so that the 24 h post-mortem pH values should be the same, however long the fish struggled before death. Experiments have confirmed this, the final pH of the muscle of cod removed quickly from a tank and stunned being similar to that of those previously exercised stressfully (32).

The measurement of pH after the completion of glycolysis therefore constitutes a simple method of assessing the carbohydrate level of the flesh (28) and, by the relationship shown in Figure 35.9, that of the liver also.

Struggling can, arguably, confer a certain benefit. *Rigor mortis* sets in as soon as the residual glycogen falls below a critical level after death. Since struggling greatly reduces the level of glycogen in the muscle, the fish enters *rigor* more quickly, and the condition lasts for a shorter time, than in a fish which dies without stress (33). This benefits farmed salmon, which should not be handled or filleted in *rigor* because it causes gaping; when they have become flaccid again after *rigor* (the 'resolution of *rigor*') they are suitable for filleting. It may take several inconvenient days before this state is reached, so some struggling before death can save money. There seem to be no advantages to processing or handling salmon by prolonging the times before or in *rigor* after harvesting, except where the salmon are to be sold intact to a customer, where the state of *rigor mortis* indicates freshness (34).

ii. Seasonal variation

It is reasonable to expect that the final pH of fish muscle should be high during the winter, because food is scarce and little carbohydrate is present in the muscle to form lactic acid after death. The fish feed continuously during the summer, so the final pH should then be consistently low. However, experimental findings do not bear this out. Figure 35.10 shows that, over a wide range of fishing grounds, the pH of cod muscle after death is high during most of the year, but that around June most of the fish exhibit low values for a short period, after which high values are restored. The approximate date when low values occur varies somewhat from year to year, but the principle is the same (35). The phenomenon appears not to occur in haddock (*Melanogrammus aeglefinus* L.) (31), but a short-term minimum pH value has been observed in June in farmed Atlantic salmon (36).

iii. Experimental starvation and refeeding

Studies of the three main constituents of cod tissues during starvation (37) have shown that they are mobilised for energy purposes in a definite order (Figure 35.11). The integrity of white muscle is more important to the survival of the fish than are the lipid reserves of the liver, so its proteins are not mobilised to supply energy until most of the liver lipids have disappeared. There is therefore a hiatus of several weeks, longer at lower temperatures and *vice versa*, before any change is seen in the protein content of the white muscle during starvation. Red muscle is generally more important to the fish than is white muscle, since it enables the fish to 'cruise' without fatigue. It therefore retains its glycogen for several weeks after the beginning of starvation, while depletion begins immediately in white muscle.

It is again reasonable to expect that, with the decline of available carbohydrate in starving cod, the activities of the enzymes that convert protein and lipid to glycogen (gluconeogenesis) would become more active, to redress the situation. However, it has been shown (38) that in fact the enzymes involved, phosphoenol pyruvate carboxykinase and alanine aminotransferase in the liver, and the fructose diphosphatase in liver, red muscle and white muscle, become steadily *less* active during starvation, though there can be a transient increase in activity during the early stages.

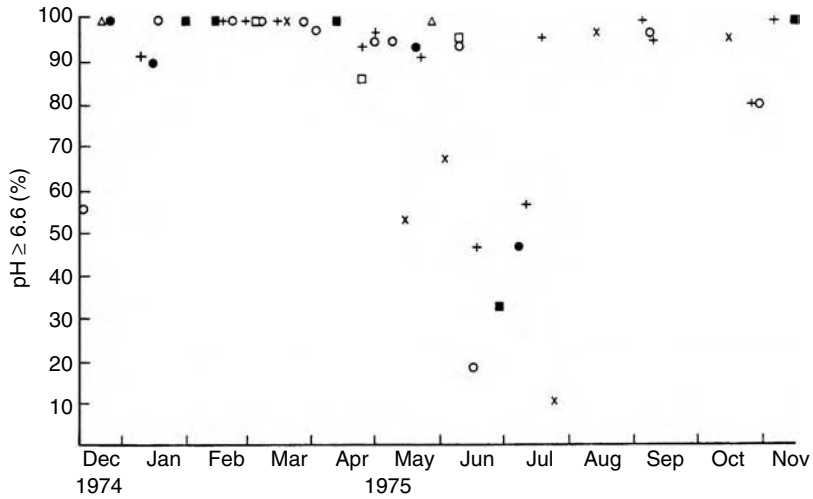

FIGURE 35.10 Proportions of batches of 20 cod, caught on various northern grounds, with post-mortem pH in the white muscle of 6.6 or more. (Reference 34.)

The starving cod adapt to decreasing glycogen resources by reducing their swimming activity, spending long hours motionless on the bottom of the aquarium. In contrast, starving rainbow trout (*Salmo gairdnerii* Richardson) do increase the activity of their gluconeogenetic enzymes, so that reasonable levels of glucose in the blood and muscle are maintained. The trout is a more physically active fish and continues to swim during starvation.

On refeeding, the sequence of change illustrated in Figure 35.11 is reversed. The muscle proteins are restored first, red muscle before white. Only after this do the liver lipids return to normal values (26).

The restoration of glycogen, however, is remarkable. There is enormous over-compensation, both in liver and muscle, during refeeding. A 20-fold increase above non-starving values of liver glycogen is possible (39). Figure 35.12 shows the effect in cod liver (26). It is noteworthy that the value after 195 days has dropped spontaneously to normal, despite the continuation of the feeding regime. Similar rises and subsequent falls are shown in red and white muscle (Figure 35.13).

The large increases in the levels of glycogen in the three tissues of starving-refed fish, compared with the level in fish fed continuously during the experiment, almost seem to indicate a loss of control or a metabolic imbalance, but studies with the DNA/RNA ratio, which varies in proportion to the vigour of protein synthesis, suggest that the over-compensation is a necessary part of the restorative process (26). The glycogen level in the red muscle reaches a maximum value after 60 days of refeeding, compared with 105 days in white muscle. The DNA/RNA ratios reach maxima at the same two points. Perhaps the energy required for protein resynthesis comes from this glycogen. The restoration of red muscle protein has priority over that of white muscle.

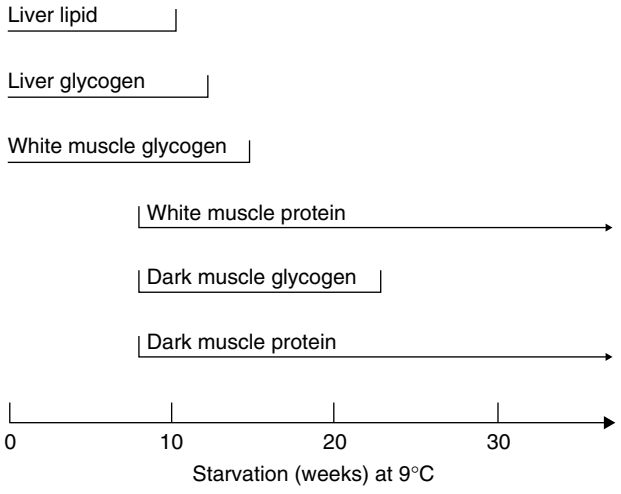

FIGURE 35.11 Diagrammatic representation of the sequence in which the principal constituents of liver and muscle are mobilised during the starvation of cod at 9°C. Time values are approximate. (Reference 25.)

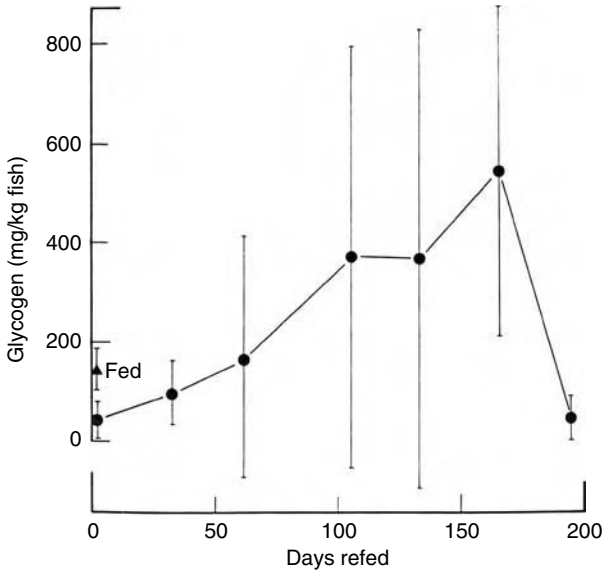

FIGURE 35.12 The excessive increase in liver glycogen during refeeding after starvation. The triangular point shows the level in fish fed throughout the experiment (never starved). (Reference 25.)

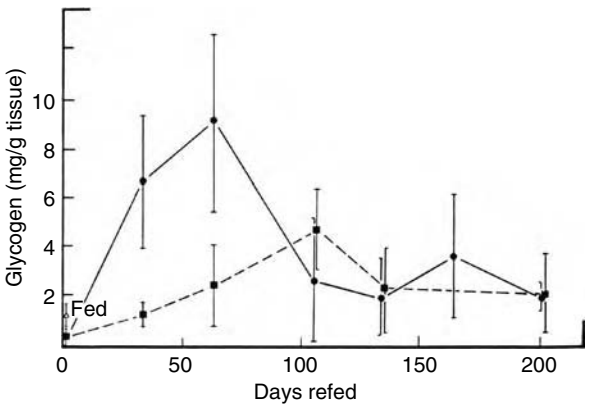

FIGURE 35.13 The excessive compensation of glycogen in red muscle (circles) and white muscle (squares) of cod, refed after starvation. Note how the maxima differ between the two types of muscle and (Figure 35.12) the liver. (Reference 25.)

A smaller glycogen overshoot is seen in fish previously starved for a shorter period, and the type of food proffered for refeeding also influences the phenomenon (26). Figure 35.14 shows that a diet of squid during refeeding results in a bigger overshoot than that resulting from a diet of herrings.

Figure 35.15 shows the corresponding final pH of the white muscle during starving and refeeding. A refeeding period of around 100 days was chosen to correspond with the glycogen maximum (Figure 35.13). A final pH lower than that usually found in fish from the

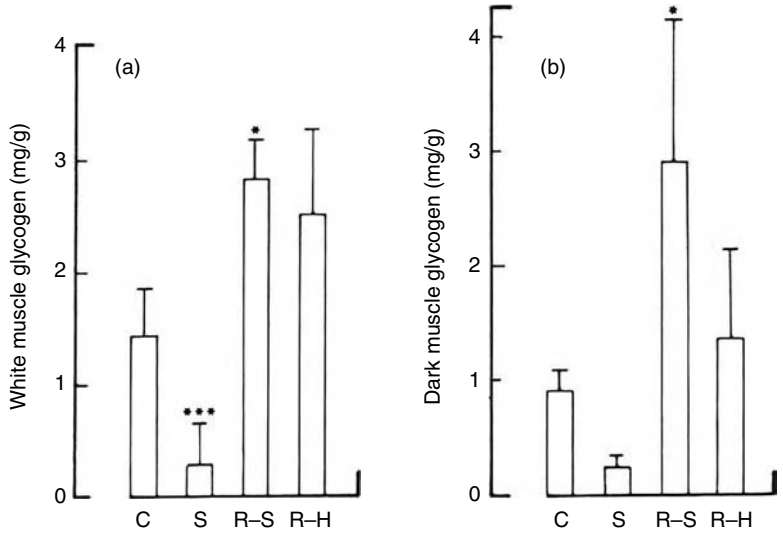

FIGURE 35.14 The effect of diet on the concentrations of glycogen in (a) white muscle and (b) red muscle in cod starved for 77 days and refed for 97 days. Asterisks show the degrees of significance from fed controls. C = control; S = starved; R-S = refed on squid muscle; R-H = refed on herring muscle. (Reference 25.)

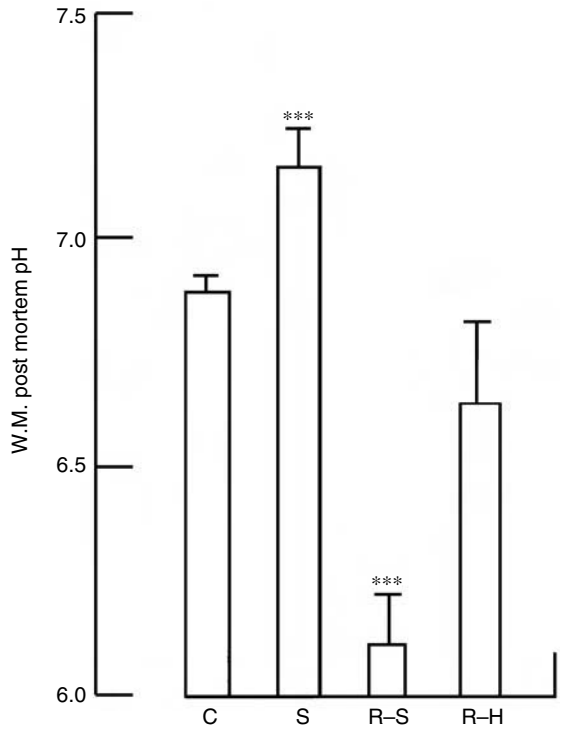

FIGURE 35.15 The final pH of white muscle in cod. Conditions and key as in Figure 35.14. (Reference 25.)

sea can be seen in the fish refed on squid. This result is thought to mirror the phenomenon seen in Figure 35.10 in free-living cod caught around June. Using the period of 100 days, one could speculate that these fish had started to feed in March (the stock used spawns around the second week in March). However, the results show too much scatter to predict the date of resumption of feeding from year to year.

III. BIOLOGICAL PHENOMENA AND FOOD SCIENCE

A. Gaping

1. Anatomical Background

Figure 35.16 shows the appearance of the cut surface of a cod fillet. The pattern of lines shows the cut edges of connective tissue sheets (*myocomma*; plural: *myocommata*) which merge with the skin on the lower surface and are joined to the vertebrae on the upper. They are made of the protein collagen (non-contractile) and bind blocks of muscle tissue (*myotomes*) together, transmitting the force of the muscular contractions used in swimming.

In the muscle tissue of warm-blooded animals such as beef, the connective tissue toughens as the animal ages, eventually resulting in a material which is a challenge to eat, even after long cooking. Fish connective tissue is much more 'frail,' and dissolves into gelatin at temperatures well below that of boiling water. It is therefore never a problem as regards the texture of the cooked product. Most of the potassium of muscle tissue is found within each contractile cell, while sodium is principally in the spaces between the cells and in the connective tissue. Figure 35.16 shows that there is a far greater proportion of connective tissue at the caudal end of the fillet, so consumers on a low-sodium diet should perhaps avoid this part.

Figure 35.17 shows (magnified) the junction between the ends of some white muscle cells on each side of a sheet

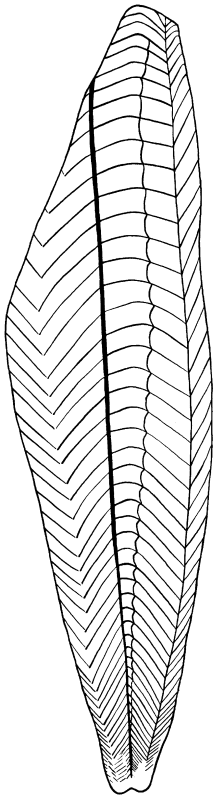

FIGURE 35.16 Drawing of the cut surface of a cod fillet (musculature next to the bone). The thin lines indicate the cut ends of the myocommata. (Reference 39.)

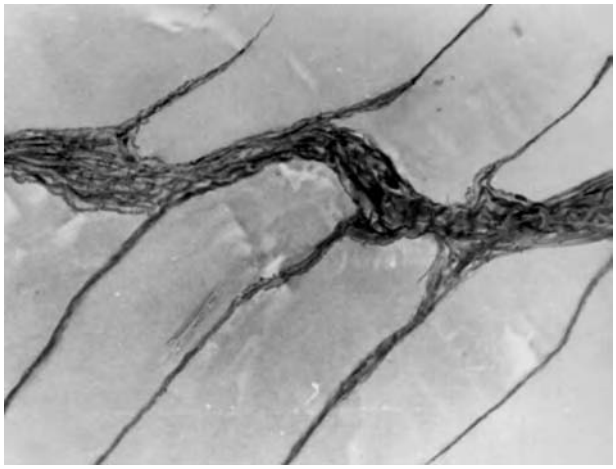

FIGURE 35.17 Photomicrograph of the junction of 4 individual muscle cells (pale areas) with each side of a myocomma (thick black stripe). The cells are about 100 microns across, and the connective tissue tubes separating each from its neighbour are shown as thin dark lines. (Author's picture. Crown copyright.)

of connective tissue, shown in black. The light grey areas are longitudinal sections of individual muscle cells, and it can be inferred that each cell is surrounded by a 'tube' of connective tissue which merges with the myocomma itself.

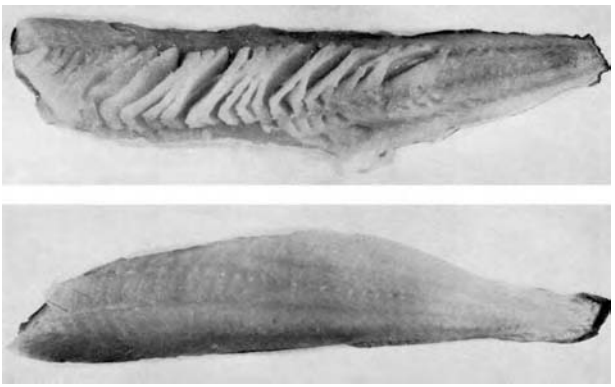

FIGURE 35.18 A bad case of gaping (upper), compared with a normal (lower) fish. Both fish were frozen 'round,' thawed and filleted, but the good specimen was frozen before *rigor mortis* and the gaping one had been preserved for 8 days in melting ice before freezing. (Crown copyright.)

It is an elegant mode of attachment, but when this junction breaks, gaping occurs (Figure 35.18).

2. Causes of Gaping

As a general rule, gaping is a problem of frozen fish. More specifically, it can be seen in fish which have been frozen intact, with or without guts in, then thawed and filleted. It is not usually a problem when they are filleted after the resolution of *rigor mortis* before freezing. Gaping is of great economic significance: a gaping fillet cannot be sliced, smoked — or sold. The difficulties associated with gaping and its commercial significance were brought home to the writer at a large processing plant, the owners of which owned the fishing boats which supplied it. At the time (June), their haddock were gaping so badly after filleting that they had to be minced and sold as a low-priced product which represented financial loss for the company. The management were in a position to control all handling procedures aboard the ships, but nothing they requested improved the situation. This fact triggered an eight-year investigation at Torry Research Station, Aberdeen.

Folk-lore from the fishermen has it that fish stuffed with food ('feedy fish') gape. This suggests that the soft flesh seen in early summer contains weak connective tissue, but experiments again showed otherwise (40). Figure 35.19 shows that it is the best-nourished fish which gape, the starved ones do not. The gaping score was assessed subjectively: a value of '1' signified a single longitudinal split in the fillet, and higher scores were based on the number of gaps between myotomes (41). The score figures are not mathematically related to one another, but the method is still a useful research tool. Figure 35.20 suggests that pH could be the factor responsible rather than softness as such, because the gaping follows the seasonal pattern of pH (42). The relationship was confirmed when

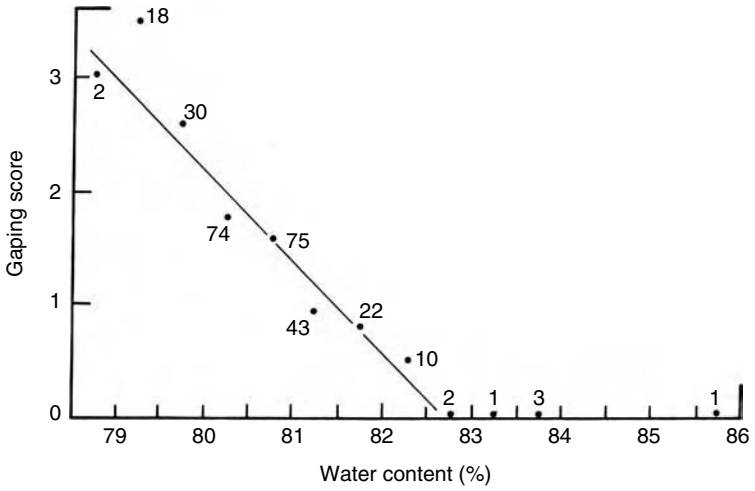

FIGURE 35.19 The relationship between the gaping of cod, frozen whole, thawed and filleted, and the water content of the white muscle. Numbers show the size of each sample wherein the water contents differed by not more than 0.5%. (Reference 41, redrawn in Reference 39.)

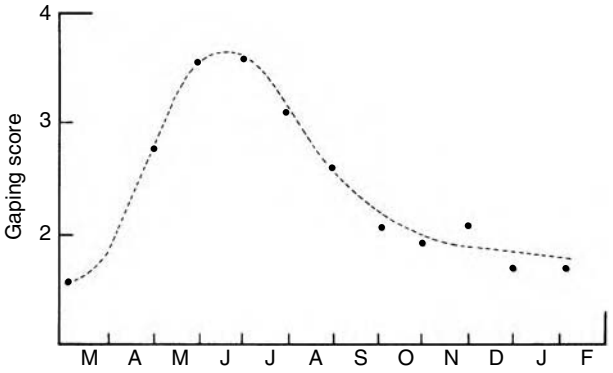

FIGURE 35.20 Seasonal variation in the gaping of cod muscle (1969–1970). Note that the peak corresponds with the period of minimum pH. (Reference 41.)

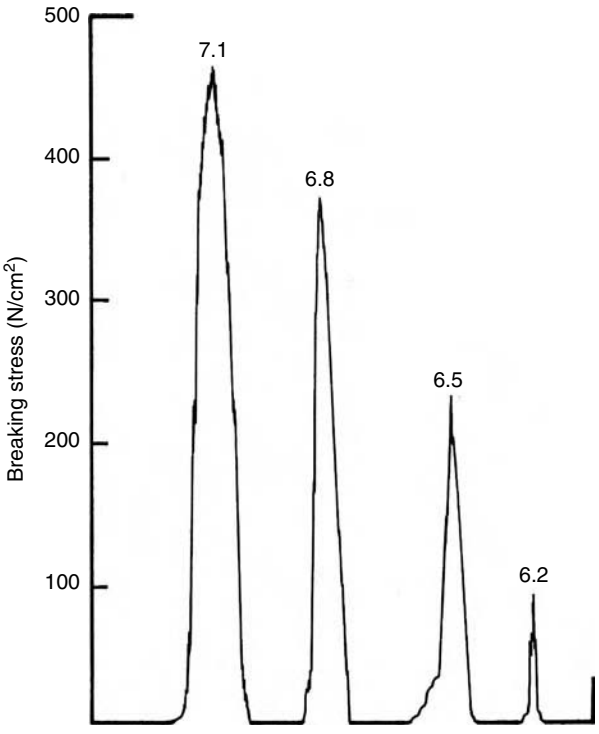

FIGURE 35.21 Tracings showing the force required to break strips of myocomma buffered at various pH values (shown above each peak) at 0. (Reference 42.)

isolated myocommata, suspended in buffers of various pH values and subjected to increasing tension until they broke, became increasingly frail as the pH decreased (Figure 35.21). The effect was reversible: myocommata which had been weakened in a buffer of low pH, then transferred to one of neutral pH, were found to have regained their strength (43). A similar relationship between season, pH and gaping has been found in farmed Atlantic salmon, the highest gaping score being in June and the lowest in January (36).

B. The Freezing Process Itself

The time between the death of the fish and freezing is important. Figure 35.22 shows that gaping is minimal in whole fish, frozen before the onset of rigor mortis and thawed before filleting. It rises when the fish have been frozen *in rigor* and rises further when frozen after the fish have become limp again (41).The phenomenon has been seen in several species of fish, but there are differences in degree (41). Haddock (*Melanogrammus aeglefinus* L.) gape the most, followed in sequence by cod, saithe (*Pollachius virens* L.), redfish (*Sebastes marinus* L.), halibut (*Hippoglossus hippoglossus* L.), and lemon sole (*Microstomus kitt* Walbaum).

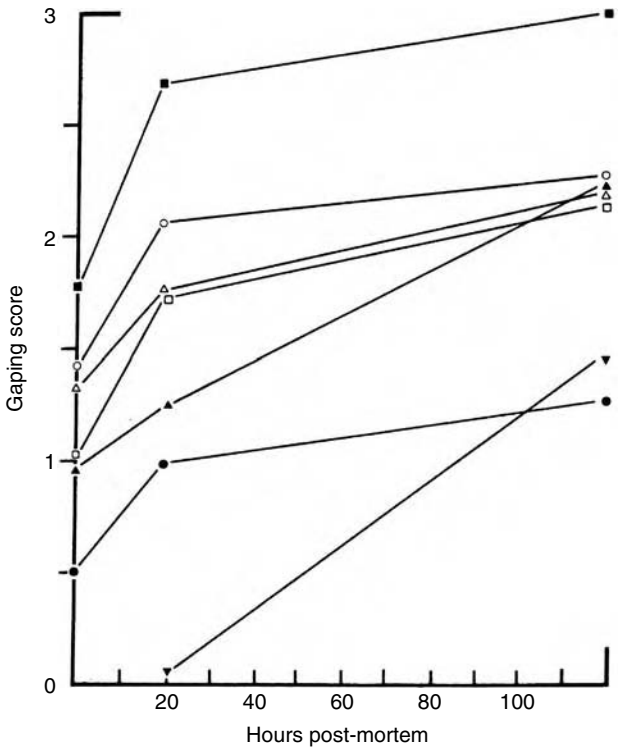

FIGURE 35.22 Gaping in fillets made from different fish species frozen at different times after death. All species were pre-*rigor* at 0 h, in *rigor* at 20 h and post-*rigor* at 120 h. Species from the top downwards: haddock, cod, saithe, redfish, halibut, lemon sole, plaice. (Reference 40.)

The lesson is clear: freeze whole fish as soon and as quickly as possible after death, bearing in mind that if they are frozen slowly, the effect is the same as that of prolonging the period preceding freezing.

The mechanism of gaping from this cause is interesting. The surface of a fillet cut before the onset of *rigor mortis* is dry to the touch, while if it is taken from a fish actually in *rigor*, it feels and looks wet. Freezing results in the solidification of this 'free' water, together with some of the water more closely associated with the contractile proteins. The frozen water becomes physically separated from the muscle cells, now dehydrated, in bodies of protein-free ice, faster freezing generating more numerous, smaller ice crystals and *vice versa*. Some tissue water is so tightly bound to the protein that it never freezes, but the proportion of freezable water is smaller in *pre-rigor* muscle than in muscle in or beyond *rigor*. Measurements on cross-sections of frozen cod muscle (44) show that the area attributable to ice is 46% of the total area in cod rapidly frozen *pre-rigor*, while in that frozen in *rigor* or after its resolution the figure is 57%. In addition, when fish are kept for longer periods in melting ice, water from outside steadily diffuses into the muscle tissue (45), resulting in further break-up of the myocommata on freezing (Figure 35.23).

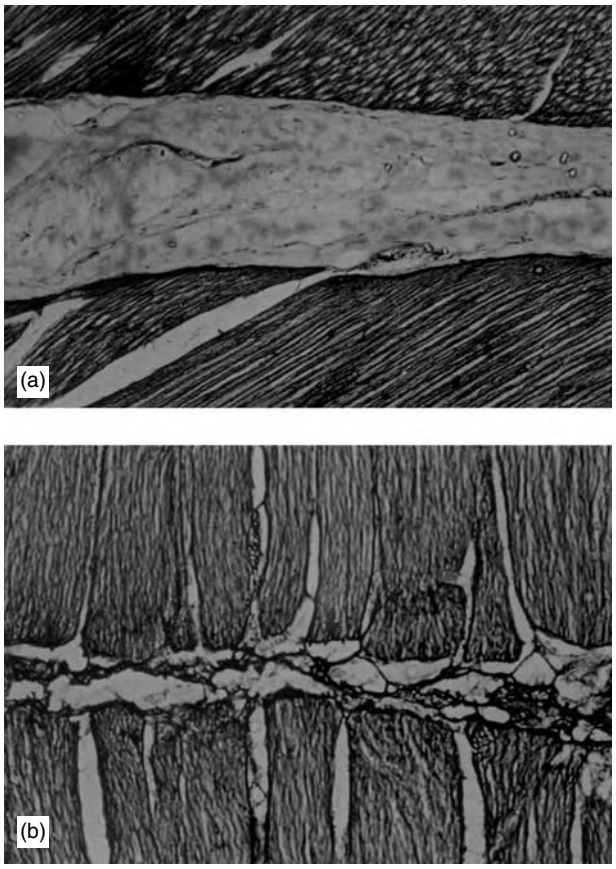

FIGURE 35.23 Sections through frozen cod muscle (small pale areas represent ice crystals). Both specimens frozen very rapidly at –80°C, but specimen (a) frozen 1 day after death, (b) after the whole, gutted fish had been held in melting ice for 8 days before freezing. The band across the middle is the myocomma, with muscle cells on either side. The tissues in (a) appear almost as fresh muscle. The myocomma in (b) is completely disrupted by ice crystals; fish in this condition gape badly. (Reference 44, Crown copyright.)

C. Handling

pH is not the sole arbiter of gaping. The intrinsic strengths of the collagen membranes vary between species. In a comparison of hake (*Merluccius merluccius* L.), cod and catfish (*Anarhichas lupus* L.), hake were found to gape more readily than the other two species and catfish did not gape under any experimental conditions, including very rough handling (46). The mean breaking stresses of myocommata were found to be 30 (hake), 87 (cod) and 142 (catfish) N/cm^3, the final pH values of all the fish being similar. The breaking stresses of skin samples were greater, but differed between the species in the same sequence as above.

In *rigor mortis* of whole fish, the muscle masses on each side of the fish contract strongly against each other, resulting in an unyielding rigidity. If the fish is curved as it enters *rigor*, this shape becomes fixed, and clearly any

attempt to straighten it before filleting would cause severe gaping in species other than catfish. Similarly, throwing rigid fish to other operatives or dropping them from a height would also cause gaping. This is common sense, but it still happens in practice.

Incidentally, if a fish is filleted before *rigor mortis* has set in, the musculature is now free to contract as it enters *rigor*. The shortened fillets, which take on a ribbed appearance, are tough to eat after cooking. If the *pre-rigor* fillet is dropped straight into a hot pan, it contracts even more and is virtually inedible because of its very rubbery texture.

D. Temperature

As stated, fish collagens dissolve as gelatin at much lower temperatures than the collagens of warm-blooded animals. The effect can be seen in Figure 35.24, where gaping increases to a maximum value when freshly-killed cod enter *rigor mortis* at 25°C. Controls at iced temperature do not gape at all (47). During heavy fishing in the summer months, the temperature of the fish could easily rise sufficiently to cause ruinous gaping if freezing were delayed. It may, however, be possible to retrieve the situation (43). Figure 35.25 shows that myocommata break more at higher temperatures, but that they are less easily broken if they are cooled to 0°C before measurement. Hence, it is vital to cool fish before further handling if they have been lying in the sun.

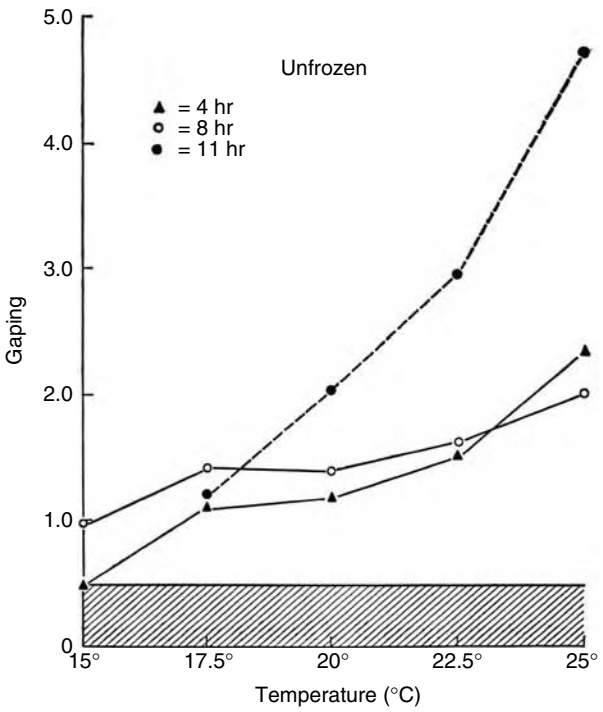

FIGURE 35.24 Gaping after filleting whole, gutted cod kept at different temperatures after death. The hatched area shows the unchanging state of controls kept in melting ice throughout the same period. (Reference 46.)

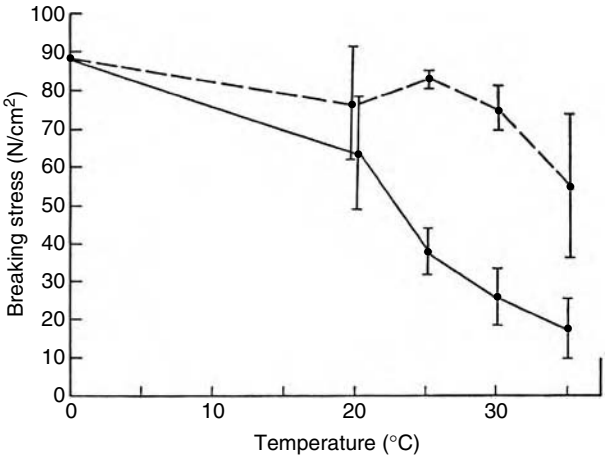

FIGURE 35.25 Breaking stress of isolated myocommata from cod kept at various temperatures for 1 h. Continuous line: measured at the actual experimental temperature. Broken line: collagen specimen cooled to 0°C before being stressed. (Reference 42.)

Rainbow trout also gape more as they enter *rigor* at higher temperatures, but *rigor* at 26°C in this species does not cause gaping: high scores require temperatures at or above 35°C. The higher water-temperatures tolerated by this species during life seem to engender a greater thermal stability in their collagen (36).

E. Size

Figure 35.26 shows that small cod gape more than large. The relationship is seen only in summer and autumn, however, disappearing or even being reversed in the winter and spring (48). Two factors are at work here: the pH of larger cod can be lower than that of smaller, varying with the season, and can over-ride the size effect.

Do any of these observations help to explain the industrial problem with haddock, described earlier? Fish of this

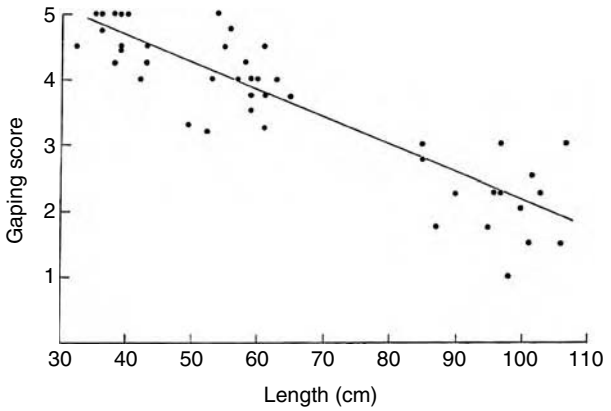

FIGURE 35.26 Influence of body length on gaping in cod caught in June 1968, frozen, thawed and filleted. r = 0.899. (Reference 47.)

species have been found to gape more than other species investigated (41), and the industrial problem was encountered in June, when the final pH values are often low. Isolated myocommata from haddock are in fact stronger than those of cod (43), but the final pH of this species has been observed to be intrinsically low, even as late as October (49), almost certainly accounting for their greater tendency to gape. The reason for the low pH is unknown.

There is scant advice for mitigating severe gaping in haddock. The fish should be put into the freezer before the onset of *rigor* if at all possible and any additional fish chilled *at once* and handled gently. Otherwise, it is better not to freeze them whole around June — though such advice may be impractical.

F. Texture

1. pH

Although the tough texture sometimes found in cooked beef is never found in fish, the latter, stored in the frozen state for too long or at too high a temperature (or both), yields a product which, after cooking, is somewhat difficult to swallow and can leave fibrous strands stuck between the teeth of the consumer. The sensation is of a dry, fibrous product and is unpleasant, especially if coupled with a rancid taste. Here we examine the texture of fish that has not been frozen, which can range between sloppy and firm.

The relationship (50) between the final pH of cod muscle and the texture as eaten is shown in Figure 35.27. The water contents of the muscle of the different fish fell within the narrow range of 80.0 to 80.9%, which is normal for well-fed cod (23). The softest fish were therefore not watery. This finding casts an interesting light on the texture of acutely starving fish, which are also sloppy and can, after cooking, be sucked through the teeth (not pleasant). The very slight effect of water content at constant pH on texture is shown in Figure 35.28. It is clear that pH is the over-riding factor governing the texture of the cooked product. Its importance in assessing the suitability of fish for processing was recognised earlier by Cowie and Little (51), who selected fish on the market for processing solely on the basis of pH, using a probe pH electrode pushed straight into the wet tissue. The dividing line between tough and acceptable frozen cod fillets has been found to apply also to fish *minces* from 16 Australian species caught by mid-water trawling and cooked after storage for up to a year at –18°C (52).

2. Cold Storage

There is little to add to what has been said already. Free water and some water associated with the protein structures of the muscle separate out as ice as the fish freezes. As cold storage continues, the individual muscle cells are less and less able to resorb the melt-water, after thawing. More water therefore drips out of the thawed fillets and the sensation of the cooked product becomes increasingly dry or fibrous.

The rate of deterioration is governed by the storage temperature; it is progressively slower at lower temperatures, but also varies with the species. Studies carried out at –14°C showed that the whiting (*Merlangius merlangus* L.) deteriorated the most quickly, reaching its limit after 10 weeks (53), whereas the lemon sole (*Microstomus kitt* Walbaum) required over 17 years to reach the same degree of deterioration (54). For this to happen, the muscle fibres must be dehydrated by the formation of ice bodies within the tissue. Frozen cod muscle deteriorates very quickly at -1.5, but no change occurs in supercooled muscle stored at the same temperature with no ice present (55).

The consequence of these phenomena is that fish which are already firm-textured through having a low final pH soon become unacceptable as a foodstuff if they are subsequently cold stored. More interestingly, high-pH fish which are sloppy-textured can actually be improved by a short period of frozen storage.

IV. THE SIGNIFICANCE OF GEOGRAPHY

A. Introduction

We have seen earlier that the colour of the red muscle of one particular stock of cod which swim great distances (the Svalbard-Lofoten stock) is more intense than that of

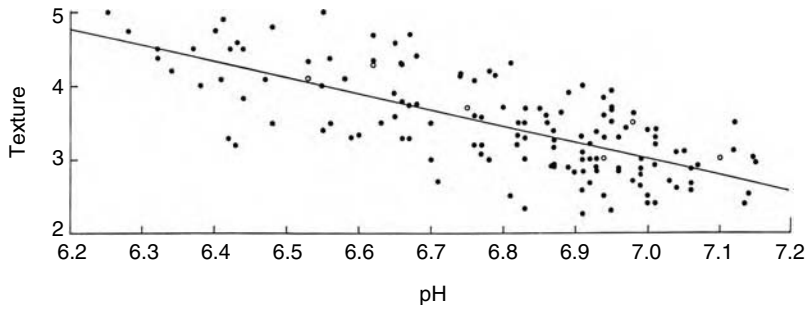

FIGURE 35.27 Influence of final pH on the texture of cooked cod fillets. Water contents of all samples limited to 80.0–80.9%. Texture scores above 3 represent firm or tough flesh, below 3 soft or sloppy. Two identical values are shown as hollow symbols. (Reference 49.)

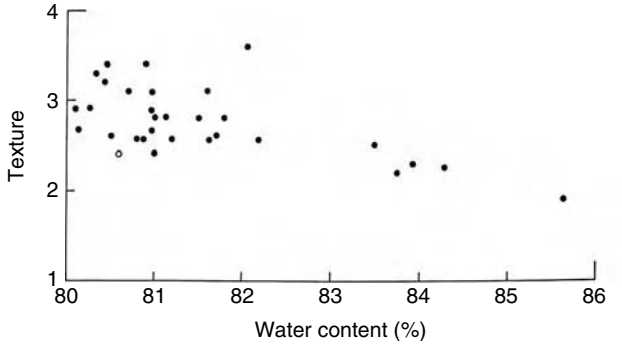

FIGURE 35.28 The influence of muscle water content on the texture of cooked cod muscle as eaten. All pH values were within range of 7.0–7.1. (Reference 49.)

more sedentary stocks. As regards food science, the effect is largely cosmetic but can lead to financial loss.We now consider whether the characteristics of any grounds are such as to affect the desirability of the fish as food.

It is easy to imagine that fish from widely-spaced enclosed bodies of water might differ from one another because of disparities in temperature, water-chemistry, identity of creatures consumed, etc. The chances of finding important differences between fish from widely spaced oceanic locations seemed much less promising, and a detailed survey was undertaken without much optimism (56). However, the results amply justified the enterprise, some characteristics of cod from the Faroe Bank (60-53 N 08-20 W) being significantly different from those of cod from the other grounds investigated.

B. The Faroe Bank Cod

1. The Fish Themselves

Figure 35.29 shows the fine appearance and corpulence of a Faroe Bank cod, quantified in Figure 35.30. Only the neighbouring Faroe Plateau cod are comparable. The livers were very large and creamy, showing how well the fish had been nourished. Early work on cod from Aberdeen Bank (57-05 N 01-15 W) showed that the water content of the muscle ranged from about 80% to 80.9% in well-fed fish during a span of twelve months (Figure 35.7), a value of about 81% or more signifying early stages of starvation (23). The white muscle of spring-caught Faroe Bank cod seems to be unique in having less than 80% of water (Figure 35.31) and more protein nitrogen (Figure 35.32) than cod from other grounds. Values for liver glycogen are high though not remarkable (56), but the final pH of the muscle is lower than in any other group (Figure 35.33). These fish were caught in the spring of 1966. Those caught in the autumn of 1968, when all the fish were sated, still maintained the uniquely low level of muscle water content, but the protein nitrogen and pH values were not remarkable. The others had caught up. The low value of muscle

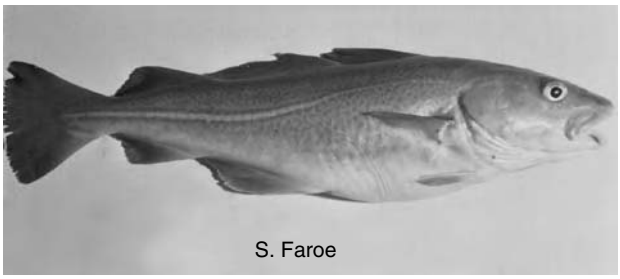

FIGURE 35.29 A cod from the Faroe Bank (length: 51 cm). (Author's picture. Crown copyright.)

water in Faroe Bank cod was observed again during surveys in September 1971 and September 1972.

In a small independent experiment (57), the total lipid content of the white muscle of Faroe Bank cod caught in the spring was 0.63%, compared with a value of 0.55% in Aberdeen Bank cod, while in the autumn the corresponding figures were 0.78% and 0.67%. This small difference appears to be important, as we shall see.

2. Consequences for Cold-Stored Cod

It has been concluded in a well-reasoned article (58) that the term 'quality' is often over-used and made to cover a variety of observations. Preferably, one should specify the parameter studied. Here we study the texture, flavour and appearance of the thawed, filleted and cooked product. Just looking at the superb appearance of the fish lying on the deck at 3 A.M. or so (night-fishing is the rule on the Faroe Bank), one instinctively feels that their overall 'quality' as an item of food must be at the top of the scale. In our survey (56), the fish were frozen whole very soon after capture, stored at −30°C for three months, thawed at low air temperatures, filleted and examined before and after cooking. These conditions are as near ideal as one can provide — but the quality scores for all three parameters were uniformly low.

a. Texture and Gaping

Because of the strong link between pH and texture, it has been suggested that the fish most suitable for long-term storage should have a pH not less than 6.6 (59) or 6.7 (60). In many of the Faroe Bank cod caught in the spring, the pH was lower than 6.6. As a result, the texture of the cooked product as tasted by a panel was firm, but that of the same fish after 3 months at −30°C, thawed and cooked, was judged to be unacceptably tough. (50). Similarly, because of the low pH of the muscle, the thawed fillets gaped. The fact of unacceptability in each case casts doubt on the suitability of these fish for freezing and cold-storage.

b. Flavour

The off-flavour developed by fish muscle during cold-storage (rancidity) has been likened to wet cardboard, boiled

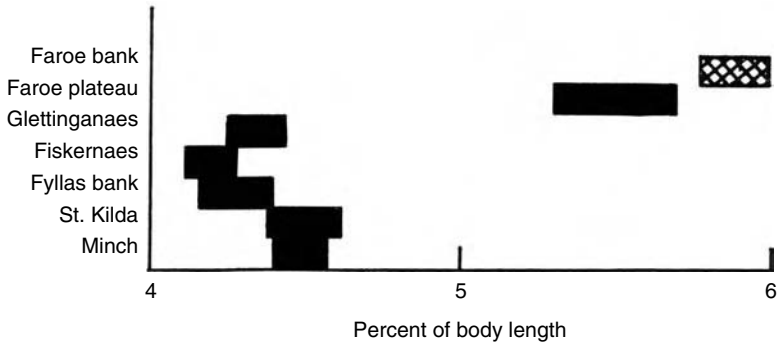

FIGURE 35.30 Corpulence of cod caught on different grounds in spring 1966, shown as the maximum diameter of the caudal peduncle expressed as a percentage of body length. Bars represent 95% confidence limits. (Reference 54.)

TABLE 35.1
Taste-panel assessment of cold-store off-flavour and off-odour of cod caught in spring 1970 on different grounds, gutted and stored for 3 months at −30°C. The fish were filleted and steam-cooked without seasoning before tasting. 0 = absent; 5 = very strong, the upper limit of commercial acceptability being about 3. Comparing the five grounds by analysis of variance by the *F* test showed that the mean results for the Faroe Bank differed significantly from the others for flavour ($P = 0.01$) and odour ($P = 0.05$). (Reference 64.)

Fishing Ground	Map Reference	Cold Store Flavour		Cold Store Odour	
		X	SD	X	SD

clothes and other poetic imagery. It results mostly from the oxidation of polyunsaturated fatty acids located primarily in the phospholipids, and has been identified as hept-cis-4 enal (61–63). Many factors govern the rate of the reaction, and the chemistry is complex: the subject has been reviewed recently in detail (64). Since the phospholipids are part of the structure of muscle cell membranes, they present a large surface area for oxidation, compared with the neutral lipids (triacyl glycerols) which are more 'compact' and contain a smaller proportion of polyunsaturated fatty acids. They are the main constituents of the fatty deposits used as stores of energy. The spatial distribution of the two types of lipid is important (64) and may help to explain inter-species differences.

Since the lipid content of cod muscle is usually less than 1%, it might be supposed that it would develop negligible rancidity compared with that found in more fatty species on cold-storage, but this is not necessarily so. The most likely reason is that the lipids of cod muscle consist almost entirely of phospholipids — triacyl glycerols make up only about 1% of the total (65).

In small samples of Faroe Bank cod, the white muscle was found to contain about 20% more total lipid than that in Aberdeen Bank cod, and this probably explains the fact that cold-storage off-flavour (and off-odour) was significantly greater in Faroe Bank cod than in cod from four other grounds (66) and considered unacceptable by the tasters (Table 35.1). Might it be possible to reduce the cold-storage off-flavour of cod by reducing their total lipid content? A further factor which may govern the propensity of frozen fish to become rancid is geographic latitude, which affects the temperature of the sea-water. The lipids of fish become progressively more unsaturated as the water becomes colder (more likely to become rancid), and *vice versa* (21, 67, 68). The purpose appears to be to ensure that the melting-points of structural lipids are below that of the environmental temperature so that they remain flexible.

Experimental starvation of Aberdeen Bank cod for 2 months (69) resulted in a water-content of 84% and some

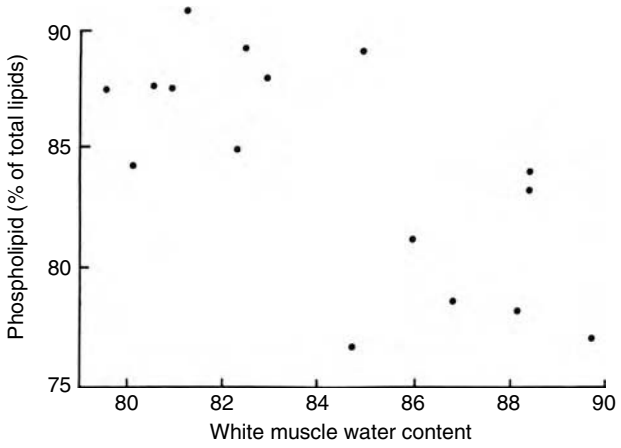

FIGURE 35.34 The decrease in proportion of phospholipids in the lipids of cod white muscle during starvation, shown by the increase in water content. (Reference 65.)

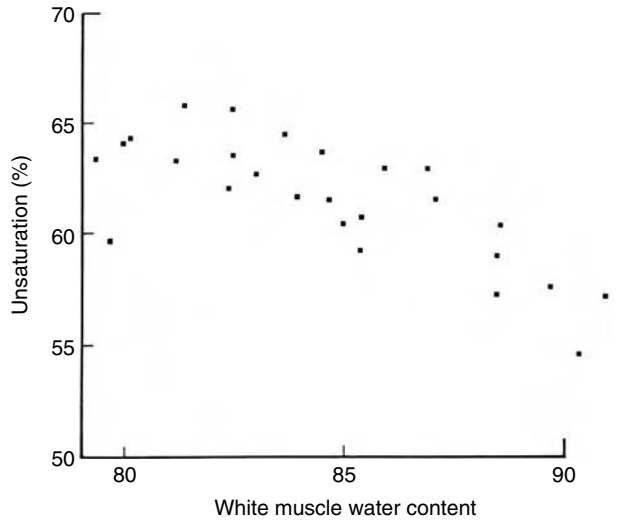

FIGURE 35.35 Decrease in the total polyunsaturation of cod white muscle lipids during starvation. Unsaturation represented as the sum of fatty acids 22:6, 22:5, 20:5, and 20:4 (% of total fatty acids). (Reference 65.)

TABLE 35.2
The effect of moderate starvation of cod on the development of off-odours and off-flavours during cold-storage at −10°C. (Reference 65.)

	Odour		Flavour	
	5 weeks	10 weeks	5 weeks	10 weeks
Fed controls (5 fish)	1.5	1.55	3.43	3.55
Starved fish (5 fish)	0.55	0.4	1.28	1.8
Difference	0.95	1.15	2.15	1.75
Significance level	1%	5%	0.1%	5%

Cis-4-heptenal values were as follows: starved cod muscle, 3.5 nmol/1000g wet muscle; fed cod muscle, 23.0 nmol/1000 g wet muscle.

reduction in the lipids of the muscle. The proportion of phospholipids (Figure 35.34) and the degree of unsaturation in the residual lipids (Figure 35.35) were also reduced. Freezing followed by cold-storage at −10°C resulted in a much reduced development of off-flavour and off-odour (Table 35.2). Analysis of hept-cis-4-enal confirmed the finding. Several factors may be involved here, although the results appear to be a simple cause and effect.

It is improbable that deliberate starvation will ever be used in practice to reduce the deterioration of flavour in cold-stored cod, but, as a water-content of 84% or more is often found naturally in late winter in this species, it suggests that advantage might be taken of the likely seasonal variation in off-flavour.

It should now be obvious that the difference between Faroe Bank cod and the others originates in an unusually rich food supply. There is a deep oceanic channel which keeps the fish separate from neighbouring stocks. We found that they were not eating particularly fatty prey, but that the stomachs were filled with echinoids, crustaceans, and sometimes fish.

3. Chilled Fresh Fish

One feature of Faroe Bank cod does favour them as an item of food, when compared with cod from at least one other ground. It keeps for a longer period in melting ice (1). This is clearly a result of the lower pH, which inhibits the activity of spoilage bacteria (70).

V. ACKNOWLEDGEMENT

The complex interactions described in this chapter have been supplemented and confirmed in species other than gadoids in a large number of reports published over 24 years by Professor Anna Kolakowska and her co-workers (71). It is a pleasure to pay tribute to the fine work of a colleague whom I have never met.

VI. CAVEAT LECTOR

The influences of geographical location on cod regarded as a foodstuff seem to be straightforward enough, but one can never assume that other species will behave in the same way. Cold-storage off-flavours develop strongly in herrings (*Clupea harengus* L.) but the off-flavour in cold-stored Atlantic salmon, another fatty species, seems to develop more slowly — salmon keep well in the deep-freezer. Triacyl glycerols in salmon muscle are found in the myocommata, so perhaps they protect the phospholipids within the myotomes from oxidation: it would be difficult to prove. Again, the starvation of rainbow trout results in a net increase in the unsaturation of the fatty acids of the flesh, but the flesh of the starving fish containing the highest concentration of docosa-hexaenoic acid does not develop more cold-storage off-flavour than those containing less (72). However, the apparent rises and falls of docosahexaenoic acid in this species are merely the results of outflow and inflow of triacyl glycerols.

There are usually traps for the unwary who try to derive generalised relationships from individual dynamic interactions. This is the way of much biological research.

36 Edible Shellfish: Biology and Science

Natalie A. Moltschaniwskyj
Tasmanian Aquaculture and Fisheries Institute, University of Tasmania

CONTENTS

I. INTRODUCTION

Commercially important edible shellfish include marine and freshwater animals that belong to two major taxonomic groups: the Mollusca and the Crustacea. The hard external shell is a common external characteristic that often results in the two groups being given the common name shellfish. Both groups are invertebrates that have no internal skeleton or vertebrae, and in most cases the external shell provides protection, support to soft body tissues, and a mechanism to deal with changes in the environment. The cephalopods (squid, cuttlefish, and octopus) do not possess an external shell, but are grouped with the shellfish by virtue of their molluscan taxonomic status.

This chapter will describe the general biology of edible shellfish species that are commonly eaten. The two major taxonomic groups will be described separately because their biology is so different. Given the importance of these species in harvest and aquaculture industries this provides the focus of research activities. The range of topics covered particularly relate to those aspects of the biology that are relevant to these animals as food, in particular the lifecycle, reproductive and feeding biology, movement, and behaviour.

II. MOLLUSCAN SHELLFISH

Molluscan shellfish have no typical shape or form and the body plan is changed and adapted to the environment (1). Edible mollusc predominantly belong to three broad groups: bivalves (e.g., oysters, mussels, and scallops), gastropods (e.g., abalone and *Trochus*), and cephalopods (e.g., squid, cuttlefish, and octopus), according to the number and arrangement of the shell(s). Bivalve molluscs have two symmetric or asymmetric shells joined by a hinge, while the gastropod molluscs have a single shell, and most of the cephalopods have no external shell. Most of the edible

molluscan shellfish are aquatic, mainly marine or estuarine, and relatively sedentary. Commonly harvested and cultured species include the ubiquitous Pacific oyster (*Crassostrea gigas*), the flat oysters (*Ostrea* spp.), scallops (*Pecten* and *Astropecten* spp.), a variety of mussel species (*Perna* and *Mytilus* spp.) and the small burrowing clam species (*Mercenaria* spp. and *Mya arenaria*), abalone (*Haliotis* spp.) and snails (*Trochus* spp.). The cephalopods either have an internal calcareous cuttlebone (cuttlefish), an internal chitinous pen (squid), or no shell (octopus). The only terrestrial edible mollusc is the land snail (*Helix*).

A. General Biology

The crystalline calcareous shell of the bivalves and gastropods is present from the larval form and provides protection from environmental changes, e.g., temperature, salinity and aerial exposure, and predators. Some species are attached to a hard substrate as adults by either a cement-like substance (e.g., oysters) or a byssus thread (e.g., mussels). The size and extent of musculature in bivalve molluscs is varied; oysters have small amounts of muscle tissue while scallops have a very large adductor muscle. Bivalves that burrow in soft sediments have an extendable muscular foot which they use to pull themselves into the sediment. Some species have limited mobility, for example, scallops can rapidly clap the two shells together which can result in the rapid ejection of water and using this jet propulsion small distances (<1 m) can be moved. Small clam species that burrow in soft sediment move by rolling around in the waves and then re-burrow using the muscular foot. Gastropods, which are more mobile than bivalves, have a large powerful muscular foot beneath the single shell which is used to pull the animal along hard substrates. The muscle tissue of scallops and abalone is the primary tissue eaten, with the gonad and digestive tissue removed, although the scallop may be marketed as "roe-on." In contrast oysters and mussels are eaten whole, typically with the gonad and digestive system as well as the small muscle. The athletes of the molluscan world are squid, which may undertake extensive migrations; the muscular body is essential for movement, respiration, and structural support.

B. Life-History

Most molluscs have a bipartite lifecycle with a relatively short planktonic free-living veliger followed by the benthic adult phase (Figure 36.1). Individuals hatch as a trochophore and within 24 hours a larval shell develops. This is followed by the development of a veliger (also referred to as D-veliger due to the distinctive D shape), which lasts between several days to a month. A short planktonic phase (<5 days) is typical of abalone species and the veligers are non-feeding. A longer veliger stage (c. 20 days) is more typical of many bivalve molluscs and the veligers actively feed on phytoplankton using the velum, a fringe of beating cilia. The velum also provides some mobility in the water column, allowing the veligers to adjust their position in the water column. The planktonic phase is important for a number of reasons as it allows offspring to colonise new areas and also for these individuals to avoid the risk of predation close to the reef. Once the veliger is ready to settle onto the substrate, a change in morphology begins and a 'pediveliger' develops, which has a foot that extends out of the shell and is able to test the substrate before deciding to settle (Figure 36.1). Once a suitable place for settlement has been selected the individual secretes either a cement or byssal threads to attach itself. The pediveliger finally undergoes metamorphosis into the adult form and takes up a sedentary lifestyle.

In some species the female brood the veligers inside her shell, e.g., the flat oyster (*Ostrea* sp.). Fertilisation occurs within the shell environment of the female, using sperm released into the water by males. Veligers are attached by the velum to the female ctenidia (gills) and they use the food filtered by the mother's ctenidia. Shortly before metamorphosis veligers are dislodged and expelled out of the mother.

The selection of settlement sites by the larvae is critical for species with a sedentary adult phase, as conditions for feeding and reproducing must ensure survival. The site must provide water currents for delivery of food and removal of faecal wastes and there must be individuals of the same species in close proximity for reproduction. Selection of settlement sites can range from general to specific, and is generally species-specific. The presence of conspecific adults can be important as this suggests a suitable environment for growth and reproduction (2). Characteristics of the rock surface, e.g., rugosity or presence of algal and bacteria

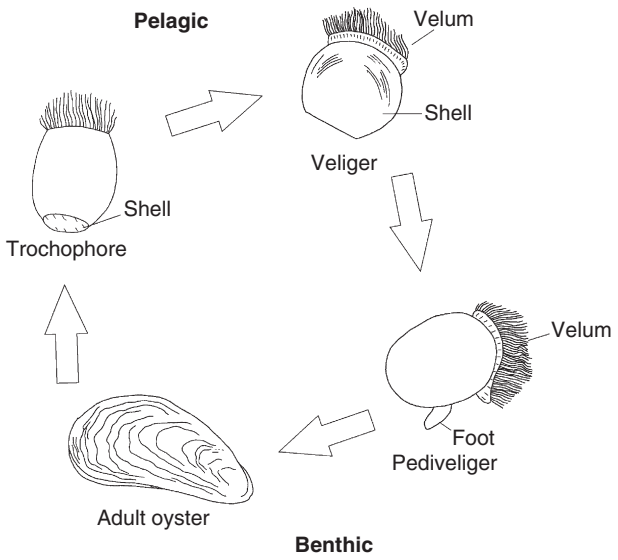

FIGURE 36.1 Lifecycle of an oyster.

species (3), or sediment characteristics of soft shores may be cues for settlement. Factors affecting settlement are of interest to ecologists, particularly with respect to human impacts on shore environments that may modify the substrate and make it become less suitable for settlement by juveniles. Many aquaculture ventures rely on collection of wild spat for on-growing to adults and are exploring suitable materials to enhance settlement rates (4). Hatcheries also need to use suitable surfaces to maximise settlement rates of juveniles. It is possible to induce settlement of pediveligers in culture conditions by exposing them to neuroactive compounds, e.g., L-DOPA. This induces settlement and the metamorphosis of the pediveliger into a spat, without the pediveliger going through the process of selecting a suitable substrate (5). The use of these compounds by shellfish hatcheries allows efficient management of stock by forcing settlement to occur when the hatchery is ready to deal with large numbers of juveniles and it also promotes synchronous settlement of larvae.

C. Reproduction

All molluscs reproduce sexually, with separate sexes in most species (dioecious), e.g., mussels and abalone. However, some species have both sexes present simultaneously (monoecious or hermaphrodism), e.g., scallops have a creamy coloured testis and orange coloured ovary present at the same time. In a few species sex change can occur (sequential hermaphrodism), with sperm being produced in smaller younger individuals, then a change to female in some bigger and older individuals. Many *Crassostrea* oyster species are hermaphroditic or will undergo sex change, which is a function of both secondary genes and/or environmental conditions (6). In oysters and mussels the reproductive tissue is not contained within a discrete organ or region of the body. Instead, gametes are produced in tissue surrounding the digestive system. Other shellfish, e.g., abalone and scallops, have a discrete organ for gamete production which is clearly identifiable.

Spawning in most temperate molluscs is seasonal, either in the spring/summer, e.g., oysters and scallops, or winter, e.g., mussels. Many tropical species may not show distinct spawning seasons, but a component of the population will always have some individuals that are reproductively mature and spawning. Prior to egg and sperm production individuals build up a store of energy reserves, usually glycogen. At some point during the year an environmental trigger, usually water temperature or day length, will stimulate the use of these glycogen reserves to produce gametes (7). Once gametes start to be produced individuals undergo a period of maturation before being ready to spawn and at this point the gonad may constitute most of the individuals' body mass. Gametes are released either in a single spawning episode or in a series of spawning episodes over several days to weeks. After the release of gametes there is a dramatic decrease in the mass of soft tissue and the flesh is flaccid and watery. As the tissue is unsuitable for consumption animals are not harvested for approximately a month after spawning to allow accumulation of carbohydrate reserves to begin.

As many molluscs are sedentary, gametes are released into the water column and fertilisation of eggs by sperm is external; this is referred to as broadcast spawning. Spawning in the population is co-ordinated to ensure that males and females release gametes simultaneously and that the density of gametes in the water is high enough to ensure high rates of fertilisation. The co-ordination of broadcast spawning within the population may be triggered by factors such as changes in water temperature or salinity, lunar and tidal cycles, and increasing or decreasing day length.

The squid, octopus, and cuttlefish have a more complex reproductive system in which, often following extensive courtship, the male passes packages of sperm (spermatophores) to the female (8). The female fertilises each egg and packages it in a jelly-like substance that provides protection for the developing embryo. Eggs are either attached to the reef or macroalgae individually (e.g., octopus and cuttlefish), laid in finger-like strands with multiple eggs in each strand (e.g., reef-associated squid) or unattached large balloon-like masses that float in ocean currents (e.g., oceanic squid) (8). Female octopus will guard and care for the eggs until they hatch, as miniature adults that are capable of jetting, inking, capturing prey, and avoiding predators. The squid and cuttlefish do not provide any parental care of the eggs or the juveniles.

D. Triploidy Production

Oysters, mussels, and clams are eaten whole without the gonad and digestive tissue removed prior to consumption. Taste tests have demonstrated that consumers prefer to eat oysters when the tissue is full and creamy and full of glycogen reserves, but before the animal is ripe with gametes (9). Given that individuals have high levels of glycogen for relatively short periods this means that marketable stock may only be available seasonally. Over the past 10 years there has been interest in the production of sterile oysters, i.e., individuals that are unable to produce gametes. In sterile individuals glycogen reserves are accumulated but not used for reproduction, resulting in the production of stock that are suitable for consumption over an extended period of the year. An additional benefit of producing sterile animals is that exotic aquaculture species may be farmed in new areas without the risk of introducing a species that may be detrimental to native flora and fauna (10).

In molluscs sterile animals have been obtained through the production of triploid individuals (11), which have 50% more chromosomal material than ordinary diploid individuals. Currently, triploid Pacific oysters are being produced by the aquaculture sector in the U.S. and

Australia (see review 12). Triploid oysters usually exhibit reduced gonad development and acceptable meat condition through the inhibition of spawning and faster growth rates (12). Currently the most popular and successful method of producing triploid molluscs is by blocking the formation and release of a polar body in the newly fertilised egg (11). The additional chromosomal material in cells prevents or limits the process of cell division associated with gamete production (meiosis), thereby causing an extra set of chromosome to be retained. Methods used to induce triploidy in oysters are either physical, e.g., temperature and pressure, or chemical, e.g., caffeine. Immersion of newly fertilised eggs in cytochalasin B, a fungal antibiotic, is currently the most effective method and is commonly used by commercial hatcheries.

Methods of triploidy induction in the aquaculture industry need to ensure a high percentage of triploids (ideally 100%), high survival rates and low rates of abnormality in the veligers, and consider operator safety and consumer acceptance. Unfortunately cytochalasin B is classified as a carcinogen and is a potential hazard to operators at bivalve hatcheries. The future use of cytochalasin B is in doubt, both because of its toxicity and because triploidy induction is not 100% effective, usually about 80%. Current research is exploring methods of producing triploids commercially that are potentially less hazardous and more reliable. One recent approach has been to cross tetraploids, individuals with double the normal genetic complement, with diploids (13). This method has successfully produced 99.9% triploids and the veligers have survivorship rates that are comparable with normal diploid oysters. Furthermore, these triploid individuals are produced without the use of artificial treatments and toxic substances.

E. Feeding

Bivalve shellfish (oysters, mussels, clams, and scallops) are filter feeders, using specialised gill structures (ctenidia) to selectively remove phytoplankton and organic matter from the water. The ctenidia have cilia that generate current and the movement of water into the animal as an inhalant flow. Each species is able to select particles within a very narrow size range (3–24 μm). Particles that are too small or too large are rejected by the ctenidia, bound in mucus, and expelled in a strand through an exhalent flow as pseudofaeces. Particles that are suitable for ingestion are passed to the mouth (labial palps) using the cilia on the surface of the ctenidia. Ingested food is bound in a strand of mucus and enters the digestive system by being drawn in by a crystalline style, which releases digestive enzymes. Once the digestive process has been completed faeces are released into the exhalent current and moved away from the animal.

Oysters can filter several litres of seawater daily and the advanced filter feeding mechanism allows bivalves to regulate the efficiency of particle retention and absorption. The rate of pumping and retention of food particles is modified in response to the density of particles in the water while maintaining respiratory functions. If the density of particles in the water is too high the ctenidia become clogged and rates of pseudofaeces production increases. Other factors that affect feeding rates in bivalves are water current, water temperature, salinity, turbidity, and dissolved oxygen (14).

Most edible gastropod molluscs are herbivorous grazers (e.g., abalone), but there are a small number that are carnivorous predators (e.g., trochus, conch, and whelks). Grazing molluscs use a radula, a protrusible tongue-like structure with a complex ribbon of teeth, with which they scrape algae and biofilm off rocks or tear and cut macroalgae. As teeth at the front of the radula wear out they are replaced by secretion of new teeth at the back of the radula. Some of the carnivorous molluscs have specialisations of the radula that allow them to bore holes through the shell of prey or harpoon prey. After maceration of food the radula carries particles of food backwards and into the digestive tract. Digestion is usually extracellular in the stomach and digestive gland.

Squid, octopus, and cuttlefish are voracious carnivorous predators. Squid and cuttlefish predominantly eat crustaceans and fish which are captured using contractile tentacles (the longest of the arms). Octopus species eat predominantly crustaceans and molluscs and they are able to deal with the hard outer parts by either drilling through the shell or in the case of bivalves pulling apart the two valves (15). Members of this group have a parrot-like beak which is used to tear tissue into small pieces and the salivary gland secretes enzymes that are used to break down flesh prior to ingestion. Once in the stomach enzymes secreted by the digestive gland continue digestive processes.

F. Shellfish-Associated Disease Outbreaks

Ingested particles, including bacteria and viruses, are digested by bivalves and then either absorbed into the tissues or excreted. As result of pathogenic micro-organisms being retained and absorbed molluscan shellfish become vectors of bacterial and viral pathogens. The rate of pathogenic micro-organism uptake and retention is a function of the density of micro-organisms in the water being filtered. Oysters may accumulate pathogens to levels as much as four times greater than levels in the water from which food is being removed (16). If shellfish (e.g., oysters) are consumed raw and whole with the digestive system still intact the pathogenic microbes present in the tissue and gut pose a health risk to the consumer. In the U.S. from 1991–1998 the consumption of raw or partially cooked shellfish resulted in more than 2,000 illnesses.

Viral agents that are of chief concern in world shellfish industries are human enteric virus, Norwalk virus,

and hepatitis A. All cases of food-borne viral diseases from shellfish have occurred due to human faecal contamination in areas where shellfish are harvested and the consumption of shellfish that is raw, steamed, incompletely cooked, or frozen. Bacterial agents, particularly *Vibrio* spp. have been identified as being pathogenic or potentially pathogenic to humans (17). Unlike virally associated disease outbreaks, contamination by *Vibrio* tends to be more sporadic and involve individual cases (18). Where outbreaks have occurred they have been associated with *V. vulnifucus* septicaemia with 50% mortality rates (19), or epidemics of cholera caused by consumption of raw shellfish contaminated with *V. cholerae* 01 (20). *Vibrio* spp. naturally occur in estuarine and marine waters and are not associated with faecal contamination; however, numbers of *Vibrio* in shellfish can increase in improperly stored shellfish (21). Some pathogenic bacteria may not naturally occur in marine and estuarine environments, but are associated with incorrect storage, faecal pollution, or infected food handlers may contaminate shellfish. Enteric bacterial pathogens that have been implicated in shellfish associated disease outbreaks are *Clostridium perfringens*, *Salmonella,* and *Shigella* (22).

A factor influencing the timing and occurrence of shellfish-related outbreaks is the ability of shellfish to selectively accumulate viruses. Selective accumulation can be attributed to the feeding mechanism when there is ionic bonding of viral particles to the shellfish mucus. There is evidence that the seasonal occurrence of shellfish-related illnesses by enteric viruses may be due to oysters undergoing seasonal physiological changes that affect their ability to accumulate viral particles (16).

Current practice to remove pathogenic micro-organisms is to put shellfish through a depuration process after harvest. This process provides conditions for shellfish to purge their digestive system of their gastrointestinal contents, thereby supposedly removing the micro-organisms that had been taken up during filter feeding. Depuration is typically conducted in an isolated system, with temperature controlled re-circulating seawater. The seawater should be continually cleaned, e.g., using a UV steriliser attached to the re-circulating system. The temperature of the system needs be stable and set at a level that encourages the shellfish to filter the clean seawater.

The ability of depuration to remove pathogens is dependent upon a number of factors. (1) The molluscs must feed normally in the system; if active pumping and filtering of seawater do not occur then microbes present in the gut will not be purged. (2) Variability in the loads of micro-organisms among individual animals may result in differential removal of pathogens. (3) The depuration conditions (water temperature and salinity) that are suitable for normal feeding are species specific. (4) Microbes that have been incorporated into body tissues will not be removed, only those pathogens currently resident in the gut and on the gills will be removed. (5) The ability of the disinfection technique to inactivate the purged microbes; if purged microbes are not killed by the disinfection system then re-infection of animals in the depuration system is likely.

G. Shellfish Toxicity

Paralytic shellfish poison (PSP), amnesic shellfish poison (ASP), and diarrheic shellfish poisoning (DSP) are caused by naturally occurring biotoxins that accumulate in molluscan shellfish (review 23). These biotoxins are caused by microscopic toxin-producing dinoflagellate phytoplankton that naturally occur in marine waters, normally in amounts too small to be harmful. However, on occasion, a combination of warm temperatures, sunlight, and nutrient-rich waters can cause rapid plankton reproduction, or "blooms." The toxins in the microalgae ingested by shellfish build up and become concentrated in the gut and somatic tissues. This may result in mass mortalities either through toxins affecting the shellfish, or high densities of phytoplankton clogging the ctenidia and causing asphyxia. The toxins also pose a health hazard to humans consuming contaminated shellfish. As cooking does not break down the toxins and many shellfish are eaten raw, the toxin is ingested by humans and other predators. Although first recognised and described in Canada, PSP and ASP have been found worldwide (24).

Paralytic shellfish poisoning is caused by a suite of neurotoxins (saxitoxins) produced by species such as *Alexandrium* spp. and *Gymnodinium catenatum*. The type and storage of paralytic shellfish toxins in bivalves species vary considerably. Mussels, clams, and scallops appear to accumulate high levels of saxitoxins, while in oysters the levels of the toxins are low or absent (23). Amenesic shellfish poisoning is linked to the presence of domoic acid produced by the diatoms *Pseudonitzschia* spp. and *Nitschia* (24). Shellfish appear to concentrate the toxin and again the response to the toxin is species specific. Scallops and mussels appear to be unaffected, while oysters become physiologically stressed. Diarrheic shellfish poisoning occurs when shellfish containing okadaic acid are eaten. Okadaic acid and its derivatives are produced by the dinoflagellates *Dinophysis* spp. and *Prorocentrum lima* (25). As with other toxins there are differential effects among the bivalve species and seasons and the length of time the toxins remain in the tissue. Blue mussels in Sweden can retain toxins for up to five months after accumulation, although high levels of toxins are not necessarily associated with any known health effects (23).

The economic cost of both human pollutants and naturally occurring biotoxins is high for countries that have shellfish harvest and aquaculture industries. The presence of toxic algae has been responsible for the collapse of bivalve populations in Alaska, and fisheries and aquaculture are closed for extended periods in countries such as Sweden,

Norway, the U.S., Spain, and Australia (23). The costs incurred with the occurrence of toxic algae blooms are associated with (1) the need to have expensive shellfish monitoring programs to assess the presence of contaminants, (2) the cessation of harvesting and selling of produce, and (3) the development and running of depuration systems. Current research is focussed on how effective the depuration process is at removing the toxins and how the toxins are removed from different organs. Understanding how toxins are accumulated, transformed, and eliminated allows the time course of the toxic episode to be predicted and hence how long harvest of animals should be suspended. It is possible that toxins are transformed in the body tissues and then excreted from the animal over time, although there is evidence that metabolism of the PSP toxins is more complex than just a transformation of toxic compounds (26).

H. Bioaccumulation and Biomonitoring

As a result of the relatively sedentary lifestyle of many shellfish and their modes of feeding (filter feeding and deposit feeding) many species ingest or uptake and retain trace metals present in the environment. Molluscan shellfish can accumulate heavy metals (e.g., copper) and organic contaminants (e.g., pesticides) in body tissues. Marine molluscs tend to accumulate arsenic, cadmium, copper, lead, mercury, silver, and zinc, but have a low tendency to accumulate chromium. As a result of the accumulation, concentrations of these trace metals in body tissues can be many times higher than present in the environment (27). This accumulation of heavy metals and contaminants has two problems. The first is that many of these animals are prey of higher order predators and as a result serious pollutants enter the food chain and are present in higher concentrations further up the food chain (biological amplification). The second problem is that many shellfish species and their predators are a food source for humans and as a result are a health hazard.

One advantage of sedentary molluscs accumulating heavy metals, viruses, and bacteria is that they provide a time-integrated measure of the bioavailability of these contaminants (see review 28). As such, some bivalves are used as sentinel species to monitor or assess concentrations of contaminants available for uptake in the environment. Such biomonitoring involves assessing the effects and levels of contaminants in the environment on animals. Uptake of contaminants varies among and within species as a function of factors such as size, age, sex, and among geographic locations due to environmental factors such as temperature and salinity. However, it is possible to move healthy individuals into cages at sampling locations and assess the levels of contaminants after a period of time. For example, mussel species (*Mytilus edulis* and *M. californicus*) are commonly used around the U.S. coastline as sentinel species for biomonitoring because they are endemic, abundant on many coastlines, and tolerate translocation. Another example, is the use of oysters to assess the bioavailability of tributyltin (29), a compound has been implicated as a cause of shell thickening in many oyster species (e.g., 30).

III. CRUSTACEAN SHELLFISH

Edible crustaceans all belong to a group known as decapods which are the largest and most specialised of the crustacean species. They are characterised by a heavily segmented body and a chitinous exoskeleton which provides an outer protective shell that is articulated like body armour. All edible crustaceans are aquatic, with most occupying marine and estuarine habitats, but some crayfish and prawns are found in freshwater. Crustaceans are benthic but highly mobile, e.g., prawns swim regularly and some lobsters undertake long migrations. Commonly harvested and cultured edible crustaceans include prawns (shrimps), both freshwater (e.g., *Macrobrachium* spp.) and marine (e.g., *Penaeus* spp. *Metapenaeus* spp.), crabs (e.g., *Callinectes sapidus, Scylla serrata*), clawed lobsters (e.g., *Homarus* spp. *Nephrops* spp.), spiny lobsters (e.g., *Palinurus* spp., *Panulirus* spp., and *Jasus* spp.) and crayfish (crawfish and yabbies).

The common names used to describe edible crustaceans are often confusing. The distinction between prawns and shrimps may be based upon the taxonomic group and the habitat of the adults (31). Freshwater species, e.g., *Macrobrachium,* are often referred to as prawns, while marine and estuarine species (e.g., penaeids) are shrimps. Alternatively, size of the adults is often used to distinguish among the two names; with shrimps being small species and larger species prawns. Similarly, there is often confusion over use of the common names lobster and crayfish. Again the distinction is made taxonomically, but generally lobsters are marine (this includes both clawed and non-clawed species), and crayfish or crawfish are freshwater.

A. General Biology

The general body plan is similar among the decapod crustaceans with two sections making up the body: the fused head and thorax (cephalothorax) and the tail (abdomen). Each section is made up of a series of segments, but the number of segments and specialisation of segments varies among species. The cephalothorax is completely fused with no external segmentation visible, the shell (carapace) surface of the cephalothorax may be smooth or covered with spines depending on the species. In contrast, the abdomen is distinctly segmented. Attached to both sections are specialised paired appendages, the number of which depends on taxonomy and function of the appendage. Around the head and mouth appendages are modified for food capture and feeding (mandibles, maxillae, and maxillipeds). The head also has antennae, antennules, and a pair

of stalked compound eyes. The corneal surface of the eyes is convex and, when on a stalk, the cornea may cover an arc of >180°. The remaining appendages (pereiopods) on the cephalothorax are used in crawling or walking. The first pair of pereiopods in lobsters and crabs is modified as a claw (chela), which may be large and distinctively coloured. Appendages attached to the abdomen (pleopods) are used for swimming, as well as egg attachment in some species, e.g., crabs and *Macrobrachium*. The last pair of pleopods (uropods) and the telson, at the terminal end of the abdomen, forms a tail fan that can be used for locomotion using a rapid flexing motion. Appendages may be specialised in some species for fighting, courting, and egg handling.

Prawns in the genus *Penaeus* and *Macrobrachium* are commercially the most important in the world. They are cylindrical with a well-developed abdomen and an exoskeleton that is thin and flexible. Many penaeid shrimps use the pleopods to excavate shallow burrows in soft bottoms during periods of inactivity. Shrimps move predominantly by rapidly beating the large fringed pleopods, but rapid flexion of the abdomen and the tail fan will allow fast backward movement.

Lobsters and crabs have a dorso-ventrally flattened body, with a heavier and stronger exoskeleton, and the strong claws (chelipeds) have a lot of musculature which is a commercially valuable part of the animal. The abdomen in crabs is reduced and folded under the cephalothorax, the uropods are absent, but large and strong legs on the cephalothorax are used for walking which is the primary mode of locomotion. Reduction of the abdomen allows rapid crawling and they commonly move sideways. In contrast to crabs, lobsters have a very well-developed tail (abdomen), which has a high monetary value given the high tail to body ratio. The legs allow lobsters to crawl while the muscular tail allows fast flexing of the abdomen resulting in rapid backward movement. Spiny lobsters (*Jasus, Palinurus,* and *Panulirus* spp.), present in both tropical and temperate waters, do not have chelipeds, and it is the meat in the tail that is prized. The shovelnose or slipper lobsters (*Scyllarus* and *Thenus* spp.) have a dorso-ventrally flattened body with short, flattened antennae, compared with the cylindrical body and long antennae in clawed and spiny lobsters.

B. Life History

Crustaceans have a more complex life history than molluscs and each stage has distinct behavioural and ecological characteristics (32). Most crustaceans have separate sexes and generally hold their eggs, either in brood sacs or attached to the abdominal appendages. Like many marine invertebrates the crustaceans have a bipartite life history, with a free-living, planktonic larval phase, followed by a benthic adult phase. The stages, forms, and time spent as larvae are highly variable among the decapod crustaceans, often depending on how much development occurs in the egg. However, all the decapod larvae undergo a series of developmental stages during which the larvae metamorphoses into a more advanced form until the final adult form is developed. The different stages of the life history are often associated with different and distinct habitats.

Penaeid prawns undergo several distinct larval and juvenile phases that are associated with different habitats (33). The embryonic phase is short and, as a result, the newly hatched larvae (nauplii) are less morphologically developed than some of the newly hatched forms of other decapod crustaceans (Figure 36.2). The nauplius is the first larval phase and it has only three pairs of appendages which are all used for swimming. Furthermore, the nauplii do not feed and are supported by the maternal yolk reserves that are present when they hatch. The nauplii metamorphose first into feeding protozoea and then a mysis (Figure 36.2), both of which live in offshore waters. Metamorphosis of the mysis produces a megalopa which migrates to brackish inshore waters. The megalopa undergoes metamorphosis into a benthic juvenile which uses estuaries as a nursery habitat. Adults then move from the estuaries back to deeper and full salinity water offshore.

Freshwater prawns, such as *Macrobrachium*, and crabs hatch out as planktonic zoea, advanced larval forms that use thoracic appendages to swim upside down (Figure 36.3). The freshwater *Macrobrachium* have a zoea that lives in estuarine environments as it needs brackish water (34); they are carnivorous, eating zooplankton, worms, and larval forms of other invertebrates. Zoea undergoes a series of developmental stages before becoming a postlarva (*Macrobrachium* prawns) or megalopa (crabs). *Macrobrachium* pelagic postlarvae move upstream towards less saline water swimming with the dorsal side uppermost. During this migration the postlarvae start to undergo the transition to the adult benthic habit. The size at which postlarvae start the upstream

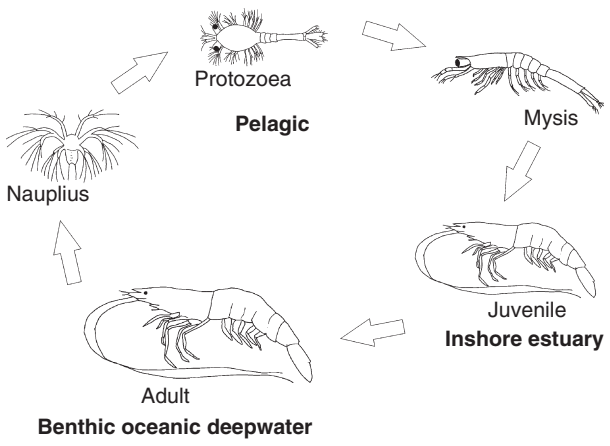

FIGURE 36.2 Lifecycle of a penaeid prawn.

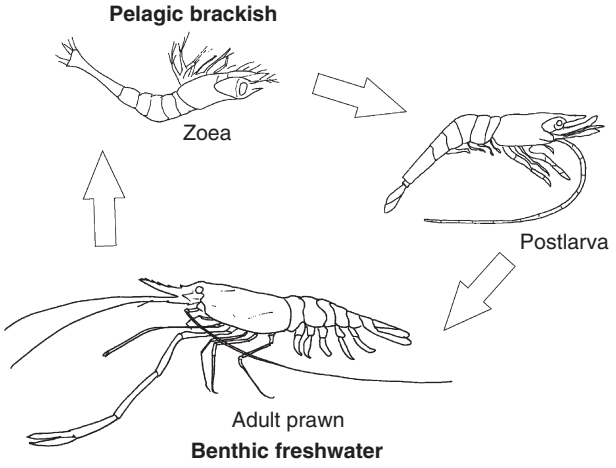

FIGURE 36.3 Lifecycle of the freshwater prawn *Macrobrachium.*

migration is thermally driven and low temperatures can bring about migration in small individuals.

The larval and post larval phase of *Homarus* lobsters is about 6–8 weeks long. They have a very short nauplius phase and quickly metamorphose into a larval form; the first three larval stages are very similar to the zoea phase of the crabs and are sometimes called mysid larvae (35). The zoea of *Homarus* lobsters undergoes a series of developmental stages, ultimately becoming a postlarva (equivalent to the megalopa). Postlarvae undertake the transition from a planktonic to a settling and finally a benthic juvenile through behavioural response to light, gravity, and water pressure. The early benthic juvenile phase is highly cryptic as these individuals use shelters until they are big enough to avoid predation.

The life history of spiny lobsters (palinurids) differs from the other decapod Crustacea in that the nauplius stage is very short (several hours) before development into a larvae (phyllosoma). The phyllosoma is dorso-ventrally flattened, transparent, and very thin (36), a body form that is suitable for the passive dispersion of these larvae in ocean water currents. The phyllosoma phase is very long, lasting as much as 391 days and potentially larvae are carried considerable distances (>1000 km). This extended dispersal phase makes it difficult to locate and collect the phyllosoma in oceanic waters and as a result little is known about their biology. There are 7–13 phyllosoma stages and the last phyllosoma stage metamorphoses into a non-feeding, transparent, and free-swimming puerulus (postlarvae). Puerulus use energy stores acquired as phyllosoma until metamorphosis into a feeding post-puerulus or juvenile. Benthic puerulus are vulnerable to predation and therefore initially hide in cracks and crevices, or in burrows. As a result of this cryptic behaviour it has been difficult to determine the cues important in the selection of settlement sites and habitats. Once juveniles are large enough to protect themselves from predators they begin to adopt a more typical adult lifestyle and a scavenging and omnivorous diet.

C. Growth and Ecdysis

The hard exoskeleton of the crustaceans is a non-living layer that plays a role in protection, gaseous exchange, and support. However, it is unable to increase in size, and therefore growth is constrained by this hard exoskeleton. An increase in size occurs only after the old exoskeleton has been shed (moult) and a new exoskeleton has formed and hardened. The process of moulting is called ecdysis and as a result the process of growth is incremental rather than continuous. During the moulting process the animal increases in size by absorption of water, but somatic growth occurs between moults. Many aspects of the life of crustaceans, including growth and reproduction, are directly under the control of the physiological changes associated with the moulting cycle.

The process of moulting can be divided into five distinct stages (37):

1. Premoult. Animals are getting ready to discard the old exoskeleton by starting to break down the exoskeleton. Enzymes are released that start dissolving the old skeleton, and calcium and other materials are absorbed from the old shell. The epidermal cells beneath the cuticle increase in size and begin to secrete the new exoskeleton which is deposited beneath the old exoskeleton.
2. Moult. As the animal increases in size through ingestion of water the internal pressure causes the weakened old exoskeleton to split at the membrane between the cephalothorax and the abdomen. The animal pulls itself out of the old exoskeleton and emerges out of the original shell. The new exoskeleton is present, but is soft and pliable and the animal is defenceless until it hardens. Water continues to be absorbed to increase body size.
3. Postmoult. The new exoskeleton hardens by the re-deposition of calcium and other soluble materials that were stored from the dissolution of the old endoskeleton. The exoskeleton is still soft and animals are vulnerable to predation.
4. Intermoult. This is the period between moults during which time the water absorbed by the animal during the moult is replaced by somatic tissue. In the early stages of the lifecycle, when the larvae and juveniles are growing quickly and undergoing metamorphosis, the intermoult periods are relatively short. However, once the adult phase is reached, moulting occurs less frequently and the intermoult periods are longer.

Crustaceans may lose appendages through accidents or shed appendages voluntarily in a process called autotomy (38). In the decapod crustaceans there is a specific site on an appendage at which autotomy can occur. This means that, regardless of where the damage has occurred, the appendage will always be dropped off at that point. Once an appendage has been shed cells at the breakpoint begin to enlarge and a regenerated appendage is formed, complete with exoskeleton. Regeneration can only occur during the premoult phase; therefore the animal cannot form a new limb until it is passes through the next moult cycle. If an individual has lost a large number of appendages then the intermoult phase may be shortened and the next moult cycle will start earlier (38).

Growth rates of many crustacean species have largely been described under culture conditions. However, models of population dynamics and stock assessment required for fisheries management rely heavily on accurate estimates of growth rates of wild animals. In fish, hard structures like scales and ear bones (otoliths) grow in such a way as to leave a record of somatic growth. However, the lack of permanent hard structures in crustaceans that contain a record of somatic growth is problematic when estimates of age are need. Tagging studies on wild populations have been used to estimate growth rates (e.g., 39); however, this relies on adequate recovery rates of tagged individuals and retention of tags during moulting cycles. Recently, it has been discovered that both freshwater and marine crustaceans have deposits of an autofluorescent neurolipofuscin that accumulates in the eyestalk ganglion and the concentration of which is correlated to the physiological age of the individual (40, 41). The neurolipofuscin pigment can be extracted from the tissue using solvents and the intensity of fluorescence is used as a measure of neurolipofuscin concentration (42). Alternatively, tissue sections prepared histologically can be viewed under a specialised microscope and the density of fluorescing granules estimated (41). As deposition rates of neurolipofuscin are related to the physiological, not chronological, age of individuals the rates of deposition are modified by environmental factors such as temperature (43). Despite this lipofuscin concentration has the potential to be used to estimate growth rates and determine year-class strength in populations for fisheries management.

D. Hormonal Control of Moulting and Reproduction

The cyclic processes of moulting and reproduction have a major impact on adult physiology and are under the control of hormones (44). The neurosecretory X-organ, located in the eyestalk of many decapod crustaceans, produces moult-inhibiting hormone (MIH) and vitellogenesis-inhibiting hormone (VIH). These hormones once released by the X-organ are sent to a sinus gland, also in the eyestalk, and then released into the hemolymph (blood). If the concentration of moult-inhibiting hormone decreases in the hemolymph this promotes the release of moulting hormones (ecdysteroids) from the Y-gland, located near the mandible muscles. Low concentrations of moulting hormones are present during postmoult and intermoult periods, but they increase during early premoult which starts the processes of moulting, followed by a decrease prior to moulting. Likewise, low concentrations of VIH result in the release of reproductive hormones and the process of egg production begins.

Although the moulting cycle is controlled hormonally factors that initiate moulting are often external, e.g., food, temperature, and day length. Given that aquaculture requires the control of all aspects of an animal lifecycle, including growth and reproduction, there is some understanding of the hormonal control of moulting and how this can be manipulated. In the 1970s it was found that destroying the eye stalk (ablation) will induce non-gravid female shrimp to mature and produce eggs. Eyestalk ablation will reduce the intermoult phase, induce stimulation of ovarian development, and accelerate the rate of ovarian development due to the absence of the moult-inhibiting and vitellogenesis-inhibiting hormones (45). Today eyestalk ablation is used in almost every marine and seawater shrimp aquaculture facility to shorten the intermoult phase, accelerate growth rates, and to produce animals with soft shells for market. In aquaculture the ability to control reproductive activities and ensure the production of eggs and sperm when required has many advantages; (1) it allows development of selective breeding programs, (2) it is possible to promote reproductive development and not be seasonally dependent on natural reproductive cycles, and (3) control spawning activities which can increase the proportion of females that spawn at any time. Therefore, hatcheries use eyestalk ablation as a way to advance reproductive activities and synchronise spawning.

E. Reproduction

The sexes are separate in the decapod crustaceans; in females a pair of ovaries and in males a fused pair of testis is located in the cephalothorax. In some species, shortly after the female becomes sexually mature she must undergo a moult at which time she is able to mate and receive sperm from males. Males have an opening (gonopore) on the last pair of walking legs through which sperm enclosed in a package (spermatophore) is deposited between the fourth pair of walking legs on the female thorax. In prawns, females have a spermatophore receptacle called a thelycum. Females lay eggs through a gonopore after sperm deposition and the sperm is used to fertilise the eggs.

Penaeid prawns release the fertilised eggs into the ocean, but most species transfer eggs to the underside of the abdomen. The egg brood is kept aerated and clean of debris by the fanning movement of the pleopods. The eggs

develop here until the larvae hatch out. A female carrying a brood of eggs is described as being in berry and the eggs can be seen as a mass of orange due to the presence of carotenoids. As the eggs develop they change colour from orange to brown and then finally grey several days before hatching. Larvae hatch from the eggs and remain attached to the brood chamber for up to 24 hours. The female dislodges the larvae by lifting her tail and vigorously beating the pleopods. Larvae are usually released at night to minimise risk of predation and on a high tide to ensure the transport of larvae away from the reef. Generally newly released larvae respond negatively to gravity and positively to light such that they move up in the water column into surface waters.

F. Feeding

Larvae and postlarvae are predators, feeding actively on phytoplankton and invertebrate zooplankton (46). They are able to feed on suspended particles and will actively chase and capture zooplankton. However, they are largely opportunistic feeders and may be cannibalistic when held in high densities. Among the adult forms there is a diversity of feeding modes, but many of the edible crustaceans are scavengers and/or predators and many species are omnivorous. The diet of scavengers (e.g., prawns) includes a range of dead plant and animal matter including detrital aggregates. The prey of predators (e.g., lobsters and crabs) includes worms, crustaceans, molluscs, and fish. Cannibalism may occur at very high densities in culture conditions, particular in crabs and especially when individuals have just moulted and are soft-shelled. Food detection is primarily through chemosensory structures on the head. The antennae and antennules can detect low concentrations of chemicals and are used for distance chemoreception, while appendages around the mouth are used for contact chemoreception and are able to detect high concentrations of organic compounds (33).

Once food is captured or found the maxillipeds are used to hold and crush, and the mandibles and maxillae are used for ingestion. At this point food is broken into fine pieces before being passed into the foregut. In decapod crustaceans the muscular foregut is divided into two chambers; a cardiac stomach and a pyloric stomach. In the cardiac stomach a gastric mill with chitinous teeth is used to further grind food down before it is passed into the pyloric stomach. Digestive processes are initiated in the foregut with the release of enzymes secreted by a digestive gland. Partially digested food is then passed from the foregut through to the mid-gut which is the primary site of enzyme activity and nutrient absorption and the final stages of digestion occur. Enzymes are produced by digestive tubules that form a glandular appendage (digestive gland), which is involved in enzyme synthesis and secretion, nutrient absorption, and lipid storage.

Although toxic poisoning in humans through the consumption of crustaceans is not typically associated in the same way that molluscan shellfish are, there is evidence that crustaceans may accumulate toxins in their tissues (review 47). Uptake of toxins by crustaceans occurs when they consume bivalves that have toxins and toxins are accumulated in the hepatopancreas (48). However, poisoning of humans rarely occurs because the muscle tissue of crustaceans is predominantly eaten, but if the whole animal is cooked (e.g., crab soup) or the digestive gland is eaten then toxins accumulated in this gland can be transferred to humans. In crabs there is evidence that toxicity may be the direct result of the consumption of the macroalgae *Jania* (47).

G. Movement and Migration

For many crustaceans planktonic larvae are typically the dispersal phase of the life history, in those species which have a very long larval phase, e.g., spiny lobster, phyllosoma, can be dispersed considerable distances. Movement patterns of phyllosoma are poorly known because of difficulties in sampling animals that occur at low densities in large oceanic water masses. More recently the approach to studying movement patterns of these larvae has involved integrating oceanographic circulation patterns with larval distribution. In some cases there is evidence that phyllosoma may be retained within gyre systems ensuring that they return to the reef. Although dispersion of larvae and phyllosoma is affected by current systems, they can actively orientate themselves in the water column and effectively control some of their movement. Many species undertake vertical migrations in the water column, thereby using water currents at different depth strata to allow some control in their return to the reef (49). For example, the Western Australian spiny lobster early in the larval phase stays in surface waters which ensures movement offshore away from the reef, but when mid- and late-stage phyllosoma avoid surface waters they are more affected by subsurface circulation which returns them back to the coast (49).

Adult lobster species undergo movements that can occur on a range of spatial scales from 100s of metres to 100s of kilometres (32). Some of these movements are temporally and spatially predictable, with directional migration involving thousands of individuals as seen in some of the spiny lobsters (50). The reasons for the movements are varied and in many cases unknown (36). However, they may be related to spawning activities, redistribution of juveniles, movement out of sub-optimal environments, facilitating exchange of genetic material, or environmental factors, e.g., temperature. In some cases during the migrations lobsters follow predictable routes in single file for 2–4 days, which can make them vulnerable to over-fishing. On the Scotian shelf tagged adult *Homarus* lobster have recorded migrations in excess of

200 km over a year, but they often return to the same area, suggesting long-range homing behaviour (32). The mechanisms used by spiny lobsters to orientate themselves and be able to undertake directional migrations and display homing behaviour are unclear. Recent work has explored the use of magnetic orientation by spiny lobsters through experiments that relocate animals and use magnets to modify the magnetic field around the individual. It appears that spiny lobsters (*Panulirus argus*) do use magnetic information to orientate themselves and be able to return home. Interestingly, individuals appear to use their relative position to the home site to orientate; in other words, they use a geomagnetic map (51).

H. Behaviour

Unlike largely sedentary molluscan shellfish, many edible crustaceans, particularly lobsters and crabs, display advanced social and reproductive behaviour (32). However, much of what is understood about decapod behaviour has been obtained in aquaculture conditions, where animals are held in high densities and inter-individual interactions are frequent. In nature most decapods are largely solitary, nocturnal, and remain hidden. Spacing and occupancy of shelters is a major aspect of their social behaviour (52). Lobsters at high densities will obtain and defend mates and shelters through dominance hierarchies. In particular, dominant males are able to evict subordinate males and are able to gain and retain mates. In contrast, at low densities dominance hierarchies are not formed, but individuals are highly territorial. Although the differences in behaviour under conditions of high and low density are evident in culture conditions, these may also be seen in the wild associated with ontogenetic changes in behaviour. For example, juvenile spiny lobsters are solitary and cryptic, but intermediate-sized individuals will aggregate together in shelters.

The use of the claws in behaviour is diverse, e.g., male fiddler crabs wave their claw to entice females into the burrow for mating, and in contrast, some lobsters and crabs will use the well developed claws in aggressive interactions. Some factors that affect aggressive interactions and their outcome are size, moult stage, and gender of the individuals involved (53). The nature of dominance interactions can range from ritualised displays to physical fights which can result in the loss of limbs. Typically individuals that are bigger and with larger claws will have a greater chance of winning encounters. However, there are distinct changes in aggression during the moult cycle. An individual may maintain a high level of aggressiveness until the point that the old shell has been moulted, possibly so shelter that will provide protection during the soft-shell state can be obtained and maintained. Recently moulted individuals will be less aggressive as the soft-shell provides little protection during interactions.

IV. CONCLUSION

The shellfish represent a biologically diverse group of marine invertebrates that includes very important harvest and aquaculture species world-wide. The sedentary lifestyle of many species makes populations vulnerable to changes in the environment that will affect recruitment of juveniles into adult populations and the quality of adults as a food source. Aspects of biology, ie growth, ecology, reproduction, feeding, and movement that have been studied in detail are often related to our need to manage wild stocks and for the successful culture of new species. Given that these are invertebrates and many of these species are low in the food chain, it may be considered that they will be less vulnerable to over-exploitation. However, the advanced behaviour and extended pelagic larval phase of some lobster species, about which we know little, means that over-fishing is possible and aquaculture of these species will be challenging.

ACKNOWLEDGMENTS

Thanks to Dr Danielle Johnston for providing invaluable expertise and discussion about crustacean biology and Dr Keith Martin-Smith for constructive review of the chapter.

37 Aquaculture of Finfish and Shellfish: Principles and Applications

C.G. Carter
Tasmanian Aquaculture and Fisheries Institute, University of Tasmania

CONTENTS

I. INTRODUCTION

Aquaculture has been described as both the art and science of growing aquatic animals and plants. It has been practiced for thousands of years by different societies using a wide variety of approaches to growing aquatic organisms in water. The origins of aquaculture will probably never be known because there are no ancient aquaculture-specific artifacts or even the remains of ponds or dams that can be distinguished from other uses such as water storage or for growing crops (1). However, there is some historical evidence from around the world that shows aquaculture has existed for thousands of years and in several different places. There is a bas-relief of fishing, probably for *Tilapia*, from fish ponds in ancient Egypt 4000–4500 years ago (1). Several types of integrated aquaculture/agriculture systems were known in South America (1) and there is the 1500–1800-year-old Ahupua'a marine aquaculture in Hawaii (2). Fish ponds were well known in Europe during the Roman Empire and Middle Ages (3). In many ways China could be considered the head and heart of traditional aquaculture, certainly in freshwater, since it is here that large scale aquaculture has the longest history and has shown the most evolution. Pond culture of common carp was recorded over 3000 years ago and about 2500 years ago Fan Li, considered the father of Chinese fish culturists, wrote "Yang Yu Ching" or a "Treatise on Pisciculture" to detail practical methods for freshwater aquaculture (4, 5). Recently, within the last half of the twentieth century, aquaculture has shifted into an industrial phase and global production has increased dramatically. Currently, aquaculture of finfish, molluscs and crustaceans (shellfish) produces 37.5 million tonnes per year and accounts for 29% of the total global fishery harvest (6). Aquaculture continues to expand and has increased its share of the global fishery from less than 4% in 1970 (6). Aquaculture has great potential to expand further and to meet an increasing human demand for protein. To accomplish this dramatic changes in current structures and practice may be necessary. The debate on sustainable aquaculture is only just beginning (7–10).

There are many ways to farm fish: they may be housed in ponds, tanks, cages and raceways; held inside or outside in salinities from freshwater through to seawater; and grown with or without other fish, animals or plants that are also available for harvesting. Aquaculture can be divided very broadly into extensive and intensive forms. It can be argued that intensive aquaculture is distinct from other forms, whereas there is a continuum from extensive to semi-intensive systems. Under intensive aquaculture, water provides physiological support for the fish but all other means of sustaining life are provided from external sources, the most obvious being the supply of nutritionally

complete feeds. Extensive aquaculture is viewed as a system which manages the natural productivity of water to grow products that can be used. The level of management, the types and magnitude of inputs and the diversity of production all contribute to the complexity of non-intensive systems. Thus, Chinese polyculture of up to eight species of finfish is a good example of semi-intensive aquaculture at one end of the continuum. Annual gross yields in Chinese polyculture are reported to reach 20 tonnes per hectare although the median is six to eight tonnes (11). In contrast, extensive systems at the other end of the continuum, such as managed lakes, would rarely exceed 0.5 tonnes per hectare per year (see p. 37-10).

Carp species account for by far the largest portion of global finfish production with the majority of these grown in China (6). Production is based around polyculture within ponds and their integration within wider agriculture systems (11). Outside of China, carp are produced in many countries and systems, including intensive pond and tank production of common carp in Europe and Israel (12) and semi-intensive pond polyculture of common, Indian and Chinese major carp in India. Aquaculture of salmonid fishes, including Atlantic salmon, rainbow trout and Pacific salmon, is the largest intensive finfish aquaculture system in the world and has now overtaken channel catfish aquaculture, one of the first intensively farmed finfish species. Many countries have some salmonid aquaculture and the major producers are Norway, the United Kingdom, Canada and Chile. Nevertheless, the various carp species with more than 15 million tonnes per year dwarf salmonid culture with one tenth of this production (Figure 37.1). The other most important finfish are *Tilapia* and milkfish (6). *Tilapia* species (1.05 million tonnes) are cultured around the world under different systems: they are the mainstay of aquaculture in Africa where they are mainly grown extensively in small ponds; they are used in semi-intensive freshwater polyculture in China, as well as being grown intensively in tanks and ponds in Israel and the United States. Milkfish (0.46 million tonnes) is a major brackish water aquaculture species in South East Asia and a large expansion occurred after the development of commercially effective artificial propagation techniques in Taiwan (13). Species new to aquaculture are constantly under development with considerable focus on higher value marine species. The major hurdle to overcome with most marine species is closure of the life-cycle, which is often technically difficult due to the small size, fragility and unknown feeding and husbandry requirements of marine larvae. Wild-caught fry or juveniles are still used in the aquaculture of many species but the long-term sustainability of this practice is questionable. This is a major challenge that may take many years to solve for some species (see p. 37-6).

Finfish account for approximately half of aquaculture production with crustaceans and molluscs accounting equally for the majority of the remainder (6). Of the top 29 aquaculture species three bivalve molluscs are in the top ten by production with over 8 million tonnes whereas the predominant crustaceans are prawns with about 1 million tonnes per year (Figure 37.1). The monetary value reflects the socioeconomic and technical basis of particular aquaculture systems so that high value prawns and salmonids have a far larger share of the total monetary value of aquaculture production than of the production weight (Figure 37.2). Although aquaculture production is based on at least 210 different plant and animal species the majority comes from the few groups discussed above (6). In 2000 (6) nine countries produced more than half a million tonnes of aquaculture product, including plants, and were headed by China (32 million tonnes), India (2 million tonnes), Japan (1.3 million tonnes) and the Philippines (1 million tonnes).

The aim of this chapter is to provide an overview of the range of aquaculture species and systems found. A more detailed discussion of the principles governing aquaculture practice will use selected examples taken from intensive and semi-intensive aquaculture.

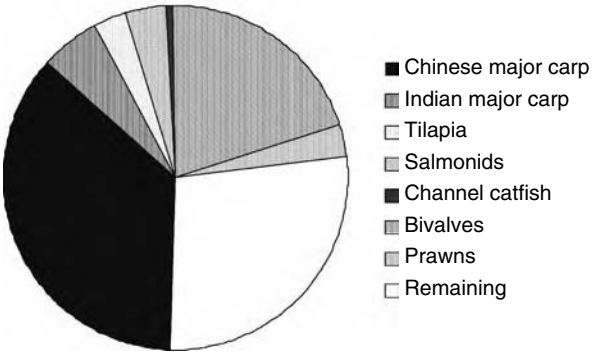

FIGURE 37.1 Distribution (% of total production weight) of major aquaculture groups in 2000 (35). Categories detailed in Table 37.1.

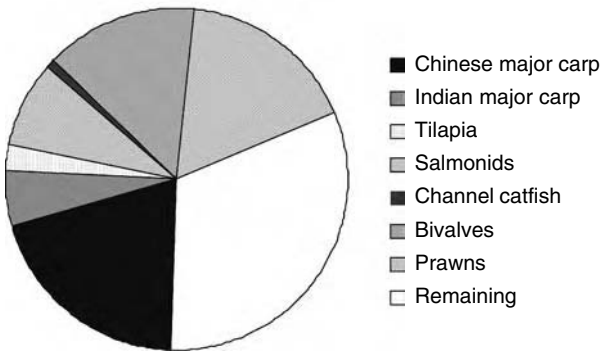

FIGURE 37.2 Distribution (% of total US$ value) of major aquaculture groups in 2000 (35). Categories detailed in Table 37.1.

II. INTENSIVE AQUACULTURE SYSTEMS

The principles that drive intensive aquaculture are based around maximising production in the shortest length of time. Intensive aquaculture is most often based on monoculture of high value species in developed countries. Animals may be contained in a wide variety of structures including net-cages (Figure 37.3), tanks, raceways and earthen ponds (Figure 37.4). Fish are held at high densities and fed nutritionally complete feeds, usually at maximum rations. As has been found in intensive agriculture industries, fish are sensitive to disease and periods of high mortality have been associated with many intensive aquaculture industries.

Reproduction and propagation of major freshwater finfish (i.e., salmonids, carps and catfish) is relatively straightforward and achieved with a high success rate. One of the important features of these finfish groups is the large

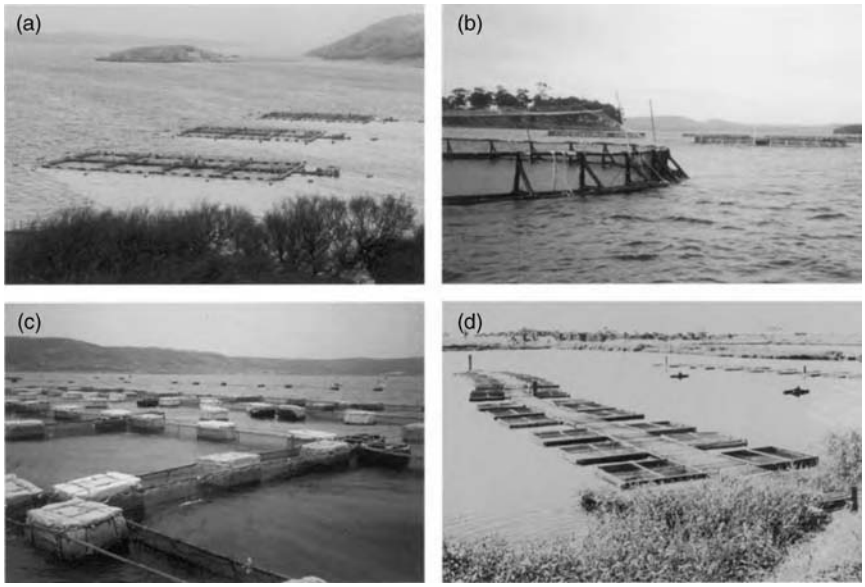

FIGURE 37.3 Use of cages in different forms of aquaculture a) 24-m^2 cages for marine Atlantic salmon farming, b) ring-cages for marine Atlantic salmon farming, c) small 4-m^2 cages for grouper farming, d) small 2-m^2 cages for barramundi grow-out in freshwater ponds.

FIGURE 37.4 Fish holding in (a) concrete tanks used for marine finfish, (b) concrete raceways for rainbow trout, (c) indoor fibreglass tanks for rainbow trout and (d) a drained earthen pond for freshwater silver perch.

size and robust nature of eggs and the ease of feeding compound feeds immediately at, or soon after, first-feeding. This is in marked contrast to marine species in which far greater investment in technologies for rearing larvae and for supplying live feeds has been made. It should be pointed out that some industries, such as Asian sea bass (14), are adopting extensive practices to produce feeding fry for intensive grow-out (see p. 37-6).

Nutrition and feed development are critical issues at present. Aquafeeds use large amounts of valuable fish meal and fish oil and considerable effort is being directed at developing alternative ingredients (15–17). The proportion of the global fish meal supply used in aquafeeds is reported to have increased from 10% (1988) to 35% (1998) (9). These authors also point out that this is due to a reallocation of a relatively static global harvest of fish meal from other feeds to aquafeeds; aquaculture has not caused any increase in fish meal production. Successful experimental feeds that are free of marine products have been developed for larger channel catfish, and following on from this the total animal meal now used in commercial catfish feeds is less than 2% (18). However, the omnivorous channel catfish is one of the few non-carnivorous finfish farmed intensively and the complete removal of marine ingredients from feeds for carnivorous species poses more difficulties. For example, salmonids have limited ability to use dietary carbohydrate (19), and this places constraints on the type of plant-based ingredients that can be used since raw meals contain large amounts of carbohydrates. A likely trend will be the development of high protein ingredients from plant and microbial sources. Products from grains and legumes such as soybean, lupins, canola and peas and microbial sources such as bacteria are currently being investigated (20, 21). Commercial Atlantic salmon feeds can contain over 38% fish oil, making the sector the major user of global fish oil production. This level of use and the probability of increased competition for fish oil from other sectors (*e.g.,* nutraceuticals) have the potential to severely restrict further expansion of salmon aquaculture. Fortunately, it now appears feasible to replace up to 50% of the fish oil in Atlantic salmon feeds with plant oils (16), although there may be salmon health implications under some circumstances (22).

Maintaining animal health and disease control are of major importance in all sectors of aquaculture. There are examples of severe disease outbreaks that have led to huge losses in production. The effects of viruses, including white spot syndrome, monodon baculovirus and yellow head virus, have almost decimated the marine prawn industry; losses up to 1996 were estimated to have reached US$ 3 billion (23). The Atlantic and Pacific salmon industries have suffered from major viral (*e.g.,* IPN, infectious pancreatic necrosis; ISA, infectious salmon anaemia), bacterial (*e.g.,* furunculosis; bacterial kidney disease) and parasitic (*e.g.,* sea lice; ameobic gill disease) diseases. There was a major outbreak of furunculosis in the early 1990s that resulted in yearly losses of US$ 77 million. Fortunately, the disease has declined since 1993 due to the use of effective vaccines (24). Vaccination against a variety of potential pathogens is now a major management procedure in the Norwegian salmon industry and over 90% of all stocks are vaccinated by injection into the intraperitoneal (visceral) cavity (24). Vaccination is only a part of the health care management programs now in place in the salmon industry. These recognise the need for trained personnel, routine monitoring and quick diagnosis; to minimise stress through appropriate stocking densities, careful and minimal handling; site rotation to break the disease cycle; cooperation between farms to ensure single-year class stocking at a location in order to prevent vertical transfer and break disease cycles (24). Aquaculture is also vulnerable to environmental impacts that include predators, blooms of toxic algae, contamination from land run-off and disasters such as oil spills. Aquatic animals are bathed in the contaminated water and it is often much more difficult to move them away from an aquatic threat compared to terrestrial situations.

Offshore marine finfish aquaculture is now being developed in response to human-related pollution and other stresses on the marine coastal environment as well as user conflicts with commercial and recreational groups (25). Technology required for holding and servicing stocks must be far more resilient than for inshore farming and greater mechanisation is needed to reduce the need for manual intervention (25). Assessment of health and growth status, removal of dead fish and feeding are required on a regular basis; grading and harvesting should be possible in any weather. This involves greater use of technology, it is more expensive to purchase and has higher running costs which must be balanced by increased production efficiency (26). There is increasing evidence that growth is faster and more efficient in larger cages (27). Large submersible cages for offshore locations are under development for several aquaculture sectors including salmon and flatfish (28). One example was the Tension Leg Cage, which could be submerged in rougher weather to reduce wave damage at the surface (28). In addition to these open production systems there have been significant advances in closed production system technology. Closed systems are usually land based, use tanks and rely on technology and management to maximise water quality and minimise water use through reuse. This is achieved with water reticulation and physical filtration systems that aid the removal of solid and suspended organic material, heat exchangers to maintain water temperature and reduce heating costs, biofilters containing a microbial flora that removes various harmful nitrogenous compounds and UV filters to reduce bacterial loads.

A. Salmonids

Around ten salmonid species (members of the family Salmonidae) are farmed in 60 countries (29) and over 90% of aquaculture is based on Atlantic salmon, rainbow trout and coho salmon. Salmonid species of interest are naturally found in temperate areas of the northern hemisphere, *Oncorhynchus* species from the Pacific and *Salmo* species from the Atlantic. Demand from recreational fisheries and aquaculture places them as global species with a considerable southern hemisphere presence (30). Rainbow trout have been cultured for many years. Denmark pioneered pond-based production of plate-sized fish at the end of the nineteenth century (30). In the last ten years Atlantic salmon has become the major salmonid species due to a huge expansion in sea-cage farming in Norway followed by Scotland, Canada and Chile. Small juvenile Atlantic salmon, called parr, have brown sides with complex patterns of spots and darker stripes. Adults are typically streamlined and silver scaled with prominent dorsal, pectoral and pelvic fins; the tail should be distinct and slightly forked although farmed fish often have worn fins. Rainbow trout has been described as the Pacific cousin of Atlantic salmon due to the similarities in shape, patterns and silvery colour as well as similar reproductive characteristics (31). Coho salmon are also known as silver salmon. Immature fish have a metallic blue dorsal surface that silvers on the sides; mature males have bright red sides and bright green heads and backs (32).

Atlantic salmon are typically anadromous (return from the sea to spawn in freshwater) with freshwater and seawater phases in their life-cycle. Mature males and females return to freshwater sometime in the 12 months before they spawn. These large impressive fish of up to 30 kilogram famously migrate up the rivers and streams that they last swam down as immature parr several years previously. Once in the spawning grounds the female makes a hollow (redd) in gravelly stream beds where the male fertilises the eggs as they are released. The buried eggs hatch into a yolk-sac stage (alevin) and emerge as fry that start feeding on animal prey. The fry grow into parr that then undergo smoltification, a metamorphosis taking several months, to enable migration into the sea. After two to five years at sea (sea-winters) the fish return as mature adults. Some fish mature and return after one sea-winter and are called grilse. Aquaculture initially recreated this natural life-cycle but varying degrees of manipulation are now used to promote rapid and uniform growth, minimise maturation and maximise harvest over as much of the year as possible.

Broodstock are often removed from a production run on the basis of size and external appearance. They are then conditioned prior to spawning. Selective breeding is used. In Norway it is estimated that 65% of the Atlantic salmon and rainbow trout produced originate from the National Breeding Program (33). This program has incorporated growth, age at sexual maturation, disease resistance and flesh quality as selection characteristics (33). Broodstock conditioning is best in freshwater and synchronous maturation is achieved through the use of hormonal preparations as well as keeping the fish under the same conditions, sometimes males and females together or sometimes in recirculating water allowing chemicals released by the fish to act as they would in the wild (29). Hand "stripping" of eggs and milt, by applying firm pressure along the abdomen, followed by gentle mixing, fertilises the eggs. Hand-stripped Atlantic salmon and rainbow trout can be re-conditioned for the next season. When larger numbers of eggs and milt are required they are removed directly following euthanasia. This procedure has to be adopted with Pacific salmon which only spawn once (30). Sperm are inactive until they touch water so contact is minimised until mixing with eggs. Eggs absorb water on fertilisation, become larger and "sticky" and then harden. Straightforward procedures are followed to ensure maximum fertilisation rates that typically exceed 95%. Fertilised eggs are then incubated under dim or red lights in gently flowing water. Adequate water flow is required to ensure good supply of oxygen and the removal of soluble wastes as well as debris. Incubators are of different designs that vary between deeper cylindrical upwellers to shallow troughs. The California or undercurrent system uses hatching trays positioned in shallow troughs and is considered the most effective design (30). On hatching the alevins use their yolk-sac before being weaned directly onto compound feeds and the fry stage is reached on loss of the yolk-sac. There is considerable individual variation in feeding success and growth rate, so size-grading is used to control size distribution and prevent cannibalism (amongst the smaller stages). Development now proceeds from the parr to the smolt stage. Attention has been focused on controlling this process in order to manage the supply of fish into the major production stage. All in all there has been a highly effective transfer of scientific and technical principles reflected by 80–90% survival from hatch to smolt (30).

Smolt usually have to be transported from the hatchery to the grow-out site; this can be by land, air or sea and care is taken to reduce stress by providing dark aerated conditions and to transfer smolt via pipes directly into the cages. The "smoltification window" describes a period during the season when parr must be of a certain size to start the process of smoltification. It is normally in the spring for Atlantic salmon but more variable for Pacific salmon. In contrast, successful sea-water transfer of rainbow trout, a non-smolting species, is related to larger size (29). The majority of Atlantic salmon on-growing is conducted in sea-cage systems. These are essentially large bag-nets held on floating frames that are anchored to ensure the frames stay in the same place. Bag-nets are five to 20 metres deep and their shape is maintained by devices such as metal

rings around the circumference of the net, weights and lead-core ropes (29). Groups of cages are usually held and anchored together and, depending on the design, they can be joined by walkways or only accessed individually by boat. Galvanised steel square-cages are typically available in 12 to 24 metre square sections. A 24 metre section would consist of a 15 by 15 metre net surrounded by walkways (Figure 37.3a). Each section incorporates floats under the walkways and sections are hinged together to expand a system and to provide flexibility in rougher seas. The other main type of sea-cage is the circular ring-cage in which a buoyant circular ring structure is used to hold a circular bag-net, mooring cables and other ancillary structures such as bird netting or feeders (Figure 37.3b). These structures can range in circumference from 60 to over 120 metres. Compared to square-cages they are usually placed further apart, allow greater water flow through a group of cages and are easier to handle independently of each other. There are a number of commercial variations of square- and ring-cages holding from a few tonnes to over 150 tonnes, approximately 40000 fish (29).

Considerable intervention has been used to manage smoltification and maturation. Controlling the supply of smolt enables stocking over more of the year and more even production throughout the year. This is particularly important when a large proportion of fish mature within one sea-winter as grilse which are smaller than older salmon (29). One-year smolt is the normal age category for smolt but half-year, one-and-a-half and two-year smolt are also produced and used (30). One-year smolt (S1) are exposed to a natural photoperiod and are transferred in spring after one year in freshwater; one-and-a-half year smolt are essentially delayed S1 and transferred in the autumn rather than in the spring like S1; Half-year smolt are transferred in autumn prior to S1 and are produced by photo-manipulation of the photoperiod that accelerates "spring." Mature salmon are not desirable in a production run. Mortality is higher in seawater; they partition feed resources into unwanted reproductive growth rather than somatic growth and develop many poor external and flesh quality characteristics that reduce marketability (29). Whether maturation occurs is highly influenced by size and nutritional status so that faster growing fish, often in warmer temperatures, will mature relatively quickly but be of a smaller size. Strategies to control the effects of maturation include the production of sterile triploid fish or the use of all female stock, since females show lower rates of maturity than males.

Selective breeding has been used as a strategy to improve Atlantic salmon and rainbow trout in Norway since 1971 (33). Initially selection was based on growth, then the frequency of grilse was incorporated to increase the age at maturation. More recent selection strategies have used disease challenge to increase disease resistance and measurements of flesh colour, fat content and fat distribution to improve meat quality (33). There has also been development and testing of genetically modified or transgenic fish. Genetically modified Atlantic salmon parr containing a growth hormone transgene (chinook salmon growth hormone gene attached to an antifreeze protein promoter sequence from ocean pout) grew at over two and half times the rate of control fish due mainly to increased feed intake (34).

B. Marine Finfish

In the majority of developed countries that use intensive aquaculture there is a premium on marine rather than freshwater finfish. Of course, not all marine finfish command the same price or kudos associated with yellowtail, tuna, halibut or grouper, for example. As yet, there is no intensive aquaculture of high value marine finfish on the scale or with the current rate of increase of Atlantic salmon. The large and important Japanese yellowtail industry produced 137000 tonnes in 2000 (35) but this was below production at the start of the 1990s. Farming yellowtail in Japan developed from holding wild-caught fish and intensified in the 1970s. Too rapid expansion and limitations due to disease and markets have led to greater controls on the industry and a reduction in production (36). Although hatchery-based propagation is possible the Japanese industry is still largely based on small (<10 gram) wild-caught fingerlings that are grown to 50–100 grams before being sold for on-growing for about 12 months to about three kilograms (37). Bluefin tuna are very valuable fish and attempts at forms of aquaculture have been under way for many years in Japan, North America, Europe and Australia (38–40). The few commercial tuna farms, mainly located in Australia and the Mediterranean, on-grow large wild-caught juvenile tuna. In Australia, for example, juvenile southern bluefin tuna shoals are caught using a purse-seine, towed back in specially designed ring-cages and transferred to moored cages for a four- to eight-month grow-out (40). The tuna are around 20 kilograms at catch and controlled grow-out allows a high level of value adding to a fishery resource. farmed tuna can treble in weight and larger tuna are more valuable per kilogram as well as on a whole-fish basis. Recently there are indications that aquaculture based on a closed life-cycle of bluefin tuna is possible; successful larval production from northern bluefin tuna that had themselves been grown in culture from larvae has been achieved (41). The research program was started over 25 years prior to successful spawning of the wild tuna in 1995–96 and indicates the high level of complexity and need for a considerable economic and time investment to achieve success. Further development will be required because there may be key differences between wild-caught and domestic broodstock that could result in poor larval quality and a low success rate in the production of viable juveniles from this second generation.

Good examples of intensive marine aquaculture in which the life-cycle is closed and that have a high production are the European sea bass and gilthead sea bream in the Euro-Mediterranean region (42), red drum in the southern United States (43), red sea bream in Japan and the Asian sea bass in South East Asia (14). European sea bass production has increased steadily over the last ten years and all aspects of production, from larval rearing to broodstock management, are considered to be under control (44). Commercial hatcheries produce in excess of 180 million juveniles for sea-based grow-out. Propagation is based on a relatively standard larval rearing protocol supplying a sequence of live feeds, rotifer followed by brine shrimp, before weaning onto a compound feed (44). European sea bass larvae first feed four or five days after hatching when they are between four and six millimetres in length. After three to four weeks they reach ten millimetres and weaning onto a high protein compound feed begins and is usually complete by 40 days. An interesting development is the successful use of a compound feed immediately at first-feeding and for the entire larval period. Consideration of supplying essential nutrients in a form that can be readily assimilated is the key to this success and achieved using ingredients such as phospholipids and hydrolysed proteins (44). Rotifers and brine shrimps form the basis of most larval rearing protocols. Rotifers are smaller and always fed first, then with brine shrimp in order to provide food for smaller individuals before only brine shrimp are used. Other variations include "greenwater" techniques, whereby microalgae are also grown because they appear to benefit both the live feed and the finfish larvae. Red sea bream are fed microalgae (day three to 25), rotifers (day three to 33), brine shrimp (day 20 to 40) and compound feed (day 20 to 60). Live feeds are often "enriched" by feeding them commercial preparations to increase concentrations of specific nutrients, particularly polyunsaturated fatty acids and vitamins.

The aquaculture of Asian sea bass or barramundi provides an interesting view of how one species has been highly adaptable and successful under many systems (14). Its natural range encompasses the northern Indian and tropical western Pacific Oceans and it is found from Iran to Australia (14). Although aquaculture production is relatively small (20000 tonnes in 1999) there is great potential for a species that can be cultured using intensive and extensive methods, indoors or outdoors, and that can be grown over the full range of salinity (from fresh to seawater) and even in brackish bore waters far from the sea. Tucker *et al*. (2002) have recently reviewed barramundi aquaculture: barramundi are catadromous (opposite to salmon) and sea water is needed for the broodstock, eggs and the first half of the larval rearing cycle. The species is also a protandrous hermaphrodite so that individuals first mature into males (after two years) and then into females (after three to five years). Barramundi can be spawned in tanks or strip spawned and this can be achieved with or without hormonal manipulation. Ambient conditions are very important for maturation and spawning. Spawning will occur regularly under summer photoperiod and temperatures: in Australia these parameters are artificially controlled in enclosed tanks to produce a regular supply of larvae from a small broodstock population (14). In more tropical locations farmed broodstock kept under natural conditions at high temperatures (27–34°C) will spawn regularly in tanks. Spawning occurs on the full moon and can be enhanced by first decreasing (also increasing temperature) and then increasing tank water depth (decreasing temperature) to recreate a high tide. Barramundi are very fecund and females produce hundreds of thousands of eggs per kilogram on each spawning. Males are stocked with females and the floating fertilised eggs are collected by nets or from the outflow water. The larvae are 1.5 millimetres when they hatch and have a yolk sac and oil globule as food reserves that are fully depleted after six days. Typically, larvae first-feed after two to three days (2.6 millimetres length) and take around 25 days to metamorphosise into juveniles (17 millimetres length). There are many approaches to larval rearing that range from intensive to extensive. Intensive procedures can be carried out in small tanks using a rotifer and brine shrimp sequence, rotifers from day two to day 15 and brine shrimp from day ten. Production methods may also incorporate a greenwater approach with the use of microalgae over the first part of larval rearing. Extensive procedures are carried out in large earthen ponds relying on natural plankton blooms initiated by fertilising the pond. Juveniles are easily weaned onto compound feeds and transferred from the nursery to grow-out stage. In Southeast Asia grow-out uses small ponds (0.08 to two hectares), coastal impoundments or smaller cages (one to 300 m^3). Several approaches to grow-out are used in Australia. These include open freshwater ponds, small cages held in freshwater ponds (Figure 37.3d), large marine cages and, because barramundi command a high market price, indoor tanks in more southerly non-tropical regions. Production is based on plate-size fish of around 400 to 700 grams and larger fish of around two to three kilograms for fillets or as "banquet" fish.

C. Abalone

Abalone are herbivorous gastropod molluscs that graze, usually nocturnally, on microalgae (attached to surfaces) and macroalgae (seaweed) (4). They have one shell with several holes along the edge for water exchange and a famously pearly inner surface. Their large muscular foot is an expensive delicacy around the world. Aquaculture started in Japan about 50 years ago and numerous *Haliotis* species are now grown commercially around the world. Production is led by China and Taiwan with Australia considered to be leading industry development through

research into areas such as feeds and nutrition, health and grow-out technologies (45). Abalone culture has been reviewed recently by Viana (2002). Farm-raised broodstock are readily available and synchronous reproduction is usually managed through the control of water temperature, water quality and high feed availability. Spawning can be induced by manipulation of temperature and light: temperature shock stimulation of spawning is created by raising water temperature to a target level and then dropping it suddenly and shifting to a dark period. Fertilised eggs hatch into non-feeding larvae which then undergo metamorphosis and leave the water column to settle on the tank floors. Diatoms (microalgae) are grown on hard surfaces and supplied for several months for the post-larvae to graze on before they grow larger and the radula becomes hard enough to graze on macroalgae. This switch takes place at about one centimetre length and abalone from one to three centimetres are then ready for grow-out to about seven centimetres. Broodstock and post-larval stages are often maintained in land-based facilities whereas grow-out may be sea- or land-based. Sea-based systems are designed to provide shelter and good water flow but feeds still have to be supplied. Abalone in land-based farms can be held in ponds, tanks, raceways or other types of enclosure. Shallow tanks with laminar water flow to minimise water use are suitable in conjunction with compound feeds but greater tank depth and water volumes are required when macroalgae are the food. Large sectors of the industry are based on the use of macroalgae as the principal and only food source for grow-out and the regular provision of large volumes of macroalgae is a major operational issue. However, abalone can still be grown intensively on macroalgae. For example, in some intensive Taiwanese farms abalone are housed in banks of many small containers that are lifted out from the water by overhead cranes, packed by hand with macroalgae and returned. Abalone are slow growing and will take up to five years to reach market size. In Australia the use of macroalgae is not thought economic and there has been a focus on developing a complete nutritionally balanced feed. As a result the time taken to reach market size has been reduced from five to less than four years. Abalone are slow feeders and feeds remain in the water for long periods of time which means significant leaching of nutrients can occur (46). A variety of technologies have been explored and include the use of high concentration of ingredients that act as binders and as nutrients (*e.g.,* wheat and maize gluten), combinations of binders and the use of microencapsulation for highly soluble nutrients (46). Growth variation is large and selective breeding programs for growth and growth efficiency are seen to be an important area for future development (45). A variety of traits such as growth rate, growth efficiency and marketable characteristics have been suggested and research has already established that heritability for survival and shell length is high enough for use in selective breeding programs (47).

III. SEMI-INTENSIVE AND EXTENSIVE AQUACULTURE SYSTEMS

Semi-intensive and extensive culture of fish in ponds is fundamentally different from intensive aquaculture. This form of pond culture uses a more holistic approach by exploiting the biological characteristics of the immediate aquatic ecosystem in fish production (48). The principles are based on the management of a pond's trophic web through alterations to the natural progression of the species balance in order to maximise conditions for fish production (48). Such alterations include efficient use of external inputs, principally organic fertilisers, the removal of species to shorten food chains or that are trophic "dead-ends" (*e.g.,* macrophytes), supplementary feeding and complex harvesting and re-stocking protocols. Pond-based polyculture, of mainly carp species, that has been refined in China and the pond-based monoculture of prawns provide examples of semi-extensive aquaculture. Large-scale changes in the types of aquaculture practiced in China are under way and intensive systems are being developed for freshwater and marine species (personal observation). Prawns are also farmed under intensive, extensive, polyculture and integrated aquaculture systems (49).

A. Chinese Finfish Polyculture

As described above the most significant contribution to global aquaculture production is made by finfish cultured using Chinese pond-based polyculture systems. Although largely based on knowledge handed down by farmers without them necessarily understanding the scientific basis of management strategies (50) there has been considerable work by provincial fisheries bureaus to document information as a basis for making improvements through a scientific approach (51). There have been dramatic increases in production over recent years. Although aquaculture is thousands of years old it is only since 1957 that Chinese major carp fry have been artificially propagated. Apart from increases in the number of fish and ponds available other areas where huge improvements have been made include training and technology transfer, effective pond design, placing greater emphasis on polyculture, increasing stocking density and increasing production through multiple harvesting and re-stocking (51, 52).

The finfish used in polyculture can be divided into four groups based on their principal food and feeding habits: plankton, macrophytes, detritus or aquatic animals (53). The major species used in polyculture are silver carp (phytoplankton), bighead carp (zooplankton), grass carp (macrophytes), mud carp (detritus) and black carp (molluscs); common carp (omnivorous feeding) are also used in high numbers. The former group of carp species are known as the Chinese major carp (Table 37.1). Other species such as the blunt nosed bream or Wuchang fish (macrophytes),

TABLE 37.1
Major Aquaculture Species with Top 20 Rank by Production Weight in 2000 (35)

Group	Name (Rank)	Scientific Name	Water, Feeding Mode
Finfish			
Chinese major carp	Silver carp (2)	*Hypophthalmichthys molitrix*	FW, filter feeder
	Grass carp (3)	*Ctenopharyngodon idella*	FW, herbivore
	Bighead carp (6)	*Hypophthalmichthys nobilis*	FW, filter feeder
	Mud carp	*Cirrhinus molitorella*	FW, detritivore
	Black carp	*Mylophryngodon piceus*	FW, carnivore
Indian major carp	Rohu (11)	*Labeo rohita*	FW, omnivore
	Catla (12)	*Catla catla*	FW, filter feeder
	Mrigal (13)	*Cirrhinus mrigala*	FW, detritivore
Other carp	Common carp (4)	*Cyprinus carpio*	FW, detritivore
	Crucian carp (7)	*Carassius carassius*	FW, detritivore
Other finfish	Tilapia (9)	*Oreochromis niloticus*	FW, omnivore
	Milk fish (16)	*Chanos chanos*	B, herbivore
	Channel catfish (20)	*Ictalurus punctatus*	FW, omnivore
	Yellowtail	*Seriola quinqueradiata*	M, carnivore
Salmonids	Atlantic salmon (10)	*Salmo salar*	M, carnivore
	Coho salmon	*Oncorhynchus kisutch*	M, carnivore
	Rainbow trout (18)	*Oncorhynchus mykiss*	FW, carnivore
Shellfish			
Bivalves	Pacific oyster (1)	*Crassostrea gigas*	B, filter feeder
(Molluscs)	Small neck clam (5)	*Ruditapes philippinarum*	M, filter feeder
	Giant ezo scallop (8)	*Patinopecten yessoensis*	M, filter feeder
	Blue mussel (17)	*Mytilus edulis*	M, filter feeder
Prawns	Tiger (14)	*Penaeus monodon*	B & M*, detritivore
(Crustaceans)	Oriental	*Penaeus chinensis*	B & M*, detritivore
	White	*Penaeus vannamei*	B & M*, detritivore
	Giant freshwater	*Macrobrachium rosenbergii*	FW & B*, detritivore

FW = freshwater, B = brackish, M = marine, * = during reproduction and larval stages.

crucian carp (detritus) and *Tilapia* species (plankton and detritus) are also important in more complex polyculture systems. Chinese finfish polyculture has been divided into two main types: the "feeding model" and the "filter-feeding model" (51). The feeding model is based on grass, black and or common carp whereas the filter-feeding model makes more use of silver and bighead carp and rarely uses black carp. Although both models are widely used the balance differs between provinces. The feeding model is prevalent in Zhejiang (89%) and Jiansu (89%) compared to Hubei (25%) and Shandong (25%) (51). The number and mix of the principal species and the use of additional species is dependent on the province and on the farm (11). Polyculture in provinces such as Zhejiang has been practiced for thousands of years. The climate is ideal for extended production over a large part of the year and the province is wealthy and very close to the huge marketplace of Shanghai. Consequently, conditions favour the feeding model and the production of species (grass, black and common carp) that are preferred in the market place. Thus, the complexity of the polyculture practiced depends on geographical location, which influences the growing season; on the historical and technological basis of aquaculture, which influence expertise and technical support; as well as on socioeconomic factors, which influence the mix of species and the inclusion of more valuable species (11).

Broodstock are grown in special ponds for four to seven years and to weights in excess of five to ten kilograms depending on the species (50). Broodstock are placed in monoculture for a pre-spawning phase where water quality and feeding are managed. Species other than common carp normally spawn in flowing rivers so the maintenance of good water quality with high oxygenation is important in these ponds. Hormonal injections are used to induce spawning and male and females are placed together in circular concrete tanks where spawning and fertilisation occur (50). The fertilised eggs sink and are carried out of the tanks to be collected from the outflow and placed into incubation systems. Large circular incubation tanks, constructed from bricks and cement, are stocked at around 800000 eggs per cubic metre of water. Once the swim bladder is formed the larvae can be removed and stocked into the nursery ponds. Rearing progresses over the summer and the first stage lasts for around 30 days. Different carp are usually kept under monoculture due to the similarity in larval diets. Soya

milk is supplied directly to the pond for feeding the larvae and early fry. Limited polyculture may be used in the later phases of fry production. Polyculture protocols use three to eight centimetre fry in different combinations of the main carp species. Stimulation of phyto- and then zooplankton blooms is managed through the application of organic fertilisers to provide food for the growing fry.

Rectangular ponds are recommended and are of different dimensions depending on the production stage: for example, fry ponds are 1.2 metre deep and less than a fifth of a hectare in area; fingerling ponds are 1.5 metre deep and up to a third of a hectare in area; grow-out ponds are two to three metre deep and up to two thirds of a hectare in area. The most efficient grow-out systems follow multiple-batch harvesting and re-stocking protocols, sometimes called "multi-grade conveyor culture," which coordinate several harvests and restocking of both fingerlings and of larger fish over the growing season. For example, in Guangdong Province 35% of ponds may be allocated to fingerling production and the rest to grow-out. The grow-out ponds will be divided for different sizes of fish. The final or "fattening" pond contains mainly bighead, grass, mud and silver carp, to be grown up to harvest size over different periods of time, as well as some common and black carp, Wuchang fish, tilapia and even snakehead (Table 37.2). In hilly regions where there are fewer ponds there is an emphasis on mixed-age culture within the same ponds. Chinese finfish polyculture is dependent on large inputs of organic fertilisers (mainly manure and composts) as well as some feed sources not available in the pond, especially terrestrial plant material for grass carp. Traditional fish farms are usually part of a larger integrated aquaculture-agriculture farm. Integrated farming, the integration of agriculture and aquaculture activities (Figure 37.5a), has several forms in China involving combinations of fish with ducks, pigs, chickens, cows and silk-worms.

TABLE 37.2
Stocking and Harvest Weights of "Fattening" Ponds in a Polyculture System in Use in Guangdong Province, China

Species	Stock Weight (Grams per Fish)	Harvest Weight (Grams per Fish)	Density* (Fish per Hectare)	Rearing Period (Days)
Bighead carp	500	1000–1500	330	40
Grass carp	250–500	1300–1500	600–1200	60–180
Mud carp	50	125	14250	180
Silver carp	250–600	700–1000	300–600	90–180
Common carp			300	
Tilapia			7500–15000	
Wuchang fish	100–250		750	
Black carp			75–150	

* = Based on 15 mu per hectare.

The integration of fish with pigs and with ducks are considered the most successful systems (54). In one documented example (55) 70 hectares of ponds produced 800 tonnes of fish (based on eight species polyculture), 400000 ducks, 1060 pigs, 123 cows and chickens to give an overall annual production of 13.5 tonnes per hectare. In fish-silk culture mulberry bushes (Figure 37.5b) are grown by fish ponds and provide leaves for silk-worms which produce manure and protein from the pupa.

Variations of finfish polyculture are found throughout the world and suit different socioeconomic situations. For example, a system of polyculture was developed in India around the Indian major carp (Table 37.1) and it now incorporates other carp species. In Bangladesh, Indian and Chinese major carp are grown in ponds under polyculture systems and sold as a cash crop. It has been shown that if smaller pond fish species are also included they provide a vital protein source for the farmer's family whereas the carp are treated only as a cash crop (56).

B. Prawns

Penaeid shrimps are the most important farmed "prawns" and over twenty species are farmed (4). The majority of production is of *Penaeus monodon* (570000 tonnes) with a sizable contribution from *P. chinensis* (219000 tonnes) and *P. vannamei* (144000 tonnes) (35). The giant freshwater prawn, *Macrobrachium rosenbergii*, is the fourth most important prawn (119000 tonnes), the majority of production being from China (48%) and Bangladesh (37%) (49). There are many similarities in aquaculture techniques for the different prawn species although there are also important differences, not least of which between the freshwater and marine species (54).

The current status of freshwater prawn aquaculture and techniques have been recently detailed in depth (49). Wild female *M. rosenbergii* migrate into estuaries where the fertilised eggs they are carrying hatch. Larvae metamorphosise through 11 stages before the post-larvae settle on the estuary bottom and migrate into freshwaters. The discovery that the larvae needed a brackish water environment for successful development is considered a major advance in the aquaculture of this species (4). Reproduction and larval rearing are now well understood. Seawater can be trucked inland to hatcheries and siting farms away from coastal areas is viewed as a major advantage of the industry (49). World production has stabilised but aquaculture may yet have great potential because there has been limited development in South and Central America or in Africa and the species characteristics are more favourable to lower intensity farming and to developing polyculture with finfish. Polyculture with finfish in ponds offers an opportunity to increase pond yields with little increased cost. Prawns feed on bottom detritus and do not compete with the finfish (49). A range of production

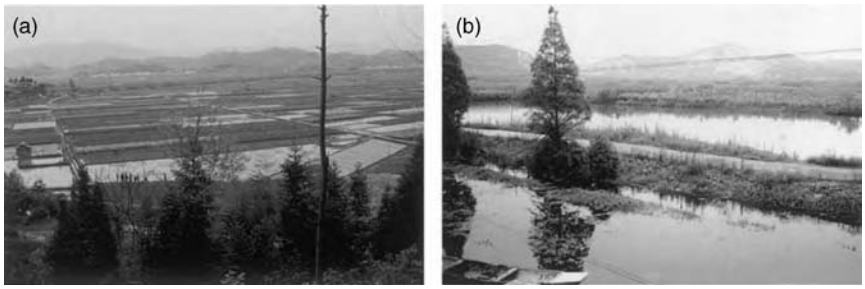

FIGURE 37.5 Chinese aquaculture showing a) view of integrated fish ponds and agriculture (photograph by Z-Y He), b) municipal fish ponds in Zhejiang Province with mulberry bushes on pond banks.

systems from extensive to intensive are used although the majority of the industry is based on semi-intensive grow-out. *M. rosenbergii* aquaculture provides a good example where the different aquaculture systems can be related to key aspects of farming. Extensive farming uses either dedicated ponds or impounded areas where there is another primary purpose such as rice fields or irrigation ditches; no feed is added; there is no control of water quality, predator or competitor species; stocking is 1–4 per square metre and production is less than 500 kilograms per hectare per year; harvesting is difficult because the water cannot be drained or seined. Intensive farming uses small concrete ponds; high water quality is maintained through high water exchange and continuous aeration; predator and competitor species are removed; nutritionally complete compounded feeds are used; stocking density is high at 20 per square meter and production is in excess of five tonnes per hectare per year; ponds are drain harvested (there are few commercial examples of intensive aquaculture). Semi-intensive aquaculture relies on daily management of water quality and water productivity to supply natural food sources; compound feeds are used to supplement pond-based food; stocking density is four to 20 per square meter and production is up to five tonnes per hectare per year (57). However, *M. rosenbergii* is territorial and density has a major effect on growth. Under semi-intensive conditions densities from four to 12 per square metre resulted in the most marked reduction in growth (57). Consequently, there has to be a balance between average growth rate and the total biomass available for harvest. An efficient semi-intensive operation would reach market weight of 30 to 60 grams in six to eight months with a survival of 50 to 80% (57).

Much of the research and development in marine prawn farming has been related to controlling spawning and larval rearing (54). Maturation, spawning and early larval stages of marine prawn species occur during the marine phase of the life-cycle, whereas the brackish waters of estuaries act as feeding grounds for post-larval and juvenile stages (4). Penaeid aquaculture was originally based on collection from the wild of either gravid females, which had mated and would then produce larvae, or post-larvae and juveniles. Hatchery techniques that allow the control and management of maturation, spawning and the fertilisation of eggs are now established (54). One of the key techniques is the removal of one eyestalk (unilateral ablation) from females. This decreases the amount of gonad-inhibiting hormone produced and therefore promotes maturation and spawning, particularly in females. The level of management is species dependent so that *P. monodon* requires ablation. Ablation is used with *P. vannamei* but it is not essential and species such as *P. japonicus* are responsive to environmental manipulation and ablation is not used (4). Broodstock diet is important and although compound feeds could be used there is a strong belief that factors contained within fresh or frozen animal food and not in compound feeds are required. Broodstock diets often contain polychaete worms, squid or bivalves, trash fish or crustacean waste. Males and females are stocked in equal numbers in spawning tanks. Eggs are collected and removed to the hatchery. Larval rearing relies on a controlled environment and maintenance of high quality seawater. A sequence of live-food starting with algae, rotifers and then brine shrimp is used. The "Galveston" method was developed in the U.S. and is more intensive; small larval rearing tanks are stocked at high densities and live-feeds supplied from separate tanks. Post-larval stages are thinned down and transferred to larger tanks or ponds. The "community culture" method originates in Japan. It is based on larger tanks and relies on promoting the growth of live feed species within the same body of water as the larvae.

Grow-out may also be conducted under intensive, semi-intensive and extensive systems: intensive (>200 prawns per square metre) practices tend to use tanks, raceways or smaller concrete ponds whereas extensive (<1 prawn per square metre) practices usually rely on larger earthen ponds or impounded areas (4). Semi-intensive management strategies are broadly similar to those described above for *M. rosenbergii* and typical prawn ponds are rectangular and of one to three hectares, although some ponds in South America are as large as 20 hectares, and around one metre deep (54). Water circulation is vital to managing water quality and food supply. Regular water exchange is practiced along with direct aeration and circulation of pond water to

ensure nutrients are re-suspended for assimilation by plankton. Production is around two to four tonnes per hectare per year. In contrast, intensive farming can be as high as 28 tonnes per hectare per year but has proved very vulnerable to disease problems (54).

IV. PACIFIC OYSTER FARMING

Pacific oyster farming has the highest production of any single aquaculture species. Production in 2000 was nearly four million tonnes and about 11% of total global aquaculture (35). Pacific oysters, originally from Japan, are very adaptable to different environmental conditions and are farmed throughout the world, having been introduced to the United States, Europe, South America, Africa and Australasia (4). They are bivalves so that a soft body is enclosed within two shells (valves) that are joined at a pointed end. The lower valve is cupped and normally the site of attachment to a substrate. The shape of the shell is very variable and heavily influenced by the environment: smooth and elongated shells result from growth on a soft substrate whereas a hard or gravelly substrate will cause flutes and corrugations as well as a deeper rounder shape (58). They inhabit brackish waters such as estuaries and feed by filtering nutrients out of the water. Consequently growth is highly dependent on the nutrient supply in the waters of the farm as well as on water temperature and quality. It takes fifteen to eighteen months to reach market size (about 100 grams) under natural conditions.

Males and females are separate and discharge sperm or eggs into water where fertilisation takes place. Between seasons they may changes sex from male to female (58). Spawning is stimulated by warming waters in the spring and summer and it may occur throughout the year at high temperatures (*e.g.,* 30–33°C in the Philippines). The larvae feed on microalgae in the water column before they metamorphosise into spat that settle out. Traditional Japanese oyster culture relied on the collection of wild spat on bamboo sticks and then on collectors suspended from rafts. Hatchery production has become more prominent although wild spat are still used. An important advantages of a hatchery-based industry is the relative ease of organising a genetic improvement program, as has been initiated in Tasmania (Australia) (59). The spat are grown until winter when they are graded and taken for one-year or two-year grow-out. Suspension of oysters in cultches and bags from floating rafts is the most common method in Japan, suspension from long-lines is more common in rougher deeper water. One-year oysters are transferred to productive waters after winter and grow rapidly. The two-year oysters are "hardened" over the first season on wooden racks positioned intertidally so that oysters are subjected to waves and air exposure. They are transferred to the grow-out areas the next season and are larger than the one-year oysters on harvest (4). Due to economic and legal restrictions on floating structures many farms still adopt bottom culture, in which the oysters are grown directly on the sea bottom (54). Off-bottom structures that are located intertidally and built into the bottom include stakes (placed vertically) or sticks (placed horizontally), stone or concrete slabs placed in bridges and wooden rack systems that support trays and bags or are used to suspend ropes carrying the oyster cultch. Suspended systems such as rafts or long-lines are placed further offshore and carry suspended trays, lines and bags. The location of oyster farms is crucial and efficient grow-out depends mainly on understanding the carry capacity of the water to maximise the use of nutrients and avoid overstocking. Minimising grading and replanting is also important. Depuration is particularly important to ensure oysters are safe to eat. They are eaten raw and being filter feeders can concentrate pathogenic bacteria, viruses, natural toxins (notably from microalgae) and pollutants.

V. SUMMARY

On the order of 300 aquatic species are cultured throughout the world and many species that are new to aquaculture will be under investigation at any one time (and often rejected after some period of research and development). In this overview I have concentrated on major species and groups, particularly on a few finfish, bivalve molluscs and decapod crustaceans (prawns). Large amounts of seaweed are also farmed. There is significant commercial farming of other vertebrate (*e.g.,* frogs, soft-shelled turtles) and invertebrate (*e.g.,* echinoderms, sea cucumbers) groups. Intensive and semi-intensive approaches were described and they emphasise the scope of aquaculture practice as well as how systems need to be appropriate to specific socioeconomic circumstances. Important challenges face aquaculture and ensuring it is sustainable. These will partly be met by increased understanding through research and the development of technological solutions. Best practice clearly does not imply only the use of intensive aquaculture; considerable improvements can be made to all systems and approaches can be transferred. Whichever system is appropriate, more emphasis will be placed on increasing efficiency and maximising the use of valuable resources. A broader view of resources will encompass multiple use of location and the environmental impact of aquaculture, disease prevention rather than control and limiting the use of chemical or antibiotic solutions, the sustainable use of feed ingredients and decreasing reliance on marine products. Biotechnology may offer increased opportunity; there is already perceived but uneven market resistance to genetically modified products. Global forces such as climate change will have important consequences in relation to which species are farmed and where species are farmed. Increased water temperatures may allow species to be grown in new regions but also end the culture of other species. The

importance of the contribution that aquaculture makes to human nutrition will continue to increase and considerable work is being done to ensure its effectiveness.

ACKNOWLEDGEMENTS

My sincere thanks go to Z.-Y. He, Zhejiang Provincial Fisheries Bureau for providing detailed information on Chinese aquaculture and for hosting my visits to his wonderful province.

38 Frozen Seafood Products: Description

Peggy Stanfield
Dietetic Resources

CONTENTS

This book is not the proper forum to discuss the manufacture of every frozen seafood product available on the market. However, regulatory agencies such as the National Marine Fisheries Service (NMFS) have issued some minimal criteria for several frozen seafood and seafood products: what they are, what types and styles are available, and so on. This chapter describes each available frozen seafood product based on the product grades issued by the NMFS. A product grade is established to achieve two objectives: ensure product safety and to minimize economic fraud.

I. FROZEN HEADLESS DRESSED WHITING

A. Description of the Product

The product described in this section consists of clean, wholesome whiting (silver hake) *Merluccius bilineraris, Merluccius albidus*, completely and cleanly headed and adequately eviscerated. The fish are packaged and frozen in accordance with good commercial practice and are maintained at temperatures necessary for the preservation of the product.

B. Grades of Frozen Headless Dressed Whiting

U.S. Grade A is the quality of frozen headless dressed whiting that possesses a good flavor and odor.

U.S. Grade B is the quality of frozen headless dressed whiting that possesses at least reasonably good flavor and odor.

Substandard or Utility is the quality of frozen headless dressed whiting that otherwise fails to meet the requirements of U.S. Grade B.

C. Determination of the Grade

Good flavor and odor (essential requirements for a U.S. Grade A product) means that the cooked product has the typical flavor and odor of the species and is free from rancidity, bitterness, staleness, and off-flavors and off-odors of any kind.

Reasonably good flavor and odor (minimum requirements of a U.S. Grade B product) means that the cooked product is lacking in good flavor and odor but is free from objectionable off-flavors and off-odors of any kind.

Arrangement of product refers to the packing of the product in a symmetrical manner, bellies or backs all facing in the same direction, and fish neatly dovetailed.

Condition of the packaging material refers to the condition of the cardboard or other packaging material of the primary container.

If the fish is allowed to stand after packing and prior to freezing, moisture from the fish will soak into the packaging material and cause deterioration of that material.

Dehydration refers to the presence of dehydrated (water-removed) tissue on the exposed surfaces of the whiting. Slight dehydration is surface dehydration which is not color-masking. Deep dehydration is color-masking and cannot be removed by scraping with a fingernail.

Minimum size refers to the size of the individual fish in the sample. Fish 2 ounces or over are considered acceptable. Smaller fish cannot be cooked uniformly with acceptable size fish.

Heading refers to the condition of the fish after they have been headed. The fish should be cleanly headed behind the gills and pectoral fins. No gills, gill bones, or pectoral fins should remain after the fish have been headed.

Evisceration refers to the cleaning of the belly cavities of the fish. All spawn, viscera, and belly strings should be removed.

Scaling refers to the satisfactory removal of scales from the fish.

Color of the cut surfaces refers to the color of the cut surfaces of the fish after heading and other processing.

Bruises and broken or split skin refers to bruises over one-half square inch in area and splits or breaks in the skin more than one-half inch in length which are not part of the processing.

Texture defects refers to the absence of normal textural properties of the cooked fish flesh, which are tenderness, firmness, and moistness without excess water. Texture defects are dryness, softness, toughness, and rubberiness.

II. FROZEN HALIBUT STEAKS

A. Product Description

Frozen halibut steaks are clean, wholesome units of frozen raw fish flesh with normally associated skin and bone and are 2 ounces or more in weight. Each steak has two parallel surfaces and is derived from whole or subdivided halibut slices of uniform thickness which result from sawing or cutting perpendicular to the axial length, or backbone, of a whole halibut. The steaks are prepared from either frozen or unfrozen halibut (*Hippoglossus* spp.). They are processed and frozen in accordance with good commercial practice and are maintained at temperatures necessary for the preservation of the product.

B. Styles of Frozen Halibut Steaks

The individual steaks of Style I, random weight pack, are of random weight and neither the weight nor the range of weights is specified.

All steaks of Style II, uniform weight or portion pack, in the package or in the lot are of a specified weight or range of weights.

C. Recommended Dimensions

(a) The recommended dimensions of frozen halibut steaks are not incorporated in the grades of the finished product since dimensions, as such, are not factors of quality for the purpose of these grades. However, the degree of uniformity of thickness among units of the finished product is rated since it is a factor affecting the quality and utility of the product.

(b) It is recommended that the thickness (smallest dimension) of individually frozen halibut steaks be not less than ½ inch and not greater than inches.

Percentage glaze on halibut steak means the percent by weight of frozen coating adhering to the steak surfaces and includes the frost within the package.

Uniformity of thickness means that the thickness is substantially the same for one or more steaks within a package or sample unit.

D. Color Defects

(a) Discoloration of drip liquor means that the free liquid which drains from the thawed steaks is discolored with blood residue usually from the dorsal aorta of the halibut.

(b) Discoloration of light meat means that the normal flesh color of the main part of the halibut steak has darkened due to deteriorative influences.

(c) Discoloration of the dark meat means that the normal color of the surface fat shows increasing degrees of yellowing due to oxidation.

(d) Non-uniformity of color refers to noticeable differences in color on a single steak or between adjacent steaks in the same package.

(e) Dehydration refers to the appearance of a whitish area on the surface of a steak due to the removal of water or drying of the affected area.

(f) Honeycombing refers to the visible appearance of numerous discrete holes or openings of varying size on the steak surface.

(g) Workmanship defects refers to appearance defects that were not eliminated during processing and are considered either objectionable or poor commercial practice.

(h) Texture defect refers to an undesirable increase in toughness and/or dryness, fibrousness, and watery nature of halibut examined in the cooked state.

III. FROZEN SALMON STEAKS

A. Product Description

Frozen salmon steaks are clean, wholesome units of frozen raw fish flesh with normally associated skin and bone and are 2.5 ounces or more in weight. Each steak has two parallel surfaces and is derived from whole or subdivided salmon slices of uniform thickness which result from sawing or cutting dressed salmon perpendicularly to the axial length, or backbone. The steaks are prepared from either

frozen or unfrozen salmon (*Oncorhynchus* spp.) and are processed and frozen in accordance with good commercial practice and are maintained at temperatures necessary for the preservation of the product. The steaks in an individual package are prepared from only one species of salmon.

B. Species

Frozen salmon steaks covered huiby are prepared from salmon of any of the following species:

Silver or coho (*0. kisutch*)
Chum or keta (*0. keta*)
King, chinook, or spring (*0. tshawytscha*)
Red, sockeye (*0. nerka*)
Pink (*0. gorbuscha*)

C. Styles

The individual steaks of Style I, random weight pack are of random weight and neither the individual steak weight nor the range of weights is specified. The steaks in the lot represent the random distribution cut from the head to tail of a whole dressed salmon.

The individual steaks of Style II, random weight combination pack, are of random weight and neither the individual steak weight nor the range of weights is specified. The steaks in the lot represent a combination of cuts from selected parts of the whole dressed salmon.

All steaks of Style III, uniform weight or portion pack, in the package or in the lot are of a specified weight or range of weights.

D. Recommended Dimensions

It is recommended that the thickness (smallest dimension) of individually frozen salmon steaks be not less than 1/2 inch and not greater than 1 1/2 inches.

General appearance defects refer to poor arrangement of steaks, distortion of steaks, wide variation in shape, between steaks greater than normal number of head and/or tail pieces, imbedding of packaging material into fish flesh, inside condition of package, frost deposit, excessive or nonuniform skin glaze, and undesirable level of natural color.

Dehydration refers to the appearance of a whitish area on the surface of a steak due to the evaporation of water or drying of the affected area.

Uniformity of thickness means that the steak thickness is within the allowed manufacturing tolerance between the thickest and thinnest parts of the steaks within a package or sample unit.

Workmanship defects refers to appearance defects that were not eliminated during processing and are considered objectionable or poor commercial practice. They include the following: Blood spots, bruises, cleaning(refers to inadequate cleaning of the visceral cavity from blood, viscera and loose or attached appendages), cutting (refers to irregular, inadequate, unnecessary, or improper cuts and/or trimmings), fins, foreign material (refers to any loose parts, of fish or other than fish origin), collar bone, girdle(refers to bony structure adjacent to fin), loose skin, pugh marks, sawdust, and scales.

E. Color Defects

Discoloration of fat portion means that the normal color of the fat shows increasing degrees of yellowing due to oxidation.

Discoloration of lean portion means that the normal surface flesh color has faded or changed due to deteriorative influences.

Nonuniformity of color refers to noticeable differences in surface flesh color on a single steak or between adjacent steaks in the same package or sample unit. It also includes color variation of the visceral cavity and skin watermarking.

Honeycombing refers to the visible appearance on the steak surface of numerous discrete holes or openings of varying size.

Texture defect refers to an undesirable increase in toughness and/or dryness, fibrousness, and watery nature of salmon examined in the cooked state.

IV. FROZEN FISH FILLET BLOCKS

A. Product Description

Frozen fish blocks are rectangularly shaped masses made from a single species of fish flesh. They are made from fillets or fillet pieces that are either skin-on and scaled or skinless. Blocks processed from skin-on fish flesh should be so labeled. The blocks should not contain minced or comminuted fish flesh. The blocks should not be made by restructuring (reworking) pieces of fish blocks into the shape of a fish block.

Dehydration is a defect that refers to loss of moisture from the surface of a fish block during frozen storage. Affected areas have a whitish appearance.

Moderate dehydration masks the surface color of the product and affects more than 5 percent up to and including 15 percent of the surface area. If more then 15 percent of the surface area is affected, each additional 15 percent of surface area affected is another instance. Moderate dehydration can be readily removed by scraping with a blunt instrument.

Excessive dehydration masks the normal flesh color and penetrates the product. It affects more than 5 percent up to and including 10 percent of the surface area. If more than 10 percent of the surface area is affected, each additional 10 percent of surface area affected is another instance. Excessive dehydration requires a knife or other sharp instrument to remove.

Uniformity of block size. This defect refers to the degree of conformity to the declared size. It includes

deviations from the standard length, width or thickness. Only one deviation for each dimension should be counted.

Moderate means a deviation of length and width of 1/8 inch (0.32 cm) or more up to and including 1/4 inch (0.64 cm). A deviation of thickness of 1/16 inch (0.16 cm) or more up to and including inch 1/8 (0.32 cm).

Excessive means if over ¼ inch (0.64 cm), each additional inch (0.32 cm) of length and width is another instance. If over (0.32 cm), each additional 1/16 inch (0.16 cm) of thickness is another instance.

Underweight refers to underweight deviations from the stated weight.

Slight means from 0.1 ounce (2.84 g) up to and including 1.0 ounce (28.35 g).

Moderate means over 1.0 ounce (28.35 g) up to and including 4.0 ounces (113.4 g).

Excessive means if over 4.0 ounces (113.4 g), each additional 1.0 ounce (28.35 g) is another instance.

An acceptable edge angle is an angle formed by two adjoining surfaces whose apex (deviation from 90 degrees) is within 0.95 cm off a carpenter's square placed along its surfaces. An acceptable corner angle is an angle formed by three adjoining surfaces whose apex is within 0.95 cm of a carpenter's square.

Improper fill is a defect that refers to voids, air packets, ice pockets, ragged edges, bumps, depressions, damage, and embedded packaging material, each of which is greater than 1/8 inch (0.32 cm) in depth, and which would result in product loss after cutting. It is estimated by determining the minimum number of 1-ounce (28.35 g) model units that could be affected adversely. For the purpose of estimating product loss, the 1-ounce (28.35 g) model unit should have the dimensions $4 \times 1 \times 5/8$ inch ($10.16 \times 2.54 \times 1.59$ cm). The total number of model units that would be affected adversely is the number of instances.

Belly flaps (napes) may be either loose or attached to a fillet or part of a fillet. The maximum amount of belly flaps should not exceed 15 percent by declared weight of the block if this amount does exceed 15 percent, each additional 5 percent by declared weight is another instance.

Each lump or mass of clotted blood greater than 3/16 inch (0.48 cm) up to and including 3/8 inch (0.95 cm) in any dimension is an instance of a blood spot. If a blood spot is larger than 3/8 inch (0.95 cm), each additional 3/16 (0.48 cm) is another instance.

Bruises include distinct, unnatural, dark, reddish, grayish, or brownish off-colors due to diffused blood. Each instance is each bruise larger than 0.5 square inch (3.32 cm^2) and less than 1.5 square inch (9.68 cm^2). For each bruise 1.5 square inch (9.68 cm^2) or larger, each additional complete 1.0 square inch (6.45 cm^2) is another instance.

Discoloration refers to deviations from reasonably uniform color characteristics of the species used, such as melanin deposits, yellowing, rusting or other kinds of discoloration of the fish flesh.

Moderate discoloration is a noticeable but moderate degree which is greater than 0.5 square inch (3.23 cm^2) up to and including 1.5 square inch (9.68 cm^2) is one instance. If the discoloration is greater than 1.5 square inch (9.68 cm^2), each additional complete 1.0 square inch (6.45 cm^2) is another instance.

An excessive degree of discoloration is greater than 0.5 square inch (3.23 cm^2) up to and including 1.5 square inch (9.68 cm^2). If the discoloration is greater than 1.5 square inch (9.68 cm^2) each additional complete 1.0 square inch (6.45 cm^2) is another instance.

Viscera and roe refer to any portion of the internal organs. Each occurrence of viscera and roe is an instance. Lace (frill) is a piece of tissue adhering to the edge of a flatfish (Order Pleuronectifonnes) fillet. For each lace, each 1/2 inch (1.27 cm) is an instance.

In skinless fish blocks, each piece of skin larger than 0.5 square inch (3.23 cm^2) up to and including 1.0 square inch (6.45 cm^2) is an instance. For each piece of skin that is larger than 1.0 square inch (6.45 cm^2), each additional complete 0.5 square inch (3.23 cm^2) in area is another instance. For pieces of skin smaller than 0.5 square inch (3.23 cm^2), the number of 0.5-square-inch (3.23 cm^2) squares fully or partially occupied after collecting these pieces on a grid is the number of instances.

Each piece of membrane (black belly lining) larger than 0.5 square inch (3.23 cm^2) up to and including 1.5 square inch (9.68 cm^2) is an instance. For pieces of membrane (black belly lining) that are larger than 1.5 square inch (9.68 cm^2), each additional complete 0.5 square inch (3.23 cm^2) in area is another instance.

For skin-on fillets that have been scaled, an instance is an area of scales over 0.5 square inch (3.23 cm^2) up to and including 1.5 square inch (9.68 cm^2). If the area is greater than 1.5 square inch (9.68 cm^2), each additional complete 1.0 square inch (8.45 cm^2) is another instance. Loose scales are counted and instances are deducted in the same manner as for skinless fillets.

For skinless fillets, the first five to ten loose scales is an instance. If there are more than ten loose scales, each additional complete count of five loose scales is another instance.

Any harmless material not derived from fish, such as packaging material, is foreign material. Each occurrence is an instance.

Bones (including pin bone and fin bone):

(i) Each bone defect to a bone or part of a bone whose maximum profile is 3/16 inch (0.48 cm) or more in length, or at least 1/32 inch (0.08 cm) in shaft diameter or width, or, for bone chips, a longest dimension of at least 3/16 inch (0.48 cm).

(ii) An excessive degree of bone defect is each bone whose maximum profile can not be fitted

into a rectangle, drawn on a flat, solid surface, that has a length of 1 3/16 inch (3.02 cm) and a width of ? inch (0.95 cm).

Fins or part fins is a defect that refers to two or more bones connected by membrane, including internal or external bones, or both, in a cluster.

(i) Moderate occurrence: Connected by membrane in a cluster, no internal bone.
(ii) Excessive occurrence: Connected by membrane in a cluster with internal bone.

Parasites are of two types:

(i) Metazoan parasites. Each such parasite or fragment of such a parasite that is detected is an instance.
(ii) Parasitic copepods. Each such parasite or a fragment of such a parasite that is detected is an instance.

Texture means that the cooked product has the textural characteristics of the indicated species of fish. It does not include any abnormal textural characteristics such as mushy, soft, gelatinous, tough, dry or rubbery.

(i) Moderate means moderately abnormal textural characteristics.
(ii) Excessive means excessively abnormal textural characteristics.

V. FROZEN MINCED FISH BLOCKS

A. Product Description

Frozen minced fish blocks are uniformly shaped masses of cohering minced fish flesh. A block may contain flesh from a single species or a mixture of species with or without food additives. The minced flesh consists entirely of mechanically separated fish flesh processed and maintained in accordance with good commercial practice. This minced flesh is made entirely from species which are known to be safe and suitable for human consumption.

B. Product Forms

Types are as follows.
Unmodified means food additives are used.

(i) Single species
(ii) Mixed species

Modified means contains food additives.

(i) Single species
(ii) Mixed species

Color classifications include:

(1) White
(2) Light
(3) Dark

Texture is described as:

(1) Coarse—Flesh has a fibrous consistency.
(2) Fine—Flesh has a partially fibrous consistency because it is a mixture of small fibers and paste.
(3) Paste/Puree—Flesh has no fibrous consistency.

C. Definitions of Defects

Deteriorative color refers to discoloration from the normal characteristics of the material used. Deterioration can be due to yellowing of fatty material, to browning of blood pigments, or other changes.

(i) Slight deteriorative discoloration—refers to a color defect that is slightly noticeable but does not seriously affect the appearance, desirability, or eating quality of the product.
(ii) Moderate deteriorative discoloration—refers to a color defect that is conspicuously noticeable but does not seriously affect the appearance, desirability, or eating quality of the product.
(iii) Excessive deteriorative discoloration—refers to a defect that is conspicuously noticeable and that seriously affects the appearance, desirability, or eating quality of the product.

Dehydration refers to a loss of moisture from the surfaces of the product during frozen storage.

(i) Slight dehydration—is surface color masking, affecting more than 5 percent of the area, which can be readily removed by scraping with a blunt instrument.
(ii) Moderate dehydration—is deep color masking penetrating the flesh, affecting less than 5 percent of the area, and requiring a knife or other sharp instrument to remove.
(iii) Excessive dehydration—is deep color masking penetrating the flesh, affecting more than 5 percent of the area, and requiring a knife or other sharp instruments to remove.

Uniformity of size refers to the degree of conformity to the declared contracted dimensions of the blocks. A deviation is considered to be any deviation from the contracted length, width, or thickness; or from the average dimensions of the blocks, physically determined, if no dimensions are contracted. Only one deviation from each dimension may be assessed. Two readings for length, three

readings for width, and four readings for thickness will be measured.

(i) Slight—two or more deviations from declared or average length, width, and thickness up to ± 1/8 inch.
(ii) Moderate—two or more deviations from declared or average length, width, and thickness from ± 1/8 inch to ± xx inch (variable, depending on products).
(iii) Excessive—two or more deviations from declared or average length, width, and thickness over ± 3/8 inch.

Uniformity of weight refers to the degree of conformity to the declared weight. Only underweight deviations are assessed.

(i) Slight—any minus deviation of not more than 2 ounces.
(ii) Excessive—any minus deviation over 2 ounces.

An acceptable edge angle is an angle formed by two adjoining surfaces of the fish block whose apex is within 3/8 inch of a carpenter's square placed along the surfaces of the block. For each edge angle, three readings will be made and at least two readings must be acceptable for the whole edge angle to be acceptable. An acceptable corner angle is an angle formed by 3 adjoining surfaces whose apex is within 3/8 inch of the apex of a carpenter's square placed on the edge surfaces. Any edge or corner angle which fails to meet these measurements is unacceptable.

(i) Slight—two unacceptable angles.
(ii) Moderate—three unacceptable angles.
(iii) Excessive—four or more unacceptable angles.

Improper fill refers to surface and internal air or ice voids, ragged edges, or damage. Improper fill is measured as the minimum number of 1-ounce units that would be adversely affected when the block is cut. For this purpose, the dimensions of a 1-ounce unit are 4 × 1 × 5/8 inch.

(i) Slight—1 to 3 units adversely affected.
(ii) Excessive—over 3 units adversely affected.

Blemishes refer to pieces of skin, scales, blood spots, nape (belly) membranes (regardless of color), or other harmless extraneous material. One instance means that the area occupied by a blemish or blemishes is equal to a 1/4 inch square. Instances are prorated on a per pound basis.

(i) Slight—5 to 15 instances per pound.
(ii) Moderate—more than 15 but less than 30 instances per pound.
(iii) Excessive—30 or more instances per pound.

Bones refer to any objectionable bone or piece of bone that is 1/4 inch or longer and is sharp and rigid. Perceptible bones should also be checked by their grittiness during the normal evaluation of the texture of the cooked product (10). Bones are prorated on a five pound sample unit basis.

(i) Slight—1 to 2 bones per five pound sample unit.
(ii) Moderate—3 to 4 bones per five pound sample unit.
(iii) Excessive—over 4 bones, but not to exceed 10 bones, per five pound sample unit.

Flavor and odor are evaluated organoleptically by smelling and tasting the product after it has been cooked.

Good flavor and odor (essential requirements for a Grade A product) means that the cooked product has the flavor and odor characteristic of the indicated species of fish and is free from staleness, bitterness, rancidity, and off-flavors and off-odors of any kind.

Reasonably good flavor and odor (minimum requirements of Grade B product) means that the cooked product is moderately absent of flavor and odor characteristic of the indicated species. the product is free from rancidity, bitterness, staleness, and off-flavors and off-odors of any kind.

Minimal acceptable flavor and odor (minimum requirements of a Grade C product) means that the cooked product has moderate storage induced flavor and odor, but is free from any objectionable off-flavors and off-odors that may be indicative of spoilage or decomposition.

Texture defects are judged on a sample of the cooked fish.

(i) Slight—flesh is fairly firm, only slightly spongy or rubbery. It is not mushy. There is no grittiness due to bone fragments.
(ii) Moderate—flesh is mildly spongy or rubbery. Slight grittiness may be present due to bone fragments.
(iii) Excessive—flesh is definitely spongy, rubbery, very dry, or very mushy. Moderate grittiness may be present due to bone fragments.

D. Additives

Minced fish blocks may be modified with food additives as necessary to stabilize product quality in accordance with the federal requirements.

The fish material should be processed and maintained in accordance with federal hygiene requirements.

VI. FROZEN RAW FISH PORTIONS

A. Description of the Product

The product described in this section consists of clean, wholesome, shaped masses of cohering pieces (not

ground) of fish flesh. The fish portions are cut from frozen fish blocks, and are packaged in accordance with good manufacturing practice. They are maintained at temperatures necessary for the preservation of the product. All fish portions in an individual package are prepared from the flesh of one species of fish.

B. Style

Style I, Skinless portions, means portions prepared from fish blocks which have been made with skinless fillets.

Style II, Skin-on portions, means portions prepared from fish blocks which have been made from demonstrably acceptable skin-on fillets.

C. Types

Type I, Uniform shaped, means all portions in the sample are uniformly shaped.

Type II, Specialty cut, is all portions not covered in Type I.

Dehydration refers to the presence of dehydrated (water-removed) tissue in the portions. Slight dehydration is surface dehydration which is not colormasking. Deep dehydration is color masking and cannot be removed by scraping with a blunt instrument.

Uniformity of size refers to the degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest in the sample.

Uniformity of weight refers to the degree of uniformity of the weights of portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions in the sample. No deductions are made for weight ratios less than 1.2 for Type I.

Blemishes refers to skin (except for Style II), blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid marked off in 1/4-inch squares 1/16 square inch) over the defect area. Each square is counted as 1 whether it is full or fractional.

Bones means the presence of potentially harmful bones in a portion. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the fish flesh and texture of skin in Style II refers to the absence of the normal textural properties of the cooked fish flesh and to the absence of tenderness of the cooked skin in Style II.

Normal textural properties of cooked fish flesh are tenderness, firmness, and moistness without excess water. Texture defects of the cooked flesh are dryness, mushiness, toughness, and rubberiness. Texture defects of the cooked skin in Style II are mushiness, rubberiness, toughness, and stringiness.

D. General Definitions

Small (overall assessment) refers to a condition that is noticeable but is only slightly objectionable.

Large (overall assessment) refers to a condition that not only is noticeable but is seriously objectionable.

Minor (individual assessment) refers to a defect that slightly affects the appearance and/or utility of the product.

Major (individual assessment) refers to a defect that seriously affects the appearance and/or utility of the product.

The net weight of the portions if glazed should be determined by the following method:

(i) Weigh the portions with the glaze intact, which gives the gross weight.
(ii) Thaw the glaze from the surfaces of the product with flowing tap water.
(iii) Gently wipe off the excess water from the surfaces with a single water saturated paper towel.
(iv) Weigh the deglazed portions, which gives the net weight.

VII. FROZEN RAW BREADED FISH STICKS

A. Description of the Product

Frozen raw breaded sticks are clean, wholesome, rectangular-shaped unglazed masses of cohering pieces (not ground) of fish flesh coated with breading. The sticks are cut from frozen fish blocks; are coated with a suitable, wholesome batter and breading; are packaged; and frozen in accordance with good commercial practice. They are maintained at temperatures necessary for preservation of the product. Frozen raw breaded fish sticks weigh up to and including 1½ ounces; are at least 3/8 inch thick; and their largest dimension is at least 3 times the next largest dimension. All sticks in an individual package are prepared from the flesh of one species of fish.

Frozen raw breaded fish sticks should contain 72 percent by weight of fish flesh determined by the official end-product method. Fish flesh content may be determined by the on-line method provided, That the results are consistent with the fish flesh content requirement of 72 percent by weight when verified by the official end-product method. Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors which may affect the relative fish flesh content.

B. Definitions

Selection of the sample unit: The sample unit should consist of 10 frozen raw breaded fish sticks taken at random

from one or more packages as required. The fish sticks are spread out on a flat pan or sheet and are examined.

Examination of sample, frozen state:

Condition of package refers to the presence in the package of loose breading and/or loose frost.

Ease of separation refers to the difficulty of separating sticks from each other or from packaging material that are frozen together during the freezing.

Broken stick means a stick with a break or cut equal to or greater than one-half the width of the stick.

Damaged stick means a stick that has been mashed, physically or mechanically injured, misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of squares ¼ inch (that is, squares with an area of 1/16 square inch each) to measure the area of the stick affected. Deductions are not made for damage less than 1/16 square inch.

Uniformity of size refers to the degree of uniformity in length and width of the frozen sticks. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length or width up to 1/4 inch.

Uniformity of weight refers to the degree of uniformity of the weights of the sticks. Uniformity is measured by the combined weight of the two heaviest sticks divided by the combined weight of the two lightest sticks. No deductions are made for weight ratios less than 1.15.

Cooked state means the state of the product after cooking in accordance with the instructions accompanying the product. However, if specific instructions are lacking, the product for inspection is cooked as follows: Transfer the product, while still in frozen state, into a wire mesh fry basket large enough to hold the fish sticks in a single layer and cook by immersing 2–3 minutes in 375°F. liquid or hydrogenated cooking oil. After cooking, allow the fish sticks to drain 15 seconds and place the fish sticks on a paper napkin or towel to absorb excess oil.

Examination of sample, cooked state:

Distortion refers to the degree of bending of the long axis of the stick. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than 1/4 inch.

Coating defects refers to breaks, lumps, ridges, depressions, blisters, or swells and curds in the coating of the cooked product. Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible. Lumps are objectionable outcroppings of breading on the stick surface.

Ridges are projections of excess breading at the edges of the fish flesh.

Depressions are objectionable visible voids or shouldow areas which are lightly covered by breading. Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating. Curd refers to crater-like holes in the breading filled with coagulated albumin. Instances of these defects are measured by a plastic grid marked off in ¼-inch squares (1/16 square inch). Each square is counted as 1 whether it is full or fractional.

Blemishes refers to skin, blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid market off in ¼-inch squares (1/16 square inch) over the defect area. Each square is counted as 1 whether it is full or fractional.

Bones means the presence of potentially harmful bones in a stick. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the coating refers to the absence of the normal textural properties of the coating which are crispness and tenderness. Coating texture defects are dryness, sogginess, mushiness, doughyness, toughness, pastiness as sensed by starchiness or other sticky properties felt by mouth tissues and/or mealiness.

Texture defects of the fish flesh refers to the absence of the normal textural properties of the cooked fish flesh which are tenderness, firmness, and moistness without excess water. Texture defects of the flesh are dryness, mushiness, toughness, and rubberiness.

VIII. FROZEN RAW BREADED FISH PORTIONS

A. Description of the Product

Frozen raw breaded portions are clean, wholesome, uniformly shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading. The portions are cut from frozen fish blocks; are coated with a suitable, wholesome batter and breading; and are packaged and frozen in accordance with good commercial practice. They are maintained at temperatures necessary for the preservation of the product. Frozen raw breaded fish portions weigh more than 1-1/2 ounces, and are at least 3/8-inch thick. Frozen raw breaded fish portions contain not less than 75 percent, by weight, of fish flesh. All portions in an individual package are prepared from the flesh of one species of fish.

B. Styles

Style I, Skinless portions, are portions prepared from fish blocks which have been made with skinless fillets.

Style II, Skin-on-portions, are portions prepared from fish blocks which have been made with demonstrably acceptable skin-on fillets.

Composition of the product.

(a) Frozen raw breaded fish portions should contain 75 percent by weight of fish flesh. Fish flesh content may be determined by the on-line method provided that the results are consistent with the fish flesh content requirement of 75 percent by weight, when verified by the official end-product method.
(b) Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors which may affect the relative fish flesh content.

Examination of sample, frozen state:

(1) Condition of package refers to the presence in the package of loose breading and/or loose frost.
(2) Ease of separation refers to the difficulty of separating the portions from each other or from the packaging material.

Broken portion means a portion with a break or cut equal to or greater than one-half the width or length of the portion.

Damaged portion means a portion that has been mashed, physically or mechanically injured. misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of squares ¼ inch × ¼ inch (that is, squares with an area of 1/16 square inch each) to measure the area of the portion affected. No deductions are made for damage of less than 1/16 square inch.

Uniformity of size refers to the degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest portions in the sample. Deductions are not made for overall deviations in length or width up to 1/4 inch.

Uniformity of weight refers to the degree of uniformity of the weights of the portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions in the sample. No deductions are made for weight ratios less than 1.2.

Cooked state means the state of the product after being cooked in accordance with the instructions accompanying the product.

C. Examination of Sample, Cooked State

(1) Distortion refers to the degree of bending of the long axis of the portion. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than ¼ inch.
(2) Coating defects refers to breaks, lumps, ridges, depressions, blisters, or swells and curds in the coating of the cooked product. Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible. Lumps are objectionable outcroppings of breading on the portion surface. Ridges are projections of excess breading at the edges of the portions.

Depressions are objectionable visible voids or shouldow areas that are lightly covered by breading. Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating. Curd refers to crater-like holes in the breading filled with coagulated white or creamy albumin. Instances of these defects are measured by a plastic grid marked off in 1/4-inch squares (1/16 square inch). Each square is counted as 1 whether it is full or fractional.

(3) Blemishes refers to skin (except for Style II), blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refers to each occurrence measured by placing a plastic grid marked off in 1/4-inch squares (1/16 square inch) over the defect area. Each square is counted as 1 whether it is full or fractional.
(4) Bones means the presence of potentially harmful bones in a portion. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.
(5) Texture defects of the coating refers to the absence of the normal textural properties of the coating which are crispness and tenderness. Defects in coating texture are dryness, sogginess. mushiness, doughyness, toughness, pastyness, as sensed by starchiness or other sticky properties felt by mouth tissues and/or mealiness.
(6) Texture defects of the fish flesh and texture of skin in Style II refers to the absence of the normal textural properties of the cooked fish flesh and to the absence of tenderness of the cooked skin in Style II.

Normal textural properties of cooked fish flesh are tenderness, firmness, and moistness without excess water. Texture defects of the cooked fesh are dryness, mushiness, toughness, and rubberiness. Texture defects of the cooked skin in Style II are mushiness, rubberiness, toughness, and stringiness.

Minimum fish flesh content—End-product determination refers to the minimum percent, by weight, of the average fish flesh content of three frozen raw breaded portions (sample unit for fish flesh determination).

IX. FROZEN FRIED FISH STICKS

A. Description of the Product

Frozen fried fish sticks are clean, wholesome, rectangular-shaped unglazed masses of cohering pieces (not ground) of fish flesh coated with breading and partially cooked. The sticks are cut from frozen fish blocks; are coated with a suitable, wholesome batter and breading; are fried, packaged, and frozen in accordance with good manufacturing practices. They are maintained at temperatures necessary for preservation of the product. Frozen fried fish sticks weigh up to and including 1½ ounces; are at least three-eighths of an inch thick; and their largest dimension is at least three times the next largest dimension. All sticks in an individual package are prepared from the flesh of one species of fish.

Frozen fried fish sticks should contain 60 percent by weight of fish flesh. Fish flesh content may be determined by the on-line method provided, that the results are consistent with the fish flesh content requirement of 60 percent by weight, when verified by the official end-product method.

Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors which may affect the relative fish flesh content.

Definitions of factors for point deductions are as follows:

B. Examination of Sample, Frozen State

(1) Condition of package refers to the presence in the package of free excess oil and/or loose breading and/or loose frost.

(2) Ease of separation refers to the difficulty of separating sticks from each other or from packaging material that are frozen together after the frying operation and during the freezing.

(3) Broken stick means a stick with a break or cut equal to or greater than one-half the width of the stick.

(4) Damaged stick means a stick that has been mashed, physically or mechanically injured, misshaped or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of squares ¼ inch (that is, squares with an area of 1/16 square inch each) to measure the area of the stick affected. Deductions are not made for damage less than 1/16 square inch.

(5) Uniformity of size refers to the degree of uniformity in length and width of the frozen sticks. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length of width up to ¼ inch.

(6) Uniformity of weight refers to the degree of uniformity of the weights of the sticks. Uniformity is measured by the combined weight of the two heaviest sticks divided by the combined weight of the two lightest sticks. No deductions are made for weight ratios less than 1.15.

Examination of sample, cooked state:

Distortion refers to the degree of bending of the long axis of the stick. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than 1/4 inch.

Coating defects refers to breaks, lumps, ridges, depressions, blisters, or swells and curds in the coating of the cooked product. Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible. Lumps are objectionable outcroppings of breading on the stick surface.

Ridges are projections of excess breading at the edges of the fish flesh.

Depressions are objectionable visible voids or shouldow areas which are lightly covered by breading. Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating. Curd refers to crater-like holes in the breading filled with coagulated albumin. Instances of these defects are measured by a plastic grid marked off in ¼-inch squares (1/16 square inch). Each square is counted as one whether it is full or fractional.

Blemishes refers to skin, blood spots, or bruises, objectionable dark fatty flesh, carbon specks or extraneous material. Instances of blemishes refers to each occurrence measured by placing a plastic grid marked off in ¼ inch squares (1/16 square inch) over the defect area. Each square is counted as one whether it is full or fractional.

Bones means the presence of potentially harmful bones in a stick. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the coating refers to the absence of the normal textural properties of the coating which are crispness and tenderness. Coating texture defects are dryness, sogginess, mushiness, doughiness, toughness, pastiness, as sensed by starchiness or other sticky properties felt by mouth tissues; oiliness to the degree of impairment of texture; and/or mealiness.

Texture defects of the fish flesh refers to the absence of normal textural properties of the cooked fish flesh, which are tenderness, firmness, arid moistness without excess water. Texture defects of the flesh are dryness, softness, toughness, and rubberiness.

X. FROZEN FRIED FISH PORTIONS

A. Description of the Product

Frozen fried fish portions are clean, wholesome, uniformly shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading and partially cooked. The portions are cut from frozen fish blocks; coated with a suitable, wholesome batter and breading; are fried, packaged, and frozen in accordance with good manufacturing practices. They are maintained at temperatures necessary for preservation of the product. Frozen fried fish portions weigh more than 11/2 ounces and are at least three-eighths of an inch thick. All portions in an individual package are prepared from the flesh of one species of fish.

Frozen fried fish portions should contain 65 percent by weight of fish flesh. Fish flesh content may be determined by the on-line method, provided, that the results are consistent with the fish flesh content requirement of 65 percent by weight, when verified by the official end-product method.

Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors which may affect the relative fish flesh content.

Ease of separation refers to the difficulty of separating portions from one another or from packaging material that are frozen together after the frying operation and during the freezing.

Broken portion means a portion with a break or cut equal to or greater than one-half the width or length of the portion.

Damaged portion means a portion that has been mashed, physically or mechanically injured, misshaped or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of squares 1/4 inch (that is, squares with an area of 1/16 square inch each) to measure the area of the portion affected. Deductions are not made for damage less than 1/16 square inch.

Uniformity of size refers to the degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length or width up to ¼ inch.

Uniformity of weight refers to the degree of uniformity of the weights of the portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions. No deductions are made for weight ratios less than 1.20.

XI. FRESH AND FROZEN SHRIMP

A. Product Description

The products are clean wholesome shrimp that are fresh or frozen, raw or cooked. Product forms are:

1. Types

(1) Chilled, fresh (not previously frozen).
(2) Unfrozen, thawed (previously frozen).
(3) Frozen individually (IQF), glazed or unglazed.
(4) Frozen solid pack, glazed or unglazed. (b) Styles. (1) Raw (uncoagulated protein).

2. Blanched (Parboiled)

Blanched means heated for a period of time such that the surface of the product reaches a temperature adequate to coagulate the protein.

Cooked-heated for a period of time such that the thermal center of the product reaches a temperature adequate to coagulate the protein.

3. Market Forms

(1) Heads on (head, shell, tail fins on).
(2) Headless (only head removed: shell, tail fins on).
(3) Peeled, undeveined, round, tail on (all shell removed except last shell segment and tail fins, with segments unslit].
(4) Peeled, undeveined, round, tail off (all shell and tail fins removed, with segments unslit).
(5) Peeled and deveined, round, tail on (all shell removed except last shell segment and tail fins, with segments shouldowly slit to last segment).
(6) Peeled and deveined, round, tail off (all shell and tail fins removed, with segments shouldowly slit to last segment).
(7) Peeled and deveined, fantail or butterfly, tail on (all shell removed except last shell segment and tail fins,with segments deeply slit to last segment).
(8) Peeled and deveined, fantail or butterfly, tail off (all shell and tail fin removed, with segments deeply slit to last segment).
(9) Peeled and deveined, western (all shell removed except last shell segment and tail fins, with segments split to fifth segment and vein removed to end of cut).
(10) Other forms of shrimp as specified and so designated on the label.

B. Examination in the Frozen State

Dehydration refers to a general drying of the shrimp flesh that is noticeable after any glaze and shell are removed. It

includes any detectable change from the normal characteristic, bright appearance of freshly caught, properly iced or properly processed shrimp.

Slight dehydration means scarcely noticeable drying of the shrimp flesh that will not affect the sensory quality of the sample.

Moderate dehydration means conspicuous drying of the shrimp flesh that will not seriously affect the sensory quality of the sample.

Excessive dehydration means conspicuous drying that will seriously affect the sensory quality of the sample.

Examination in the fresh or thawed state indicates the following.

Uniformity of size refers to the degree of uniformity of the shrimp in the container to determine their conformity to the declared count.

Black spots, improperly headed (throats), and improperly cleaned ends refer to the presence of any objectionable black or darkened area that affects the desirability or sensory quality of the shrimp, whether the market form is shell-on or peeled. Objectionable black spot refers to more than three instances of penetrating black spot that is visible but difficult to measure because of its small size (approximately the size of a pencil point): or any areas larger than a pencil point that penetrates the flesh: or aggregate areas of non-penetrating surface black spot on the shell or membrane that is equal to or greater than 1/3 the area of the smallest segment.

Assessments are made on individual shrimp:

Throats are those portions of flesh and/or extraneous material from the head (cephalothorax) that remain attached to the first segment after heading.

Pieces of shrimp, broken or damaged shrimp:

Piece means for a count of 70 or less unglazed shrimp per pound (0.45 kg) any shrimp that has fewer than five segments, with or without tail fins attached: or, for a count of more than 70 unglazed shrimp per pound (0.45 kg), any shrimp that has fewer than four segments: or, any whole shrimp with a break in the flesh greater than 2/3 of the thickness of the shrimp where the break occurs.

Broken shrimp means a shrimp having a break in the flesh greater than 1/3 of the thickness of the shrimp.

Damaged shrimp means a shrimp that is crushed or mutilated so as to materially affect its appearance or useability.

Unusable material includes the following:

Legs refer to walking legs only, whether attached or not attached to the body (heads-on market from excepted).

Loose shell and antennae are any pieces of shell or antennae that are completely detached from the shrimp.

Flipper refers to any detached tail fin with or without the last shell segment attached, with or without flesh inside.

Extraneous material means any harmless material in a sample unit that is not shrimp material.

Unacceptable shrimp refers to abnormal or diseased shrimp.

Head refers to the cephalothorax, except for heads-on shrimp.

Inadvertently peeled and improperly peeled shrimp refer to the presence or absence of head, shell segment, swimmeret, or tail fin, which should or should not have been removed of certain market forms. (Shell-on shrimp with tail fins and/or telson missing is inadvertently peeled, but if the last segment of flesh is missing, the shrimp is damaged.)

Improperly deveined shrimp refers to the presence of dark vein (alimentary canal) containing sand or sediment or roe which should have been removed for peeled and deveined market forms. For shrimp of 70 count per pound (0.45 kg) or less, aggregate areas of dark vein or roe is a defect that are longer than one segment is a defect. For shrimp of 71 to 500 count per pound (0.45 kg), aggregate areas of dark vein or roe defect that are longer than two segments are a defect.

Note: This does not pertain to the last segment. For shrimp of over 500 count per pound (0.45 kg), dark vein or roe of any length is not a defect.

Examination in the cooked state:

Texture. The texture of cooked shrimp should be firm, slightly resilient but not tough, moist but not mushy. Texture as a defect refers to an undesirable toughness, dryness, or mushiness which deviated from the normal characteristics of the species when freshly caught, properly processed, and cooked.

Slight means slightly tough, dry, but not mushy.

Moderate means moderately tough, dry or mushy.

Excessive means excessively tough, very dry or very mushy.

XII. FROZEN RAW BREADED SHRIMP

The U.S. FDA has provided the following standards for frozen raw breaded shrimp.

A. Description

Frozen raw breaded shrimp are whole, clean, wholesome, headless, peeled shrimp which have been deveined where applicable of the regular commercial species, coated with a wholesome, suitable batter and/or breading. Whole shrimp consist of five or more segments of unmutilated shrimp flesh. They are prepared and frozen in accordance with good manufacturing practice and are maintained at temperatures necessary for the preservation of the product.

Frozen raw breaded shrimp is the food prepared by coating one of the optional forms of shrimp with safe and suitable batter and breading ingredients. The food is frozen.

The food tests not less than 50 percent of shrimp material as determined by prescribed method

The term shrimp means the tail portion of properly prepared shrimp of commercial species. Except for composite units, each shrimp unit is individually coated. The optional forms of shrimp are:

(1) Fantail or butterfly: Prepared by splitting the shrimp; the shrimp are peeled, except that tail fins remain attached and the shell segment immediately adjacent to the tail fins may be left attached.
(2) Butterfly, tail off: Prepared by splitting the shrimp; tail fins and all shell segments are removed.
(3) Round: Round shrimp, not split; the shrimp are peeled, except that tail fins remain attached and the shell segment immediately adjacent to the tail fins may be left attached.
(4) Round, tail off: Round shrimp, not split; tail fins and all shell segments are removed.
(5) Pieces: Each unit consists of a piece or a part of a shrimp; tail fins and all shell segments are removed.

The above information is categorized as follows.

1. Styles

Style I, Regular Breaded Shrimp, are frozen raw breaded shrimp containing a minimum of 50 percent of shrimp material.

Style II, Lightly Breaded Shrimp, are frozen raw breaded shrimp containing a minimum of 65 percent of shrimp material.

2. Types

Type I-Breaded fantail shrimp subtypes are:

Subtype A. Split (butterfly) shrimp with the tail fin and the shell segment immediately adjacent to the tail fin.

Subtype B. Split (butterfly) shrimp with the tail fin but free of all shell segments.

Subtype C. Split (butterfly) shrimp without attached tail fin or shell segments.

Type II-Breaded round shrimp subtypes are:

Subtype A. Round shrimp with the tail fin and the shell segment immediately adjacent to the tail fin.

Subtype B. Round shrimp with the tail fin but free of all shell segments.

Subtype C. Round shrimp without attached tail fin or shell segments.

Type III-Breaded split shrimp.

3. Definitions and Methods of Analysis

(a) Fantail shrimp:

This type is prepared by splitting and peeling the shrimp except that for Subtype A the tail fin remains attached and the shell segment immediately adjacent to the tail fin remains attached.

For Subtype B, the tail fin remains, but the shrimp are free of all shell segments.

For Subtype C, the shrimp are free of tail fins and all shell segments.

(b) Round shrimp: This type is the round shrimp, not split. The shrimp are peeled except that for Subtype A, the tail fin remains attached and the shell segment immediately adjacent to the tail fin remains attached.

For Subtype B, the tail fin remains, but the shrimp are free of all shell segments.

For Subtype C, the shrimp are free of all shell segments and tail fins.

B. Composite Units

Each unit consists of two or more whole shrimp or pieces of shrimp, or both, formed and pressed into composite units prior to coating; tail fins and all shell segments are removed; large composite units, prior to coating, may be cut into smaller units.

The batter and breading ingredients referred to are the fluid constituents and the solid constituents of the coating around the shrimp. These ingredients consist of suitable substances which are not food additives as defined by regulations. If they are food additives as so defined, they are used in conformity with established regulations. Batter and breading ingredients that perform a useful function are regarded as suitable, except that artificial flavorings, artificial sweeteners, artificial colors, and chemical preservatives, other than those specifically permitted are not suitable ingredients of frozen raw breaded shrimp. Chemical preservatives that are suitable are:

1. Ascorbic acid, which may be used in a quantity sufficient to retard development of dark spots on the shrimp; and
2. The antioxidant preservatives listed in the regulations that may be used to retard development of rancidity of the fat content of the food, in amounts within the limits prescribed.

The label should name the food, as prepared from each of the optional forms of shrimp specified, and following the numbered sequence of the following data

(1) "Breaded fantail shrimp." The word "butterfly" may be used in lieu of "fantail" in the name.
(2) "Breaded butterfly shrimp, tail off."

(3) "Breaded round shrimp."
(4) "Breaded round shrimp, tail off."
(5) "Breaded shrimp pieces."
(6) Composite units:

If the composite units are in a shape similar to that of breaded fish sticks the name is "Breaded shrimp sticks"; if they are in the shape of meat cutlets, the name is "Breaded shrimp cutlets."

If prepared in a shape other than that of sticks or cutlets, the name is "Breaded shrimp _____," the blank to be filled in with the word or phrase that accurately describes the shape, but which is not misleading.

The word "prawns" may be added in parentheses immediately after the word "shrimp'' in the name of the food if the shrimp are of large size; for example, "Fantail breaded shrimp (prawns)." If the shrimp are from a single geographical area, the adjectival designation of that area may appear as part of the name; for example, "Breaded Alaskan shrimp sticks.''

The names of the optional ingredients used should be listed on the principal display panel or panels of the label with such prominence and conspicuousness as to render them likely to be read and understood by the ordinary individual under customary conditions of purchase. If a spice that also imparts color is used, it should be designated as "spice and coloring,'' unless the spice is designated by its specific name. If ascorbic acid is used to retard development of dark spots on the shrimp, it should be designated as "Ascorbic acid added as a preservative'' or "Ascorbic acid added to retard discoloration of shrimp.''

If any other antioxidant preservative is used, such preservative should be designated by its common name followed by the statement "Added as a preservative.''

Frozen raw lightly breaded shrimp complies with the provisions of frozen raw breaded shrimp except that it contains not less than 65 percent of shrimp material and that in the name prescribed the word "lightly'' immediately precedes the words "breaded shrimp.''

Factors affecting qualities that are measured on the product in the unbreaded or thawed debreaded state are degree of deterioration, dehydrations, sand veins, black spot, extra shell, extraneous material, and swimmerets.

Dehydration refers to the occurrence of whitish areas on the exposed ends of the shrimp (due to the drying of the affected area) and to a generally desiccated appearance of the meat after the breading is removed.

Deterioration refers to any detectable change from the normal good quality of freshly caught shrimp. It is evaluated by noting in the thawed product deviations from the normal odor and appearance of freshly caught shrimp.

Extraneous material consists of nonedible material such as sticks, seaweed, shrimp thorax, or other objects that may be accidentally present in the package.

Slight: Slight refers to a condition that is scarcely noticeable but does affect the appearance, desirability, and/or eating quality of breaded shrimp.

Moderate: Moderate refers to a condition that is conspicuously noticeable but that does not seriously affect the appearance, desirability, and/or eating quality of the breaded shrimp.

Marked: Marked refers to a condition that is conspicuously noticeable and that does seriously affect the appearance, desirability, and/or eating quality of the breaded shrimp.

Excessive: Excessive refers to a condition that is very noticeable and is seriously objectionable.

Halo: Halo means an easily recognized fringe of excess batter and breading extending beyond the shrimp flesh and adhering around the perimeter or flat edges of a split (butterfly) breaded shrimp.

Balling up: Balling up means the adherence of lumps of the breading material to the surface of the breaded coating, causing the coating to appear rough, uneven, and lumpy.

Holidays: Holidays means voids in the breaded coating as evidenced by bare or naked spots.

Damaged frozen raw breaded shrimp: Damaged frozen raw breaded shrimp means frozen raw breaded shrimp that have been separated into two or more parts or that have been crushed or otherwise mutilated to the extent that their appearance is materially affected.

Black spot: Black spot means any blackened area that is markedly apparent on the flesh of the shrimp.

Sand vein: Sand vein means any black or dark sand vein that has not been removed, except for that portion under the shell segment adjacent to the tail fin when present.

Extra shell: Extra shell means any shell segment(s) or portion thereof, contained in the breaded shrimp except the first segment adjacent to the tail fin for Type I, Subtype A, and Type II, Subtype A.

XIII. FROZEN RAW SCALLOPS

A. Description of the Product

Frozen raw scallops are clean, wholesome, adequately drained, whole or cutadductor muscles of the scallop of the regular commercial species. The portion of the scallop used should be only the adductor muscle eye whichcontrols the shell movement. Scallops should be washed, drained, packed, andfrozen in accordance with good manufacturing practices and are maintained attemperatures necessary for the preservation of the product. Only scallops of asingle species should be used within a lot.

1. Styles

Style I are solid pack scallops are frozen together into a solid mass.

(1) Substyle a. Glazed.
(2) Substyle b. Not glazed. (b) Style II. Individually quick frozen pack (IQF) scallops are individually quick frozen. Individual scallops can be separated without thawing.

(1) Substyle a. Glazed.
(2) Substyle b. Not glazed.

2. Types

(a) Type 1. Adductor muscle.
(b) Type 2. Adductor muscle with catch (gristle or sweet meat) portion removed.

Dehydration refers to the loss of moisture from the scallops surface during frozen storage. Small degree of dehydration is color-masking but can be easily scraped off. Large degree of dehydration is deep, color-masking, and requires a knife or other instrument to scrape it off.

Extraneous materials are pieces or fragments of undesirable material that are naturally present in or on the scallops and which should be removed during processing.

An instance of minor extraneous material includes but is not limited to each occurrence of intestines, seaweed, etc., and each aggregate of sand and grit up to ½-inch square and located on the scallop surface. Deduction points should be assessed for additional instances of intestines, seaweed, etc., and aggregates of sand and grit up to ½-inch square.

An instance of major extraneous material includes but is not limited to each instance of shell or aggregate of embedded sand or other extraneous embedded material that affects the appearance or eating quality of the product.

Texture refers to the firmness, tenderness, and moistness of the cooked scallop meat, which is characteristic of the species.

Net weight means the total weight of the scallop meats within the package after removal of all packaging materials, ice glaze, or other protective materials.

XIV. FROZEN RAW BREADED SCALLOPS FROZEN FRIED SCALLOPS

A. Product Description

Frozen raw breaded scallops are:

(1) Prepared from wholesome, clean, adequately drained, whole or cut adductor muscles of the scallop of the regular commercial species, or scallop units cut from a block of frozen scallops that are coated with wholesome batter and breading;
(2) Packaged and frozen according to good commercial practice and maintained at temperatures necessary for preservation; and
(3) Composed of a minimum of 50 percent by weight of scallop meat.

Frozen fried scallops.

Frozen fried scallops are:

(1) Prepared from wholesome, clean, adequately drained, whole or cut adductor muscles of the scallop of the regular commercial species, or scallop units cut from a block of frozen scallops that are coated with wholesome batter and breading;
(2) Precooked in oil or fat;
(3) Packaged and frozen according to good commercial practice and maintained at temperatures necessary for preservation; and
(4) Composed of a minimum of 50 percent by weight of scallop meat.

The styles of frozen raw breaded scallops and frozen fried scallops include the following.

Style I Random pack:

Scallops in a package are reasonably uniform in weight and/or shape. The weight or shape of individual scallops is not specified.

Style II Uniform pack:

Scallops in a package consist of uniform shaped pieces that are of specified weight or range of weights.

1. Types

(a) Type 1. Adductor muscle.
(b) Type 2. Adductor muscle with catch (gristle or sweet meat) portion removed.

Appearance refers to the condition of the package and ease of separation in the frozen state and continuity and color in the cooked state.

"Condition of the package" refers to freedom from packaging defects and the presence in the package of oil, and/or loose breading, and/or frost. Deduction points are based on the degree of the improper condition as small or large.

"Ease of separation" refers to the difficulty of separating scallops that are frozen together after the frying operation and during freezing.

"Continuity" refers to the completeness of the coating of the product in the cooked state. Lack of continuity is exemplified by breaks, ridges and/or lumps of breading. Each 1/16 square inch area of any break, ridge, or lump of breading is considered an instance of lack of continuity. Individual breaks, ridges, or lumps of breading measuring less than 1/16 square inch are not considered objectionable. Deduction points are based on the percentage of the scallops within the package that contain small and/or large instances of lack of continuity.

Workmanship defects refer to the degree of freedom from doubled and misshaped scallops and extraneous material. The defects of doubled and misshaped scallops are determined by examining the frozen product, while the defects of extraneous materials are determined by

examining the product in the cooked state. Deduction points are based on the percentage by count of the scallops affected within the package.

Doubled scallops. Two or more scallops that are joined together during the breading and/or frying operations

Misshaped scallops. Elongated, flattened, mashed, or damaged scallop meats.

Extraneous material. Extraneous are pieces or fragments of undesirable material that are naturally present in or on the scallops and which should be removed during processing.

Examples of minor extraneous material include intestines, seaweed, and each aggregate of sand and grit within an area of 1/2-inch square.

Examples of major extraneous material include shell, aggregate of embedded sand or other extraneous embedded material that affects the appearance or eating quality of the product.

Texture in the cooked state

Texture of the coating:

Firm or crisp, but not tough, pasty, mushy, or oily

Moderately tough, pasty, mushy, or oily

Excessively tough, pasty, mushy, or oily

Texture of the scallop meat

Firm, but tender and moist

Moderately tough, dry, and/or fibrous or mushy

Excessively tough, dry, and/or fibrous or mushy

Character.

Character refers to the texture of the scallop meat and of the coating and the presence of gristle in the cooked state.

(1) *Gristle.* Gristle (type 2 only) is the tough elastic tissue usually attached to the scallop meat. Each instance of gristle is an occurrence.
(2) *Texture* refers to the firmness, tenderness, and moistness of the cooked scallop meat and to the crispness and tenderness of the coating of the cooked product. The texture of the scallop meat may be classified as a degree of mushiness, toughness, and fibrousness. The texture of the coating may be classified as a degree of pastiness, toughness, dryness, mushiness, or oiliness.

XV. FROZEN NORTH AMERICAN FRESHWATER CATFISH AND CATFISH PRODUCTS

A. Scope and Product Description

The descriptions apply to products derived from farm-raised, or from rivers and lakes, North American freshwater catfish of the following common commercial species and hybrids thereof:

(1) Channel catfish (*Ictalurus punctatus*)
(2) White catfish (*Ictalurus catus*)
(3) Blue catfish (*Ictalurus furcatus*)
(4) Flathead catfish (*Pylodictis olivaris*)

Fresh products will be packaged in accordance with good commercial practices and maintained at temperatures necessary for the preservation of the product. Frozen products will be frozen to 0°F (−18°C) at their center(thermal core) in accordance with good commercial practices and maintained at temperatures of 0°F (−18°C) or less.

The product may contain bones when the principle display panel clearly shows that the product contains bones.
Product presentation.

Catfish products may be presented and labeled as follows:

1. Types

(1) Fresh, or
(2) Frozen.

2. Styles

(1) Skin on, or
(2) Skinless.

Market forms include but are not limited to the following:

(1) Headed and gutted.
(2) Headed and dressed are headed and gutted usually with fins removed. This form may be presented with or without the dorsal spine and with or without the collar bone.
(3) Whole fillets are practically boneless pieces of fish cut parallel to the entire length of the backbone with the belly flaps and with or without the black membrane.
(4) Trimmed fillets are whole fillets without belly flaps.
(5) Fillet strips are strips of fillets weighing not less than ¾ ounce.
(6) Steaks are units of fish not less than 1 1/2 ounces in weight which are sawn or cut approximately perpendicular (30 degrees to 90 degrees) to the axial length or backbone. They have two reasonably parallel surfaces. The number of tail sections that may be included in the package must not exceed the number of fish cut per package).
(7) Nuggets are pieces of belly flaps with or without black membrane and weighing not less than ¾ ounce.

3. Bone Classifications

(1) Practically boneless fillet.
(2) Bone-in (fillet cut, with bones).

Dehydration applies to all frozen market forms. It refers to the loss of moisture from the surface resulting in a whitish, dry, or porous condition:

Slight: surface dehydration which is not color masking (readily removed by scraping) and affecting 3 to 10 percent of the surface area.

Moderate: deep dehydration which is color masking, cannot be scraped off easily with a sharp instrument, and affects more than one percent but not more than 10 percent of the surface area.

Excessive: deep dehydration which is color masking, and cannot be easily scraped off with a sharp instrument and affects more than 10 percent of the surface area.

Condition of the product applies to all market forms. It refers to freedom from packaging defects, cracks in the surface of a frozen product, and excess moisture (drip) or blood inside the package. Deduction points are based on the degree of this defect.

Slight refers to a condition that is scarcely oticeable but that does not affect the appearance, desirability or eating quality of the product.

Moderate refers to a condition that is conspicuously noticeable but that does not seriously affect the appearance, desirability, or eating quality of the product.

Excessive refers to a condition that is conspicuously noticeable and that does seriously affect the appearance, desirability or eating quality of the product.

Discoloration applies to all market forms. It refers to colors not normal to the species. This may be due to mishandling or the presence of blood, bile, or other substances.

Slight: 1/16 square inch up to and including one square inch in aggregate area.

Moderate: greater than one square inch up to and including 2 square inches in aggregate area.

Excessive: over 2 square inches in aggregate area. Also, each additional complete one square inch is again assessed points under this category.

Uniformity will be assigned in accordance with weight tolerances as follows:

Weight of portion: 0.75 to 4.16 ounces

Moderate: Over 1/8 ounce but not over 1/4 ounce above or below declared weight of portion

Excessive: In excess of 1/4 ounce above or below declared weight of portion 4.17 to 11.20 ounces

Moderate: Over 1/8 ounce but not over 1/2 ounce above or below declared weight of portion

Excessive: In excess of 1/2 ounce above or below declared weight of portion 11.21 to 17.30 ounces

Moderate: Over 1/8 ounce but not over 1/8 ounce above or below declared weight of portion

Excessive: In excess of 1/8 ounce above or below declared weight of portion

Skinning cuts apply to skinless market forms. It refers to improper cuts made during the skinning operation as evidenced by torn or ragged surfaces or edges, or gouges in the flesh which detract from a good appearance of the product.

Slight: 1/16 square inch up to and including 1 square inch in aggregate area.

Moderate: Over one square inch up to and including 2 square inches in aggregate area.

Excessive: Over 2 square inches in aggregate area. Also, each additional complete one square inch is again assessed points under this category.

Heading applies to the presence of ragged cuts or pieces of gills, gill cover, pectoral fins or collar bone after heading. Deduction points also will be assigned when the product is presented with the collar bone and it has been completely or partially removed.

Slight: 1/16 square inch up to and including one square inch in aggregate area.

Moderate: Over one square inch up to and including 2 square inches in aggregate area.

Excessive: Over 2 square inches in aggregate area. Also, each additional complete one square inch is again assessed points under this category.

Evisceration applies to all market forms. It refers to the proper removal of viscera, kidney, spawn, blood, reproductive organs, and abnormal fat (leaf). The evisceration cut should be smooth and clean. Deduction points are based on the degree of defect.

Slight: 1/16 square inch up to and including 1 square inch in aggregate area.

Moderate: Over 1 square inch up to and including 2 square inches in aggregate area.

Excessive: Over 2 square inches in aggregate area. Also, each additional complete one square inch is again assessed points under this category.

Fins refer to the presence of fins, pieces of fins or dorsal spines. It applies to all market forms except headed and gutted or headed and dressed catfish or catfish steaks. Deduction points also will be assigned when the product is intended to have the dorsal spine but it has been completely or partially removed.

Slight: Aggregate area up to including one square inch.

Moderate: Over one square inch area up to and including 2 square inches.

Excessive: Over 2 square inches in aggregate area. Also, each additional complete one square inch is again assessed points under this category.

Bones (including pin bone) apply to all fillet and nugget market forms. Each bone defect is a bone or part of a bone that is 3/16 inch or more at its maximum length or 1/32 inch or more at its maximum shaft width, or for bone chips, a length of at least 1/16 inch. An excessive bone defect is any bone which cannot be fitted into a rectangle, which has a length of 1 9/16 inch and a width of 1/8 inch. In market forms intended to contain bones, the

presence of bones will not be considered a physical defect.

Skin refers to the presence of skin on skinless market forms. For semi-skinned forms, a skin defect is the presence of the darkly pigmented outside layers. Points will be assessed for each aggregate area greater than 1/2 square inch up to and including one square inch.

Bloodspots refer to the presence of coagulated blood.

Bruises refer to softening and discoloration of the flesh. Both bloodspots and bruises apply to all market forms. Points will be assessed for each aggregate area of bloodspots or bruises greater than 1/2 square inch up to and including one square inch.

Foreign material refers to extraneous material, including packaging material, not derived from the fish that is found on or in the sample. Each occurrence will be assessed.

Texture applies to all market forms and refers to the presence of normal texture properties of the cooked fish flesh, i.e., tender, firm, and moist without excess water. Texture defects are described as dry, tough, mushy, rubbery, watery, and stringy.

Moderate: Noticeably dry, tough, mushy, rubbery, watery, stringy.

Excessive: Markedly dry, tough, mushy, rubbery, watery, stringy.

CONTENTS

GENERAL PRINCIPLES FOR THE FREEZING, STORAGE AND THAWING OF SEAFOOD

I. INTRODUCTION

Fish and shellfish are perishable and, as a result of a complex series of chemical, physical, bacteriological, and histological changes occurring in muscle, easily spoil after harvesting. These interrelated processes are usually accompanied by the gradual loss or development of different compounds which affect fish quality. The quality changes are highly influenced by many factors, the most important of which is temperature. If fresh fish is not properly stored, exposure to ambient temperature can cause serious deterioration in fish quality. Commercially, icing or chilling continues to play a major role in slowing down bacterial and enzymatic degradation of fish muscle. However, this process is not designed to totally eliminate changes in quality, since it only offers protection for 2–3 weeks, depending on the species.

Freezing preservation of food is an excellent method of preservation with wide applications. Freezing inhibits the activity of food spoilage and food poisoning organisms and the low storage temperature greatly slows down the enzymatic and biochemical reactions which normally occur in unfrozen foods. Freezing accomplishes these objectives in two ways: the lowering of the temperature of the food and the removal of water by converting it into ice. Lowering the temperature to below freezing point inhibits the growth and activity of many, but not all, microorganisms. Converting most of the water into ice with the concomitant increase in concentration of the dissolved substances reduces the water activity of the food to the point where no microorganisms can grow. Although biochemical reactions slow down at lower temperature, they will, unlike microbiological activities, progress even at low commercial freezer storage temperatures. In addition, conversion of water into ice initiates complex physical and physicochemical changes that can cause general deteriorative quality changes not ordinarily occurring in fresh foods. Pre-freezing processing, such as blanching, freezing and storage conditions should therefore be selected, individually, for each product to minimize the effect of these deteriorative reactions.

In most foods frozen commercially, water is the major component. Most of the water in the tissue dissolves soluble cell components, while a small part is bound up in hydrates and in macromolecular colloidal complexes.

In addition, much of the aqueous solution is part of the gel-like or fiber-like structures in the cell. The most obvious change that occurs on freezing is the solidification of water, which means that water is removed from its normal position within the tissues. It appears that removal of water from its normal position is only partly reversible upon thawing, leading to "drip" and other changes. "Drip" is the exudate from thawed tissue which is difficult in practice to distinguish from any superficial moisture or "glaze." There is sometimes an apparent enhanced susceptibility to invasion by microorganisms owing to the moist surfaces which occur during thawing. The conversion of water into ice increases the concentration of soluble cell components (in some cases to the point where they become saturated and precipitate), changes the pH of the aqueous solution and consequently affects the amount of water that is involved in the colloidal complexes and in the gel-like and fiber-like structures. The concentration of cell components leads to a high concentration of electrolytes, some of which interpose themselves in the polypeptide chains of proteins, leading to protein denaturation. In living cells this often leads to death (for example, freezing and frozen storage causes a slight reduction in number of most microorganisms), but in foods, which usually consist of dead tissue prior to freezing, it can lead, during storage, to irreversible changes in texture (e.g., toughness in fish) and to undesirable biochemical reactions (enzymatically produced off-flavors). An understanding of freezing therefore involves physical, physico-chemical, and biochemical aspects.

As mentioned above, freezing is an excellent process for keeping the original quality of foods, such as fish, for longer periods of time (commercially, up to 12 months or more). Freezing and subsequent frozen storage are particularly useful in making seasonal species of fish, like herring and mackerel, available all year round. In addition, freezing preservation is also applied in a number of different products made from various fish species. For example, tuna is frozen on board large commercial fishing vessels, brought to land, and then thawed for canning process. In the production of various value-added fish products, freezing is applied to breaded and battered fish sticks, fillets, steaks, or nuggets. Likewise, high-quality fish are usually filleted, frozen, and eventually sold to consumers.

Ideally, there should be no distinguishable differences between fresh fish and frozen fish after thawing. If kept under appropriate conditions, fish in the frozen state can be stored for several months or more without appreciable changes in quality. However, it is now well recognized that deteriorative changes take place in fish and seafood during freezing, frozen storage and thawing, which influence the quality of final products. Considerably more knowledge of the basic structure of fish muscle and its chemical composition is essential to understanding these changes that occur during processing.

II. NATURE OF FISH MUSCLE

Fish muscle has a unique arrangement of muscle fibers. It is divided into a number of segments called myotomes, which are separated from one another by a thin sheath of

connective tissue called the myocomma or myoseptum. The number of myotomes in fish is dependent on the size of fish, while their diameters vary from head to tail (1). There are two major types of fish skeletal muscles, white and red. The red or dark muscle lies along the side the body next to the skin, particularly along the lateral lines, and may comprise up to 30% of fish muscle, depending on the species (2). Cells in red or dark muscle contain more lipids than those in white muscle (3, 4); they are basically employed for sustained swimming activities, functioning aerobically using lipids for fuel. In addition, red muscle has more mitochondria (5) but less sarcoplasmic reticulum than white muscle (6). It has a large supply of oxygen and a high content of myoglobin, the colored compound that gives its red color. These characteristics, coupled with the presence of the large amount of lipid, particularly among the fatty species, present a serious problem on preservation because of increased susceptibility of this muscle to lipid oxidation. The red muscle of some species has also been reported to contain enzymes that are responsible for chemical reactions such as lipid oxidation and the conversion of trimethylamine oxide (TMAO) to dimethylamine (DMA) and formaldehyde (FA) (7, 8). The shape of red muscle area in different species varies considerably. Lean fish such as flounder, hake, sole, cod, pollock, and whiting have a very small amount of red muscle, which lies along the fish skin, whereas the fatty and semi-fatty fish species have larger areas of red muscle.

White muscle, on the other hand, constitutes the majority of fish muscle. Unlike red muscle, it has minimal myoglobin and a restricted blood supply (5). Often referred to as the "fast" tissue (9), it is used for anaerobic activities such as short bursts of swimming activity. This muscle exhibits rapid, powerful contractions, the energy for which is produced by reducing glycogen to lactic acid anaerobically (5).

Intermediate between these two types of muscle are intermixed red and white muscle, commonly referred to as "mosaic" muscle (10). In some fish, this is a thin layer of muscle that separates the red from white muscle. However, in other fish, such as salmon, carp, and trout, this muscle is scattered throughout the body of the fish.

The chemical composition of fish varies, depending on several factors, such as age, species, gender, maturity, method of catch, fishing grounds, and other seasonal and biological factors. Even within the same species, chemical composition may vary significantly. Generally, fish contain a considerable amount of protein, lipid, and water, and small amounts of vitamins and minerals. Other components such as non-protein nitrogenous compounds are also present in the muscle. These include urea, taurine, peptides, free amino acids, and nucleotides such as inosine and hypoxanthine (11). These compounds, together with the macronutrients found in fish muscle, may be particularly important to fish processors, since they are frequently used as spoilage indices.

III. PHYSICAL ASPECTS OF FREEZING

A. Formation of Ice

From a physical point of view, fish, land animal, and vegetable tissues can be roughly considered as dilute aqueous solutions. When they are chilled below 0°C, ice crystals form at a temperature characteristic of the product and the initial freezing point (FT), which is also the temperature at which the last ice crystals melt on thawing. The freezing point directly depends on the molar concentration of dissolved substances presented, but not on the water content. Fruits, for example, have high water content and a freezing point of -2 to -3°C, while fish contain less water, yet have a freezing point of about -1 to -2°C. The difference is due to the high sugar and acid content in fruits as compared with the low solute content of fish meat. Ice formation occurs during freezing only after a certain degree of supercooling (supercooling is the phenomenon of reducing the temperature of a solution or material below its freezing point without crystallization occurring) has been achieved, and the formation of ice is accompanied by a heating up of the supercooled product close to the freezing point. In commercial practice, the amount of supercooling is usually insignificant.

As the products are progressively cooled below their initial freezing point, more and more water will be turned into ice and the residual solutions will become more and more concentrated. If, at any time, the products are heated, some of the ice will be turned to water that will then dilute the residual solutions. The ratio of ice to residual solution in frozen foods is a function of temperature and initial concentration of solutes. At a temperature lower than -40°C, there is little or no measurable change in the amount of ice presented in most frozen foods. The percentage ratio of freezing (RF) of frozen foods is usually estimated as follows:

$$\text{RF}\ (\%) = 100 - [(\text{FT/temp. frozen food}) \times 100]$$

where RF represents the percentage ratio of freezing and FT represents the freezing point of the frozen food.

B. Ice Crystal Size

Once water has started to freeze, the rate of ice formation is a function of the rate of heat removal, as well as of the rate of diffusion of water from the surrounding solutions or gels to the surface of the ice crystals. At slow rates of cooling few crystallization centers are formed and the ice crystals grow to a relatively large size. The water in the cell diffuses through the cell wall, leaving the cells in a collapsed condition. Very large ice crystals (few crystals) can lead to mechanical damage to the food product. The cells become physically separated over relatively long distances. As the freezing rate increases, the number of ice crystals increases

while their size decreases. Many studies have been done on the effects of size and location of ice crystals on the quality of frozen food. It appears that, for most foods, the size and distribution of ice crystals, encountered in commercial practice, have relatively little effect on organoleptic quality. However, very slow freezing results in undesirable effects like "drip" on thawing, while very fast freezing may improve the texture of some products.

C. Dimensional Changes

The volume change accompanying the conversion of pure water into ice is about 9%. The volume change of foods as a result of ice formation is less, about 6%, because only part of the water present is frozen and because some foods contain spaces. This volume change has to be taken into account in equipment design. In very fast freezing (for example, immersion of large items in liquid nitrogen), it can lead to the build-up of excessive pressure inside the product, causing breaking and shattering.

D. Completion of Freezing

The freezing process is, for practical purposes, completed when most of the freezable water at the thermal center of the product has been converted into ice, which coincides for most products with the temperature at the thermal center becoming colder than −10°C. Removal of the product from the freezing equipment before this point is reached may result in slow freezing at the thermal center. It is preferable to freeze the product until the equilibrium temperature (average temperature) is −18°C or colder.

E. Desiccation of Frozen Foods

1. During Freezing

It is inevitable that a proportion of water of a product without packaging will evaporate during freezing. The faster the freezing, the smaller the amount of evaporated water. If the product is enclosed in a water-vapor-proof package before freezing, the moisture that escapes from the packet will be nil, but when there is an air gap (on the order of millimeters) between the surface of the product and the internal surface of the package frost may be deposited inside the package to the same extent as moisture evaporates from the product.

For products frozen unpackaged, moisture loss varies from 0.5 to 1.5% or more, depending on the temperature, rate, and method of freezing, as well as the type of product. The colder the air temperature, the less moisture the air can absorb before it is saturated. Faster freezing methods lower the surface temperature of the product quickly to a value where the rate of moisture evaporation or sublimation is small. Where the surface of a product consists of a moisture-resistant layer (skin of the fish or fat on beef, for example), moisture losses are reduced in comparison with products with cut surfaces (fish fillets, hamburger patties, for example). Proper freezer design for a given product is, therefore, an important factor in minimizing moisture loss during freezing.

2. During Storage

Moisture loss during frozen storage is a more serious problem because of the length of storage usually involved. Tight-fitting water-vapor-proof packaging avoids all apparent moisture loss. Many frozen foods, however, are still stored unpackaged or packaged in water-vapor permeable materials. In these cases, moisture loss depends on the average ambient temperature and the temperature of the evaporator, as well as on the temperature fluctuations occurring during storage, and increases with increasing storage temperature, increasing frequency, and amplitude of temperature fluctuations, and with increasing difference between the storage temperature and the lower temperature reached by the evaporator. It should be noted that the saturated vapor pressure of frozen foods is equal to that of pure ice at the same temperature.

If a water-vapor-proof packaging does not fit tightly around the product, desiccation of the product still occurs, but the water removed remains inside the package as frost. The mechanism appears to be as follows:

a. The layer of air between product and packaging is subject to temperature variations. As the outside temperature decreases, the temperature of the inside surface of the packaging at a certain moment drops below the product surface temperature and ice on or in the product will sublime and condense on the inside of the package.
b. When the ambient temperature increases, the process is reversed. However, the water vapor will condense on the product surface rather than in the cellular structure from which it evaporated.
c. As the cooling-heating cycle recurs, the crystals on the product surface tend to follow package temperature more closely than the mass of the product, and this results in further sublimation of ice from the product.

Frost in packages of frozen foods can amount to several percent of the product weight. Because it leads to ready access of oxygen into the product, frost formation may, with some foods, increase quality deterioration.

The effects of temperature fluctuation depend on the average storage temperature. At warmer storage temperatures, a given temperature fluctuation results in a much larger change in ice vapor pressure than at colder temperatures. As a result the effect of temperature fluctuations on desiccation increases with a warmer storage temperature.

Excessive drying, in addition to leading to undesirable loss of weight, can accelerate oxidative changes by causing the loss of an added glaze, and also by causing the removal of ice from the superficial parts of the frozen products, thus allowing a free access of oxygen to the internal tissues. Some parts of the surface of protein foods may be highly desiccated and their structure even irreversibly deteriorated; light spots known as "freezer burn" occur on the surface and the appearance of produce may become unacceptable. Animal foods (fish, poultry, game) in particular can be affected severely by freezer burn.

F. Change in Ice Crystal Size in Frozen Foods during Storage

The changes in shape and size of the ice crystals in frozen foods are caused by periodic variations in temperature experienced during storage; the greater the amplitude of these variations, the greater will be the changes.

G. Thermal Radiation in Frozen Food Storage

Thermal radiation has a significant effect on frozen foods in open display cabinets. In these, the top layer of packages may reach a temperature up to 10°C warmer than the average cabinet temperature leading to quality losses. The temperature of the packages in the top layer represents a thermal equilibrium between the energy transferred by radiation and the energy transferred by conduction and convection. The effect of radiation depends on the emissivity of the radiating surfaces, e.g., the package and the ceiling or walls. (Emissivity characterizes the surface state as far as radiation is concerned. Emissivity reaches a maximum equal to 1 in the case of an ideally absorbing and emitting body (black body) and is zero in the case of a perfect reflector; the latter does not emit or absorb any radiative energy.) The important radiation is that in the far infrared range (wavelength 8 to 10.10 m) and not that of visible light. A reflecting canopy placed about the open area of the cabinet or packaging in bright metallic foil reduces radiation energy gain markedly. Bright metallic foil packaging may reduce product temperature at the top layer of display cabinets by as much as 6–8°C.

IV. PHYSICO-CHEMICAL ASPECTS OF FREEZING

A. Composition and pH Changes during Freezing

Freezing converts a large proportion of the water present in foods into ice and hence makes the remaining solution more concentrated in dissolved, colloidal, and suspended substances. This increased concentration causes a change in acid-base equilibrium (pH) important in the stability of many colloids and suspensions. Shifts in pH (usually towards the acid side) of up to 1 pH unit have been observed under these conditions.

A second result of this increased concentration is the precipitation of salts and other compounds that are only slightly soluble, such as phosphate. This can result in drastic pH changes (up to 2 pH units) and changes the salt composition of the aqueous solution in foods. These changes often affect the physico-chemical systems in food irreversibly. It has been shown, for example, that lactic dehydrogenase, a muscle enzyme, and lipoproteins, an important egg yolk constituent, are irreversibly damaged by a pH decrease from 7 to 5 and by increased phosphate concentration during freezing.

B. Physico-Chemical Changes in Frozen Foods

Textural properties and the initiation and acceleration of several biochemical reactions depend on the physical chemistry of food constituents and hence are affected by the physico-chemical changes brought about by freezing. Loss of water binding properties, resulting in drip, is an example of textural changes, while removal of enzymes from cell particles, allowing them free access to substrates in other parts of the cell, is an example of biochemical reactions initiated and accelerated by freezing. Other physico-chemical changes in frozen foods are actomyosin changes in muscle, leading to toughening (fish) or dryness (poultry), loss of turgor in fresh fruits and vegetables, and gelation of egg yolk.

Many physico-chemical changes increase with increased salt concentration in the unfrozen phase, but will decrease with decreasing temperature as a result of the lower mobility of the salt in the unfrozen phase and the general effect of temperature on chemical reactions. Consequently, physico-chemical changes are most damaging in the range between the freezing point of a food and about −10°C. It is important therefore to expose frozen foods for as short a time as possible to this temperature range, both during freezing and during thawing.

C. Effects of Preparation and Packaging on Frozen Fish

Product preparation and packaging significantly affect the quality and shelf life of frozen fish. If not properly controlled, these processes result in some deleterious effects after prolonged storage.

1. Product Preparation

Product preparation, in particular, produces a considerable effect on shelf stability of frozen fish. Whole and eviscerated fish have longer shelf stability than fillets, while minces can usually only be stored for a much shorter period of time. Crawford et al. (12–14) observed

this difference during several studies using hake. Minced blocks exhibited reduced quality and accelerated deterioration during storage when compared to intact fillets. This characteristic of minces, which is more apparent among the gadoids, is probably due to the mincing action applied to the fish flesh, which results in tissue damage and subsequently more rapid deterioration. In addition, mixing of red and white muscle during mincing may also result in the dispersion of lipids and some of the enzymes present in the red muscle, leading to greater susceptibility of the minced tissue to deteriorative changes.

2. Packaging Materials and Methods

An efficient packaging system is essential to offset the detrimental quality changes that occur during frozen storage. Packaging materials and methods are obviously designed not only to protect the product from microbial and chemical contamination, dehydration, and physical damage, but also to protect the environment from the packaged product. Fish and seafood can leak gases or unsightly fluids, which may have unpleasant odors. Therefore, the choice of appropriate packaging materials and methods for frozen fish is a critical factor in terms of shelf-life extension.

Studies have shown that packaging systems affect the quality and shelf stability of frozen fish. For instance, vacuum packaging is well established as a method to provide an oxygen-free environment to minimize the problems associated with lipid oxidation and dehydration during frozen storage.

Several studies have shown the effectiveness of this method for frozen storage of some species of fish. For example, it has been reported that frozen blocks of fillets vacuum packed in moisture-proof films showed high degrees of acceptance and desirable frozen characteristics (12). Likewise, Santos and Regenstein (15) reported the effectiveness of vacuum packaging for inhibiting lipid oxidation in frozen mackerel fillets. Ahvenainen and Malkki (16) examined the influence of packaging on frozen herring fillets stored at different temperatures. They found that vacuum-packed product covered with metallized cardboard had a longer shelf life than a product vacuum packed and stored without cardboard. Vacuum packaging, on the other hand, need not be used if lipid oxidation is not the limiting factor affecting the shelf life of a product. Although the effect or absence of oxygen in packages on some fish species must be considered, other packaging methods such as glazing and the use of heat-sealable packaging films should also be considered. Pacific hake minced blocks stored in moisture-proof, vapor-proof packaging films exhibited superior quality over glazed samples (12). Likewise, Colokoglu and Kundacki (17) observed frozen mullet packed in plastic films with low permeability to oxygen and moisture to have a longer shelf life than when unpacked in the glazed form. However, it should be noted that glazing is still considered to be the cheapest means of protecting frozen fish during storage and transport. Glazing provides a continuous film or coating that adheres to the frozen product, which retards moisture loss and the rate of oxidation.

Many different glazes are available, including (a) those with inorganic salt solutions of disodium acid phosphate, sodium carbonate, and calcium lactate, (b) alginate solution, otherwise known as the "Protan" glaze, (c) antioxidants such as ascorbic and citric acids, glutamic acid, and monosodium glutamate, and (d) other edible coatings such as corn syrup solids (18). Ice glaze is particularly important in handling frozen fish in developing countries. For products intended for short-term storage, glazing can be practically utilized as a viable alternative to storage without a protective covering. For instance, Jadhav and Magar (19) concluded that glazing was a cheaper alternative to expensive packaging systems for glazed Indian mackerel (*Rastrelliger kanagurta*) stored at −20°C. Glazed samples had a shelf life of 6 months, while samples without a protective covering lasted only 3–4 months.

3. Effects of Freezing, Frozen Storage, and Thawing on Color, Appearance, and Consumer Acceptance

One problem encountered during handling, freezing, and storage of fish is the difficulty in retaining the color and appearance of the meat. Changes in color and appearance of fish occur even immediately after catch. Blood pigments become noticeably discolored to various degrees after some period of time. The natural oils in fish play an important role in these color changes. The color of these oils is produced by the colored pigments dissolved in them which vary from one species to another. These pigments are subjected to considerable oxidation when the fish is frozen and stored. This then results in meat color darkening to either dark brown or, in some cases, black. This discoloration occurs especially when the fish is stored for an extended period of time. Some fish, like tuna, develop discoloration during frozen storage, reportedly due to oxidation of myoglobin to met-myoglobin in fish blood (20). Other species, such as salmon, swordfish, and shark, also exhibit color changes during storage. Salmon has a pink meat, but when subjected to oxidation its color slowly fades and, in extreme cases, may completely disappear after prolonged storage. Swordfish, on the other hand, develops green discoloration beneath its skin during frozen storage which, according to Tauchiya and Tatsukawa (21), is due to the development of sulfhemoglobin, a product of oxidation. Shark flesh also discolors and occasionally develops off-odors during storage, most probably as a result of the presence of high amounts of trimethylamine oxide. Interestingly, these

marked differences in the color and appearance of frozen fish are quite noticeable in fish sold either as steaks or as fillets, especially when cross-sectional cuts of the fish are made, which permits a comparison of the color of the exposed fish surface with that of the inner portion.

In shrimp, the rapid formation of black pigments, widely known as "melanosis," occurs within a few hours after death and is enhanced by exposing the shrimp to air (oxygen). It can occur within just 2–12 hours of exposure. The oxidation reaction leading to the formation of these black pigments can occur at 0°C; however, at −18°C, no visible spots were detected at up to 3 months of storage (22). Below this temperature, it is believed that melanosis can still positively occur. It should be noted, however, that although black spots do not necessarily make shrimp unfit for human consumption, such discoloration is usually associated with spoilage, resulting in a decrease in market value. In other shellfish, such as crab and lobster, the development of blue or black discoloration, otherwise known as "blueing," is one of the most troublesome problems. Blueing may occur after freezing or during frozen storage, or it may appear after thawing and subsequent air exposure or even shortly after cooking. Needless to say, these changes in color and appearance of fish and shellfish significantly affect consumer acceptance. When consumers select frozen fish, if these products can be seen through the packaging material used, the color and appearance of the frozen product provide an indication as to its degree of quality. As shown in Table 39.1, undesirable appearance and discoloration of samples have been observed in different frozen whole fish and fillets obtained from Singapore supermarkets (23). Preventing such quality changes is of great commercial importance, since they detract not only from the consumer acceptability of the products but their shelf stability as well.

Thawing also influences the color and appearance of frozen fish and, inevitably, its consumer acceptability. Depending on the thawing technique used, discoloration may occur in fish and other seafood. For instance, when shrimp are thawed at temperatures higher than 0°C, black discoloration or melanosis may occur. This is due to the unnecessary exposure of the shrimp to air, leading to oxidation. A phenomenon known as "shimi" occurs in frozen-thawed fish meat. Shimi are the undesirable blood spots observed in the belly portion of carp on thawing and are also the distinguishable spots tainting frozen-thawed tuna meat (24). The latter condition is probably due to the blood vessels that remain in unbled tuna meat prior to freezing. When thawed, these blood vessels produce unsightly spots in the meat.

It is possible to determine if the product has been properly thawed and then refrozen. This is particularly noticeable in packaged frozen fish, where spaces on the sides of the package may be filled with a frozen cloudy liquid, known as thaw drip. Such muscle drip was originally attributed to the rupturing of cell walls caused by ice crystal formation during freezing, resulting in excess drip during thawing. However, it has been postulated that drip or exudate formation is directly related to the capacity of the fish protein to hold moisture (25). This unsightly exudate from fish muscle indicates, among other things, inappropriate handling, prolonged ice storage prior to freezing, frozen storage at inappropriate cold-storage temperatures, or improper thawing. If not properly controlled, freezing, frozen storage, and thawing generally result in quality changes in fish and seafood that in most cases render the product unacceptable to consumers.

TABLE 39.1
Characteristics of Some Frozen Fish Purchased in Singapore Supermarkets

Fish	Thawed-State Characteristics
Herring, whole	Skin and meat show rusting
Mackerel, whole	Surface dehydrated, skin and meat show rusting, spongelike meat
Mackerel, whole	Rancid smell in skin and meat
Chinese Pompret, whole	Dehydration at lower part of belly and fin
Chinese Pompret, whole	Head and belly parts yellowish discolored, spongelike meat
White pompret, whole	Skin and meat show rusting, spongelike meat
Jew fish, whole	Slight rancid smell in skin
Lemon sole, whole	Surface dehydrated, spoiled and rancid smell, spongelike meat
Haddock, fillet	No smell, spongelike meat, cracks
Cod, fillet	No smell, spongelike meat
Flounder, fillet	No smell

4. Effects of Freezing, Frozen Storage, and Thawing on Palatability Attributes

Changes in the texture, odor, and flavor of fish and seafood affect their palatability. Fresh fish have a distinct succulence and a delicate odor and flavor, which are characteristic of the species. These attributes change noticeably when fish is frozen and stored for prolonged periods of time. Interestingly, the changes that influence the palatability of frozen fish and seafood can all be measured organoleptically and, to some extent, chemically.

a. Change in texture

Frozen fish gradually loses its juiciness and succulence after freezing and subsequent frozen storage. Such textural changes, reportedly caused by protein denaturation (26–29), are more pronounced in some species of fish, specifically the gadoids. In these species, the chemical breakdown of TMAO to DMA and FA and the subsequent cross-linking of FA to muscle protein (30) produce the

textural breakdown in the gadoids and result in a "cottony" or "spongy" texture. Fish muscle that has undergone such changes tends to hold its free water loosely like a sponge. When eaten, the fish muscle loses all its moisture during the first bite, and subsequent chewing results in a very dry and cottony texture.

In some species devoid of TMAO-degradation products, muscle fibers also tend to toughen and to become dry during freezing and storage. This is particularly true for most of the nongadoid species and for crab, shrimp, and lobster when stored for prolonged periods. In contrast, the effect of the thawing method on the texture of fish muscle basically depends on the product form. For instance, whole fish, when thawed, exhibits less textural change than filleted fish, basically as a result of the presence of the backbone, which serves as structural support for the flesh. In terms of the effect of the thawing method, it has been reported that microwave thawing results in higher gel strength of minced samples, when compared to samples thawed under running water (20°C) and samples thawed at room temperature (31). Consequently, the extent of textural changes depends upon the species of fish and upon the condition of handling, freezing, duration of frozen storage, and the thawing method used.

Several methods have been developed to objectively measure such textural changes, in addition to the gathering of comparative data from sensory evaluations. From texture analysis of minced fish, Borderias et al. (32) concluded that hardness as measured by the Kramer Shear cell and puncture (penetration) tests was highly correlated with the sensorial perceived firmness of raw samples, while a compression test was found to be a valuable technique for characterizing the cohesiveness and elasticity of both raw and cooked fish minces.

Alterations in the texture of frozen fish fillets, on the other hand, are difficult to measure objectively, mainly due to the textural variability that exists within the fish fillets, which is associated with the flakiness and the orientation of the muscle fibers (33). Several attempts have been made to determine the extent of textural changes in fish fillet, including those tested using fish minces (32). However, significant correlations were not obtained.

An instrumental method that may work on fish fillets is the deformation test using the Instron Universal Testing Machine equipped with a flat compression plate. As a nondestructive test (34), it can potentially be modified to conform to the irregular shape and the segmented structural orientation of fish fillets.

b. Changes in odor and flavor

Other important changes that affect the palatability of frozen fish include changes in the flavor and odor of fish and seafood. Fish are often described as having a "fishy" odor and flavor. Although the term sounds unpleasant, it can also be used to describe the pleasing taste and odor characteristics of freshly caught fish. Such pleasant, palatable characteristics may be retained as long as the fish are promptly and properly frozen, stored, and thawed. However, the transformation of these attributes to unpleasant and unacceptable traits occurs very rapidly in some fish species, particularly the fatty fish species.

Changes in the delicate flavor of fish and seafood generally occur in three distinct phases during frozen storage: (a) the gradual loss of flavor due to loss or decrease in concentration of some flavor compounds (35, 36), (b) the detection of neutral, bland, or flat flavor, and (c) the development of off-flavors due to the presence of compounds such as the acids and carbonyl compounds that are products of lipid oxidation. These phases, however, only apply to those species with originally delicate, sweet, and meaty flavors. Other species, such as hake, have an originally bland flavor (35), but develop off-flavors during prolonged frozen storage.

Changes in odor occur in two phases: the loss of characteristic odor and the development of off-odors, which render the frozen product unacceptable. Generally, fish and seafood initially have a fresh, seaweed odor, which can be retained even after freezing and frozen storage. However, gradually such odor is lost, and eventually an unpleasant odor is given off, particularly when abused with inappropriate storage temperature. The development of unpleasant odor is due either to lipid oxidation, a reaction more apparent among the fatty fish species that results in the production of a strong oily, blow oily, or rancid odor, or to the degradation of TMAO, which leads to the production of an unpleasant ammonia odor. Other species such as white hake (*Urophysus tenuis*) initially give off weak odors of sweet, boiled milk, but when frozen storage is extended, hake assumes weak off-odors (often described as milk jug odor) followed by a sour milk odor.

V. BIOCHEMICAL ASPECTS OF FREEZING

A. Post Mortem Glycolysis and Lipid Oxidation

Fish muscle obtains energy by hydrolyzing adenosine triphosphate (ATP). At any one moment, its concentration is relatively small. During life it is quickly re-synthesized using the energy produced when glycogen is oxidized to carbon dioxide and water. On death of the fish metabolism in the muscle continues for some time. Post mortem glycolysis, however, is a relatively inefficient process and it cannot maintain ATP at its *in vivo* level. Once ATP has fallen to a critical concentration it can no longer prevent the major proportion of the muscle actin and myosin from cross-linking. This causes the loss of elasticity known as rigor mortis and usually a slow irreversible contraction. The continuing production of lactate and H^+ ions causes the pH of the muscle to fall from its *in vivo* value of about

7.2 to the so-called ultimate pH, which is usually about 5.5. A pH of 5.5 is near the isoelectric point of the muscle proteins, at which they have minimum water holding capacity and a consequent relatively high tendency to drip on thawing. A higher ultimate pH, therefore, means a greater water holding capacity than at a lower pH. The quantity of glycogen present in the muscle at the moment of slaughtering will clearly determine how far the pH will fall during post mortem glycolysis. Like most chemical reactions post mortem glycolysis is temperature dependent. It is generally found that the lower the temperature at which this process occurs, the slower is its rate. Thus if the carcass is maintained at body temperature after death, the rate of pH fall, of ATP depletion, and of rigor mortis onset is fast. If, however, the muscle is chilled quickly, these changes are slowed down and the water holding capacity of the muscle remains relatively high.

There is no practical "cold shortening" problem with fish properly chilled after catching. Fish muscle shows the least shrinkage if held at about 0°C. At warmer temperatures the shrinkage and weight loss are greater and they may be quite substantial for a fillet removed from the skeleton pre-rigor and kept at room temperature. One qualitative difference between fish and meat is the generally lower glycogen content in fish than in meat animals rested before death. Consequently, the post mortem fall of pH in fish is smaller and the resistance against surface bacterial growth less than in meat. In many fish species, therefore, bacterial spoilage is an overwhelming factor.

The fat composition of fish differs markedly from that of meat because fish fat contains a higher proportion of polyunsaturated fatty acids. Although this factor may vary with species and is also influenced by dietary fat intake, it nevertheless implies that fish, in particular fatty fish, are very prone to development of rancidity by auto-oxidation. Such rancidity may even develop in fatty fish held before freezing, but it is particularly during storage of frozen fish that great care in packaging and the use of low temperatures are necessary to preserve quality.

B. Denaturation of Muscle Proteins

The proteins of fish muscle differ from those of meat especially in their higher susceptibility to cold store damage. Frozen storage of fish causes an increase of drip loss on thawing, toughness, coarseness, and dryness on cooking, and loss of the desired glossy pellicle on smoking. These changes are highly associated with the so-called protein denaturation caused by freezing and subsequent storage. They are temperature dependent, with the maximum rate of development being in the range −1 to −5°C. They are considerably slowed down by colder storage temperatures. Many techniques have been used to measure these changes, such as extractable protein in salt solutions (ionic strength 0.5–1.0) which has been most widely used. The changes are mostly in the myofibrillar protein of fish muscle. In general, the sarcoplasmic proteins seem to be more stable on freezing and subsequent storage. This kind of "protein denaturation" is associated with the reaction of certain free fatty acids or their oxidized products on the myofibrillar proteins. Recently it has been found that the ultimate pH attained by fish can considerably affect texture. Thus, low pH in cod is associated with more pronounced toughness and larger drip loss on thawing.

Drip loss, some changes in flavor and taste, and an undesirable softening occur in freeze-thawed fish muscle. When the frozen and thawed fish was cooked, the succulence and water holding capacity greatly decreased and some undesirable changes in texture such as toughness, coarseness, and dryness occurred. Compared with unfrozen fresh meat, the functional properties such as emulsifying capacity, lipid binding properties, water holding or hydrating capacities and gel forming ability were lower in the frozen stored fish muscle. Most of the studies indicated that denaturation of muscle proteins plays a dominant role in the quality changes of frozen stored fish muscle. The fish muscle proteins have been found to be much less stable than those of beef, pig, and poultry muscles (38). The amount of extractable actomyosin decreased with the duration of storage, while no significant change in sarcoplasmic proteins was observed during frozen storage of cod and other fish (36–38). Since the decrease in soluble actomyosin correlated well with palatability scores, it was proposed that denaturation of actomyosin is the major cause for the decrease in eating quality of frozen fish. Although the change in extractable actomyosin is regarded as the primary criterion of freeze denaturation, it still must be noted that extractability data cannot indicate precisely how much protein is denatured and how much is native. According to previous studies, results from electron microscopic analyses (39), decreases in actomyosin peak (20s–30s) areas on ultracentrifugal analysis (40, 41) and viscosity of soluble actomyosin with duration of storage (41, 42) suggested the aggregation of muscle proteins occurred during frozen storage. In addition to aggregation, dissociation of f-actomyosin into f-actin and myosin also occurred. It appeared that the dissociated F-actin, as thin filaments, became entangled and aggregated and that the dissociated myosin monomers folded into globular form. At advanced stages of freeze denaturation, large masses with diffuse outlines were frequently found, indicating the formation of aggregation complex of actin and myosin (43).

ATPase activity of actomyosin and myosin, another property of myosin related to its contractile function, also decreased with the increase of frozen storage (40–42, 44–47). During frozen storage, changes in isolated actomyosin and myosin have been sought in the number of –SH groups (40–42, 44–47), titratable acid groups (48), and net charge (49), and in the salting-out profiles (50, 51). Connell (52) attributed the insolubilization of frozen

stored cod actomyosin to the denaturation of myosin rather than actin. However, isolated carp actin denatured progressively with myosin during frozen storage as demonstrated by SDS-PAGE (53). During the initial frozen storage, it appears that both myosin and actin undergo denaturation, while denaturation of tropomyosin and troponin was observed during elongated frozen storage (53).

Decreases in the solubility, viscosity, ATPase activity, and number of SH groups of frozen stored rabbit, mackerel, milkfish, amberfish, tilapia, and trout were observed (44–47, 54, 55). Although Connell (56) ascribed the intramolecular aggregation of muscle proteins to the formation of non-covalent bonds (57) rather than to the formation of disulfide bonds, the involvement of SH group in the denaturation of muscle proteins during frozen storage has been emphasized by Buttkus (54, 55) and Jiang et al. (44–47). From the studies thus far reported, the crosslinkage of myosin is ascribed to the formation of disulfide bonds, hydrophobic bonds and hydrogen bonds during frozen storage. Free SH groups are firstly oxidized to disulfide bonds. However, only a small decrease was found in the number of free SH groups during frozen storage. Therefore, the changes appear to be the result of rearrangements of disulfide bonds from intra-molecular to intermolecular through a sulfhydryl-disulfide interchange reaction.

Myofibrils, a systematically organized complex of myofibrillar proteins, undergo some structural changes during frozen storage of fish. The most noticeable change is the fusion of the myofibrils as illustrated by cell fragility method (58, 59) and fragmentation into short pieces at the Z-bands (60–63). More recently, studies have been done on the denaturation of enzymes during frozen storage (64, 65). Inactivation of enzymes with globular molecule was considered to be due to the unfolding of intra-molecular structure (66).

Many hypotheses have been proposed to explain the denaturation of muscle proteins (67–70). They include: 1) the effect of inorganic salts concentrated into the liquid phase of the frozen system; 2) water-activity relations; 3) reactions with lipids; 4) reaction with formaldehyde derived from trimethylamine (in fish); 5) auto-oxidation; 6) surface effects at the solid-gas interface; 7) effects of heavy metals; and 8) effects of other water-soluble proteins (such as protease). Among these hypotheses, effects of lipids (67–72), formaldehyde (73–77), and gas-solid interface of myofibrillar proteins caused by free fatty acids and/or lipid peroxides must occur during frozen storage. Jarenback and Liljemark have shown by electron microscopy that, in muscle frozen stored with added linoleic and linolenic hydroperoxides, myosin became resistant to extraction with salt solution (78). However, recent studies on isolated muscle protein indicate that proteins undergo denaturation in the absence of lipids, formaldehyde, heavy metals and water-soluble proteins. Another popular view is the so-called "salt-buffer hypothesis" which gives attention to the effects of highly concentrated salt solution in the unfrozen phase of frozen muscle proteins. The concentrated salt solution may denature the proteins (67–72).

One of the most prevalent chemical reactions to occur in fish muscle during freezing and frozen storage is the complex phenomenon of protein denaturation. It has been postulated that the rupturing of different bonds in the native conformation of proteins in frozen fish is followed by side-by-side aggregation of myofibrillar proteins, specifically myosin, brought about by the formation of intermolecular cross-linkages (27, 79). It is also believed that the significant decrease observed in the center-to-center distance between the thick filaments of the A-band of the sarcomere after prolonged frozen storage favors the formation of cross-linkages between molecules and stiffens the fibers (78). Such intermolecular cross-linkages result in aggregation (30), which leads to the formation of high-molecular-weight polymers (80, 81) and subsequent denaturation of myosin during frozen storage.

Several relevant theories on protein denaturation in relation to fish moisture and freezing damage have been formulated. One theory worthy of note is that of protein denaturation being affected by the freezing out of water. The conformation of most native proteins has the hydrophobic side chains buried inside the protein molecule. However, some of these hydrophobic side chains are exposed at the surface of the molecule itself. It has been suggested that the water molecules arrange themselves around these exposed hydrophobic side chain groups so as to minimize the energy of the oil/water interface and, at the same time, act as a highly organized barrier, which mediates the hydrophobic/hydrophilic interactions between protein molecules (81). These water molecules form a network of hydrogen bonds, which contribute to the stability of the highly organized three-dimensional structure of the proteins. As water molecules freeze out, they migrate to form ice crystals, resulting in the disruption of the organized H-bonding system that stabilizes the protein structure. As the freezing process continues, the hydrophobic as well as the hydrophilic regions of the protein molecules become exposed to a new environment, which may allow the formation of intermolecular cross-linkages (30), either within the same protein molecule, causing deformation of the three-dimensional structure of the protein, or between two adjacent molecules, leading to protein-protein cross-links.

Freezing also concentrates solids, including mineral salts and small organic molecules, within the remaining unfrozen aqueous phase in the cell (82), which results in changes in ionic strength and possibly pH, leading to the denaturation of the protein molecule (83). Love (84) considered this concentrated salt in the unfrozen phase to be the main protein denaturant in the frozen muscle system. If proteins are denatured over time in the presence of concentrated solutes, it is reasonable to believe that longer exposure of protein molecules to these denaturants (e.g., slow

freezing) should be avoided. However, further work must be conducted to determine the effect of the rate of freezing on shelf life of frozen fish as related to the solute concentration effect.

Several methods have been established to determine the extent of protein denaturation during frozen storage of fish and seafood. According to Jiang and Lee (85), protein quality is more sensitively reflected by the enzymatic activities in the muscles than by its extractability, since small microstructural changes in protein molecules can cause more alterations in the enzymatic activities than in extractability. For example, the actomyosin Ca ATPase, which measures the activity of myosin, can be used as an index of protein quality. Since this ATPase is capable of hydrolyzing the terminal end phosphate group of ATP to give ADP (68), this particular enzymatic activity can be determined by measuring changes in the amount of inorganic phosphate present in the muscle. The loss of enzymatic activity reflects the extent of freeze damage and alteration of the protein structure in the muscle system. Connell (79) reported a loss in Ca ATPase activity in muscle during frozen storage. In a more recent study using mackerel, Jiang and Lee (85) observed a loss of ~66% of the original Ca ATPase activity of actomyosin after 6 weeks of storage at –20°C.

Visual examination under a transmission or scanning electron microscope is a powerful technique used in the determination of textural changes in fish muscle due to denaturation. The electron microscopic studies of Matsumoto (30) were able to detect damage to the native structure of the protein: aggregation and an entangled mass were observed. However, results from this technique have to be interpreted cautiously since the fixing processes of tissue or any tissue section may create artifacts by altering the ultrastructural images or by masking the microchanges in the muscle tissue.

The extent of protein denaturation in frozen fish muscle can also be determined by conducting several tests of protein functionality. The physicochemical properties that affect the behavior of protein molecules during processing are defined as the functional properties of the fish myosystem, which include protein homogenate solubility, emulsifying and water-retention properties, gelation, and viscosity (86). The most popular tests to determine the extent of protein denaturation during frozen storage of fish, in relation to its functionality, are determination of the loss in solubility or extractability of proteins and measurement of the water-retention properties of the fish muscle system.

C. Effects of Freezing, Frozen Storage, and Thawing on Nutritional Value

Considerable emphasis has been given to the influence of freezing, frozen storage, and thawing on quality indices such as appearance/color, texture, flavor, odor, and the chemical reactions that accompany such organoleptic changes. Less attention has been given to yet another useful area, i.e., the influence of such treatments on the nutritional value of frozen fish and seafood.

Put simply, considerable attention is given to sensorial perceived attributes because if consumers reject a frozen product on display, it is not purchased or eaten regardless of its nutritional value. Conversely, if consumers are attracted to a frozen product, they tend to buy it whether it has the needed nutrients or not. However, as the market shifts to the development and merchandising of products to meet the demands of health-conscious consumers, the nutritional value of frozen fish becomes of great importance.

When fish and seafood are frozen, and subsequently stored and thawed, protein denaturation occurs in muscle tissues. As a result, formation of thaw drip becomes apparent and consequently leads to the leaching out of dissolved materials. Likewise, there is an increase in the release of a watery "cook liquor" when the product is heated. Such water losses result in the loss of water-soluble proteins; however, such losses do not result in any measurable decrease in the nutritive value of the protein (87). However, such losses lower the proportion of sarcoplasmic proteins in the fish tissue and may also lead to a small loss of water-soluble vitamins and minerals.

Other quality changes, such as lipid oxidation, can also influence the nutritional value of frozen products. Oxidized fish lipids, such as lipid hydroperoxides, may induce oxidative changes in sulfur-containing proteins, producing significant nutritional losses (88).

D. Effects of Freezing, Frozen Storage, and Thawing on Intrinsic Chemical Reactions

When frozen fish are subjected to excessively prolonged cold storage at temperatures above –30°C, a series of intrinsic chemical reactions occurs in fish tissues. These reactions include protein denaturation, breakdown of TMAO, and lipid oxidation.

1. Breakdown of Trimethylamine Oxide

Quite obviously, protein denaturation during frozen storage produces extensive textural changes and deterioration in fish. These changes are more pronounced in some species of fish, specifically the gadoids, and are related to another intrinsic chemical reaction, the breakdown of TMAO.

TMAO is commonly found in large quantities in marine species of fish. It is believed that these species use TMAO for osmoregulation (89). Among the marine species, the elasmobranches contain more TMAO than the teleosts. Among the teleosts, the gadoids have more TMAO than the flatfish. Except for burbot, freshwater species have a negligible amount of TMAO in their muscles, since they

do not take in TMAO in their diet beyond their bodies nutritional requirements, and they promptly excrete any excess.

After death, TMAO is readily degraded to DMA and FA through a series of reactions. This conversion of TMAO to DMA and FA is typically observed in frozen gadoid species such as cod, hake, haddock, whiting, red hake, and pollock (7).

The presence of air (oxygen) affects DMA and FA formation. It has been suggested that oxygen may actually inhibit the reaction by interacting with metal ions, which otherwise would accelerate the TMAO degradation (90). Lundstrom et al. (91) observed that red hake (*Urophysis chuss*) minces stored in the absence of oxygen showed more rapid DMA and FA formation than red hake fillets stored in air. Likewise, the presence of air (oxygen) in packaged white hake (*Urophysis tenuis*) significantly prolonged the shelf life of the frozen samples (15).

TMAO degradation to DMA and FA was enhanced by the presence of an endogenous enzyme (TMAOase) in the fish tissues, as observed in cod muscles by Amano and Yamada (92). They also found an enzyme in the pyloric ceca of Alaskan pollock (*Pollachius virens*), which was believed to cause DMA and FA formation in this species (93). However, evidence also exists which demonstrates that breakdown of TMAO to DMA and FA is nonenzymic in nature (94, 95). The breakdown of TMAO, whether enzymatically or nonenzymatically induced, is believed to produce destabilization and aggregation of proteins.

TMAO has been postulated to be responsible for stabilizing proteins against conformational changes and thermal denaturation (96). However, the conversion of TMAO to DMA and FA has been implicated in gadoid textural problems during frozen storage (12, 97, 98).

It has been suggested that TMAO's breakdown product, FA, may produce cross-linking of muscle proteins (30) due to its high reactivity: FA can covalently bond with various functional groups of proteins, such as the amino, imino, guanido, phenolic, imidazole, and indole residues. This reaction induces both intra- and intermolecular cross-linkages of the molecules, thus producing conformational changes.

However, textural changes may also occur during frozen storage for fish species devoid of the TMAO-enzyme system (99). Such textural changes must then be attributed to another type of mechanism that does not involve the cross-linking of protein molecules due to the presence of FA. Gill et al. (99) reported that the presence of FA in red hake resulted in the covalent cross-linking of troponin and myosin light chains, forming high-molecular-weight aggregates. However, when haddock, a species that does not produce FA, was examined, the same cross-linkages were not found at the molecular level, although textural toughening was observed, but not as pronounced as that in red hake. Based on these observations, they suggested that textural changes in haddock were probably due to secondary bonds, such as hydrogen or electrostatic bonds, and not due to FA cross-links.

Clearly, the presence of FA is not the only factor involved in textural changes during frozen storage. However, with certain species of fish, it appears to be of primary importance.

To objectively determine the extent of textural deterioration due to DMA and FA formation and subsequent reactions, the measurement of DMA content is recommended. Due to the equimolar formation of DMA and FA in fish muscle and the observed high reactivity of FA, DMA content is routinely used as an index. Consequently, the DMA test indirectly measures the FA value in fish muscle. However, use of this test is limited to those species known to produce DMA and FA during frozen storage.

2. Lipid Oxidation

Another chemical reaction generally associated with quality changes during freezing, frozen storage, and thawing is lipid oxidation. This phenomenon most commonly occurs in fatty fish and is considered one of the major causes of frozen shelf-life reduction.

Lipid oxidation results in the development of a condition described as "oxidative fat rancidity." The extent of oxidation in fish lipids varies with the quantity and the type of lipids in the fish muscle, i.e., fatty species are more prone to oxidation than lean species, and species with more highly unsaturated fatty acids are less stable than the other species. When oxidative rancidity progresses sufficiently, it leads to the development of obvious off-taste and odor, resulting in reduced shelf life.

Changes in fish lipids may be related to changes in protein during frozen storage. Several reports indicate that the unstable free radical intermediates formed during autoxidation attack the protein molecules, leading to the formation of protein free radicals (88). These protein free radicals may cross-link with other proteins to form protein-protein aggregates and with lipids to form protein-lipid aggregates (7).

Another possible mechanism for reaction between oxidized lipids and proteins occurs through stable oxidation products such as malonaldehyde, propanal, and hexanal (26), which covalently react with specific functional groups on protein side chains, including the –SH group of cysteine, the amino group of lysine, and the N-terminal amino group of aspartic acid, tyrosine, methionine, and arginine (11). Such interactions increase the hydrophobicity of proteins, making them less water soluble. Free fatty acids (FFA) formed during autoxidation produce indirect effects on textural degradation by promoting protein denaturation (86). FFA are believed to bind myofibrillar proteins, specifically actomyosin, rendering it unextractable (26, 29). According to Sikorski et al. (29), when the hydrophobic sites of FFA interact with protein molecules, the protein molecules

become surrounded with a more hydrophobic environment, which subsequently results in a decrease in protein extractability. This interaction may occur through hydrophilic and hydrophobic forces (29).

Several techniques have been developed to assess the extent of lipid oxidation in fish muscle. The most common techniques include (1) the peroxide value (PV) test, which measures the amount of hydroperoxides or peroxides formed during autoxidation (this test provides only a means for predicting the risk of rancidity development) and (2) the thiobarbituric acid (TBA) test, which measures the amount of malonaldehyde formed upon the decomposition of hydroperoxides during the second stage of oxidative rancidity. Other methods are also undoubtedly available. Therefore, the choice of techniques depends on several factors, such as the accuracy required and the availability of equipment.

VI. MICROBIOLOGY

Most matters of animal and plant origin used as human food are subject to microbiological attack as well as chemical, biochemical, and physical changes. At room temperatures the microbial attack is often so rapid that all the other changes play only a minor role. Microorganisms in all food raw material release enzymes into substrates during their growth. Changes brought about by the activities of these microbial enzymes will alter the odor, flavor, texture, and appearance of the product. Occasionally this is advantageous but in general it causes deterioration and spoilage. The purpose of preservation, however it is accomplished, is to prolong the storage life of the particular food and this is done either by killing the microorganisms or by inhibiting their activity and multiplication.

Freezing and subsequent storage will kill some of the microorganisms present in the unfrozen material, but this is a slow and variable process depending, in part, upon the nature of the food. Thus freezing cannot be relied upon to substantially reduce bacterial contamination present in the foodstuff. The hygienic state of the product before freezing is consequently all-important. Storage at temperatures colder than −12°C inhibits microbial growth and therefore is one effective method of preserving food against microbial spoilage.

Three aspects of microorganisms in frozen foods will be considered.

A. The Resistance of Microorganisms against Freezing and Frozen Storage

Some pathogens are more resistant to freezing than are ordinary spoilage organisms. A direct examination for common or expected pathogens should therefore be carried out. Most of the common pathogenic bacteria are Gram-negative. This group is more sensitive to freezing, frozen storage, and thawing than are the Gram-positive spoilage organisms.

B. Multiplication of Microorganisms in Frozen Foods

Even when microbial growth is completely inhibited, the frozen product can still deteriorate due to the activity of the released microbial enzymes which can still catalyze undesirable biochemical reactions in the food. When the handling of fish before freezing is improper, there is the danger that microorganisms may have released sufficient enzymes and toxin to affect the quality of the frozen product. For example, if lipases are produced before freezing, they can cause marked hydrolysis of fats in fatty fish even when stored at −30°C. If fish has been held at relatively high temperatures before freezing, any pathogens present could multiply and some may produce toxins. The latter will survive freezing and constitute a health hazard. A product destined for freezing should receive the same degree of hygienic handling as that which is to be stored at chill temperature.

Several psychrotrophic microorganisms can multiply at freezing temperatures. In practice, bacterial growth does not occur below temperatures of −10°C. This is probably due to the increasing concentration of soluble salts and organic compounds in the unfrozen water which will decrease the water activity of this fraction. Only the most drought-resistant microorganisms such as fungi and yeasts can grow in these physiologically very dry substrates and this is why these organisms are the ones which are still capable of growing at temperatures colder than those at which bacteria can grow. Yeasts are not reported to multiply below −12°C and fungi not below −18°C. It must, however, be noted that microbial growth is extremely slow at these temperatures and, for practical purposes, can be disregarded below −10°C. During any long retention in the upper freezing range down to −10°C yeasts or fungi may develop and form visible colonies on the surface of the frozen substrate.

C. Microbiology of Thawed Foods

On thawing, frozen foods will spoil almost at the same rate as would be expected from unfrozen products with the same microbial population maintained at similar temperatures. Condensation of moisture on the surface of the product should be avoided as during thawing it may cause a speeding up of microbial growth.

Pathogenic organisms may grow and produce toxin in food without rendering the food unpalatable. They will be occasionally observed in any food even hygienically prepared. Contamination even with small numbers of pathogenic bacteria during preparation of foods for freezing should therefore be avoided as far as practicable.

Competition between different types of microorganisms is important if food that will be further prepared after thawing is stored in the thawed state before such preparation. A food lacking a normal flora of spoilage organisms but contaminated with a few pathogens is more likely to present a health hazard than the same food contaminated to the same degree with normal spoilage flora. In the case of frozen foods allowed to thaw slowly, the psychrotrophic flora is likely to dominate and may so alter the substrate as subsequently to inhibit or slow down the multiplication of any pathogens present when thawing is complete. Packaging exerts little effect on the spoilage pattern; even vacuum packing causes a negligible increase in the growth rate of anaerobes like *Clostridium botulinum* during storage after thawing.

D. Effects of Freezing, Frozen Storage, and Thawing on Microbiological Quality and Safety

It is readily apparent that spoilage changes in fresh fish occur most commonly as a result of bacterial activity. The species of bacteria vary according to storage temperature. In fish stored in ice, *Alteromonas*, *Achromobacter*, and *Flavobacter* spp. predominate. At temperatures between 35 and 55°C, *Micrococcus* and *Bacillus* spp. constitute the main microflora. Some of these microorganisms produce very active proteolytic enzymes, which produce odor, flavor, and textural problems.

When fish and seafood are frozen, the microorganisms present in their tissues are generally inactivated. Thus, during frozen storage, microbiological changes in fish tissue are usually minimal. Microorganisms not destroyed by the freezing process generally do not grow and in some cases die off slowly. Although some microorganisms survive storage at very low temperatures, their activities are suppressed, and bacterial numbers may be considerably reduced if recommended temperatures are maintained (100). The temperature below which microbial growth is considered minimal ranges from −10 to −12°C (101). Microorganisms, however, that survive and remain inactivated during frozen storage resume growth when the fish is thawed and may then lead to microbial spoilage of the thawed product.

Frozen fish are far from sterile and cannot therefore be considered a microbiologically safe product. The microbial activities in fish after thawing depend on the degree of freshness of the raw material, the natural microflora in the fish tissues, and the thawing technique utilized.

1. Stability of Frozen Products

The effects of various freezing conditions on quality and shelf stability of frozen fish and seafood have received considerable attention recently. Studies have dealt with either the stability of the frozen product as related to storage temperature and fluctuation in storage temperature or the effectiveness of food additives in providing shelf stability to frozen products.

a. Effects of storage temperature

The apparent effects of storage temperature on shelf-life stability of frozen fish are related to protein denaturation and lipid oxidation. The effects of temperature on protein denaturation have been comprehensively studied (37, 102). Maximum denaturation is reported to occur at −4°C in cod muscle (36), while changes in extractable proteins in haddock have been found to be greatest at −2 to −6°C (103).

The rate of lipid oxidation and the accumulation of FFA were observed to increase with temperature (77). In a study using various species of fish, it was observed that maximum production of FFA due to enzymic activities of lipases occurred at −12 to −14°C (104), while the maximum rate of lipid hydrolysis was detected at temperatures just below freezing (105).

Storage at much lower temperatures can, therefore, prolong the shelf life of frozen fish. For example, cod stored at −160°C showed no detectable deterioration after 6 months of storage (77). Even at −65 and −50°C, frozen samples exhibited very few changes after 9 months of storage. Such observations also suggest that low storage temperatures limit the problems associated with protein denaturation and lipid oxidation during frozen storage.

Several studies have been conducted in an attempt to determine the shelf life of frozen fish at different temperatures and to establish storage temperatures that can minimize quality deterioration in specific groups of fish. Poulter (106) reported that *Rastrelliger brachysoma* (club mackerel) stored at −10°C remained acceptable until the ninth month of storage, whereas samples kept at −30°C were rejected after 12 months of storage. *Scomber scombrus* (Atlantic mackerel) stored unwrapped at −18°C were rejected after 3 months of storage, while samples at −26°C remained acceptable until the sixth month of storage (107). Early rejection of fatty species at relatively low temperatures is reportedly due to the development of rancid flavor and odor. Several studies have also reported the same dependence of shelf life for different fish species on temperature (15, 108, 109).

Clearly, fish composition has an appreciable effect on shelf-life stability of frozen fish. For instance, in a comprehensive study using different fish species, it was found that fatty fish such as mackerel, salmon, herring, sprat, and trout had a shelf life of 2–3 months at −18°C, whereas lean fish such as cod, flounder, haddock, ocean perch, and pollock exhibited storage stability of up to 4 months at the same storage temperature (110).

Based on several studies, it is recommended that those species most susceptible to oxidative rancidity be stored at very low temperatures (at least −29°C) while species less susceptible to rancidity should be stored at temperatures between −18 and −23°C (18). For species with textural

problems due to the TMAO breakdown, the storage temperature must be below −30°C.

b. Effects of fluctuations in temperature

Fluctuations in storage temperatures affect the shelf-life stability of frozen products due to an increase in the size of the ice crystals formed in fish tissues (26). With slight increases in temperature, small ice crystals melt faster than larger ones, so that when the temperature drops again, the melted ice refreezes around the large ice crystals, forming larger crystals. These large crystals accelerate freezing damage, leading to shorter storage stability.

c. Use of food-grade additives

The effectiveness of different food-grade additives has also received considerable attention recently. The most commonly used types of additives for fish and seafoods function either as antimicrobial agents or as antioxidants.

i. Antimicobial agents

Additives are commonly used in the food industry to prevent the growth of bacteria, yeast, and molds. The selection of an antimicrobial agent or any combination of agents is rather complicated, especially when dealing with fish. The effectiveness of an antimicrobial agent depends on several factors, such as the moisture content of the product and the presence of other microbial inhibitors like smoke and salt.

Several antimicrobial agents have been tested for fishery products. For instance, the sorbic acid salt, potassium sorbate (KS), has been found useful in extending the shelf life of fresh fish. Studies have demonstrated that KS, when applied as part of the ice, increased ice storage stability of red hake and salmon up to 28 and 24 days, respectively (111, 112). KS, in combination with modified atmosphere packaging (MAP), was also determined to be an effective method for prolonging the shelf life of fresh whole and filleted haddock on ice (113).

The shelf life of fresh fish may also be extended under refrigerated conditions with the use of Fish Plus, which exhibits its preservative effect due to the combined action of components such as citric acid, polyphophates, and potassium sorbate. Citric acid lowers the muscle pH, which consequently creates an optimum environment for potassium sorbate to exhibit its antimicrobial effects. Dipping in Fish Plus has been found to extend the shelf life of lingcod on ice to as much as a week (114). Fish Plus may also be used on frozen fish.

ii. Antioxidants

An antioxidant is a substance capable of delaying or retarding the development of rancidity or other flavor deterioration due to oxidation. It is normally used in conjunction with freezing to reduce the rate of autoxidation during frozen storage. Antioxidants delay the development of rancidity by either interfering with the initiation step of the free radical reaction or by interrupting the propagation of the free radical chain reaction (115).

The kinetic of antioxidative action was considered to be that antioxidants act as hydrogen donors or free radical acceptors (AH) and react primarily with ROO· , not with R· radicals.

$$\mathrm{ROO\cdot} + \mathrm{AH} \longrightarrow \mathrm{ROOH} + \mathrm{A\cdot}$$

A low concentration of this chain-breaking antioxidant (AH) can interfere with either chain or initiation, producing nonradical products:

$$\begin{matrix} \mathrm{A\cdot} + \mathrm{ROO\cdot} \longrightarrow \\ \mathrm{A\cdot} + \mathrm{A\cdot} \longrightarrow \end{matrix} \text{nonradical products}$$

Different versions of the antioxidant mechanism have been suggested by different authors (100, 115).

Other antioxidants may function as metal-complexing agents, which partly deactivate the trace metals, often present as salts of fatty acid (100), which would otherwise promote the oxidative reaction. Citric, phosphoric, ascorbic, and erythorbic (isoascorbic) acids are typical metal-chelating agents.

Among these antioxidants, erythorbic acid was used in studies by Kelleher et al. (116) and Licciardello et al. (35) of shelf-life stability of frozen fish. This antioxidant was emphasized due to encouraging results with the use of its salt, sodium erythorbate, in retarding oxidation in whiting, chub mackerel, and white bass fillets (35, 117, 118). Licciardello et al. (35) demonstrated the effectiveness of erythorbic acid in the retardation of oxidative rancidity in fillet blocks of Argentine hake stored at −18°C.

However, the use of erythorbic acid is limited to fish species in which rancidity is the main problem. Kelleher et al. (116) demonstrated the effect of this compound on the frozen storage of red hake (*Urophysis chuss*), a gadoid species, in which lipid oxidation is not the limiting factor for shelf-life extension. They found that the rate of DMA formation at −18°C in samples dipped in erythorbate solution was significantly greatly than the rate in untreated samples. Such effect of erythorbic acid on DMA formation may be explained by the fact that this acid acts as an alternative and preferred scavenger of oxygen, leaving metal ions that would otherwise bind to oxygen and be inactivated, available to catalyze the degradation of TMAO to DMA and FA (119).

APPLICATIONS

I. HYGIENE IN THE PREPARATION OF FROZEN SEAFOOD

Most foods and food products are susceptible to attack by microorganisms and they are always contaminated by a variety of such organisms present in the food production chain. Foodstuffs are subjected to further contamination

during preparation for freezing as a result of contact with the hands of factory staff during preparation, packaging and transport, and with air or water.

In view of the hazards to health and the effect of microbial contamination on quality, every effort must be made to reduce such contamination to a reasonable level during the preparation of foodstuffs for freezing. Throughout the world frozen foods have very seldom been the cause of food poisoning incidents.

A. Human Contamination

As pathogenic bacteria like *Salmonella* and *Staphylococcus* frequently derive from human sources, it is of vital importance that factory employees are aware of the basic concepts of good personal hygiene: the need for frequent washing and the wearing of clean clothes, overalls, hair covering, etc. The use of rubber gloves and a protective mask for the mouth may be desirable in some instances. When gloves are worn they must be thoroughly cleaned and inspected before use. Medical supervision is advisable and in some cases should be made compulsory. Notices in lavatories should draw attention to personal hygiene, especially the need for hand washing. Soaps, hand creams, or dips containing antiseptic agents should be readily available.

B. Buildings and Equipment

Design of the building should ensure that both the buildings and drains are vermin proof. Interior walls, floors, and ceilings should be finished with a non-flaking surface capable of withstanding detergents and sanitizers. All corners should be rounded to facilitate cleaning. The building should be large enough to house production equipment so that all sides of the equipment are accessible for cleaning.

Entrance to the process area should be supplied with adequate washing facilities with foot-operated taps. Wood, which is almost impossible to sanitize, should not be used in contact with food. All windows should be both bird and fly proof.

Equipment usually becomes soiled with organic residues, which act as carriers of microorganisms. It should be designed and constructed to prevent hygienic hazard and permit easy and thorough cleaning. All surfaces should have a smooth, hard, waterproof finish. Cutting boards should be of a hard material; plastic is preferable to wood. Cleaning and disinfection of the food handling area, including equipment and utensils, should be carried out at frequent and regular intervals. Waste materials should be frequently removed, in covered containers, from the working area during factory operation. Processes should be so separated — either in space or time — as to avoid recontamination of products in which the "bacterial load has already been reduced." For cleaning purposes an ample supply of potable water should be available. Chlorinated water is effective both for in-plant use (when concentrations of around 5 to 10 ppm are appropriate) and for sanitation of equipment and surfaces (when concentrations of around 100 to 200 ppm are used) but this should be followed by a rinse. Organic residues inactivate chlorine which, therefore, should only be used to sterilize already clean surfaces. Chlorine can be responsible for flavor loss or taint (due to the formation of chloramines or chlorophenols). Removal of the chlorine (by thiosulphate addition, often combined with treatment in activated carbon towers) is practiced, especially in ice cream producing plants.

C. Cross-Contamination

During the preparation of food for freezing, all efforts should be taken to avoid a build-up of an undesirable microbial population. For some foods, handling should take place at sub-ambient temperature in temperature-regulated rooms, and where a heat treatment is a part of the processing this should be so severe that most of the microorganisms are killed. After heat treatment, the food should be promptly cooled to avoid multiplication of the surviving bacteria in the critical zone between 50 and 10°C. Cooling water, if used, should be chlorinated.

D. Bacteriological Control

Proper organization of the various processes from the hygienic point of view is essential and a constant watch should be kept for lapses in hygiene. This should include a bacteriological control of the various stages in the processing line. Bacteriological methods are now available that give a good estimate of the bacterial load of the raw material and of food contact surfaces. Methods that give a rapid result are especially useful, as they supply plant management with information on the bacteriological state of products actually under preparation.

The results of the examinations should be shown to the factory staff in order to make them comprehend the vital importance of hygiene in food production. Preferably, courses in food hygiene should be held at regular intervals for employees. The aim should be to give those engaged in food production a thorough understanding of the hazard involved.

The above considerations concerning personal hygiene, equipment, and preparation of foods also applies to handling of frozen foods in catering establishments. Thawing of frozen foods in these establishments should be completed as quickly as possible, and any storage of the food after thawing should be in a refrigerator.

II. PACKAGING

A. General Requirements

Not only must packaging used for frozen foods meet all the requirements of normal packaging but it must

also meet requirements of packaging suitable for food such as:

- Chemical inertness and stability;
- Freedom from taint and odor;
- Freedom from toxic materials which may migrate into the food;
- Impermeability, or nearly so, to water vapor and other volatile constituents as well as to any odors from the surroundings;
- Suitability for use in automatic packaging systems;
- Suitable size and shape for display in retail cabinets;
- Protection from bacterial contamination and filth;
- Ease of opening; and
- An attractive appearance.

In addition to these general requirements for food packages, frozen food packages should also:

- Be of such shape as to allow rapid freezing except for I.Q.F. (Individually Quick Frozen);
- Permit volume expansion in the freezing process;
- Be impermeable to liquids and have good wet strength and resistance to water and weak acid;
- Be able to withstand low temperatures, not becoming excessively fragile at cold temperatures encountered during the freezing process;
- Not adhere to the contents in the frozen condition;
- Have a high reflectivity to reduce heat gain by radiation during display in retail cabinets;
- Be impervious to light as far as practicable; and
- Surround the product closely, leaving the minimum of air entrapped, thus limiting sublimation during storage.

B. Packaging Materials

A wide variety of materials have been used in devising packaging systems for various frozen foods, e.g., tinplate, paper, paper-board with a wax or plastic coating, aluminum foil, plastic film, thermoformed plastics, and laminated combinations of these materials.

Low permeability to water vapor is an important characteristic of packaging materials for frozen foods. Table 39.2 compares the permeability of commercially available packaging materials.

1. Paper-Board Packages

Paper-board package for foods is generally in the form of folded cartons, either directly printed or provided with printed wrappers on the outside and in some cases with plastic coated liners. The following coating or laminating materials are commonly used:

- Wax blends (paraffin and micro-crystalline compositions);
- Plastics, e.g., polyethylene or polypropylene (on one or both sides);
- Aluminum foil.

TABLE 39.2
Water Vapor Permeability*

Film Type, 0.025 mm (1 mil)	Transmission Rate at 38°C (100°F), 90% RH
Polyvinylchloride	120–190 g/m^2.24 h
Polyamid (Nylon)	120g/m^2.24h
Polyester (Mylar)	25 g/m^2.24 h
Polyethylene, low density	19 g/m^2.24 h
Polyethylene, high density	6g/m^2.24h
Cellophane MST-type	5–23 g/m^2.24 h
Polyvinylidene chloride (Saran)	1.5–5 g/m^2.24 h

* The data given in this table refer to a test temperature of 38°C and the ranking order between different materials in respect to water vapor permeability. Water vapor permeability of a good package should not exceed about 0.2–0.5g/m^2.24h at −20°C and 75% RH. The important factor, however, is not just the water vapor permeability of the packaging material, but that of the complete package.

2. Wrappers and Bags

Materials most commonly used are: waxed paper; hot melt or plastic coated paper; aluminum foil; coated cellulose films such as MSAT (moisture-proof, scalable, anchored, and transparent); and plastic films, such as polyethylene (PE), polypropylene (PP), and polyvinylidene chloride (PVDC) films. Also of importance are the laminated materials built up from two or more of the above-mentioned materials or other films. Common combinations are cellulose and PE films, sometimes with a PVDC coating.

These materials are used as over wraps, liners, and as single or double wall bags. The bags are either of the prefabricated type or are formed from roll stock on a filling machine.

Particularly important are shrink-wrap materials because of their ability to adhere close to the product, leaving few if any air pockets. Shrink-wrap bags require evacuation of entrapped air before shrinking. Some of these bags can withstand boiling water and, therefore, the package can be used for end-cooking of the product before serving.

3. Wooden Boxes

Often used for fish, wooden boxes require an inner liner or glaze on the product to guard against desiccation.

4. Rigid Aluminum Foil Packaging

These packages, in the form of trays, dishes, and cups, are generally covered with a crimped-on aluminum sheet or a sheet of aluminum foil laminated to paper-board. Normally used for prepared foods and pastries, etc., they allow rapid heating of the product in the package before serving.

5. Semi-Rigid Plastic Packages

These are mostly manufactured from high density PE or PP in the form of trays and plates, covered by a lid; as with aluminum foil, these can also be used for prepared foods requiring heating before serving, providing only gentle heat, such as steaming, is employed.

6. Tin and Composite Containers

These are used mainly for frozen juices which often have a mobile liquid phase even at cold store temperatures. A more recent development is to use coated paper-board in the body and aluminum for the ends, coupled with an easy opening device.

7. Shipping Containers

These are normally manufactured from different materials such as solid, corrugated fiber-board or vulcanized fiber-board paper, and plastics. They are often good heat insulators.

C. Packaging Machinery/Packaging Systems

An essential requirement of any package used in modern industry is that it should form a part of a system which enables the packages to be formed, filled, sealed, and handled mechanically on an integrated packaging line.

1. Form-Fill-Seal Machines

These machines form pouch-shaped or tray-shaped packages from heat-scalable plastic films or laminates or plastic-coated papers in roll form. The packages are formed and filled in the machine simultaneously or consecutively; these machines can work either in a vertical or a horizontal plane.

2. Cartoning System

These can be top filled, end filled, or side filled but irrespective of these differences each machine should perform the operations of erecting, filling, and sealing.

3. Shrink Film Wrapping Equipment

These machines apply shrink film materials from rolls around a given number of consumer-sized packages to form a unit, often replacing cases or boxes. After the application of the film, mostly in the form of a sleeve wider than the width of the contents, the unit is passed quickly through a hot air oven which shrinks the film tightly around the unit.

III. BULK PACKAGING

The practice of storing frozen food in bulk has increased considerably for the following reasons:

- The economy of storage space thus achieved;
- The ability to separate an intricate labor-intensive further processing packaging operation from the essential processing and freezing operation carried out when the raw material is available;
- Flexibility in final package sizes of various produces.

Bulk packaging is extensively applied to fruit and vegetables and to a lesser extent to meat, fish and poultry. Individually frozen products, the form of freezing particularly applied to vegetables, is most suitable for bulk storage. Products may also be bulk frozen into blocks, this method is used primarily for fish and meat.

After freezing, vegetables such as peas, corn, beans and sprouts can be stored on site in silos holding one or more hundreds of tons. Bins of corrugated board, metal or timber construction, with polyethylene liners providing a moisture vapor barrier and protection against dirt, can be used for storage or shipping. Smaller containers may be multi-wall paper sacks, corrugated boxes or fiber drums provided with polyethylene liners. Storage temperatures should be constant to prevent formation of clumps which have to be removed during repacking. This operation normally consists of tipping the contents out of the bulk container, breaking any clumps before passing the product over a screen or through an air-cleaner to remove small pieces prior to visual inspection and repacking, care being exercised over the hygiene requirements of this operation.

Frozen-at-sea whole fish is frozen in blocks or individually. In both cases, the fish, if not packaged, should be glazed prior to storage to minimize desiccation. Some fish is slabbed as skin-on fillets or made into blocks of skinned and boned fish for later cutting; both packs should be cartoned or bagged to minimize desiccation.

IV. FREEZING

Freezing is simply the crystallization of ice in muscle tissue and includes the consecutive processes of *nucleation* and *growth*. These processes are central to the effects of different freezing rates and subsequent effects on meat quality. Meat does not freeze immediately when its temperature drops below the freezing point and the latent heat (i.e., heat required during the phase change during crystal

formation) has been removed. In other words there is a degree of *supercooling*. The greater the supercooling, the greater the number of nuclei formed. The number of nuclei is greatest in the extracellular space, and they are only formed within the cell when the rate of heat removal is higher. As soon as the nuclei form, they begin to grow by the accumulation of molecules at the solid/liquid interface. However, the way they grow depends on the microgeometry and the temperature distribution ahead of the freezing front, in a complex way, as a consequence of dendrite formation with supercooling in front of the dendrite growth. An important concept is *characteristic freezing time*, which is a measure of the local freezing rate and is defined as the time during which the point under consideration decreases from −1°C (freezing commences) to −7°C (when 80% of the water is frozen). The growth of extracellular ice crystals also takes place at the expense of intracellular water. This leads to partial dehydration of the muscle fibers and subsequent distortion. At high characteristic times (slow freezing), the ice crystals are larger and the tissue distortion is greater.

The freezing process can rapidly minimize physical, biochemical, and microbiological changes in the food. This preservative effect is maintained by subsequent storage of the frozen food at a sufficiently cold temperature.

A. Freezing Process

The freezing process can be divided into three stages:

Stage 1: Cooling down from the initial temperature of the product to the temperature at which freezing begins. It must be borne in mind that the act of placing a product in a freezing apparatus does not render it "safe." Time will elapse before warm food passes out of the microbiologically hazardous temperature zone; this is particularly the case if freezing is carried out in slowly moving air as in the freezing of bulk products such as berries for subsequent jam manufacture.

Stage 2: This step covers the formation of ice in the products and extends from the initial freezing point to a temperature about 5°C colder at the center of the product. The major part of the freezable water will be converted to ice and this quite small reduction in temperature is accompanied by a massive enthalpy change.

Stage 3: Cooling down to the ultimate temperature for storage. When leaving the freezer, the frozen product will have a non-uniform temperature distribution: warmer in the center and coldest at the surfaces. Its average temperature will correspond to the value reached when the temperature of the product is allowed to equalize. In general, it is recommended to cool the product in the freezer to an equilibrium temperature of −18°C or colder. Product leaving the freezer with a warmer temperature will be stored for some time in relatively unfavorable conditions. Cooling down to storage temperature may take days or weeks.

B. Freezing Time

The effective freezing time is determined not only by the initial and final temperature of the product and its change in enthalpy but also by the temperature of the heat transfer medium. The dimensions (especially the thickness) and shape of the product unit affect the overall heat transfer, which includes the surface heat transfer coefficient α and the heat conductivity λ characteristic of the product. When freezing by air blast α depends on the air velocity and the shape of the product. In an air blast freezer, the rate of freezing increases with increasing air velocity to an optimum value. The refrigeration load necessary to remove the heat produced by the fans increases with the cube of the air velocity; this factor should be taken into consideration when designing air blast freezers. It is important to direct the air circulation in such a way that all the product is equally exposed to the air current. In packaged food the packaging material presents a resistance to the heat transfer, depending on its thickness and conductivity. This resistance is increased considerably if air is trapped between the package and the product.

The freezing time as a function of the thickness of fish fillets in packages frozen in a plate freezer (α=200 kcal/m^2.°C including the packaging) and in a blast freezer with medium air velocity (α=20 kcal/m^2.°C) with heat removed from both sides of the package, is shown in Figure 39.1(a) (120). This graph indicates that during plate freezing the heat conductivity of the product is the main factor determining freezing time; it also shows that during air freezing the heat resistance of the surface (including packaging material) plays a dominant role for the product thickness encountered in practice.

Figure 39.1(b) (120) shows the freezing time for 450 g fish fillet packs as a function of the overall heat transfer, including the influence of some types of packages used in contact freezing. This graph indicates that the type of packaging alone may increase the freezing time in a plate freezer by 2.5 times, and the surface heat transfer resistance by some 4 times. The freezing of packaged foods takes longer in an air blast freezer than in a plate freezer under comparable conditions. In the freezing of packaged food, where the λ-value is influenced by the air inside the package, the difference in freezing rate between plate and blast freezing diminishes as does the influence of packaging material.

C. Freezing Rate

Freezing must always be fast enough to minimize the development of microbiological and enzymatic changes in the product. A freezing process which occupies a matter of days will, in most cases, lead to deterioration in the frozen foodstuffs.

In the past, the beneficial effect of very rapid freezing on the quality of frozen foods has been overestimated: within certain limits the rate of freezing does not

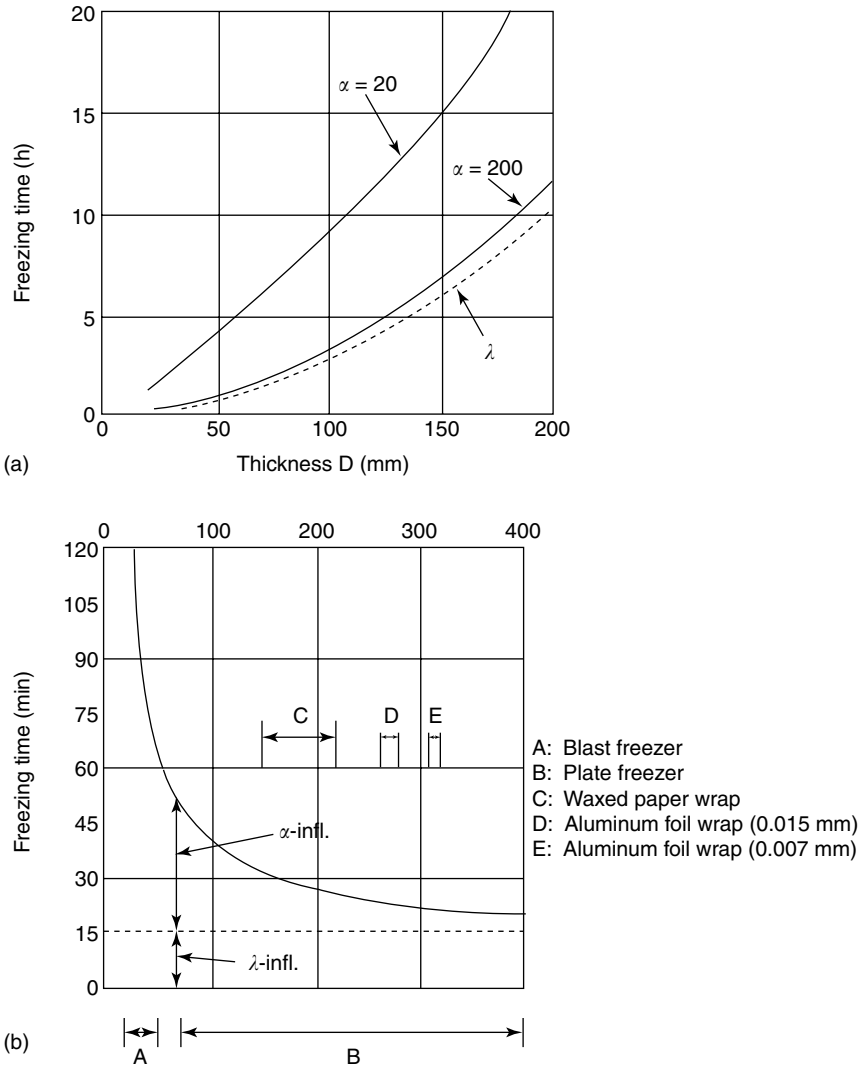

FIGURE 39.1 (a) Freezing time in hours as a function thickness D, of a slab of fish fillets frozen by removal of heat from two opposite sides of the package, for two values of the surface heat transfer coefficient $\alpha=20$ and $\alpha=200$ kcal/m^2. °C. A temperature of -30°C is assumed for the cooling medium (air, cold plates) and the process is considered to be completed when a temperature at the thermal center of -15°C is reached. The total freezing time is divided into two parts, one due to the influence of the internal conduction resistance ("λ-infl."), the other to the surface heat resistance, including package ("α-infl."). (b) Freezing time in minutes for a 32 mm thick 450 g package of fish fillets as a function of the surface heat transfer coefficient. The total time is divided according to the influence of conduction resistance ("λ-infl.") and surface resistance, including package ("α-infl."). The normal range of blast freezers and plate freezers is indicated. The influence of some types of packages in plate freezing is also shown.

materially affect the quality of most foods. This should not be interpreted to mean that the rate of freezing has no effect on the quality of frozen foods: most foods suffer from being frozen very slowly; a few foods demand ultra-rapid freezing. Fish and poultry seem to be more vulnerable to very slow freezing than most other foods, and meat (beef, pork, lamb) rather less. Strawberries and beans have a better texture and water holding ability if frozen ultra-rapidly while fruits and vegetables with a higher starch content such as peas are not as sensitive to freezing speed.

In commercial practice mean freezing rates vary between 0.2 and 100cm/h; 0.2cm/h (slow freezing) for bulk freezing in blast rooms, 0.5 to 3 cm/h (quick freezing) for retail packages in air blast or plate freezers, 5 to 10 cm/h (rapid freezing) for individual quick freezing of small-sized products, e.g., in a fluidized bed and 10 to 100 cm/h (ultra rapid freezing) by spraying with or immersion in liquid gases. For freezing of retail packages freezing rates faster than 0.5 cm/h and for I.Q.F. products rates faster than 5 cm/h are considered satisfactory in most cases. Only very susceptible foods (such as tomatoes)

may be improved by increasing the freezing to above 10 cm/h. At these rates care should be taken to avoid cracking. When freezing larger units, such as beef quarters, with a mean freezing rate of 0.1 cm/h a freezing time of 3 to 5 days is unavoidable and times up to 5 days are quite common.

The rate at which freezing takes place can be considered both at micro and macro levels. At the micro level, freezing rate is described in terms of the speed with which the freezing front moves through the freezing object. At the macro level, the rate at which any given part of the object is cooled determines the temperature profile for that part, and thus has an important bearing on the biochemistry and microbiology of that part.

The undesirable changes in meat during freezing are associated with formation of large ice crystals in extracellular locations, mechanical damage by the ice crystals to cellular structures through distortion and volume changes, and chemical damage arising from changes in concentrations of solutes. The fastest freezing rates are associated with the least damage (121). Differences in freezing rate modify meat properties. Ice crystallization and its growth in meat tissues are discussed by Calvell (122).

Freezing commences when the surface temperature of the meat reaches its freezing temperature. A continuous freezing front forms and proceeds from the exterior to the interior. Extracellular water freezes more readily than intracellular water because of its lower ionic and solute concentration. Slower freezing favors the formation of pure ice crystals and increases the concentration of solutes in unfrozen solutions. Intracellular solutions are often deficient in the nucleation sites necessary to form small ice crystals. Such conditions favor the gradual movement of water out of the muscle cells, resulting in a collection of large extracellular ice crystals and a concentration of intracellular solutes. Freezing damage arises from massive distortion and damage to cell membranes. Such effects have implications during thawing as the large extracellular ice crystals produce drip during thawing. The structural changes that occur also obliterate the recognizable muscle structure.

Fast freezing results in small ice crystal formation in both intracellular and extracellular compartments of the muscle and very little translocation of water. Drip loss during thawing is thus considerably reduced, and the surface reflects more light than that of slowly frozen meat. Consequently, the cut surface appearance is more acceptable.

D. Freezing Methods and Equipment

Freezing equipment may be divided into the following main groups with regard to the medium of heat transfer: the metal group includes plate freezers and air (gaseous medium) blast freezers the liquid group includes immersion freezers and the evaporating liquid group includes liquid nitrogen and liquid fluorocarbon equipment.

While blast freezers are used for all kinds of products, packed or unpacked, blocks or I.Q.F. products, the Plate freezer and Immersion freezer accept only packaged product, and evaporating liquid freezers are used only for I.Q.F. products.

1. Plate Freezers

In a plate freezer the product is pressed by a hydraulic ram between metal plates which have channels for the refrigerant. This arrangement gives very good heat transfer of metal contact. This high thermal efficiency is reflected in short freezing times, provided the product itself is a good heat conductor, as is the case with fish fillets or chopped spinach. It is important that the packets are well filled and the metal trays that are used to carry the packets are not distorted.

The advantage of good heat transfer at the surface is gradually reduced with increasing thickness of the product. For this reason the thickness is often limited to a maximum of 50 mm.

The pressure from the plates maintained throughout the freezing process practically eliminates the "bulging" that may occur in air blast tunnels; the frozen packets will maintain their rectangular shape within close tolerances.

There are two main types of plate freezer: horizontal plate freezers and vertical plate freezers.

a. Horizontal plate freezer

Usually this type has 15–20 plates (Figure 39.2). The product is placed on metal trays, which are pushed in between the plates manually. This calls for a high labor content in the loading and unloading operation.

In order to obtain automatic operation of a horizontal plate freezer, the whole battery of plates is movable up and down in an elevator system. At the level of a loading conveyor the plates are separated. Packages which have been accumulated on the conveyor are pushed in between these plates, simultaneously discharging a row of frozen packages at the opposite end of the plates. This cycle is repeated until all frozen packages have been replaced. Then the space between the plates is closed and all plates are indexed up.

b. Vertical plate freezer

The vertical plate freezer was developed mainly for freezing fish at sea. It consists of a number of vertical freezing plates forming partitions in a container with an open top. The product is simply fed from the top. The frozen block is discharged either to the side, upwards, or down through the bottom. Usually this operation is mechanized; the discharge of product often being assisted by a short hot gas defrost period at the end of the freezing cycle and the use of compressed air to force the product out.

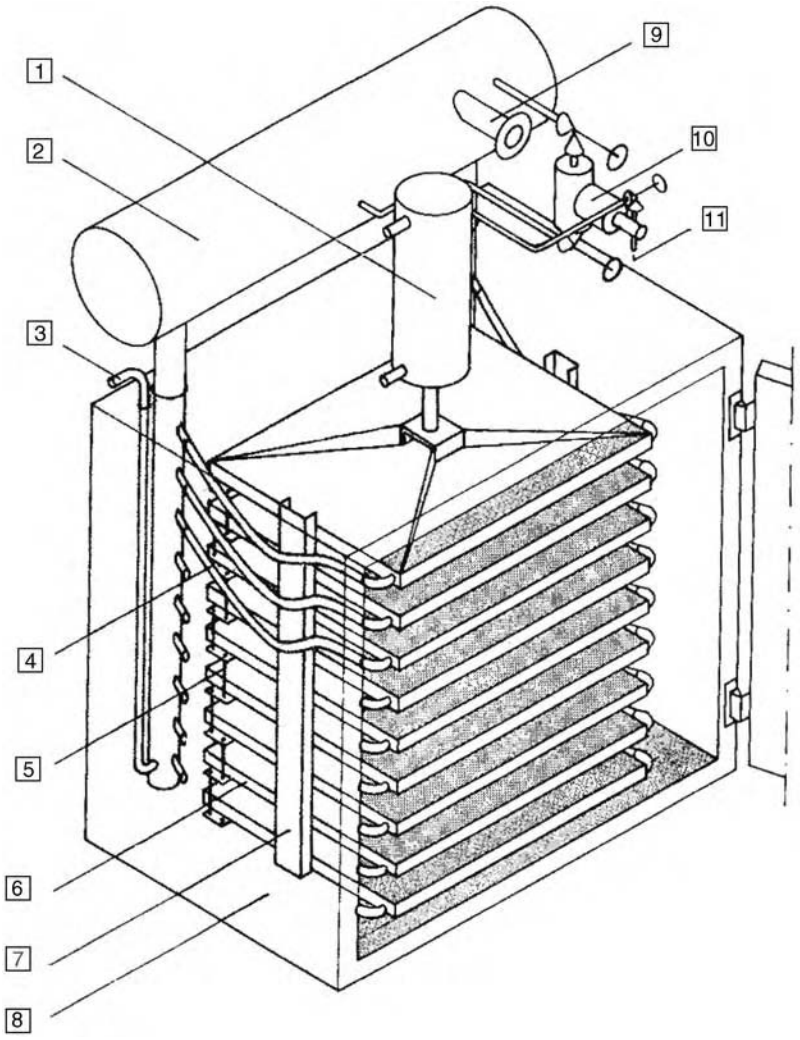

FIGURE 39.2 Horizontal plate freezer. (1. Hydraulic cylinder, 2. Liquid separator, 3. Hot gas defrost, 4. Flexible hoses, 5. Link bolts, 6. Freezing plate, 7. Guide, 8. Insulated cabinet, 9. Suction outlet, 10. Float valve, 11. Liquid inlet.)

2. Air Blast Freezers

Some foods, mainly bulk products such as beef quarters and fruits, for further processing are frozen in rooms with or without forced air circulation. Unless the room has been designed for freezing and equipped with suitable coolers and fans the freezing rate is very slow, resulting in an inferior quality for practically all products. If the room is also used for storage of frozen products the temperature of these products may rise considerably and the evaporators may frost up so quickly that the total refrigeration capacity is reduced below what is required to maintain the temperature of the store.

Good commercial practice for freezing in air blast uses include tunnel freezers, belt freezers, and fluidized bed freezers.

a. Tunnel freezers

In tunnel freezers the product is placed on trays, which stand in or pass through the tunnel in racks or trolleys one behind the other or singly. An air space is left between the trays.

The racks or trolleys are moved in and out of the freezer by manual power or by a forklift truck (stationary tunnels), pushed through the tunnel with a pushing mechanism (push-through tunnel) or are carried through by driving equipment, chain drive, etc. (carrier freezer) or slid through (sliding tray freezer). Tunnels are also used for freezing hanging meat carcasses mostly carried on a suspension conveyor.

Tunnel freezers are equipped with refrigeration coils and fans which circulate the air over the product in a controlled way (see Figure 39.3). Guide devices, properly locating the trays of food, lead to uniform freezing.

Tunnel freezers are very flexible freezers. Products of every size and shape, packaged or unpacked, can be frozen in stationary and push-through tunnels. They are used primarily for freezing packaged products. Unpacked products tend to stick to the trays, which may cause

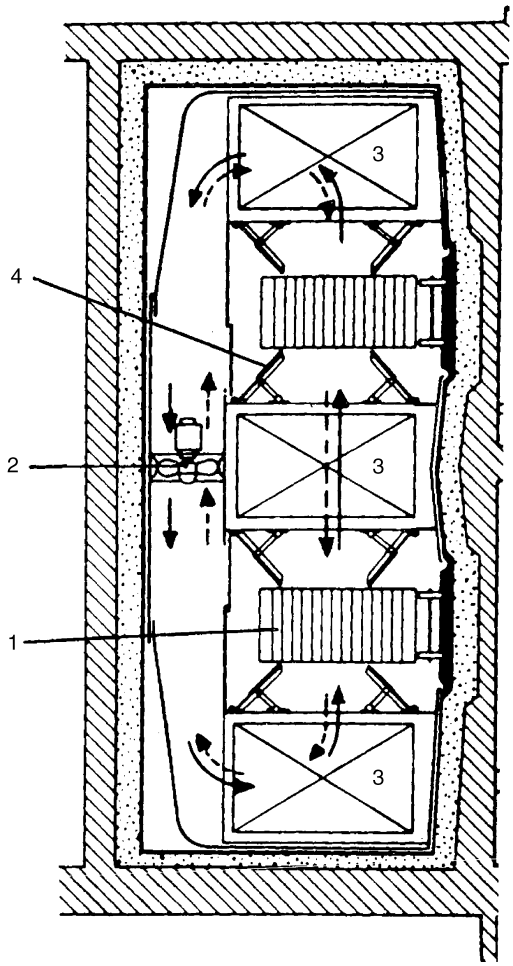

FIGURE 39.3 Sectional drawing of a push-through tunnel freezer. (1. Trolleys with trays, 2. Reversing fans, 3. Air coolers, 4. System of baffles which allows adjustment of the air flow.)

weight losses and time-consuming handling in releasing, cleaning, and transport of the trays. To obtain free flow products, improved handling, and an increase in the freezing rate, individual quick freezing (I.Q.F.) is preferred.

b. Belt freezers

Belt freezers are provided with a single belt (single-belt freezers, see Figure 39.4) or with belts positioned above each other which may run in the same or in opposite directions to increase throughputs and to reduce floor space (multi-belt-freezers) or as a spiral belt wound round a rotation drum stacking up to 30 tiers of the belt above each other (spiral-belt freezers). The belt, generally made of wire mesh, remains inside the freezer so that ancillary equipment for in and out feeding is necessary. Alternatively, the belt is carried to the outside as in some spiral-belt freezers. This arrangement has the advantage that the products can be placed on the belt in the processing room, where the operation can be supervised, before entering the freezer, and the product will remain undisturbed until removed at the outlet (Figure 39.4). The belt is supported by rails and driven by passing around the rotating drum.

Modern belt freezers have vertical air flow so that the air is forced through the product layer. In freezing small products such as beans or cherries good contact with all product particles is thus created. In single-belt freezers with high air velocities the products may agitate. In all belt freezers care should be taken to spread the product uniformly across the total belt width to avoid "channeling," where the air stream bypasses the product.

Belt freezers are used mainly for freezing unpackaged products, e.g., I.Q.F. products. They are especially suitable for foods that need careful handling.

c. Fluidized bed freezer

Fluidization occurs when particles of fairly uniform shape and size are subjected to an upward air stream. At an air velocity depending on the characteristics of the product, the particles will float in the air stream, each one separated from the other, but surrounded by air and free to move. In this state the mass of particles behaves like a fluid. If the product is contained in an inclined trough which is fed at the higher end the fluidized mass moves towards the lower end, as long as more product is added. The product is thus frozen and simultaneously conveyed by air without the aid of a mechanical conveyor (Figure 39.5).

The use of the fluidization principle has the following advantages when compared with a belt freezer:

1. The product is always truly individually frozen (I.Q.F.). This applies even to products with a tendency to stick together, e.g. French style (sliced) green beans, sliced carrots, and sliced cucumber.
2. Independence of fluctuations in load. If partly loaded the air distribution will be the same as for full load, i.e., no hazard of channeling. If over-loaded no product flows onto the floor.
3. Reliability is improved when freezing wet products because the deep fluidized bed can accept products with more surplus water.

An important factor in the overall operation economy of a blast freezer is the weight losses during freezing. Improperly designed equipment will have losses of 5% or more whilst a "well-designed" freezer normally operates with only 0.5 to 1.5% loss for unpackaged products. Part of the weight losses are dehydration losses, which require particular consideration. Weight loss is minimized by low air temperatures and good heat transfer, i.e., high air velocities.

A freezing tunnel that is intended for packaged products should not, without due consideration, be used for thin unpackaged products, e.g., fillets of fish. The result may be that the relation of coil surface to product surface is put out of balance so that air temperature in the tunnel rises with resulting high weight losses. The coil may not be able to accommodate sufficient quantities of frost

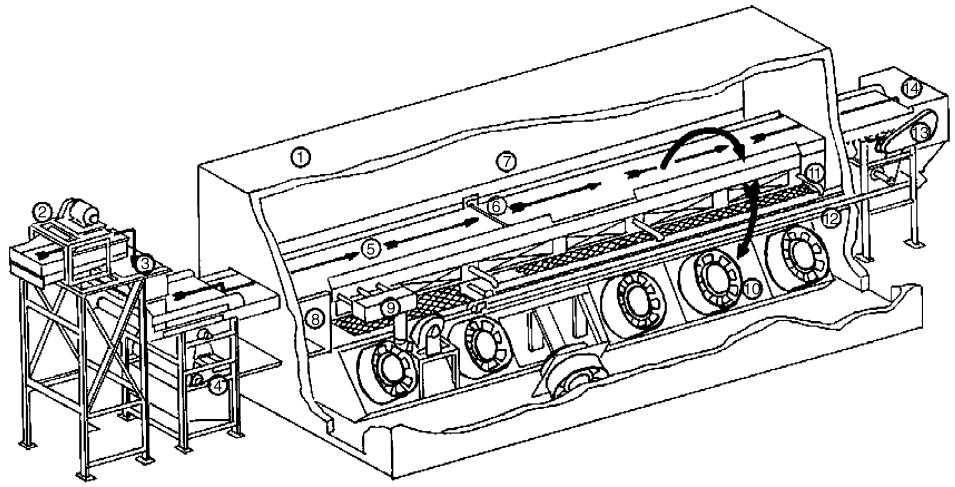

FIGURE 39.4 Single belt freezer. 1. Insulated wall of the tunnel, 2. De-watering vibrator, 3. Loading hopper, 4. Belt drying system, 5. Variable speed belt (open mesh belt), 6. Product spreader, 7. FIGURE 39.5 Fluidized bed freezer. (1. Unfrozen product conveyor, 2. Product trough, 3. Frozen product discharge, 4. Air coolers, 5. Fan.)

which results in reduced heat transfer or reduced air flow, both contributing to high weight losses.

It is important to note that in a vapor tight package containing a product that is not homogeneous, e.g., beans or broccoli, the heat transfer inside the package is carried out by air. The heat transfer is very poor, because there is no air circulation. The result is evaporation of moisture, which actually may be greater than it would have been without the package. This moisture remains as frost on the inside surfaces of the package, so that it is not usually recorded as a weight loss. The influence on product quality is, of course, the same whether the dehydration is recorded or not.

Higher velocities of air give better heat transfer. However, it is not sufficient just to increase the fan power. The most important factor is to direct the air circulation in such a way that every product particle is efficiently and equally exposed to the air current. It is also important to study the conditions of the individual particles because a close study may reveal surprisingly uneven air flows.

3. Immersion Freezer

For irregularly shaped products, e.g., chicken, the best heat transfer is achieved in an immersion freezer. This consists of a tank with a cooled freezing medium, e.g., a salt or propylene glycol solution. The product is immersed in this brine or sprayed while being conveyed through the tank.

Immersion freezers are most commonly used for surface freezing of poultry to obtain a good color. The final freezing is effected in a separate blast tunnel or cold store.

The latter alternative, however, involves quality hazards because of slow freezing of the core.

The product must be protected by an absolutely tight, high quality packaging material. The brine on the package is washed off with water at the exit of the freezer.

4. Evaporating Liquid Freezers

Mainly two liquids or freezants are used: liquid nitrogen (LN2) and liquid fluorocarbon freezant (LFF).

a. LN2 freezer

Liquid nitrogen at −196°C is sprayed onto a single belt freezer. The nitrogen evaporates and is allowed to escape to the atmosphere after the vapors have been used for precooling of the products (Figure 39.6).

The very high freezing rate results in improved textures, particularly in certain fruits and vegetables while with other products there seems to be little quality advantage compared with other freezing methods. LN2-freezing may result in cracking of the product surface if sufficient precautions are not taken.

Like immersion freezers LN2 freezers are often used only for surface freezing. If final freezing is to be carried out the LN2 consumption is of the order of 1.0–1.5 kg per kg of product which makes the operation rather expensive. In spite of this, the low investment and simple operation make this method economical for certain productions, especially in-line processes.

b. LFF system

The freezant is a specially purified dichlorodifluoromethane (fluorocarbon) which has a boiling point of −30°C at atmospheric pressure. The equipment consists of a container with openings at the top. The product is introduced into the container and dropped into a flowing stream of freezant (Figure 39.7). Owing to the extremely good heat transfer the surface is frozen instantaneously so the product may be stacked on the horizontal freezing belt, where it is sprayed with freezant until finally frozen. A discharge conveyor brings the product up and out of the freezer. It is claimed that fluorocarbon leaves only small residues in most products. Experiments in this area are continuing.

On contact with product the freezant evaporates. The vapors are recovered (with only a slight loss) by condensation on the surfaces of the refrigerator, the latter remaining in the container with only small losses to the atmosphere. There is no measurable product weight loss due to dehydration using this method.

V. STORAGE

If the quality of frozen food is to be maintained during its storage life, the correct temperature must be selected for the expected period of storage. During the storage period, the following hazards to quality must be avoided:

1. A low relative humidity in the cold store.
2. Retention beyond the expected storage life.
3. Fluctuations in temperature (both during storage and in the process of loading, unloading, and dispatching vehicles).
4. Physical damage to the product or packaging during the course of storage or handling.
5. Contamination of the product by foreign bodies or vermin.

These hazards can be avoided by ensuring:

a. That the design of the cold store is appropriate to the duty it will be required to perform, and is such that these hazards are, to the greatest extent possible, eliminated at the design stage.

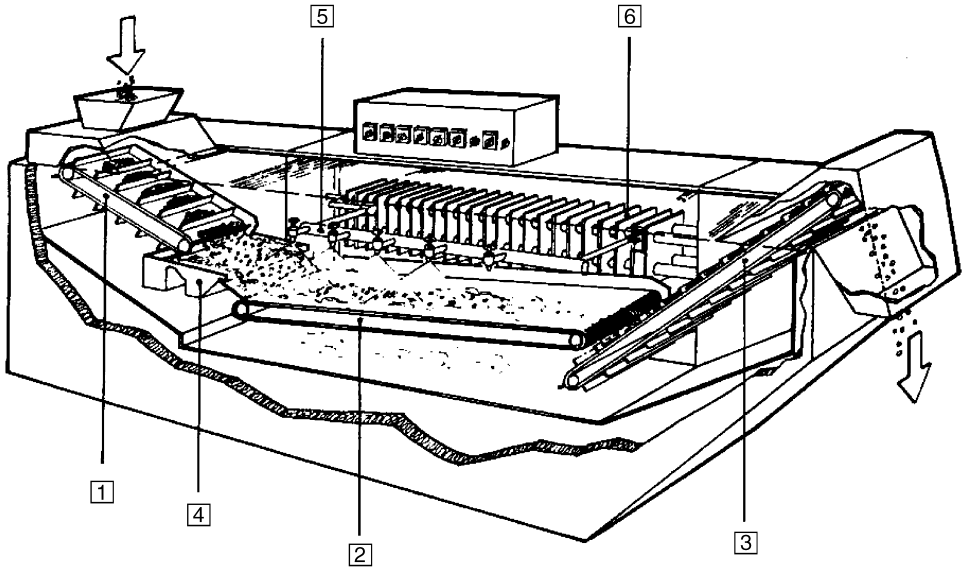

FIGURE 39.7 Liquid fluorocarbon freezer. (1. Product input conveyor, 2. Freezing conveyor, 3. Frozen product exit conveyor, 4. I.Q.F. bath, 5. Spray nozzles, 6. Condenser.)

b. That operation methods, designed to avoid such dangers, are laid down and strictly adhered to.

Small fluctuations in temperature are normal and unavoidable. They should, however, be kept at a minimum both in amplitude and duration in order to minimize the amount of weight loss by drying and in-package desiccation.

A. Cold Store Design

The general design of a cold store is determined by the requirements for effective and safe handling of the merchandise, and a suitable storage climate for the products. The normal arrangement is that rooms are built side by side between road and railway loading banks; thus, all rooms can communicate directly with the loading banks and traffic yards. Today cold stores are frequently built with prefabricated concrete or steel structures. The insulation can be placed on the outside or the inside of the structure. Internal structure means that the insulation will form an unbroken envelope around the building. The insulation is well protected by the structure, internal installations are easy to fix, there is no hung insulated ceiling which can cause problems, and extensions are very simple to carry out.

It is essential that considerable thought should go into the definition of the duties the cold store has to perform. A clear statement has to be prepared of the maximum and average daily activity expected to take place in the cold store:

1. Quantity of each product to be received.
2. Temperature at which each product will be received.
3. Maximum number of operatives and trucks working in the cold store at any one time.
4. Number of anticipated door openings.
5. Maximum quantity to be out-loaded at any one time.

These considerations must be taken into account when calculating the maximum expected heat load. The temperature difference between the surface area of the cooling coils and the required room temperature should be as small as possible and not more than about 6°C.

1. Frost Heave

Frost heave under cold stores is prevented by a special under-floor heating system or a ventilated space under the floor. The heating system may consist of an electrical mat or a pipe grid cast into the sub-floor; glycol or oil is circulated in the pipes. The liquid is often heated by surplus heat from the refrigeration plant.

2. Insulation

The insulation represents a large percentage of the total cost for a normal cold store. It is, therefore, very important that it is designed from an economical point of view. However, one must also consider that the insulation value has an influence on the storage climate in that the transmission losses mean dry heat is entering the cold room. The choice of insulation system must be carried out carefully. The vapor barrier on the warm side must be completely water vapor tight, the insulation should contain no heat bridges, and the internal cladding must be hard, hygienic, and give

a pleasant appearance. Today most cold store insulations are carried out with prefabricated panels, slabs of polyurethane foam, expanded polystyrene, mineral fiber, or cork. Where special attention must be given to the risk of fire, the insulation is combined with a special fire wall or the insulation is carried out with fiber glass between special insulation studs. The vapor barriers may consist of thin gauge aluminum, galvanized steel sheets, or heavy gauge polyethylene sheets. The joints are sealed with special sealing compounds. The internal cladding may be either profiled plastic, laminated galvanized steel sheet, or aluminum sheet. Good concrete kerbing and, in some cases, dunnage battens protect the internal finish and ensure that the merchandise is not stacked directly against the wall.

3. Refrigeration System

The refrigeration system must be designed with regard to the requirements of the climatic conditions for the stored merchandise. It must be adequate to allow for sufficient safety on peak days and summer conditions. The air coolers must be designed and located so that an even temperature can be maintained throughout the cold store even under severe conditions and without generating high air velocities in the cold store. Large evaporator surfaces and air distribution through air ducts or false ceilings will normally ensure this. Air ducts may be omitted if the cooling surface is divided on several cooler units distributed in the room so that the air velocity from the cooler fans is kept at a moderate level.

The most common refrigeration system for large cold stores is a two-stage compressor system with pump circulation of the cold refrigerant to the air coolers. The most common refrigerant is ammonia but halogenated hydrocarbons have also been used in some cases. For small cold stores a direct expansion, one-stage compressor system using halogenated hydrocarbons is widely used. In order to improve safety and make control easier and cheaper most modern refrigeration plants are automated. The degree of automation may vary but normally the room temperature, compressor capacity, lubrication, cooling water, defrosting, pumps, fans, current and voltage of the main supplies, etc. are controlled and supervised by a central control panel in the engine room.

4. Lighting

A cold store is a working place for fork lift drivers and others concerned with the handling of the products. Thus the lighting in the cold store must be good but at the same time it must be remembered that the lighting is adding to the heat load in a cold store. Lamps with a very high power/lighting ratio should be used. Mercury lamps are superior from this point of view and they are often used even if they can cause a slight discoloring of meat products during long storage. A normal cold store should have an average lighting of 100 lux at floor level and of 200 lux in break-up areas.

5. Layout

The layout of the storage space should be such as to reduce to the maximum extent possible the ingress of warm air and the exposure of product to atmospheric temperatures. Where possible, product should be conveyed from factory areas into cold store by means of conveyors in insulated tunnels. There should be no facility for any accumulation of product in ambient temperature. If the operation is a palletized one, then palletization of the product should take place in the cold store in an area set aside for this purpose. Port doors should be provided so that the maximum amount of traffic in and out is handled in this fashion and the product is completely protected from temperature changes during loading/unloading operations.

For safety reason, no glass should be allowed inside the cold store in any unprotected position. Translucent plastic visors should be placed around lamps or any other essential glass.

6. Jacketed Stores

Jacketed stores allow storage at near 100% relative humidity and at uniform and constant temperatures. These conditions, which greatly reduce weight losses of unpackaged foods and frost formation inside packaged frozen foods, are obtained by circulating the refrigerated air in a jacket around the load space to absorb the heat conducted through the insulation before it can enter the load space (Figure 39.8). This technique also increases the life and reduces the maintenance of the structure by preventing condensation and frost formation in the insulation.

7. Equipment

In equipping the store care should be taken to choose equipment which is suitable to the product being handled and which minimizes the possibility of damage or contamination; thus, timber pallets are suitable for properly packed products but lightly packed semi-processed stock may need a pallet constructed in metal or some similar washable and less easily damaged material.

It is likely, for economy reasons, that the store will be designed to maximize the use of height, and to this end some means of support for the product must be provided, e.g., racks, pallet posts, or pallet cages. The layout of pallets in the cold store should be such that damage to the products is minimized. Whilst accepting the need for maximum utilization of space, gangways and turnings should be wide enough for product to be moved without damage, while space should be allowed between lanes of pallets to permit the withdrawal or placing of a pallet when the adjacent lanes are full.

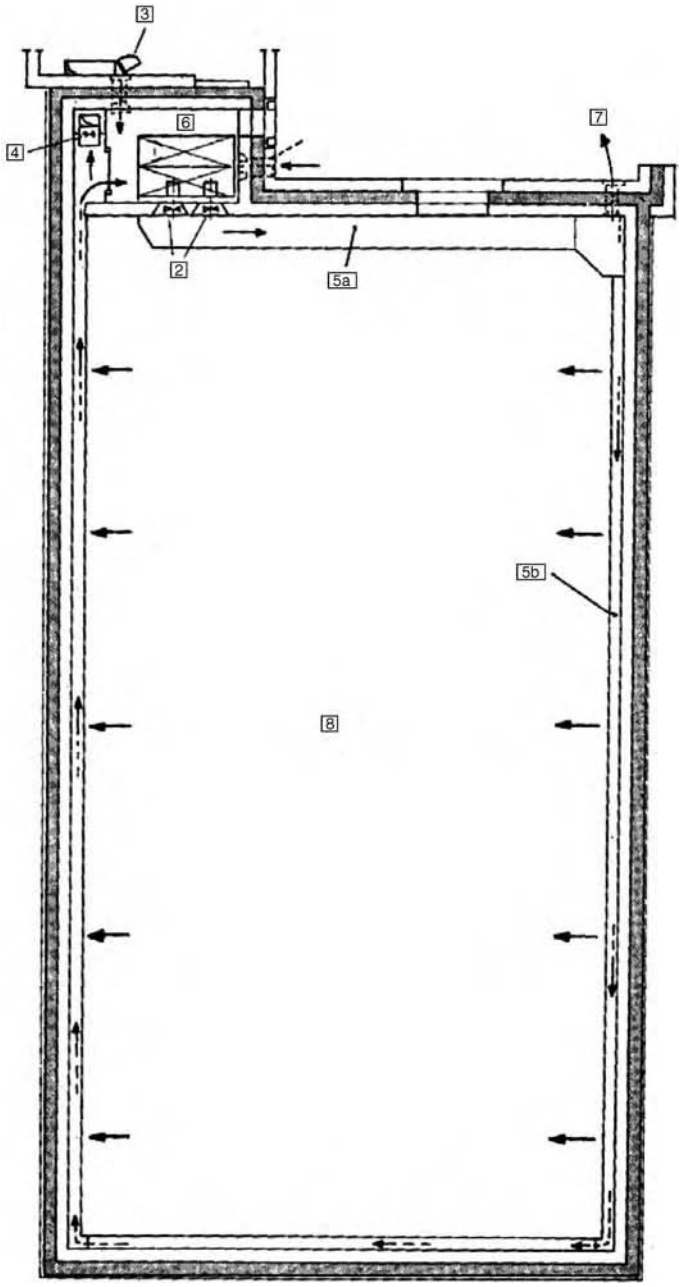

FIGURE 39.8 Jacketed store. [1. Air coolers, 2. Fans, 3. Fresh air duct, 4. Air vent, 5a. Air ducts, 5b. Jacket, 6. Air cooler enclosure, 7. Cooling orifice to antechamber, 8. Cold room. This type of jacketed store serves two purposes thanks to the two-speed fans: (a). At the lower speed, the air only circulates in the jacket. This is the classic operation of jacketed stores (arrows marked thus). (b). At the higher speed, the air enters the store through a system of movable vents which open via the effect of the increased air pressure. Through this means, one can complete the cooling of foodstuffs which may have been subjected to warming up prior to being introduced into the cold store (arrows marked thus).]

8. Operating Methods

It is important that everyone working in a cold store always bear in mind the prime objective of minimizing the exposure of products to ambient temperatures. Methods of handling and routes should be laid down which do not permit the product being placed in ambient temperature. If it is not possible to load a vehicle by means of a port door or some similar method which gives complete protection and the only alternative is to traverse a loading bank, then the complete vehicle load should be assembled inside the cold store and conveyed direct to the vehicle without being placed on the loading bank. A similar procedure should apply in reverse for unloading. Doors

should never be left open other than when personnel or goods are passing through them, and duration should be as short as practicable.

VI. THAWING

Most frozen food processors find it necessary to thaw stock of frozen material in some of their operations, and if thawing is not carried out carefully, quality and yield can suffer. This section sets out the broad principles involved in the thawing techniques available, and indicates some of the problem areas. Irrespective of the procedure involved, heat energy must be supplied, most of it being required to melt the ice in the food. About 300 kJ are required to thaw 1 kg of white fish from a starting temperature of −30°C. The figure for fatty herrings is smaller, about 250 kJ, because of the lower water content of herrings. Thawed materials spoil in the same way as their unfrozen equivalents and must be kept chilled until required; this can often be achieved conveniently by removing the product from the defroster just before thawing is complete so that the product has its own small reserve of "cold."

There are two principal groups of thawing methods: those in which heat is conducted into the product from the surface and those in which heat is generated within the product. In the first group, heat is applied to the surface of the product by exposing it to sources such as hot radiating surfaces, warm air, warm water, heated metal plates, or steam under vacuum. In the second group, heat is generated within the product by such means as electrical resistance, dielectric, or microwave heating. Surface heating methods are much more commonly used than are internal heating methods.

A. Surface Heating Methods

When using surface heating methods, thawing time for a product decreases with:

a. Decrease in physical size of the product;
b. Increase in thermal conductivity (or, more precisely thermal diffusivity) of the thawed product;
c. Increase in temperature difference between the surface of the product and its surroundings;
d. Increase in the movement of the surrounding medium relative to the product surface; and
e. Increase in humidity of the surroundings.

Since the thermal diffusivity of thawed product is less than that of frozen, surface thawing methods suffer from the inherent disadvantage that resistance to heat transfer increases progressively once thawing has started.

All surface heating methods can take advantage of a programmed temperature difference between the surface and the surroundings; the temperature of the surroundings is arranged to start high, and to decrease as the surface warms up to a predetermined level, usually below the temperature where bacterial activity or surface damage could be a hazard to the quality of the food. Thawing times are greatly increased if the product is encased in packaging material. Thus packaging material should be removed where possible.

B. Still Air Thawing

If thawing is conducted in still air, the air temperatures should not exceed 20°C and facilities for supplying heat to the room in which the product is laid out to thaw may be required. Air temperatures greatly in excess of the above should be avoided since the outer layer will warm up and spoil before the center is completely thawed. A typical block of sea frozen whole cod 9 cm thick will take up to 20 h to thaw under these conditions. This time can be reduced by separating the fish as soon as they can be separated without damage. Single fish, 10 cm thick, will take about 8 to 10 h to thaw.

1. Air Blast Thawing

A relative humidity of greater than 90% is advantageous both in reducing weight loss or shrinkage and also in obtaining a high level of heat transfer. Air velocities of 12-18 m/min at a temperature of 6–8°C for 3–5 days or 100 m/min for 2–2.5 days are needed for packages of boneless meat, whereas pork sides are normally thawed at 4–5°C for 2–4 days. Air speeds of the order of about 300 meters per minute at temperatures not exceeding 20°C with the air fully saturated with moisture will thaw sea frozen fish blocks 10 cm thick in 4 h. Higher air velocities at cool temperatures lead to surface desiccation while any higher temperature will lead to microbial growth on the heated surface.

C. Water Thawing

This method is not normally applicable to meat and with fish there is a risk that fillets or cut surfaces will become waterlogged and lose flavor but water thawing can be used satisfactorily for frozen whole fish, even though there may be a slight loss of pigments. Usually there is a slight gain in weight, which is lost again when the fish is filleted.

The temperature of the water being circulated around the frozen fish or sprayed onto the fish should be no warmer than 20°C and the water itself should flow at not less than 30 cm per minute so as to obtain rapid thawing. The thawing time for a block of whole cod 10 cm thick in water at 20°C moving at about 120 cm per minute is similar to that in an air blast defroster using humid air at the same temperature, i.e., about 4 h.

When frozen fish blocks are thawed in still water, water temperatures may, in the initial stages, marginally exceed 20°C, but the thawing should be arranged so that the fish surface temperature does not exceed 20°C.

D. Vacuum Thawing

In this method the product lies on racks inside a container from which the air has been evacuated. Water, usually at about 18°C, is allowed to evaporate freely from heated vessels inside the container. In the absence of air, transfer of water vapor from a heated vessel to the product occurs readily, the water vapor giving up its latent heat on condensation. The advocates of this method claim faster thawing than other surface heating methods for products less than about 10 cm thick.

E. Double Contact Thawing

Plate frozen raw material lends itself particularly to plate thawing in an arrangement similar to that of a multi-plate freezer, with a liquid circulating through the plates (at a temperature not exceeding 20°C providing the necessary heat. A 10 cm block of whole cod when thawed between plates at 20°C for 5 h is ready for filleting 3.5 h later, making a total of 8.5 h for complete thawing. Care must be taken not to allow distortion of the blocks to occur during cold storage since this will lead to poor contact with the plates during thawing. Thawing fluid or semi-fluid food in a vertical plate apparatus may be carried out using temperatures as high as 40–50°C as long as the melted material is allowed to run away from the plates continuously.

F. Internal Heating Methods

Internal heating methods rely on the use of applied electric fields which cause movement of the electric charges inherent in all products. The molecules of the product take up this energy of movement and the food warms up. The amount of heat generated in this way is strongly dependent on the electrical characteristics of the product. Since food is not usually homogeneous, there can be marked variations in the rate of heating of different parts of the food. Furthermore, for any particular component in the food, the rate of heating usually increases as the product thaws, making runaway heating a hazard. If these factors can be accommodated, the great advantage to be gained is extremely rapid, uniform thawing.

G. Electrical Resistance Thawing

In this method, the product is sandwiched between electrodes and an electric current is passed through the product. Some preliminary warming is usually necessary to achieve good electrical contact and a satisfactorily high starting current. In practice this method has so far been used for thawing blocks of fish fillets up to 5 cm thick and weighing about 3 kg but it has not been found suitable for thicker blocks of fillets, blocks of whole fish (except herring), or single whole fish.

H. High Frequency Thawing

In the dielectric method, a high frequency electric field is applied to electrodes astraddle the product, but not physically in contact with it. The commonly used frequencies are either in the range 27 to 100 MHz (dielectric or high frequency heating) or 915 to 2450 MHz (microwave heating, where the energy is directed at the product enclosed in a chamber). The product must be reasonably homogeneous and regular in shape to achieve uniform heating. If the block is not homogeneous, or is irregular in shape, some parts may become overheated before the remainder is thawed. It has been found that if irregular blocks of fish are first immersed in water, thawing becomes uniform. The time taken for a 10 cm block of whole cod is typically just less than 1 h. Partial thawing by microwave is also used, thereby increasing the capacity of the thawing equipment. By going to the higher frequencies, the field strength can be substantially increased and thawing time reduced to a matter of minutes. Penetration into the food mass decreases so that the thickest block of meat which can be completely thawed at 2450 MHz is 3 to 4 cm.

In summary, freezing, frozen storage, and thawing affect the quality and shelf stability of fish and seafood. If kept under appropriate conditions, fish and seafood can be stored in the frozen state for several months without appreciable changes in quality. During frozen storage, microbiological changes in fish and seafood are very minimal. On the other hand, a series of changes such as protein denaturation, lipid oxidation, texture deterioration, loss of fresh odor and flavor, various enzymatically induced reactions, loss of volatile constituents, nutritional losses, and changes in moisture take place in fish and seafood when subjected to excessively prolonged frozen storage. Likewise, such changes may also occur in freeze-thawed fish and seafood. Quantitative evaluation of the influence of freezing, frozen storage, and thawing on fish and seafood is rather complex. The different variables that influence quality are related to one another. Therefore, it becomes almost impossible to describe some quality changes without actually discussing the other related changes that occur in fish tissues.

ACKNOWLEDGMENT

The information in this chapter is based on "Freezing seafood and seafood products: Principles and applications," by S. T. Jiang and T. C. Lee, in *Handbook of Frozen Foods*, edited by Y. H. Hui et al., Marcel Dekker, New York, 2004.

40 The Application of Gene Technology in the Wine Industry

Miguel A. de Barros Lopes, Eveline J. Bartowsky, and Isak S. Pretorius
The Australian Wine Research Institute

CONTENTS

I. INTRODUCTION

Wine plays a major role in the economies of many nations. The world's annual wine production from about 8 million hectares of vineyards totals around 27 billion litres (1). Shifting consumer preferences, globalisation and other economic factors have forced an evolution of the international wine industry from a "cottage industry" of independent producers to global networks of consumer-conscious enterprises (2,3).

An increasing gap between wine production and wine consumption has given rise to an annual oversupply of 15–20% in the global market. There is a growing demand for cost-effective production of wine with minimised

resource inputs, improved product quality, increased health benefits and low environmental impact. It is widely expected that advances in molecular biology and bioinformatics will help equip the wine industry with the tools to tailor grapevines and microbial starter strains, enhancing wine quality, purity, uniqueness and diversity (1,2,4).

Grape and wine research, fueled by greater understanding of basic cellular and molecular biology governing targeted traits and by considerations of future use, promises to be a powerful dynamo of technological progress in this increasingly market-oriented industry (2). It is therefore crucial that basic and applied research not be treated as separate ventures. Rather, grape and wine research, both in problem selection and experimental design, should be aimed at increasing fundamental understanding in a context responsive to the applied needs of producers and consumers.

This review passes familiar light through new prisms to demonstrate that ignoring gene technology imperils the international wine industry, despite the current vocal opposition to genetically modified organisms (GMOs) and products (1–5). This perspective is supported by examples of genetically improved grapevine prototypes showing increased productivity, efficiency, sustainability and environmental friendliness, particularly with regard to improved pest and disease control, water use efficiency and grape quality. Examples of genetically tailored microbial starter strains include those that could play a role in improving the fermentation, processing and preservation of wines, as well as those with the capacity to enhance the wholesomeness and sensory quality of wine.

II. THE GENETIC IMPROVEMENT OF GRAPEVINES FOR WINE PRODUCTION

A. Grapevine Species and Cultivars

Grapevine belongs to the genus *Vitis*, consisting of two sub-genera, *Euvitis* and *Muscadinia*. The preferred wine grape species, *Vitis vinifera*, originated in Europe and consists of about 5000 cultivars (6). However, only a few select and ancient cultivars are relied on for commercial wine production. As a result of the wine industry's reliance on established varietal names and predictable wine styles to sell its products, there has not been a great incentive to breed new *V. vinifera* cultivars. Nevertheless, breeding programmes significantly impacted on the development of rootstock varieties resistant to soil-borne pests and pathogens, as well as to negative abiotic conditions (7). Improvements to rootstock and scion cultivars initially relied largely on arbitrary selections of natural mutations that enhanced cultivation or some aspect of fruit and/or wine quality and were later followed by the more directed, clonal selection schemes (5,8).

B. Genetic Features and Techniques for the Analysis and Development of Grapevines

A dramatic new day in plant improvement is dawning, warmed by molecular biology, genetic transformation and functional genomics. Several plant genomes have now been fully sequenced, and though the accessibility of the grapevine genome is restricted by size and complexity, there are now intense multinational studies underway of the *Vitis* genome.

A growing number of plant species are becoming viable candidates for genetic transformation through *Agrobacterium*-mediated and biolistic bombardment technologies. The grapevine, however, has been resistant to genetic transformation: difficulties include finding tissue culture systems that can withstand the new techniques and subsequent selection regimes (5,8,9). Nevertheless, there are today a few grapevine scion and rootstock cultivars of commercial importance that can be genetically transformed with relatively little difficulty. The emphasis is gradually shifting from developing the technology to implementing it to generate useful plant lines.

C. Targets for the Genetic Improvement of Grapevine Varieties

The genetic improvement of grapevine cannot occur in the absence of knowledge of the fundamental processes supporting the physiological responses to be altered. In the early days of limited genetic resources, genes with known functions were introduced into plant species in the hope of developing improved phenotypes. This approach, although problematic, demonstrated the value of adding application to theory. It is an exciting time, as the plant sciences enter a new era and the list of gene sequences, including those of grapevine, grows and becomes available. Potential areas for the genetic improvement of grapevine are discussed below and summarised in Figure 40.1.

1. Improving Disease and Pest Resistance

As genetic engineering of crop plants evolves, its primary focus remains upon enhanced disease tolerance. Single genes can confer disease resistance in plants, making individual gene transfers into plant genomes perhaps the best approach to control fungal, viral, bacterial and insect pathogens. Almost all of the approaches to enhanced disease tolerance in plants take advantage of the natural interactions between host and pathogen (10). In the battle for survival, host and pathogen evolve simultaneously, making those interactions fluid and complex.

There are currently two major approaches to manipulating disease tolerance in plants. The first is introducing a gene product with known anti-pathogen activity at high

Disease and pest resistance

Fungal tolerance
- Chitinases and glucanases
- Thaumatin-like proteins - *Vvtl1*
- Stillbene phytoalexins - *stsy, vst1* and *vst2*
- Copper/zinc superoxide - *Cu/Zn SOD*
- Ribosome inactivating proteins (RIPs)
- Detoxifying enzymes (NADPH-dependent aldehyde reductase, Vigna radiata-Eutypine reducing enzyme)
- Polygalacturonase-inhibiting protein (PGIP)
- Antifungal peptides (plant and insect)

Bacterial tolerance
- Antimicrobial peptides - lytic peptides, Shiva-1, defensins
- Disfunctional import and integration protein encoding gene - virE2delB from *Agrobacterium*

Viral tolerance
- Virus coat proteins
- Virus movement proteins
- Replicases
- Proteinases
- 2,5 Oligoadenylate synthase

Grapevine cultivation

Resistance to water stress
- Aquaporins - TIPs (tonoplast integral proteins); PIPs (plasma membrane integral proteins)

Oxidative damage
- Carotenoid biosynthesis genes
- Adh (alcohol dehydrogenase) genes
- SOD (cystosolic CuZnSOD, chloroplast-residing CuZnSOD, mitochondrial residir MnSOD)

Osmotic stress
- Proline accumulation - Vvp5cs (1-pyrroline-5-carboxylate)
- Polyamines -Vvoat (γ-ornithine aminotransferase)

Cold tolerance
- Antifreeze from fish

Vitis vinifera

Grapevine quality

Sugar accumulation and transport
- Phloem loading and unloading - plant and yeast invertases
- Sugar transport - *Vvsuc11, Vvsuc12, Vvsuc27, Vvht1* and *Vvht2*

Colour development
- Ripening related processes - Myb, auxin and ABA
- Anthocyanins - Ufgt (UDP-glucose:flavanoid 3-*O*-glucosyltransferase)

Reduced browning
- Silencing of polyphenol oxidase

Seedlessness
- Baransae gene

FIGURE 40.1 Methods for the improvement of *Vitis vinifera*.

copies or in an inducible manner into the host to optimise the plant's innate defence responses. The other approach relies upon pathogen-derived resistance (PDR): a pathogen-derived gene is expressed inappropriately in time, form or amount during the infection cycle, preventing the pathogen from maintaining infection. PDR is at the root of most antiviral strategies and much of the activity in the genetic transformation of grapevine varieties.

Transgenic grapevines have been generated for providing viral resistance (10); in most of these cases expressing the virus coat protein achieved PDR. More recently, resistance to virus infection has also been achieved by expressing anti-sense to virus movement proteins (11) and replicase proteins.

Various studies have examined the expression of grapevine chitinases, β-1,3-glucanases, thaumatin-like proteins and stillbene synthetic enzymes with regard to fungal infection and grape ripening (12–14). Several of these enzymes have been shown to possess antifungal activity (15–18) and it has been demonstrated that in some cases, transgenic expression of genes encoding the proteins leads to increased resistance (18,19). Research has also shown that transgenic expression of a detoxifying enzyme enhances resistance to *Eutypa lata* (20). In addition, a gene from the American wild grape species *Muscadinia rotundifolia* has been introgressed into a succession of pseudo back crosses of *V. vinifera*. Using this strategy, resistance to *Oidium tuckerii* (powdery mildew) has continued to segregate as a single gene, thereby making the gene an important candidate for the development of a transgenic method to confer powdery mildew resistance in *V. vinifera*.

Obtaining transgenic plants resistant to pathogenic bacteria has been less successful; the expression of the lytic peptide Shiva-1 has been reported (21), and induced expression of several defence genes have been detected in response to bacterial pathogens (13,22).

We are witnessing the onset of a new era in plant cultivation, as old problems are being addressed in new ways. Transgenic grapevines expressing heterologous antiviral and antifungal genes are currently undergoing field testing, the first 'prototypes' of manipulated disease tolerance in grapevine. The technology will undoubtedly become more sophisticated, raising the possibilities of multiple gene transfers and long-term and stable expression of transgenes along with the use of highly specific inducible regulatory sequences.

The process of generating and analysing transgenic plants has yielded considerable knowledge about the nature of plant-pathogen interactions and the disease resistance pathways that operate in plants. Model plants transformed with the various targeted genes become important resources when the nature of the manipulations and their effect *in planta* are further analysed with state-of-the-art technologies, such as transcriptomics, proteomics and metabolomics (23). A range of *Arabidopsis thaliana* mutants blocked in certain pathways of pathogen defence also provide extremely valuable information regarding the functions of genes (24). The disease pathways are now fairly well characterised and much emphasis is currently being placed on clarifying the trigger systems of defence and the subsequent signal transduction processes leading to the various forms of defence.

2. Improving Grapevine Cultivation

Genetic transformation technology carries with it the tantalising prospect of developing plant lines able to adapt to adverse climatic conditions, enhanced by greater understanding of stress tolerance in plants and basic knowledge of key aspects of plant growth and development. Ongoing efforts to develop transgenic grapevines with improved cultivation prospects are focussing on processes such as carbon-partitioning, modes of sugar translocation, water transport and the role of aquaporins, as well as the regulation of these processes. These efforts also deal with important limitations to cultivation such as drought and salt stress, photo-damage and freezing tolerance (25).

To date, a transgenic grapevine expressing antifreeze genes from Antarctic fish has been reported as a mechanism to provide cold tolerance (25). However, plant stress responses are complex pathways of interacting proteins driven by a range of signals attenuated or amplified by equally complex processes. This biological interaction is more difficult to manipulate with single or even multiple gene additions; knowledge of the control mechanisms and alterations thereof might prove more feasible. With this view, the accumulation of proline and polyamines are two examples in grapevine that have been studied. The regulation of key genes in these biosynthetic pathways is providing insight into their involvement in abiotic stress (26,27). Furthermore, the expression of several stress related genes has been shown to be activated during the grape ripening (28,29).

Crop prediction is another area of attention. One of the most difficult issues facing viticultural production is the understanding and management of crop load and quality in the face of seasonal and environmental variation and change in market demand. Most recently, a study of how related genes in grapevine are organised and interact was made possible by the identification of the genes involved in flowering and fruitfulness in *A. thaliana*. For example, the chimera that results in pinot meunier can be separated into a conventional pinot and a mutant pinot form in which fruitfulness is dramatically increased even in juvenile plants. This dramatic change is the result of a single DNA base change in a single gene affecting vegetative and floral development of the vine (30).

3. Improving Grape Quality

Winemakers want small grapes of specific colour and ripeness as measured by the indicators of sugar, acids and phenolics. Researchers are investigating the basic processes of berry ripening and, particularly, ripening signals. Grapevine, a non-climacteric fruit, is studied for the biochemical, hormonal and environmental signals that influence ripening processes such as pigment production, sugar accumulation, transport and the formation of aroma components. The means of glucose/fructose accumulation during ripening is coming to light with the identification and analysis of grape berry genes encoding invertases and sugar transporters (31). The expression of flavenoid biosynthetic genes, responsible for colour development, coincide with hexose accumulation in berries (32–34). The importance of UDP glucose flavanoid-3-glucosyl transferase (UFGT) in the control of berry colour has been highlighted by comparison of gene expression in red and white grapes (35,36), and recent results indicate that Myb genes are involved in regulating UFGT (37). A number of genes that influence grape berry softening have also been isolated (38–40). Auxin and abscisic acid (natural hormones regulating growth and physiology) affect the expression of genes involved in the ripening process and have been implicated in the control of grape berry ripening (41). The aim of this approach is to meet the quality parameters of grapes with the formation of desirable or novel products by changing the metabolic flux through the important biosynthetic pathways active in the ripening berry.

To reach these goals grapevine biotechnology will have to draw upon considerably more knowledge of the underpinning processes as well as upon improvements in transformation technology. Targeted gene insertion and deletion technologies will make these and other innovative prospects more feasible.

III. THE GENETIC IMPROVEMENT OF WINE YEAST FOR ALCOHOLIC FERMENTATION

A. Yeast Species and Strains

Saccharomyces cerevisiae is unquestionably the most important yeast species in winemaking, but it competes with many other species for dominance. The ubiquitous fruit yeast, *Hanseniaspora uvarum* (anamorph *Kloeckera apiculata*), is the most common yeast isolated from grapes,

and many other non-*Saccharomyces* species are also present in the initial stages of spontaneous alcoholic ferments. As the ethanol concentration increases and other conditions change, various yeasts prevail in sequence, until *S. cerevisiae* multiplies to be the dominant species (42).

Not surprisingly, in such a complex environment the yeast ecology is highly variable and dependent on geographic location, viticulture and winemaking practices. Over the last decade, the pace of microbial ecology research has been accelerated by the application of molecular methods. A widely used rapid species identification method is PCR-RFLP (*p*olymerase *c*hain *r*eaction-derived *r*estriction *f*ragment *l*ength *p*olymorphism) of the ribosomal RNA genes (43). Using this method highlights the unpredictability of wine yeast ecology. In some wines for example, there is an almost total absence of apiculate yeast (*Hanseniaspora* sp.), yielding to *Candida stellata, Metschnikowia pulcherrima* or even *S. cerevisiae* during the initial stages of fermentation (44). In other cases non-*Saccharomyces* species persist to the end of fermentation (45). Molecular methods have also begun to accent the role of other *Saccharomyces* sensu stricto species, as well as interspecific hybrids of *Saccharomyces* yeasts in vinification (46–48).

Recently developed molecular methods, in particular mitochondrial DNA RFLP, have been used to analyse fermentation ecology at the species as well as strain level. The most unexpected finding is the number of strains of the same species coexisting during fermentation, with some wines showing over 100 different *S. cerevisiae* strains at the end of fermentation (44,45). Other technologies such as denaturing gradient gel electrophoresis (DGGE) have been developed that no longer require the plating of yeast prior to identification. Using this method new non-culturable species have been discovered in wine (49).

Wines made from spontaneous ferments are often described as more complex and fuller than inoculated wines. It is common practice, nevertheless, in many wineries to inoculate with a specific strain of *S. cerevisiae*, for rapid fermentation and a more consistent product with a reduced possibility of microbial spoilage. It also allows winemakers to use preferred strains to produce wines of a chosen style. With the future availability of yeast strains that can improve multiple facets of the winemaking process, the advantages offered to winemakers performing inoculated ferments with both *Saccharomyces* and non-*Saccharomyces* strains will expand.

B. Genetic Features and Techniques for the Analysis and Development of Wine Yeasts

Several genetic methods are available for the improvement of wine yeast. These include the selection of mutants with the desired properties, the combination of traits by mating and sporulation/dissection of *S. cerevisiae* strains, and the use of protoplast fusion to introduce novel traits of other species (1). Although these classic genetic methods have been used successfully for the development of new strains, they lack the precision and capability of gene cloning.

Specific characteristics of *S. cerevisiae* make it a model experimental organism (50). *S. cerevisiae* multiplies rapidly, shares many cellular regulatory mechanisms with humans and has a stable haploid and diploid life cycle. It has numerous suitable markers, plasmids and promoters for the regulated expression of chosen genes and undergoes efficient homologous recombination, permitting the precise deletion of selected genes. The *S. cerevisiae* genome was the first eukaryotic genome to be completely sequenced and this, along with its facile genetics, has made it an excellent research organism in the post-genomic era (51,52).

There have been major technical developments since the complete *S. cerevisiae* DNA sequence was published. Yeast deletion libraries are available in different mating types and ploidy that possess a set of approximately 6000 yeasts strains, each with a different single gene deleted. Phenotypic and chemical screens of these libraries make clear the biological function of each of the 6000 genes (53,54). The transcriptional response of each gene to different environmental conditions using microarrays is identifying genes that are important to wine fermentation [reviewed in (55)]. These conditions include the response to ethanol, osmotic stress, high and low temperature, high and low pH, copper, limited nitrogen and sugar, anaerobicity and progression into stationary phase (56–61). Microarray experiments are also being used to compare genome structure and gene expression in different grapevine isolates and commercial wine yeast (62–64). Proteomic approaches are being used in parallel to uncover the post-transcriptional changes that occur in different environmental conditions and genetic backgrounds in yeast (65). Of particular importance to wine is the emergence of metabolomics (66,67), which attempts to analyse all the metabolites produced by an organism in response to environmental or genetic changes. This will be fundamental to further understanding of how genetic and environmental changes impact on flavour and aroma.

The opportunity now exists to exploit these research findings and technological developments to produce genetically improved wine yeast strains of great value to the wine industry.

C. Targets for the Genetic Improvement of Wine Yeast Strains

Molecular genetics in wine yeast is being used to improve several aspects of winemaking, including fermentation performance, processing efficiency, sensory attributes and wine wholesomeness. These are summarised in Figure 40.2. Many of these aspects have been described in recent reviews (1,3,68), and the emphasis in this section is on current advances in this area as detailed in the latest literature.

Fermentation performance

Dessication tolerance

- Increased trehalose and glycogen accumulation - *nth1*Δ, *ath1*Δ and ↑*GSY2*
- Increased expression of aquaporins - ↑*AQY1* and ↑*AQY2*
- Increased accumulation of proline and charged amino acids - *put1*Δ, ↑*PRO1* and *car1*Δ

Fermentation stress

- Osmotic tolerance by modifying glycerol metabolism - ↑*GPD1,* ↑*GPD2,* ↑*GPP2*
- Ethanol tolerance by increasing sterol accumulation and ATPase activity - ↑*SUT1,* ↑*SUT2,* ↑*PMA1,* ↑*PMA2*

Nutrition

- Improved sugar transport - ↑*HXT3,* ↑*HXT6,* ↑*HXT7,* ↑*SNF3* and *FSY1*
- Improved nitrogen utilisation - *ure2*Δ, ↑*PUT1* and ↑*PUT4*

Control of indigenous microorganisms

- Increased sulfur dioxide - *met2*Δ, *met10*Δ and ↑*MET14*
- Hydrogen peroxide production - *GOX1*
- Expression of zymocins and bacteriocins - *PED1* and *LCA1*
- Expression of lysozyme, chitinases and glucanses - *HEL1*, *CTS1* and *EXG1*

Processing

Protein clarification

- Expression of yeast haze protection factors - invertase, *HPF1* and *HPF2*

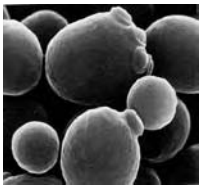
Cell floculation and flotation

- Controlled cell sedimentation by regulating expression of flocculins *FLO1* and *FLO11*
- Vellum formation - *FLO11*/*MUC1*

Polysaccharide clarification

- Glucanases, pectinases, xylanases, arabinofuranosidases - *END1*, *EXG1*, *CEL1*, *BGL1*, *PEL5, PEH1, XYN1–5*, *ABF2* and ↑*PGU1*

Saccharomyces cerevisiae



Wine wholesomeness

Resveratrol

- Increased resveratrol by grape stillbene synthesis - *4CL9/216*, *Vst1*

Ethyl carbamate and biogenic amines

- Decreased ethyl carbamate by decreasing urea formation - *car1*Δ, *URE1*
- Decreased biogenic amines by inhibiting bacterial growth

Sensory Attributes

Grape derived flavours

- Release of colour and flavour trapped in skin by expressing polysaccharide-degrading enzymes
- Release of terpenols by the expression of glycosidases - *END1*, *EXG1* and *BEG1*
- Modified terpenol concentrations by altering ergosterol biosynthesis and terpenol biotransformation
- Release of volatile thiols

Yeast secondary metabolites

- Enhanced production of desired esters by modifying transferases and esterases - ↑*ATF1* and ↑*IAH2*
- Optimised higher alcohol production modification of *BAT1*, *BAT2, ILE*, *VAL* and *LEU* genes
- Low ethanol wine yeast - ↑*GPD1,* ↑*GPD2, ald6*Δ and *GOX1*
- Modified sulfur metabolism - *met10*Δ *met14*Δ, *mxr1*Δ, ↑*MET25,* ↑*MET17* and ↑*SSU1*
- Malolactic fermentation - *mleS*, *mae1* *mae2* and *LDH1*
- Optimised phenol production - *PAD1*

FIGURE 40.2 Methods for strain development of wine yeast. Photograph kindly provided by Dr Alan Wheals.

1. Improving Fermentation Performance

Sluggish and stuck ferments remain a major concern of the wine industry. The wine environment is very stressful for yeast and harsh conditions must be overcome to produce high-quality wines (69). Like all living organisms, yeast has mechanisms in place allowing it to respond quickly to a changing environment. A general environmental stress response (ESR) participates in a wide range of cellular functions, including cell wall modification, fatty acid metabolism, protein chaperone expression, DNA repair, detoxification of reactive oxygen species and energy generation and storage (57). In addition to the general stress response, specific strategies to combat distinct stresses are essential for the survival of yeast in the fermenting grape must environment.

a. Desiccation stress

The desiccation process, part of the production of active dried yeast, challenges the wine yeast to a mixed stress that, although not well defined, appears to share some properties with freezing and osmotic stress. Several metabolites increase the survival of *S. cerevisiae* cells exposed to physical or chemical stresses and have been implicated in the efficiency of reactivating dried wine yeast starter cultures. As a result, there is strong incentive to develop wine yeast strains that accumulate these metabolites.

Disabling the trehalose hydrolysis pathway, thereby increasing cellular trehalose concentrations by deleting the *NTH1* or *ATH1* (neutral and acidic trehalase) genes has been shown to increase freezing and dehydration tolerance in a laboratory and commercial baker's yeast (70,71). The build-up of a second carbohydrate storage molecule, glycogen, is thought to provide the yeast with a readymade energy source upon reactivation of dried yeast. It has been reported that a wine strain overexpressing the *GSY2* (glycogen synthase) gene accumulates glycogen and has enhanced viability under glucose limitation conditions (72). Overexpression of the *AQY1* and *AQY2* (aquaporin) genes also confers freeze tolerance upon both laboratory and commercial baking strains (73). Whether these changes prove to be an advantage to active dried yeast remains to be determined.

It has been shown that proline and charged amino acids provide desiccation and freeze tolerance. Deletion mutations in the *PUT1* gene, encoding proline oxidase, and a dominant mutation in the proline biosynthetic *PRO1*

gene (γ-glutamyl kinase), increase intracellular proline and show higher desiccation, freeze and/or osmo-tolerance (74,75). A deletion mutation in the arginine degrading enzyme *CAR1* (arginase) increases arginine and glutamic acid levels and provides freeze tolerance (71).

b. Fermentation stress

The high concentration of sugar in grape juice imposes an osmotic stress on yeast. As indicated above, proline and trehalose accumulation both provide osmotolerance to yeast. The main osmolyte in yeast, however, is glycerol. In response to an osmotic stress, a MAPK cascade is activated and the two key genes in glycerol biosynthesis *GPD1* (glycerol-3-phosphate dehydrogenase) and *GPP2* (glycerol-3-phosphatase) are rapidly and transiently induced greater than 50-fold (61). Mutations in these genes are osmosensitive whereas mutations that increase their expression enhance osmotolerance (76). It has been reported that commercial wine yeast strains overexpressing either *GPD1* or *GPD2* have a slight growth advantage at the beginning of fermentation (77,78).

The primary cause of most sluggish and stuck fermentations is a high concentration of ethanol, an effect that can be augmented by a number of intrinsic and environmental factors. The physiological basis of ethanol toxicity is complex and not fully understood (59). A major target appears to be cell membranes, in which ethanol increases membrane fluidity and permeability, and impairs the transport of sugars and amino acids. The modification of *SUT1*, *SUT2*, *PMA1* and *PMA2* genes results in increased sterol accumulation and ATPase activity, thereby increasing the resistance to ethanol.

Zymocidal wild yeast may also inhibit the growth of the inoculated wine yeast strain and contribute to sluggish or stuck fermentation (79). Rapid progress in understanding sensitivity to killer toxins is being made, encouraging the development of broad-spectrum zymocidal resistance in wine yeast (80–82).

c. Utilisation of nutrients

Sugar uptake appears to limit complete sugar utilisation during vinification and is strongly influenced by conditions such as ethanol concentration and nitrogen availability. The low affinity hexose transporter Hxt3p and high affinity transporters Hxt6p and Hxt7p play particularly important roles in wine fermentation (83). It is possible that increased expression of these transporters will decrease the occurrence of stuck fermentation. Two hexose transporter homologues, Snf3p and Rgt2p, are required for glucose sensing. Snf3 is specifically required for inducing a number of *HXT* genes under low glucose conditions. Dominant *SNF3* mutants constitutively express hexose transporters and are resistant to translational inhibition upon glucose withdrawal (84,85), providing a potential mechanism for wine yeast improvement.

Nitrogen is the nutrient most often limiting wine fermentations; its deficiency can lead to cessation of fermentation as well as to the production of off-flavours such as hydrogen sulfide. A wine yeast strain carrying a mutation in the *URE2* gene, which represses expression of proline transport and metabolic genes, increases the availability of proline and arginine as nitrogen sources (86,87). However, *ure2Δ* strains possess pleotropic phenotypes. A more specific method may be to specifically target the proline permease and utilisation proteins (encoded by the *PUT* genes) (88). Global gene expression studies of wine yeast growing under differing nitrogen conditions will be important for identifying other genes that can improve fermentation under limiting nitrogen conditions (56,58).

An alternative source of nitrogen in vinification is from autolysis of the yeasts themselves (89). It is possible that a subset of yeast could be targeted to lyse toward the end of fermentation by adjusting the regulation of the cell integrity pathway (90).

d. Control of indigenous microorganisms

Uncontrolled microbial growth can alter the chemical composition of wine and detract from its sensory properties. The excessive use of chemical preservatives to control the growth of unwanted microbes can affect the quality of wine; it also faces increasing consumer resistance. As a response, wine yeast starter cultures that express antimicrobial enzymes or peptides are being developed.

Wine yeast producing increased sulfur dioxide (SO_2) concentrations could be useful for suppressing the growth of indigenous microbes, providing a means of reducing SO_2 as an antimicrobial and antioxidation agent in wine. Decreasing Met10p (sulfite reductase) and Met2p (serine acetyl transferase) activity or increasing Met14p (adenosine 5′ phosphosulfate kinase) activity leads to increased SO_2 production and has been shown to provide flavour stability to beer (91–93). Expression of hen-egg lysozyme or the *Aspergillus niger* glucose oxidase gene (*GOX1*) in yeast offers additional alternatives (94). The expression of *GOX1* in a wine yeast resulted in the production of hydrogen peroxide that can lead to oxidation toxicity of bacteria (95).

An alternative method is the use of a wine yeast with broad spectrum zymocidal activity. Whereas *S. cerevisiae*'s zymocins have a narrow killing range, the zymocins of *Pichia anomala*, *Willopsis saturnus* and *Kluyveromyces lactis* have been shown to be active on many species common in grape juice, including spoilage yeasts such as *Dekkera bruxellensis* (96). Several of the zymocins have been cloned in *S. cerevisiae;* the mechanisms of action are being established (80,97). Although these zymocins are generally less active at low pH, continuing advances in understanding the pH dependence of protein stability should make it possible to engineer more suitable zymocins for winemaking (98).

The zymocin zygocin, produced by the salt-tolerant yeast *Zygosaccharomyces bailli*, is also active against

filamentous fungi (99). However, heterologous expression in *S. cerevisiae* causes the yeast to commit suicide. Some success in producing yeast that kill filamentous fungi by attacking the cell wall has been achieved by expressing the *CTS1* chitinase and the *EXG1* endoglucanase genes (100). Although zymocidal yeasts have also been shown to be active on bacteria, the focus in wine research has been on the production of strains that secrete bacteriocins or bacteriolytic enzymes (e.g., lysozyme) to suppress growth of undesirable bacteria. Secretion of the *Pediococcus acidilactici* and *Lactobacillus plantarum* bacteriocins in *S. cerevisiae* produced a yeast that killed sensitive bacteria (101,102).

2. Improving Wine Processing

Following alcoholic fermentation wine is further processed to achieve clarity and physiochemical stability. The fining and clarification processes often involve expensive and laborious practices that generate large volumes of lees for disposal. This causes wine loss and may remove important aroma and flavour compounds from the remaining wine. To minimise the impact of these practices an increasing spectrum of commercial enzyme preparations are being added to grape must and wine. Generating yeast that remove proteins and polysaccharides and causes cells to flocculate offers an alternative strategy to the addition of costly enzymes.

a. Protein clarification

Heat-induced protein haze is caused by thaumatin-like proteins and chitinases, which are pathogenesis-related grape proteins (103). These proteins slowly denature and aggregate, resulting in light dispersing particles forming in wine. Under winemaking conditions, proteases have been unsuccessful in degrading haze proteins (104). However, a number of glycoproteins have been found to visibly reduce haze formation in wine, including yeast invertase (105) and two mannoproteins from *S. cerevisiae* known as haze protection factors (HPF) (106).

b. Cell flocculation and flotation

Rapid settling of yeast is advantageous to post fermentation processing. Yeast flocculation, which entails an interaction between cell surface lectins and mannans, involves many genes in *S. cerevisiae* (107). *FLO1* has been the best studied and shown to impart flocculation to beer and wine strains (108,109). Given that the timing of flocculation is important, *FLO1* and *FLO11* were expressed from the *HSP30* promoter, linking flocculation to a heat shock towards the end of fermentation (110).

In sherry, the yeast trap carbon dioxide and float to the surface forming a vellum. Several cell wall proteins have been implicated in vellum formation but the process appears complex and is likely to be multigenic (111). The similarities between vellum and biofilm formation point to Flo11p/Muc1p as a candidate gene in the process (112).

3. Improving Wine Sensory Attributes

The endless variety of wine flavours stems from complex interactions among hundreds of metabolites. *S. cerevisiae* accounts for the major changes between grape must and wine, modifying the chemical, colour, mouth-feel and flavour complexity of wine by assisting in the extraction of compounds from solids present in grape must, modifying grape derived molecules, and producing yeast metabolites (113).

a. Grape derived flavours

(i) Polysaccharide degrading enzymes. Polysaccharide degrading enzymes facilitate wine clarification and increase juice yield; they can also lead to the release of colour and flavour compounds trapped in the grape skins. A wide variety of heterologous genes encoding polysaccharide degrading enzymes have been expressed in *S. cerevisiae* (114). Pectin degradation was increased by yeast co-expressing two bacterial pectinase genes, pectate lyase from *Erwinia chrysanthemi* and polygalacturonase from *Erwinia carotovora* (115), or the pectate lyase gene from *Fusarum solani* (116). The overexpression of the endopolygalacturonase-encoding gene (*PGU1*) from *S. cerevisiae* in a wine yeast strain resulted in a higher concentration of terpenols (nerol and geraniol) in the wines, which displayed sensory differences to wines made with the parent yeast (117).

A number of glucanase genes from bacteria, yeast and filamentous fungi have been expressed, either on their own or together in commercial wine strains (114). These yeasts were able to degrade glucans effectively. Similarly, a number of xylanases have been expressed in *S. cerevisiae.* Although the levels of secreted enzymes are still below the concentrations required for the effective removal of polysaccharides, a degree of clarification has already been achieved. Preliminary trials also indicate that some of the modified yeast lead to the release of colour and flavour compounds entrapped in the grape skins.

(ii) Glycosidases. Yeast can increase wine flavour by releasing terpenols present as non-volatile glycosides in grapes. Expression of a β-1,4-endoglucanase gene from the filamentous fungus *Trichoderma longibrachiatum* in a wine yeast produced a wine with increased aroma intensity (118). The impact on flavour release of co-expressing three glucanase genes from *S. cerevisiae* (*EXG1*), *Bacillus subtilis* (*END1*) and *Butyrivibrio fibrisolvens* (*BEG1*) in a yeast remains to be determined (119).

Yeast can influence the concentration of terpenols by two other means: first, strains containing mutations in ergosterol biosynthesis have been shown to produce geraniol, citronelol and linalool (120), and second, it has been shown that yeast are able to convert one terpenol into another. As the terpenols have distinct aromas and sensory thresholds, these biotransformations might have a significant effect on wine sensory properties (121,122).

(iii) Volatile thiols. A number of potent thiol compounds have been shown to provide the basis for the varietal aromas of Sauvignon Blanc and Scheurebe wines (123), and are present in wines made from other cultivars. The sulfur-containing volatiles are present as a cysteine conjugate in grape juice and are released during fermentation by the action of yeast. Release is strain dependent, indicating that the concentrations of the thiols in wine can be regulated by genetically modifying the yeast (124).

b. Yeast secondary metabolites

(i) Esters. The characteristic fruity aromas of wine are caused mainly by the acetate esters of higher alcohols and the C_4-C_{10} ethyl esters. Overexpression of alcohol acetyl transferase genes (*ATF*) has a marked affect on ester formation (125–127). In wine, the concentrations of ethyl acetate, iso-amyl acetate, and 2-phenylethyl acetate increased as much as 10-fold, and the acetic acid concentration decreased by more than half in an *ATF1* overproducing strain (126). In saké strains, isoamyl acetate (banana-like aroma) concentrations have been modified by adjusting the *ATF1*/*IAH2* (isoamyl acetate esterase) balance (128).

(ii) Alcohols. Higher alcohols can contribute positively to wine complexity, but at excessive levels are regarded to have a negative influence on wine quality. They are also important precursors to ester formation. They are produced either anabolically or catabolically, by the breakdown of branched chain amino acids (129). The role of the anabolic pathway has been recently studied by deleting the aminotransferase genes *BAT1* and *BAT*2, the mutations leading to a decreased formation of isobutanol, isoamyl and active amyl alcohols (127,130).

(iii) Low ethanol wine yeast. High ethanol can affect the sensory properties of wine, giving it a perceived 'hotness' as well as suppressing overall aroma and flavour. Moreover, health-conscious consumers are demanding lower alcohol content in wines. Diverting the flow of sugar away from ethanol synthesis and into the glycerol pathway has been achieved by overexpressing the glycerol phosphate dehydrogenase genes, *GPD1* and *GPD2*, in wine strains (77,78,131). Acetic acid (vinegar) concentrations in these strains are increased to unacceptable levels. The acetaldehyde dehydrogenase activity encoded by the *ALD6* gene appears to be the main contributor to the oxidation of acetaldehyde during fermentation (132). A laboratory yeast overexpressing *GPD2* and lacking *ALD6* had the desired effect of producing more glycerol and less ethanol, but without the increase in acetic acid (133). A 'metabolic snapshot' (67) of the glycerol overproducing ferments also demonstrated how seemingly unrelated biochemical pathways can be modified by the change in a single gene (133).

A second strategy used to decrease ethanol is the expression of the *A. niger* glucose oxidase gene (*GOX1*) into *S. cerevisiae*, resulting in a 2% decrease in ethanol (95). The glucose in grape juice is thought to be converted to D-glucono-δ-lactone and gluconic acid, and is thus not available for conversion to ethanol.

(iv) Sulfur metabolism. Due to its low sensory threshold, the rotten egg aroma of hydrogen sulfide (H_2S) is highly undesirable in wine. Modification of genes required for sulfur metabolism leads to a significant decrease in hydrogen sulfide production (134–136). In *SSU1* overexpressing strains, a plasma membrane protein specifically for the efflux of sulfite from yeast (137), the sulfite is secreted prior to reduction to sulfide (93). Increases in *SSU1* expression also confer SO_2 resistance to *S. cerevisiae* strains. Many wine yeast strains that show natural resistance to sulfide have undergone chromosome translocation, positioning the *SSU1* gene downstream of a stronger promoter, and consequently causing its increased expression (138).

(v) Malolactic fermentation. During malolactic fermentation (conducted by certain species of lactic acid bacteria) L-malic acid is decarboxylated to L-lactic acid, which reduces wine acidity. *S. cerevisiae* is unable to transport malic acid into the cell and is inefficient in metabolising malic acid. The construction of a *S. cerevisiae* strain which is able to deacidify wine has been successfully demonstrated by expressing the malolactic gene (*mleS*) from *Lactococcus lactis* and the malate permease gene (*mae1*) from *Schizosaccharomyces pombe* (139).

In an attempt to redirect glucose carbon to lactic acid, the lactate dehydrogenase-encoding genes from *Lactobacillus casei*, the filamentous fungus *Rhizopus oryzae* and bovine muscle were expressed in yeast. As much as 20% of the glucose was converted into lactic acid in these strains (140,141).

(vi) Phenols. The decarboxylation of phenolic acids to volatile phenols can make a positive contribution to wine when present in appropriate concentrations. Although *S. cerevisiae* possesses a phenolic acid decarboxylase, *POF1* (*PAD1*), it displays low activity. Expressing the phenolic acid decarboxylase or *p*-coumaric acid decarboxylase from *Bacillus subtilis* and *Lactobacillus plantarum*, respectively, gave an approximate twofold increase in volatile phenol formation in a laboratory strain (142).

4. Improving Wine Wholesomeness

During the last few years it has become widely accepted that wine contains protective compounds that when consumed in moderate quantities reduce the likelihood of contracting certain diseases. However, a number of unwanted compounds are also present in wine. Generating improved yeasts that produce the correct balance of these compounds will be important for enhancing the health benefits of wine.

a. Resveratrol

Resveratrol, a polyphenolic phytoalexin found mainly in grape skins, has been associated with a large number of

health benefits, including the decreased risk of coronary heart disease, cancer prevention and treatment, and neuroprotection (60). Expression of the *Candida molisciana bgiN* gene, encoding a β-glucosidase, showed an increase in resveratrol in white wine. Release of glucose moieties from the glucoside form of resveratrol was the suggested mechanism (116). Also, yeast with altered phenylpropanoid metabolism, expressing the coenzyme A lyase gene and the grape stillbene synthase gene (*Vst1*), can synthesise resveratrol (143).

b. Ethyl carbamate

Ethyl carbamate, a suspected mammalian carcinogen, is formed through the chemical reaction of ethanol and citrulline, urea or carbamyl phosphate. In a saké strain disrupted for the *CAR1* arginase gene, no urea or ethyl carbamate was produced (144).

c. Biogenic amines

Biogenic amines are neurotoxins that can trigger hypotension and migraines, lead to histamine toxicity and produce carcinogenic nitrosamines (145). These biogenic amines originate from decarboxylation of amino acids by bacteria, including malolactic species (146,147). Wine yeast strains that inhibit bacterial growth may offer a solution.

IV. THE GENETIC IMPROVEMENT OF WINE BACTERIA FOR MALOLACTIC FERMENTATION

Malolactic fermentation (MLF), conducted by malolactic bacteria, is an important step in the grape vinification process, particularly in red wines. Most often MLF will occur after the alcoholic fermentation; however, it is not limited to this stage of winemaking. The role of MLF is threefold: wine deacidification by the conversion of L-malic acid to the 'softer' L-lactic acid, microbial stability and wine flavour modification.

This section will not elaborate on the biochemistry of MLF. Rather it will discuss the bacteria involved in the process, summarise the genetics of the malolactic bacteria and postulate potential genes that could be manipulated in order to improve the malolactic reaction, increase stress tolerance of the bacteria, and/or favourably alter the sensory profile of the wine. The ability to genetically alter the malolactic bacterial genome will depend upon the development of a suitable genetic transfer system (transformation, conjugation or transduction), which currently is unavailable.

A. Lactic Acid Bacteria Species and Strains

The wine bacteria associated with MLF belong to the family of lactic acid bacteria (LAB). This group of bacteria is involved with the fermentation of a range of food products, including milk, vegetables, meat and fruit, especially grapes. The malolactic bacteria are encompassed in four genera, *Lactobacillus (Lb.)*, *Leuconostoc (Lc.)*, *Oenococcus (O.)* and *Pediococcus (P.)* from within the larger group of LAB. The species in these genera can be characterised by their ability to tolerate low pH, high ethanol concentration and by their ability to grow in wine. Those most commonly associated with wine are *Lb.brevis*, *Lb. plantarum*, *Lb. hilgardii*, *Lc. mesenteroides*, *O. oeni, P. damnosus* and *P. pentosaceus*. *Oenococcus oeni*, formerly known as *Leuconostoc oenos* (148), is the LAB species most commonly associated with wine, as it is particularly well adapted to the harsh wine environment (low pH, high ethanol content, low nutrients) (149). For a more detailed description of LAB taxonomy the reader is referred to several reviews [(150,151); *Bergey's Manual of Determinative Bacteriology*, 1986)].

Even though it is postulated that species of *Lactobacillus* and to a lesser extent *Pediococcus* species may conduct the deacidification reaction in spontaneous MLF, species of these two genera are more likely to be associated with spoilage of wine than with positive sensory attributes.

B. Genetic Features and Techniques for the Analysis and Development of Lactic Acid Bacteria

The *O. oeni* genome has been sequenced in its entirety by two different groups (University of California, Davis with the group of D. Mills and at ESBANA, Dijon, France with the groups of J. Guzzo and A. Lonvaud-Funel). This sequence information will greatly enhance the initial work on the *O. oeni* genome (150–153) and add to the limited number of genes that have been characterised. Though *O. oeni* is an important organism in winemaking, knowledge of its genetics is limited. The current lack of a genetic transfer mechanism into *O. oeni* further hampers genetic characterisation of this organism.

Considerable research has been done on other LAB, particularly those from the dairy industry. Substantial work has been devoted to the genetics of *Lactobacillus* sp. but to a lesser extent in *Pediococcus* sp. Numerous vectors have been constructed to introduce modified genes into *Lactobacillus* species and strains. These vectors are designed to enable easy movement between Gram-positive and Gram-negative organisms utilising dual replicons (origin of replication) and antibiotic markers. Also available are temperature-sensitive features on a few of these plasmids. Some of these plasmids/vectors also function in *Leuconostoc* sp., which is the closest LAB genus to *Oenococcus*. Many of these vectors may be suitable for *O. oeni*.

Another approach to improving industrially important *O. oeni* strains is the use of a new technology known as genome shuffling (154,155). This technique involves using a classical strain improvement method to generate

populations with subtle improvements. Next, these populations are shuffled by recursive pool-wise protoplast fusions. Genome shuffling has been successfully applied to improve acid tolerance in a poorly characterised industrial *Lactobacillus* strain (156) and appears to be broadly useful for the rapid development of tolerance and other complex phenotypes in industrial organisms.

C. Targets for the Genetic Improvement of Malolactic Bacterial Strains

Potential improvements to MLF by the genetic modification of *O. oeni* are presented in Figure 40.3. It would be of obvious interest to construct an *O. oeni* strain which is able to ward off potential competitors, improve its ability to cope with the harsh wine environment, increase its efficiency in the bioacidification of wine-conversion of malic acid to lactic acid, and/or to provide mechanisms to improve the organoleptic qualities of wine. Such an organism would not necessarily possess all these attributes, but generating a selection of improved *O. oeni* would be of great benefit to the wine industry.

1. Improving Fermentation Performance

a. Adaptation to environmental stress

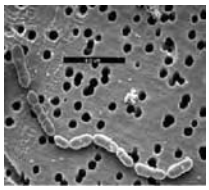
It has been demonstrated that *O. oeni* responds to various environmental stresses, such as high alcohol, acid and sulfur dioxide (SO_2) concentrations, by producing heat shock and stress proteins (*hsp18*, *clpX* and *trxA*) (157). The manipulation of these genes could lead to improved tolerance of *O. oeni* to wines with conditions at the upper limit of *O. oeni* tolerance. The elevated expression of these heat and stress proteins may also aid the commercial production of *O. oeni* for direct inoculation into wine, by better preparing the bacterial cells for the harsh wine environment.

Fermentation performance

MLF efficiency
- Malolactic enzyme
- (*mleR*, *mleA*, *mleP*)
- Increase the efficiency of malate metabolism

Stress
- Heat shock and stress proteins
- (*hsp18*, *clpX*, *trxA*)
- Regulation of production could lead to improved tolerance to wine conditions, especially alcohol (high EtOH, 14–15%)

Oenococcus oeni



Wine wholesomeness

Arginine / Ethyl carbamate
- *Arc* cluster (arginine metabolism)
- Arginine metabolism leads onto ethyl carbamate (animal carcinogen)
- Manipulation of *arc* cluster could lead to ↓ ethyl carbamate production

Biogenic amines
- ↓ histindine decarboxylase (*hdc*) activity to reduce the concentration of histidine in wine

Antimicrobial
- ↑ bacteriocin production (pediocin, lactocin, nisin) might result in↑natural removal of selected spoilage LAB during MLF
- Cyclic peptides produced by *Lb. plantarum* and *P. pentosaceus*; ↑natural removal of selected spoilage fungi during MLF

Sensory attributes

Diacetyl
- Buttery, nutty, butterscotch notes
- *alsS, alsD* (α-acetolactate synthase and decarboxylase)
- ↑↓ synthesis of diacetyl
- Δ *ldh* (drives reaction towards pyruvate and onto diacetyl)
- Modulation of aroma and flavour in wine

Esters
- ↑ acyl transferases (*atf*) and ↓ esterase activity
- ↑ aroma profile of wine

Glycosidase
- *bgl* (β-glucosidase)
- Clone other genes required for sequential release of disaccharide bound aglycon; ↑ aroma and flavour

Mouth-feel
- Polysaccharides β(1→3)glucanase
- Other mouth-feel contributors
- (glycerol, mannoproteins)

FIGURE 40.3 Methods for strain development of lactic acid bacteria. Photograph kindly provided by Dr Jeffery Broadbent.

b. Improved efficiency of malate catabolism

The genes for malate metabolism have been cloned from *O. oeni* and three genes *mleR* (regulator), *mleA* (enzyme) and *mleP* (permease), have been identified (139). In order for malate metabolism to be initiated and to proceed efficiently in wine, a bacterial population density of at least one million cells/mL is needed. To increase the conversion efficiency of L-malate to L-lactate, it is necessary to understand the regulation of *mleA* by *mleR* and determine the rate limiting step for malate metabolism, especially important at low cell density. A rapid adaptation of the *O. oeni* cell to its harsh wine environment may also ultimately enhance the catabolism of L-malate.

2. Improving Wine Wholesomeness

a. Arginine/ethyl carbamate

The role that MLF plays in ethyl carbamate formation remains unclear. Arginine, a quantitatively important amino acid of grape must and wine, is a precursor to ethyl carbamate. Lactic acid bacteria vary in their ability to degrade arginine; experiments conducted in a synthetic and a laboratory vinified wine demonstrated a correlation between arginine degradation, citrulline production and ethyl carbamate formation during MLF conducted by an *O. oeni* and *Lb. buchneri* strain (158–160). The arginine catabolism (*arc*) gene cluster of *O. oeni* (161) has been cloned and characterised, thus providing a basis for manipulating the *arc* genes and reducing the potential of ethyl carbamate production.

b. Biogenic amines

Biogenic amines have undesirable physiological effects when consumed at high concentrations. The major biogenic amines in wine are histamine, phenylethylamine, putrescine and tyramine (162–164). Their concentration is lowest after alcoholic fermentation and increases variably in most wines during MLF (165). Wine-associated LAB, including *O. oeni,* have been shown to decarboxylate amino acids to their corresponding amines (166). This decarboxylation reaction is purported to favour growth and survival in acidic media, since it induces an increase in pH and can also provide energy to the LAB (167). LAB vary in their ability to produce the various amines.

The *O. oeni* histidine decarboxylase gene (*hdc*) has been cloned and characterised (168). A PCR-based test has also been developed for the detection of amino acid decarboxylating genes in LAB (169). The manipulation of the *hdc* gene in *O. oeni* strains with other desirable characteristics would ensure that reduced concentrations of histidine are present in wine.

c. Antimicrobial activity

The use of bacteriocin-producing LAB species/strains in other food industries, especially the dairy industry, has met with considerable success. A pediocin-producing *Lb. plantarum* strain was shown to efficiently combat the spoilage of cheese by *Listeria monocytogenes* (170). Furthermore, the expression of pediocin PA-1 from *Pediococcus acidilactici* or plantaricin 423 from *Lb. plantarum* by the introduction of the respective genes into *S. cerevisiae* has been shown to effectively eliminate LAB from an alcoholic fermentation (101). A similar strategy could be used to introduce the necessary genes into *O. oeni*.

3. Improving Wine Sensory Attributes

a. Diacetyl

One of the most important flavour compounds associated with MLF is diacetyl (a diketone, 2,3-butanedione), which can impart a 'buttery' or 'butterscotch' flavour to wine (171–173). Diacetyl is principally formed during MLF by the bacterial metabolism of citric acid. This diketone is also an important flavour compound in the dairy industry, providing the characteristic 'buttery' flavour of many fermented milk products.

The metabolism of diacetyl is well understood (174–176) and the environmental factors that influence its formation and degradation in wine have been established (177–179). The diacetyl pathway has been amenable to genetic manipulation, leading to overproduction of diacetyl in *Lactococcus lactis* (180). With the inactivation of the lactate dehydrogenase gene (*ldh*) in *L. lactis*, there was an accompanying alteration to the metabolic flux, eliminating lactic acid as a metabolic end product and producing ethanol, formate and acetoin. Acetoin is a degradation product of diacetyl and is considered flavourless in wine because of its high aroma threshold. The overexpression of α-acetolactate synthase (*ilvBN* genes in *L. lactis*) leads to an increased production of acetoin (the reaction is driven towards acetoin and away from diacetyl), whereas the inactivation of the *aldB* gene (encoding α-acetolactate decarboxylase) resulted in an increased production of α-acetolactate and diacetyl at the expense of acetoin. The latter scenario is quite desirable in the dairy industry. The analogous genes [*alsS* (α-acetolactate synthase) and *alsD* (α-acetolactate decarboxylase)] have been cloned and sequenced from *O. oeni* (181), providing a means of altering diacetyl concentrations in wine. An alternative strategy would be to inactivate the citrate permease gene (*citP*), thus removing the initial substrate for diacetyl. Such a natural mutant of *O. oeni* has been isolated and is commercially available (MT01, Lallemand).

b. Glycosidases

Many potential aroma and flavour compounds are found in grapes and wine as glycosidically bound aglycons (monoterpenes, norisoprenoids, benzene derivatives and aliphates). Though β-glucosidase activity has been demonstrated in *S. cerevisiae* and *O. oeni* (182), both have limited ability to release the disaccharide glycosides.

Improving release of glycosides in *O. oeni* strains following MLF using similar methods to those described in yeast could lead to enhanced grape variety aroma in the wine.

c. Esterases

Various sensory studies pre and post MLF have shown that the fruity qualities of a wine may be enhanced after MLF (183,184). An improved understanding of the formation and further metabolism of esters [acyl alcoholtransferase (ester synthesising enzymes) and esterases (ester catabolising enzymes)] in *O. oeni* could lead to the enhancement of specific, desirable esters.

d. Bitterness

Bitterness is a spoilage problem, primarily in red wine, that can be associated with LAB, including *O. oeni* strains. The fermentation of glycerol can lead to the formation of acrolein, which when it reacts with phenolic hydroxyl groups, results in wine bitterness. The manipulation of the pathway of glycerol catabolism, for example the glycerol dehydratase, may lead to reduced acrolein formation.

The presence of certain peptides is also a potential cause of bitterness in wine. Bitterness due to proteolytic action and formation of short peptides has been studied extensively in dairy LAB. There appears to be a minimal proteolytic activity associated with *O. oeni* and the peptide transport system of *O. oeni* is poorly understood. A better understanding of potential bitter wine peptides and their formation could reduce the occurrence of bitterness in some wines.

e. Mouth-feel properties

Numerous MLF sensory studies and anecdotal evidence point to changes in the texture and body of the wine following MLF, with reports indicating a fuller, richer, longer aftertaste (183). The chemical changes contributing to these favourable mouth-feel properties are poorly understood. The deacidification process itself contributes substantially to changes in mouth-feel, with the consequent increase of pH and decrease in titratable acidity. In addition, the L-lactic acid feels softer than L-malic acid. Other contributors to wine mouth-feel or taste perception have been suggested, including polysaccharides, glycerol and mannoproteins. The contribution of MLF in this area remains to be studied.

MLF has great potential to further enhance wine qualities by retaining or altering the aroma/flavour profile of the wine as well as by conferring microbial stability. However, the genetics of *O. oeni* for all these processes are still not well understood. With the availability of the complete *O. oeni* genome sequence, the development of an efficient gene transfer system into *O. oeni* and the understanding of the various pathways, 'tailor-made' *O. oeni* strains will become possible.

V. THE FUTURE OF GENETICALLY IMPROVED GRAPEVINES, YEASTS AND BACTERIA IN THE WINE INDUSTRY

Molecular genetic research has much to offer the wine industry. It is a powerful technology for studying the regulation of pathways in grapevine, yeast and bacteria, thus providing an understanding of how viticulture and winemaking practices impact on grape and wine quality. In some cases, especially yeast and bacteria, identifying the important genes will provide non-GM improvement strategies. Molecular techniques are also starting to dominate systematics, simplifying *Vitis* varietal identification and wine microbial ecological studies.

This review has focused upon the use of molecular techniques to produce GM grapevines and wine microbes that can provide major advantages to the wine industry and wine consumer. Several obstacles, however, must be overcome before these techniques can be put to use. These include scientific and technical issues, a number of regulatory and economic concerns and the public perception of GM foods (5).

A. Scientific and Technical Obstacles

The bacterium *Escherichia coli* and plants such as *Zea mays* and *Arabidopsis thaliana* have been used as experimental model organisms for many decades, but the study of important wine bacterial species and *Vitis vinifera* is much more recent. Similarly, although laboratory strains of *S. cerevisiae* are easily manipulated, wine yeast have characteristics such as homothallism, polyploidy, and the lack of auxotrophic markers that make them more difficult to manipulate. There is increasingly rapid progress, however, in the molecular improvement of these organisms, and as important genes continue to be identified, the potential for use of GMOs in the wine industry will continue to expand.

B. Regulatory, Economic and Political Obstacles

Most countries' legislation and regulations applying to the use of GMOs and the approval of GM foods are now broadly similar and fall into two categories. The approach exemplified by the regulations of the United States of America takes the view that each case of a GMO needs to be considered on its merit and there is no *a priori* reason to assume that the use of GM plants and microbes is of itself more risky than conventional methods of introgressing new genes into organisms and products. The arguments used in this approach are those of 'substantial equivalence' and statutory approval usually requires several obvious assurances, such as that there be no additional threat to human health or the environment. The second approach is exemplified by the European Union's

regulatory system that takes the view that GM material has an intrinsic level of risk beyond that accepted in non-GM products. The regulations are framed around this philosophy and the requirements to demonstrate the properties of GMO-based material are substantially more rigorous than those placed upon the introduction of food material bred by conventional genetic means.

While genetically improved grapevines, yeast and bacteria need some form of economic protection, patents covering many of the tools used in genetic engineering, including the genes themselves, leave little 'freedom to operate' (185). If commercialisation of GMOs is to be viable, it is imperative that intellectual property issues be addressed.

There is also a belief that patents on genetically engineered organisms give an unfair advantage to certain large multinational producers, thereby concentrating economic power in their hands. With the visibility of the anti-globalisation movement and a surplus of wine in some countries, it is possible that the commercialisation of improved GM wines could be misused to justify technical barriers to free trade.

Bottle labelling is another hurdle. The marketing of wine relies to a great extent on label integrity and product identity, and it is hoped that wines exhibiting improved flavour and colour characteristics will be able to retain the established varietal names. It may also become obligatory to label GM wines as such, and it is not clear whether this will be detrimental to the sale of these wines (186). For example, the European Union and Japan have recently introduced new legislation such that all food products with more than 0.9% and 0.5% GM content, respectively, will have to be labelled as GM. Any GM food product derived from GM ingredients but whose presence is undetectable in the product will also have to be labelled.

Much of the wine industry is bound by tradition and regional culture, making it particularly unreceptive to technological change. In addition, there is a concern that GM wines will become standardised, and lose their mystique and romanticism. Quite to the contrary, gene technology will allow winemakers to diversify their products and provide even greater consumer choice.

C. Public Perception Obstacles

The public perception of GM foods has been, so far, that the potential risks outweigh the benefits. Sensationalist reporting has increased public fears of 'Frankenfoods,' which of course spread far more readily than good sense or wise science. Ironically the potential advantages to consumers and the environment are numerous, and include a healthier and better product and agricultural sustainability. To reverse negative perceptions it is essential that scientists ensure the trust of the public by providing balanced, understandable information on the safety and environmental risks associated with GMOs (187).

It should be remembered that the improvement of foods has been going on for many thousands of years, initially by selection and later by selective breeding, and unwanted and indeterminate changes have been routinely transferred along with the desired modifications. These methods are completely acceptable to consumers, if they are even aware of them. Genetic engineering provides a more precise means of bringing about the intended changes, which together with recent developments in the field of metabolomics, offers techniques to produce foods that comply with the test of 'substantial equivalence' (188,189).

Evaluating potential environmental risks of GMOs is more difficult, and will have to be examined on a case-by-case basis (190). Meanwhile, improvements in the technology continue to reduce the potential of risk (191). Guidelines for the release of GMOs in most countries require the absence of any selective advantage conferred by the transgenic organism that could allow it to become dominant in natural habitats. Again, improved molecular techniques such as Real Time PCR should assist in evaluating competitiveness (192,193).

The nature of the modification will also influence consumer acceptance. Whereas some modifications do not add foreign DNA, others require the insertion of antibiotic or herbicide resistant markers often considered undesirable. Some genetic modifications cross species barriers; these are more likely to generate debate and allow objectors to pose religious and moral questions.

In winemaking the yeast and bacteria are not present in the final product, and the clarification of wine removes nucleic acid, including that of the grapes. This should allay consumer fears that they are ingesting modified DNA (194).

VI. CONCLUSIONS AND OUTLOOK

In many respects wine is no longer seen as a dietary beverage, but as a non-essential luxury product, offered to consumers along with many other luxury products. The international wine industry is obviously in business to attract a fair proportion of the consumers' disposable income in competition with other luxury goods and services. To do so it must offer products that exhibit desirable and pleasurable characteristics to the consumer, continue reducing its impact on the environment, and offer a competitive quality/price ratio while remaining profitable for the producers.

Competitors of the wine industry, e.g., producers of other alcoholic beverages, do not hesitate to employ new technology as it becomes available. Winemakers must become more sophisticated about the application of new scientific and technological knowledge while still respecting the cultural roots and traditions associated with winemaking. The ongoing research into the genetic improvement of grapevines and wine microbes as outlined in this chapter

provide the global wine sector with an enormous opportunity to improve the quality/price ratio of wine by embracing biotechnological innovations.

In the medical world the uses of GM products are accepted and widespread. In agriculture the uptake in the field crop industries has been steadily increasing to the degree that in 2002 almost 60 million hectares of GM field crops were being grown worldwide. And this trend toward greater acceptance is likely to continue. With the rapid growing power of bioinformatics and the dawn of the 'omics' era in molecular biology it is widely expected that high quality information and 'precision' gene technology will increasingly allow grape and wine biotechnology to be harnessed for the good of the producer, consumer and environment. That is why some optimists even claim that gen*omics*, transcript*omics*, prote*omics* plus metabol*omics* equal econ*omics*!

Reality looms in the form of agronomic, business, regulatory and social hurdles currently blocking commercial availability of GM grapes and wine. But the smart money is saying that the benefits to the industry such as minimised resource inputs, improved product quality, increased health benefits and low environmental impact will ultimately put gene technology in the winner's circle.

ACKNOWLEDGMENTS

Research conducted at The Australian Wine Research Institute is supported by Australia's grapegrowers and winemakers through their investment body the Grape and Wine Research and Development Corporation, with matching funds from the Australian Government.

Part C

Food Analysis

41 Food Analysis: Basics

S. Suzanne Nielsen
Department of Food Science, Purdue University

CONTENTS

I. INTRODUCTION

Foods are analyzed for chemical composition and characteristics for a variety of reasons in the food industry, including nutrition labeling and quality control (1–5). The analyses may be performed continuously within the processing line, or samples are collected and analyzed in the quality control laboratory or sent to an outside analytical laboratory. In the latter two cases, samples must be properly selected and prepared for analysis, then analyzed and the data interpreted. Selecting the method of analysis depends on a variety of factors, including the objective of the testing, characteristics of the method and the food products, and needed accuracy and precision. Out of necessity, methods used during processing and on final products are typically rapid, while more time-consuming and accurate methods are specified to suppliers of raw ingredients and used for nutrition labeling of the final product. Whatever the method of analysis, data obtained must be handled appropriately and interpreted as the basis for decision-making. These basics of food analysis are necessary whether the method being utilized is wet chemistry, spectroscopy, chromatography, or some other method.

II. WHY ANALYSES ARE DONE

Demands of consumers, strong competition within the food industry, and government regulations and international standards all contribute to the need for analysis of food products and ingredients.

A. Consumers

Safety, quality, nutrition, and good value are all important to consumers as they select their foods for purchase. It is increasingly a challenge for the food industry to meet the demands of consumers. Consumer interest in food safety has increased the testing for allergens and pesticide residues. Consumer concern about food materials that have been genetically modified using biotechnology has led to testing of foods and raw materials for such modification. Consumer interest in the relationship between diet and health has increased the importance of testing foods to allow for certain nutrient content claims (e.g., low fat) and health claims (e.g., dietary saturated fat and cholesterol, and the risk of coronary heart disease) (1).

B. Food Industry

To manage product quality, food companies must apply analytical methods across the entire food supply chain, from the raw ingredients to the final product (Table 41.1).

TABLE 41.1
Types of Samples Analyzed in a Quality Assurance Program for Food Products

Sample Type	Critical Questions
Raw materials	Do they meet your specifications?
	Do they meet required legal specifications?
	Will a processing parameter have to be modified because of any change in the composition of raw materials?
	Are the quality and composition the same as for previous deliveries?
	How does the material from a potential new supplier compare to that from the current supplier?
Process control samples	Did a specific processing step result in a product of acceptable composition or characteristics?
	Does a further processing step need to be modified to obtain a final product of acceptable quality?
Finished product	Does it meet the legal requirements?
	What is the nutritive value, so that label information can be developed? Or is the nutritive value as specified on an existing label?
	Does it meet product claim requirements (e.g., "low fat")?
	Will it be acceptable to the consumer?
	Will it have the appropriate shelf life?
Competitor's sample	What are its composition and characteristics?
	How can we use this information to develop new products?
Complaint sample	How do the composition and characteristics of a complaint sample submitted by a customer differ from a sample with no problems?

From: SS Nielsen, ed. Food Analysis, 3rd ed. New York: Kluwer Academic, 2003 (Ref. 1).

Analyzing various types of samples in the food processing system can help answer questions critical to the success of the business. Heavy emphasis is placed on the quality of raw ingredients, which reduces the need for extensive testing during processing and on the final product. Responsibility for ingredient testing has been shifted largely from the food companies to the ingredient suppliers. Most food companies have "select suppliers" who are given detailed ingredient specifications. These suppliers are asked to do the analytical testing and provide a "certificate of analysis" to show compliance with these specifications. Limited additional testing of ingredients may be done upon receipt by the food company. In some cases, a food company arranges to receive a small sample of the ingredient to check for particular characteristics before accepting a large shipment of the ingredient (1).

C. Government Regulations

Government regulations dictate certain types of analyses (6). Three examples follow of food analysis required based on federal regulations in the U.S. First, nutrition labeling regulations in the U.S. are a major driver of the analysis of foods (Table 41.2). Chemical analysis of foods is required not only for the nutrition label itself, but also for making nutrient content claims that characterize the level of a nutrient (e.g., low fat, reduced sodium, high calcium) or health claims (e.g., folate and neural tube defects, soluble fiber from whole oats and coronary heart disease). Second, the U.S. Food and Drug Administration (FDA) has established standards of identity for certain food products. These standards often include which ingredients a food must contain, the maximum levels for inexpensive ingredients (e.g., water), the minimum levels for expensive ingredients (e.g., fat), and recommended analytical methods to determine the chemical composition. Table 41.3 summarizes food analysis-related information from the standard of identity for several food products. The recommended methods of analysis specified in standards of identity are typically from the *Official Methods of Analysis* of AOAC International (formerly known as the Association of Official Analytical Chemists, AOAC) (7). Third, grade standards established by the U.S. Department of Agriculture, while voluntary rather than mandatory, are used often as quality control tools. These grade standards classify products in a range from substandard to excellent in quality. This information is useful both to consumers (e.g., Grade A eggs) and to institutions (schools, hospitals, military) that purchase foods. Grade standards often include not only chemical composition characteristics (e.g., soluble solids and titratable acidity distinguish Grade A and B orange juice), but also sensory evaluation and visual appearance.

TABLE 41.2
Typical Methods Used for Nutrition Labeling Tests[a]

Item on Nutrition Label	Typical Analysis
Calories	Calculated from content of protein, total carbohydrate (or total carbohydrate less the amount of insoluble dietary fiber), and total fat (4, 4, and 9 calories per gram, respectively)
Calories from Fat	Calculated from total fat (9 calories per gram)
Total Fat	Extraction with petroleum or diethyl ether (e.g., Soxhlet or Goldfish methods), sometimes preceded by acid hydrolysis; Roese-Gottlieb or Mojonnier methods; Babcock; sum of fatty acid content by gas chromatography
Saturated Fat	Gas chromatography
Cholesterol	Gas chromatography
Sodium	Inductively coupled plasma-atomic emission spectroscopy, Atomic absorption spectroscopy, Mohr or Volhard titration, ion selective electrodes
Total Carbohydrate	Calculated as % Total carbohydrate = 100% − (% Moisture + % Protein + % Fat + % Ash)[b]
Dietary Fiber	Gravimetric-enzymatic method
Sugars	High performance liquid chromatography
Protein[c]	Kjeldahl, nitrogen combustion (Dumas)
Vitamin A	High performance liquid chromatography
Vitamin C	2, 6-Dichloroindophenol titration, microfluorometric assay
Calcium	Inductively coupled plasma-atomic emission spectroscopy, atomic absorption spectroscopy
Iron	Inductively coupled plasma-atomic emission spectroscopy, atomic absorption spectroscopy

[a]Nutrition labeling regulations of the United States Nutrition Labeling and Education Act of 1990.

[b]Moisture content may be determined by methods such as oven (e.g., forced draft oven, vacuum oven, rapid moisture analyzer), distillation, or Karl Fischer titration. Ash content for the purpose of calculating total carbohydrate content is usually done by dry ashing in a muffle furnace.

[c]Protein methods given are for determining content. If protein is expressed as a percent of the Daily Value, protein quality must be determined by either the Protein Efficiency Ratio method (foods for infants or children under four years of age) or the Protein Digestibility-Corrected Amino Acid Score method (foods other than for infants).

D. International Standards

Many food companies must meet not only the regulations of individual governments, but also standards set by international organizations. For example, standards published in the *Codex Alimentarius* by the Codex Alimentarius Commission are intended to facilitate international trade of foods, ensure fair business practices, and protect the health of consumers. These standards make necessary the analysis of raw agricultural commodities and processed food products being imported or exported (6).

III. WHERE ANALYSES ARE DONE

The need continues for collecting samples from the processing line for analysis in the quality control laboratory or by an outside analytical laboratory, but there is increasing interest in continuously monitoring the quality characteristics of foods in line as they are being processed. Such analysis better ensures the quality of the final product and reduces the need for further testing of the final product before distribution. Infrared spectroscopy, one of the main tools used for this application (8), is described in more detail in Chapter 43, Spectroscopy Basics. However, briefly, infrared spectroscopy measures the absorption of radiant energy, in the near- or mid-infrared region of the electromagnetic spectrum, by molecules in foods. The frequency of energy absorbed depends on the functional groups of the molecules being measured, and the amount of energy absorbed is related to the concentration of the food constituent of interest. Other methods of analysis are being used and further studied for on-line analysis applications.

Samples collected from the processing line may be analyzed immediately using equipment stationed very near the processing line (e.g., rapid moisture analyzer to check moisture content of cereals; portable colorimeter to check color). However, often samples collected from the processing line are transported to an established quality control laboratory where generally rapid methods are used to test quality characteristics as part of the quality management plan. For less routine analysis and for nutrition labeling tests, collected samples may be sent to outside analytical laboratories. These analytical laboratories often are certified laboratories with highly trained and experienced personnel, and often are equipped with expensive analytical instrumentation. For example, a typical quality control laboratory would not be set up to do analyses for dietary fiber or certain vitamins, but samples for these analyses could be sent easily to an analytical laboratory.

IV. STEPS IN ANALYSIS

Analysis of foods involves three main steps: 1) selecting and preparing the sample, 2) performing the analysis, and 3) calculating and interpreting the results.

Collecting the sample and preparing it for analysis, which are covered in more detail in the next section, are much more difficult and important than they would appear. Non-homogeneity of food and ingredients, along with uneven distribution of certain constituents, make collecting a representative sample a challenge. Conditions of sample preparation and the instability of certain food constituents make it difficult to ensure that the composition and characteristics of the sample collected are identical to those of the sample subjected to the analytical procedure.

TABLE 41.3
Chemical Composition Requirements of Some Foods and Ingredients with Standards of Identity

Section in 21 CFR[1]	Food Product	Requirement	AOAC METHOD[2] Number in 13th Ed.	Number in 17th Ed.	Name/Description
131.125	Nonfat dry milk	Moisture ≥ 5% by wt.	16.192	927.05	Vacuum oven
		Milkfat ≤ 1.5% by wt.	16.199–16.200	932.06A, 932.06B	Roese-Gottlieb
145.110	Canned applesauce	Soluble solids ≥ 9%, expressed as % sucrose, °Brix	22.024	932.14A	Refractometer
168.20	Glucose syrup	Total solids ≤ 70%,mass/mass (m/m)	31.2088–941.14A, 941.14B 31.209		Vacuum oven, with diatomaceous earth
		Reducing sugar ≥ 20% m/m (dextrose equivalent, dry weight basis)	31.220(a)	945.66(a)	Lane-Eynon
		Sulfated ash ≤ 1% m/m, dry weight basis	31.216	945.63B	Dry ashing
		Sulfur dioxide ≤ 40 mg/kg	20.106–20.111	962.16A–963.20C	Modified Monier-Williams

[1]CFR, Code of Federal Regulations (2004).

[2]*Official Methods of Analysis* of the Association of Official Analytical Chemists (AOAC) International.

Each food or ingredient component or characteristic to be tested may require a unique assay. Descriptions of wet chemistry, spectroscopy, chromatography, and other methods for food analysis are given in subsequent chapters. However, for any particular assay, the analyst doing the assay needs to consult manuals, reference books, and articles for details on the necessary chemicals, reagents, equipment, and step-by-step instructions. It must be stressed that glassware and other labware used must be clean and equipment properly checked and calibrated.

The results obtained from performing the assay of food components and characteristics are utilized to make decisions and take action. A later section of this chapter deals in more detail with data handling and assessing its reliability. The analytical data obtained can be evaluated and integrated with other relevant information to address food quality-related problems. Such data are critical not only for quality assurance, but also in product formulation and process design.

V. SAMPLING AND SAMPLE PREPARATION

A. Sample Collection

Sample collection and sample reduction methods must be developed to ensure a representative sample is being subjected to analysis (9, 10). The choice of a sampling plan is affected by four factors: 1) purpose of the inspection, 2) nature of the product, 3) nature of the test method, and 4) nature of the population being investigated (11). Sampling plans are typically applied to heterogeneous (versus homogeneous) populations, for which it is more difficult to obtain a representative sample. Sampling plans are designed to examine either attributes (i.e., to decide acceptability based on whether the sample possesses a certain characteristic, e.g., *Clostridium botulinum*) or variables (i.e., to estimate the amount of a substance or characteristic on a continuous scale, e.g., color). Variable sampling generally requires a smaller sample size than attribute sampling (12).

Three types of sampling plans exist: 1) single (one sample of a specified size, to allow accept/reject decisions), 2) double (select two samples, then make accept/reject decisions after testing one or both samples), and 3) multiple (reject low-quality lots and accept high-quality lots quickly; do further sampling of intermediate quality lots). No sampling plan is free of risks. The two types of risks associated with sampling are consumer risks and vendor risks. The consumer risk is the probability of accepting a poor quality product. The vendor risk is the probability of rejecting an acceptable product.

Sampling may be done manually by a person or continuously using some mechanical system. If operating properly, the continuous sampling should be less prone to human bias than is manual sampling.

Ideally the sampling method is statistically sound. However, sometimes nonprobability sampling is unavoidable. With such sampling, a representative sample of the population cannot be collected. Preferably one can do probability sampling, which has a statistically sound basis to obtain a representative sample and eliminate human error. Probability sampling ensures random samples, and allows calculation of sampling error and the probability of including any item of the population in the sample.

Samples collected for analysis must be clearly labeled in preparation for sample preparation and then analysis.

Samples collected for official or legal purposes must be sealed to protect from tampering, and the chain of custody must be clearly identified.

B. Preparation of Samples

The *Official Methods of Analysis* of AOAC International (7) gives detailed instructions on preparation of specific food samples for analysis, determined by the nature of the food and the type of analysis to be done. Such instructions include size of samples collected, particle size reduction, and storage of samples.

Samples that are too large in mass must be reduced. The mass can be reduced by spreading the sample on a clean surface, dividing into quarters, and collecting the two opposite quarters. The process can be repeated until a sample of manageable size is obtained. The method can be adapted to liquids by using four containers (9).

Grinding is used commonly to reduce particle size so more homogenous samples can be obtained and samples are suitable for analysis. Grinding procedures often specify the mesh size, meaning the number of openings per linear inch of mesh. A 40-mesh size, meaning very small particles, is used for assays that involve an extraction, such as lipid analysis. A 20-mesh size gives larger particles used for moisture or total protein analyses.

The various types of mills used for grinding differ in their mode of action and appropriate applications. A common concern in grinding is the loss of moisture due to air exposure or heating. Grinders are sometimes water cooled to reduce heating, and samples are sometimes ground frozen.

In addition to protecting samples from moisture loss during grinding, it is necessary to handle and store samples in such a way as to avoid several other potential problems. Enzymes naturally present in foods can degrade the food constituents to be analyzed. Enzyme action can be slowed or stopped by freezing, heat denaturation, or other means appropriate for the specific enzyme. Unsaturated lipids and some vitamins and pigments are especially sensitive to oxygen and light. This makes it necessary to store some samples under nitrogen in the dark, or analyzed as soon as possible after collection. Microbial growth in samples prior to analysis can change the chemical composition. Freezing, drying, and chemical preservatives may be used alone or in combination to prevent microbial problems.

VI. SELECTING THE METHOD AND DOING THE ASSAY

A. Objective

The objective of the measurement is a major factor in determining the choice of the method of analysis (1). For example, time-consuming, accurate, official methods are used for nutrition labeling purposes, while rapid, less accurate methods are applicable for on-line measurements. Well-equipped and well-staffed analytical laboratories are the best to utilize methods referred to as reference, definitive, official, or primary. The manufacturing floor in a food processing facility would more appropriately use rapid secondary or field methods. For example, results from the secondary, rapid refractive index method for sugar analysis used on the manufacturing floor can be correlated to the primary method of high performance liquid chromatography used in the analytical laboratory. Likewise, moisture analysis data from a time-consuming forced draft oven method can be related to that of a moisture balance unit used in a pilot plant.

B. Characteristics

The characteristics described and questions raised in Table 41.4 are useful in choosing a method of analysis for a particular application. The characteristics related to validity of the method (i.e., accuracy, precision, specificity, and sensitivity) are critical, and will be discussed further in the next section on data handling. The time, equipment, and personnel availability are major factors to consider. A careful assessment of advantages and disadvantages of methods for particular applications makes it easier to make an appropriate choice.

C. Food Matrix

Some analytical methods are very robust and can be applied to all food types, but most methods are not so widely applicable (13, 14). The major chemical components of a food, i.e., the food matrix, can affect the performance of many analytical methods. Fat, protein, and carbohydrate are the three major food components expected to have the strongest effect on analytical method performance. For example, the high fat or sugar content of certain foods can cause interferences in some assays. Extraction steps and digestion procedures can be necessary and specific, depending on the food matrix. Because food systems are quite complex and varied, one technique for analysis of a particular component cannot be applied to all foods. Rather, multiple techniques and procedures must be considered for application to any particular food matrix.

D. Official Methods

The availability of official methods has made easier the choice of methods for analyzing specific food components and characteristics (1). Such official methods have been carefully developed, standardized, and compiled by several nonprofit scientific organizations. Official methods make it possible to compare results between different laboratories that use the same procedure. These methods also provide a way to evaluate new and more rapid assays.

TABLE 41.4
Criteria for Choice of Food Analysis Methods

Characteristic	Critical Questions	Characteristic	Critical Questions
Inherent properties			
• Specificity/ Selectivity	Is the property being measured the same as that claimed to be measured, and is it the only property being measured? Are there interferences? What steps are being taken to ensure a high degree of specificity?	• Equipment	Is the method very sensitive to slight or moderate changes in the reagents? Do you have the appropriate equipment? Are personnel competent to operate equipment?
• Precision	What is the precision of the method? Is there within-batch, batch-to-batch, or day-to-day variation? What step in the procedure contributes the greatest variability?	• Cost	What is the cost in terms of equipment, reagents, and personnel?
		Usefulness	
		• Time required	How fast is it? How fast does it need to be?
• Accuracy	How does the new method compare in accuracy to the old or a standard method? What is the percent recovery?	• Reliability • Need	How reliable is it from the standpoints of precision and stability? Does it meet a need or better meet a need?
Applicability of method to laboratory		***Personnel***	Is any change in method worth the trouble of the change?
• Sample size	How much sample is needed? Is it too large or too small to fit your needs? Does it fit your equipment and/or glassware?	• Safety • Procedures	Are special precautions necessary? Who will prepare the written description of the procedures and reagents?
• Reagents	Can you properly prepare them? What equipment is needed? Are they stable? For how long and under what conditions?		Who will do any required calculations?

From: SS Nielsen, ed. Food Analysis, 3rd ed. New York: Kluwer Academic, 2003 (Ref. 1).

AOAC International is a volunteer organization dedicated to providing methods that perform with accuracy and precision under usual laboratory conditions. Members of AOAC International select published methods or develop new methods, then collaboratively test the methods in their own laboratories. The program to validate methods is carefully managed, with a specified number of laboratories involved, samples per level of analyte, controls, control samples, and the review process. If methods are found acceptable, they are adopted as official methods (initially as first action, and then as final action). Adopted methods are published in the *Official Methods of Analysis* (7), which is published about every four to five years and contains methods appropriate for a wide range of products and other materials (Table 41.5). New methods and revisions to current methods are published in supplements to the most recent edition of the book.

Other books of official methods of analysis related to foods and ingredients include the following:

1. *Approved Methods of Analysis*, published by the American Association of Cereal Chemists (AACC) (15); methods are mostly applicable to cereal products (e.g., tests for physical dough properties, baking quality, staleness/texture).
2. *Official Methods and Recommended Practices* published by the American Oil Chemists' Society (AOCS) (16); methods are applicable mostly to fat and oil analysis (e.g., vegetable oil, oilseed by-products, detergents, lecithin).
3. *Standard Methods for the Examination of Dairy Products*, published by the American Public Health Association (17); methods are applicable to milk and dairy products; chemical methods are for acidity, fat, lactose, moisture/solids, added water.
4. *Standard Methods for the Examination of Water and Wastewater*, published jointly by the American Public Health Association, American Water Works Association, and the Water Environment Federation (18).
5. *Food Chemicals Codex*, published by the Food and Nutrition Board of the National Research Council/National Academy of Sciences (19); contains methods for the analysis of food additives.

TABLE 41.5
Table of Contents of Official Methods of Analysis of AOAC International, 17th Edition (Ref. 7)

Chapter	Title	Chapter	Title
1	Agriculture liming materials	26	Distilled liquors
2	Fertilizers	27	Malt beverages and brewing materials
3	Plants	28	Wines
4	Animal feed	29	Nonalcoholic beverages and concentrates
5	Drugs in feeds	30	Coffee and tea
6	Disinfectants	31	Cacao bean and its products
7	Pesticide formulations	32	Cereal foods
8	Hazardous substances	33	Dairy products
9	Metals and other elements at trace levels in foods	34	Eggs and egg products
10	Pesticide and industrial chemical residues	35	Fish and other marine products
11	Waters; and salt	36	Flavors
12	Microchemical methods	37	Fruits and fruit products
13	Radioactivity	38	Gelatin, dessert preparations, and mixes
14	Veterinary analytical toxicology	39	Meat and meat products
15	Cosmetics	40	Nuts and nut products
16	Extraneous materials: isolation	41	Oils and fats
17	Microbiological methods	42	Vegetable products, processed
18	Drugs: Part I	43	Spices and other condiments
19	Drugs: Part II	44	Sugars and sugar products
20	Drugs: Part III	45	Vitamins and other nutrients
21	Drugs: Part IV	46	Color additives
22	Drugs: Part V	47	Food additives: Direct

24	Forensic sciences	49	Natural toxins
25	Baking powders and baking chemicals	50	Infant formulas, baby foods, and enteral products

E. Cautions in Analysis

Basic guidelines for performing analytical methods appropriately caution the analyst with regard to proper use of blanks, sources of contamination, and other potential sources of error (e.g., equipment, analyst technique) (20). Problems with blanks, contamination, and other sources of error greatly affect the accuracy and precision and therefore the usefulness of data obtained.

A reagent blank is a sample that contains the reagents used in the sample analysis, in the appropriate quantities, but without any of the material being analyzed. For example, the reagent blank in the phenol-sulfuric acid method for total carbohydrate would contain sulfuric acid and phenol in the appropriate quantities, but water in place of any carbohydrate-containing sample. That reagent blank would be used to zero the spectrophotometer before reading the absorbance of the carbohydrate-containing samples. Use of a reagent blank is especially important in many mineral analyses to account for any mineral contamination in the reagents.

Contamination can be a source of error in many assays, but is especially a problem when the quantities of the compounds of interest in the food are very small. Such is the case in mineral analysis, because mineral levels in the food can be very low and since glassware and the water used can contain significant quantities of minerals. In the case of mineral analysis, any glassware used must be acid washed and reagents must be of the highest analytical grade possible.

Some of the sources of error in analytical methods are often overlooked. Especially when faced with a set of questionable data, the analyst or supervisor must do some problem solving and identify the factors that contributed to the problem. For example, one must ask if the sample analyzed was representative of the sample as a whole, and whether or not it may have been modified in composition and characteristics during sample preparation. Did the analyst follow in detail the analytical procedure? Was the equipment properly standardized and used? Table 41.6 gives a partial list of sources of error that can cause data gathered to be inaccurate and show low precision.

VII. VALIDITY OF METHOD

Validity of the data obtained using a specific analytical method can be assessed in multiple ways. As a first approach to evaluate the usefulness and validity of an analytical method being related to sensory characteristics,

TABLE 41.6
Sources of Laboratory Error

A. Sample Collection and Handling
1. Representative
2. Proper preparation
3. Stability (time, temperature, light, oxygen)
4. Identification throughout analysis

B. Analytical Errors
1. Sample and reagent measurements (weighing, pipetting)
2. Procedural steps (timing, mixing, order of reagents)
3. Range and sensitivity limitation

C. Reagents
1. Preparation; initial and periodic checking
2. Conditions of use (temperature, mixing)
3. Stability; storage conditions
4. Contamination

D. Instruments
1. Limitations
2. Operation
3. Routing checking

F. Calibration
1. Blanks
2. Linearity limits
3. Standards

G. Data Handling

H. Special Problems
1. Personal attitudes and techniques
2. Laboratory water

one should ask a very practical question. How do the differences detected and the variability seen between samples by the analytical method compare to the detected differences and acceptability to a consumer? Also, how does the variability seen between samples by the analytical method compare to the variability of the specific characteristic inherent in processing of the food (1)?

A common test of validity is assessing the inherent characteristics of the method, including accuracy, precision, specificity, and sensitivity, as described in the next section. Of major assistance in assessing accuracy is the use of standard reference materials, which can be obtained from various organizations (e.g., in the United States from the National Institute of Standards and Technology). Control samples internal to the laboratory also can serve as a standard reference material. Such a sample can be prepared by careful selection of an appropriate type of sample (i.e., closely matching the matrix of the samples to be analyzed by a specific method). These control samples should be gathered in a large quantity, mixed and prepared to ensure homogeneity, then packaged in small quantities and stored properly. The control samples can be analyzed routinely when test samples are analyzed. Besides standard reference materials, another test of method accuracy is using check samples (21). Organizations such as the AACC and AOCS offer check sample services, providing test samples to evaluate method reliability. Subscribing laboratories can check the accuracy of their data for specific types of check samples supplied, comparing their values against the statistical norm for those same samples obtained from other subscribing laboratories.

VIII. RELIABILITY OF ANALYSIS AND DATA HANDLING

A. Accuracy and Precision

Reliability of a method is judged largely on its accuracy and precision (22–24). How close the experimental measure is to the correct or true value is referred to as accuracy. How close replicate measures are indicates reproducibility, which is referred to as precision. Standard reference materials or internal control samples are very useful in assessing accuracy since they should provide the true value. The percent relative error is the value commonly used to assess accuracy, comparing the experimental mean to the true value.

$$\% \text{ Relative error} = [(\text{Experimental mean} - \text{True value})/\text{True value}] \times 100$$

Standard deviation (SD) measures the variability of the experimental values (x_i) around the mean ($\bar{x}$), and is the initial value calculated to assess precision:

$$SD = \frac{\sqrt{\Sigma(x_i - \bar{x})^2}}{n} \tag{41.1}$$

With the mean and standard deviation, one can calculate the coefficient of variation, which relates the size of the standard deviation to the mean. This allows one to compare the precision of multiple sets of data for which the mean values differ.

$$\text{Coefficient of Variation (CV)} = \frac{SD}{\bar{x}} \times 100\% \tag{41.2}$$

Other useful terms associated with precision and accuracy are confidence interval, standard error of the mean, and relative deviation from the mean.

B. Specificity

The specificity of a method is how well the method detects and measures the compound of interest, and only

that compound. Some analytical methods are intended to be nonspecific (e.g., lipid extraction with organic solvents), and others very specific (e.g., enzyme test kit to measure glucose). Both types of methods can be very useful, when chosen appropriately for the particular application (22).

C. Sensitivity and Detection Limit

Sensitivity of a method describes how small of a change can be made in the test material before we see a difference in readout from an instrument. This term relates the size of the change in the measuring device to the change in concentration of the compound of interest. Detection limit, a related but different term, describes the lowest possible increment or amount that we can detect with some degree of confidence. Below that lower limit, we cannot be sure if something is present. If one is working near the detection limit for a particular assay, it may be possible to concentrate the sample (22).

D. Standard Curves

For analytical methods, two variables (e.g., concentration and absorbance) are commonly related to one another using a standard curve. The concentration of analyte in a sample is determined by the response measured, which is related to a known amount of standard. Usually a set of standards is prepared at several concentrations, subjected to the assay conditions, and the appropriate analytical measure is taken (e.g., absorbance, volume of titrant, chromatography peak area). Generally, the concentrations of the standards (the independent variable) are plotted on the x-axis, and the measured values (the dependent variable) are plotted on the y-axis, to generate a standard curve. The best-fit line of this relationship is mathematically determined using a mathematical procedure called linear regression, and the equation of the line can be determined. The equation of a straight line is described by $y = mx + b$, where y is the dependent variable, x is the independent variable, m is the slope of the line, and b is where the point on the line intercepts the y-axis (i.e., y-intercept). Ideally all the data points for a standard curve would fall exactly on a straight line, but various sources of error limit this possibility. Values called the correlation coefficient or coefficient of determination can be calculated to mathematically describe how well the data fit a straight line. The equation of that line can be used to calculate the concentration of an analyte of unknown concentration (x), once the measured value (y) for that sample has been determined (22).

E. Reporting Results

Results from analytical methods are commonly reported as a mean and the standard deviation (or some other measure of precision). To appropriately state the sensitivity of the assay and make the data meaningful, one must report the value with the correct number of significant figures. Detailed guidelines exist to help determine the appropriate number of significant figures to report. Rules also exist for rounding off numbers. Generally for analytical procedures, extra numbers are carried forward in the calculations, and the rounding is done on the final answer. Finally, mathematical tests exist for rejecting data obtained that do not match other data gathered. Rejecting data, and therefore excluding them in the final data calculations, must be very carefully considered. It is not the solution to a problem of consistently poor accuracy and precision (22, 24).

42 Analysis of the Chemical Composition of Foods

Eunice C. Y. Li-Chan
Food, Nutrition and Health Program, The University of British Columbia

CONTENTS

I. INTRODUCTION

The chemical composition of a food is of utmost importance from many standpoints, including nutrition and health, toxicology and safety, and stability to microbiological, chemical or physical changes. Analysis of these food components is required for regulatory purposes, to provide the data upon which nutrition labels and health claims are based, and for the information of health-conscious consumers. Food analysis is also used to monitor the stability or, conversely, the deterioration or reactivity of food components as a function of processing or storage conditions throughout the food

distribution chain, which can influence decisions to control parameters for the purpose of quality assurance.

Foods are often characterized by the composition of their chemical components. However, a wide range in the precise levels of those constituents may in fact exist, due to intrinsic biological variability, multiplicity of cultivars and variants of each species, or as a result of geographical location, environmental and seasonal influences, or from the application of genetic engineering. Furthermore, the chemical composition of foods may also be influenced by natural or unintentional contaminants, by processing or upon storage. This potentially wide range of composition and characteristics leads to difficulty in defining the chemical composition of foods, and to issues of validating authenticity or detecting adulteration issues (1).

Given the fact that the constituents comprising foods are very large, both in number and diversity, it is not surprising that the analysis of the chemical composition of foods also encompasses a wide scope as well as a large number of techniques. Chapter 41 describes some key considerations for selecting the most appropriate method, including the objectives of the analysis, nature of the sample, and the available resources. The reported quantity of a food component may depend on the method used for its analysis. There is a need to develop standard specifications for food commodities, as well as more precise nomenclature and detailed description and classification of foods and their components (2), and identification of key foods for food composition research (3). The use of International Network of Food Data Systems (INFOODS) tagnames has been proposed to provide clarity when describing the new nutrient variables (4). Examples of tagnames are described in Tables 42.1 A–D (5).

An overview of the chemical composition of foods can be obtained by conducting proximate analysis, which refers to the measurement of the major components of food, namely moisture, minerals or "ash," lipids, proteins, and carbohydrates. However, even within this simplified classification of food composition, the method of analysis is influential and should be clearly stated when reporting data, as illustrated in the tagnames for fat, protein, and carbohydrate (Tables 42.1 B–D, respectively.).

Further analysis of the composition is often conducted to meet the requirements for nutritional labeling, such as the contents of particular minerals and vitamins, cholesterol, saturated, monounsaturated and polyunsaturated fatty acids, simple sugars, and dietary fiber (6). Table 42.2 lists the nutrients in the United States Department of Agriculture's National Nutrient Database (7), while Table 42.3 shows the nutrients listed in the Canadian "Nutrition Facts Table Core Nutrition Information" as well as the methods of analysis used by the Canadian Food Inspection Agency (8).

More detailed analyses, usually preceded by fractionation and purification steps, are available to determine the precise nature of individual constituents. For example, rapid advances in proteomics have enabled sequence analysis of the multitudes of proteins naturally occurring in a cell, including isoforms or variants that may differ from each other by a single amino acid (9). Similarly, sophisticated instrumental analyses have been developed

TABLE 42.1A
Examples of INFOODS Tagnames Describing Moisture and Ash Contents and Energy Value of Foods

INFOODS Tagname	Component	Comments
<DM>	Dry matter	
<WATER>	Water Synonym: moisture	
<ASH>	Ash Synonym: minerals	
<ENER>	Energy, method of determination unknown Synonyms: kilojoules; kilocalories; calories; food energy	The tagname should be used if it is not known whether the energy value represents gross energy or total metabolizable energy. It should also be used if it is known that the energy value was calculated from the proximate components but the conversion factors used are unknown.
<ENERA>	Energy, gross; determined by direct analysis using bomb calorimetry Synonyms: kilojoules; kilocalories; Calories; food energy	
<ENERC>	Energy, total metabolizable; calculated from the energy-producing food components. Synonyms: kilojoules; kilocalories; calories; food energy	In addition to a value for the quantity of total metabolizable energy, includes a description or listing of the conversion factors used to calculate this energy value from the proximate quantities.

TABLE 42.1B
Examples of INFOODS Tagnames for Selected Food Components Related to Fat and Fatty Acids

INFOODS Tagname	Component	Comments
<FAT>	Fat, total; Synonym: total lipid	
<FATCE>	Fat, total; derived by analysis using continuous extraction	The Soxhlet method has often been used to analyze for total fat using continuous extraction. This method tends to underestimate the total fat value of a food.
<FATRN>	Fatty acids, total trans	
<FASAT>	Fatty acids, total saturated	
<FACID> :	Fatty acids, total	Two data items are required for tagname <FACID>: the total quantity of fatty acids and identification of the conversion factor used to calculate this value from the quantity of total fat.
<FADT>	Fatty acids, total double trans	Some countries are planning actions to limit these acids (not single trans) from foods, e.g., chocolate.
<FAESS>	Fatty acids, total essential	This value is the sum of linoleic acid, linolenic acid, and arachidonic acid.
<FAFRE>	Fatty acids, total free	
<FAMS>	Fatty acids, total monounsaturated	
<FAPU>	Fatty acids, total polyunsaturated	
<FAPUN3>	Fatty acids, total omega-3 polyunsaturated	

Source: Taken from "Tagnames for food components" on the INFOODS website at http://www.fao.org/infoods/tagnames_en.stm (accessed June 18, 2003), from Klensin et al. (5).

for the identification and quantitation of positional and geometric isomers of fatty acids in lipids (10, 11), and the nature of monosaccharide building blocks and their linkages in oligo- or polysaccharides (12).

It is beyond the scope of this chapter to describe all these aspects of food analysis. This chapter will primarily focus on methods for proximate analysis for the composition of major components of foods, and will briefly allude to some of the other components that are part of the nutrition facts listed on food labels in North America. An overview will be given of the principles and considerations behind official methods and some rapid methods of analysis, and some of the recent trends in analysis of chemical composition of foods will be explored.

The reader is encouraged to consult two excellent textbooks by Nielsen (13) and Pomeranz and Meloan (14) for more in-depth discussion on proximate analysis, and other methods of food analysis, as well as the principles behind some of the instrumental methods used in analysis. Primary literature sources such as the *Journal of Food Composition and Analysis* should be consulted for current trends and issues of interest in the analysis of chemical composition of foods. Detailed protocols for official methods of analysis have been compiled by various scientific organizations (e.g., AOAC International, the American Association of Cereal Chemists, the American Oil Chemists' Society, the International Dairy Federation), government agencies (e.g., the Food and Drug Administration in the United States, Health Canada and the Canadian Food Inspection Agency in Canada), and international bodies (e.g., the International Organization for Standardization and the Codex Alimentarius Commission). In addition to publications about methods for analysis, most of these scientific organizations and government agencies have useful information on analysis of chemical composition of foods at their websites. As a good starting point, the reader is encouraged to browse the internet addresses provided in the chapters by Nielsen (15) and Nielsen and Metzger (6). The Compendium of Methods for Chemical Analysis of Foods on the Health Canada website (http://www.hc-sc.gc.ca/food-aliment/csipc/fr-ra/e_chem_analysis_ foods.html) (16) is also a useful resource. Global standards are coordinated by the Codex Alimentarius Commission (for example, see references 17–19), and detailed information such as standards, the current meetings and deliberations of expert committees, etc. are described at its official website (http://www.codexalimentarius.net/index_en.stm#) (20).

II. PROXIMATE ANALYSIS

Pomeranz and Meloan (14) defined proximate analysis as "the determination of the major components (moisture, minerals, carbohydrates, lipids, and proteins)." The data from proximate analysis are typically included in standard tables of composition of foods, such as the U.S. Department of Agriculture Nutrient Database for Standard Reference (7). The following sections provide an overview on the methods that may be used for determining each of the major components in proximate analysis. Many of the methods cited here are official methods of AOAC International (21; accessible also on CD-ROM), and the reader is encouraged to refer to

TABLE 42.1C
Examples of INFOODS Tagnames Describing Protein and Nitrogen Contents of Foods

INFOODS Tagname	Component	Comments
<NNP>	Nitrogen, non-protein	
<NPRO>	Nitrogen, protein	
<NT>	Nitrogen, total	Determined by Kjeldahl method
<PRO->	Protein, total; method of determination unknown	The <PRO-> tagname should be used for a total protein value when it is not known whether the value was the result of a direct analysis or whether it was calculated from total nitrogen, protein nitrogen, or amino nitrogen. The <PRO-> tagname should also be used if it is known that the total protein value was calculated from one of the nitrogen components, but the conversion factor used in the calculation is unknown.
<PROA>	Protein, total; determined by direct analysis	
<PROCN>	Protein, total; calculated from amino nitrogen	Two pieces of data are associated with the tagname <PROCNA>. The first is the quantity of total protein and the second is the conversion factor used to calculate total protein from amino nitrogen. Note: The total protein found in food tables is rarely calculated from amino nitrogen. <PROCNT> is the appropriate tagname for total protein in most cases.
<PROCNP>	Protein, total; calculated from protein nitrogen	Two pieces of data are associated with the tagname <PROCNP>. The first is the quantity of total protein and the second is the conversion factor used to calculate total protein from protein nitrogen. Note: The total protein found in food tables is rarely calculated from protein nitrogen. <PROCNT> is the appropriate tagname for total protein in most cases.
<PROCNT>	Protein, total; calculated from total protein nitrogen	Three pieces of data are associated with the tagname <PROCNT>. The first is the quantity of total protein; the second is a keyword which identifies the source of the conversion factor used to calculate the total protein from total nitrogen; and the third is the actual conversion factor used. If possible, all three pieces of data should be included with <PROCNT>. However, it is acceptable to include only the keyword or the conversion factor (rather than both) with the total protein value if one or the other is unknown. If the conversion factor used was generated from a source other than one of those identified by the available keywords, the conversion factor should be listed without any keyword information.

these methods and the original references cited therein for more detail. The reader is also referred to other chapters in this handbook for descriptions of various spectroscopic techniques and other instrumental methods of analysis, as well as more detailed coverage of protein and fat analysis.

A. Water (Moisture)

The moisture content of foods can range from 0 (e.g., for granulated sugar or vegetable oil) to over 90% (e.g., in raw watermelon or cucumbers) (22). The determination of the water or moisture content of a food and, conversely, of the dry matter or total solids (% solids = 100% − % moisture), is important not only to provide a basis for expressing the content of the other components on a wet- or dry-basis, but also as an important factor in food stability and quality. Moisture assays can be one of the most important analyses performed on a food product and yet one of the most difficult in terms of obtaining adequate precision and accuracy (22).

1. Overview of and Considerations for Moisture Determination

Water may exist in foods in free form, as tightly adsorbed water, or as chemically bound water of hydration. The percentage of water that is actually measured is dependent on the method used for its analysis, and it is therefore important to always state the exact methodology used when reporting

TABLE 42.1D
Examples of INFOODS Tagnames for Selected Food Components Related to Total Carbohydrate, Fibre, Starch, and Sugars

INFOODS Tagname	Component	Comments
<CHO->	Carbohydrate, total; method of determination unknown	
<CHOCDF>	Carbohydrate, total; calculated by difference	This value is calculated using the following formula: 100 g minus total grams of water, protein, fat, and ash
<CHOCSM>	Carbohydrate, total; calculated by summation	This value is the sum of the sugars, starches, oligosaccharides, and carbohydrate dietary fibre.
<CHOAVL>	Carbohydrate, available	This value includes the free sugars plus dextrins, starch, and glycogen.
<CHOAVLM>	Carbohydrate, available; expressed in monosaccharide equivalents	This value includes the free sugars plus dextrins, starch, and glycogen.
<FIBAD>	Fibre; determined by acid detergent method	Includes cellulose, lignin, and some hemicelluloses
<FIBADC>.	Fibre, acid detergent method, Clancy modification	
<FIBC>	Fibre, crude	The crude fibre method of fibre analysis is obsolete
<FIBHEX>	Hexoses in dietary fibre	
<FIBINS>	Fibre, water-insoluble	Sum of insoluble components from the AOAC total dietary fibre method; includes primarily lignin, cellulose, and most of the hemicellulose Values for <FIBINS> may also be obtained by subtracting soluble fibre from total dietary fibre, i.e., by subtracting the value of <FIBSOL> from the value of <FIBTG>.
<FIBND>	Fibre; determined by neutral detergent method	Includes lignin, cellulose, and insoluble hemicellulose
<FIBSOL>	Fibre, water-soluble	Sum of soluble components from the AOAC total dietary fibre method; includes primarily algal polysaccharides, gums, pectins, and mucilages
<FIBTG>	Fibre, total dietary; determined gravimetrically by the AOAC total dietary fibre method	Sum of the water-soluble components and the water-insoluble components of dietary fibre; can be calculated by adding the values of <FIBSOL> and <FIBINS>; includes all non-starch polysaccharides and lignin
<FIBTS>	Fibre, total dietary; sum of non-starch polysaccharide components and lignin	Sum of the polysaccharide components of dietary fibre measured sequentially on the same sample (for example, by using the Southgate colorimetric procedure) plus lignin measured gravimetrically
<FIB->	Fibre; method of determination unknown	Note: Tagname <FIB-> is used to identify fibre values which represent unknown fibre components or which were obtained by unknown methods. Additional tagnames for fibre may be created to identify fibre components or specific methods of analysis that are not currently addressed in this listing.
<STARCH>	Starch, total	The sum of all polysaccharides yielding glucose after hydrolysis with suitable enzymes; includes amylose, amylopectin, glycogen, and dextrins
<STARCHM>	Starch, total; expressed in monosaccharide equivalents	The sum of all polysaccharides yielding glucose after hydrolysis with suitable enzymes; includes amylose, amylopectin, glycogen, and dextrins.
<STARES>	Starch, resistant Synonym: retrograded starch	
<SUGAR>	Sugars, total	Sum of free monosaccharides and disaccharides.

moisture content. Methods for moisture determination include oven drying, distillation, and titration, as well as methods based on physical properties. Some of these methods are described in further detail in the following sections.

In addition to moisture content, water activity (a_w) is often measured and used as an indicator of the availability of water in food for chemical or enzymatic reactions or microbiological growth. Water activity is defined as the ratio of the partial pressure of water above a sample to the vapor pressure of pure water at the same temperature, and is commonly measured by sensors that measure the relative humidity of the sample atmosphere after equilibration, or by a variation of this method known as the chilled mirror technique (22).

It is important to bear in mind that some foods are prone to either gain moisture from or lose moisture to the surrounding atmosphere, depending on the nature of the food constituents, the relative humidity and temperature of the environment, and other parameters such as surface area. Detailed protocols for sampling and sample preparation have been described for different categories of foods (21), and should be followed to ensure that representative samples reflecting the composition of the food can be obtained for the analysis.

2. Oven Drying Methods

The principle of moisture determination by oven drying is based on evaporation of water from the sample, and calculation of moisture based on loss in weight. Oven drying methods are therefore considered as "indirect" methods, since moisture is not actually determined per se.

While the theory behind moisture determination by oven drying is simple, and routine simultaneous analysis of multiple samples is possible, in practice many factors must be considered. The amount of moisture removed during oven drying is influenced by many variables, including the time and temperature of drying, the type of oven used, and the type of sample.

Although the boiling point of pure water is 100°C, the presence of solutes raises the boiling point. This boiling point elevation continues throughout the drying process, as the sample becomes increasingly concentrated upon the removal of water. In theory, the higher the drying temperature, the more complete the moisture removal and the shorter the time required. It has been reported that a temperature of 250°C is required to obtain the true moisture content, assuming no adsorbed water present at the temperature in question (22). However, in practice, volatilization, deterioration, and chemical reactions of the constituents may occur at high temperatures, and it is prudent to use the minimum temperature that will allow moisture removal at an acceptable rate (14, 22). Drying in a vacuum oven may be preferred for some food samples since the boiling point is lower under vacuum, and the absence of air can minimize oxidative reactions especially of high fat samples during drying.

Using vacuum ovens and forced draft or convection ovens, the temperatures and times specified for various products typically range from 70–130°C and 1–16 hours, respectively. For example, the time-temperature combinations are 1 h at 130±3°C for solids (total) and moisture in flour (AOAC Official Method 925.10), 6 h at 70±1°C in a vacuum oven for moisture in dried fruits (AOAC Official Method 934.06), 16–18 h at 100–102°C in an air oven or 2–4 h at ca 125°C in a mechanical convection or gravity oven for moisture in meat (AOAC Official Method 950.46B(a) and (b)). More rapid drying, on the order of minutes, can be accomplished using infrared or microwave ovens for drying. Official methods stipulating different temperature-time combinations or oven types for the same food material have been approved for some

TABLE 42.3
Methods of Analysis Used by the Canadian Food Inspection Agency for the Nutrition Facts Table Core Nutrition Information

Nutrient	Method Reference	Technique
Calories	Atwater Method (Guide to Food Labelling and Advertising, section 6.4.1)	Application of Atwater factors to fat, carbohydrate and protein content
Fat (Sum of fatty acids expressed as triglycerides)	AOAC 996.06*	Capillary Gas Chromatography using SP2560 100m × 0.25mm, 0.2μm film column
Fatty acids: Saturates (all fatty acids that contain no double bonds) *trans* (unsaturated fatty acids that contain one or more isolated or non-conjugated double bonds in trans configuration)	AOAC 996.06*	Capillary Gas Chromatography using SP2560 100m × 0.25mm, 0.2μm film column
Cholesterol	AOAC 994.10*	Direct Saponification and Capillary Gas Chromatography
Carbohydrate (mono- and di-saccharides + starch+ fibre+sugar alcohols+ polydextrose)	By Difference (100-%ash-%moisture-%protein-%fat)	Determination by applicable AOAC method for Ash, Moisture, Protein, Fat
	HPB FA-78**, available carbohydrate, in special cases	Acid and enzymatic hydrolysis followed by redox titration
Fibre	AOAC 992.16* (Mongeau) or AOAC 985.29* (Prosky) (as in Guide to Food Labelling and Advertising 6.4.4.3)	Gravimetric determination after defatting and enzymatic hydrolysis of protein and carbohydrate (starch). (Results found non-compliant by Mongeau method should be confirmed by Prosky method)
Sugars (all monosaccharides and disaccharides)	AOAC 980.13* (modified HPLC column and mobile phase)	Aqueous food extraction followed by HPLC-RI
Protein	AOAC 981.10* AOAC 993.13*	Nitrogen by Kjeldahl or Combustion
Vitamin A (retinol and derivatives and beta carotene expressed as retinol equivalents, RE)	AOAC 992.04* (Method A-12 (version 3.0) 1993**) Determination of Vitamin A in milk, infant formula, and other complex food commodities. JAOAC. 76: 2, 1993	HPLC determination of vitamin A with UV detection
	Method A-7** HPLC Determination of Vitamin A in margarine, milk, partially skimmed milk, and skimmed milk. JAOAC 63: 4, 1980	HPLC determination of vitamin A with UV detection
	Method LPFC-200** The fluorometric determination of Vitamin A in dairy products. J. Dairy Sci. 55:1077 (1992)	Fluorometric determination of vitamin A
Vitamin C (L-ascorbic acid and L-dehydroascorbic acid and their derivatives, calculated as mg equivalents L-ascorbic acid)	HPLC-C1 (1992)** Determination of vitamin C by HPLC. foods, e.g., AOAC Official Methods 925.23, 990.19, and 990.20 for solids (total) in milk. The final choice of the appropriate method may depend on factors such as the need for speed, or further analyses using the dried material, or the availability of equipment. In order to determine the optimal temperature and time for drying of specific food products or using new equipment not described in the official methods published by scientific organizations, analysts should conduct their own trials and establish the appropriate conditions based on the resultant drying curves.

Additional steps conducted prior to oven drying are recommended for some types of samples. For example, a two-stage drying process involving a steam bath for predrying is frequently suggested for liquid products, while air-drying and grinding are performed prior to oven drying for samples such as bread or grain. Since surface area and porosity of the sample influence rate and efficiency of drying, and since surface crust formation, or case hardening, can impede moisture removal, sand or other inert material may be added prior to drying of food materials which have a tendency to lump together or to form a surface crust, such as dehydrated fruits or other foods high in sugar.

3. Distillation Methods

The moisture content of spices, nuts, oils and other foodstuff with relatively low moisture content can be measured directly through distillation methods (e.g., AOAC Official Methods 986.21 and 969.19 for spices and cheese, respectively). Water is co-distilled with an immiscible solvent with a high boiling point; the distilled water is condensed, collected, and measured in a collecting vessel or trap. Since direct measurement of water is involved, distillation methods can provide better accuracy and precision than oven drying methods based on weight loss, especially for low-moisture samples. However, it should be noted that samples are still exposed to high temperatures during distillation, and therefore these methods are not suitable for analysis of heat-sensitive foods. In addition, distillation techniques are not easily amenable to routine testing of multiple samples.

4. Chemical Methods – Karl Fischer Titration

The Karl Fischer titration method is suitable for low-moisture foods that are sensitive to decomposition or volatilization under vacuum or high temperatures, such as dried fruits and vegetables (AOAC Official Method 967.19), candies and chocolates (AOAC Official Method 977.10), roasted coffee beans, oils and fats (AOAC Official Method 984.20). Several modifications of the original Karl Fischer method, which was based on the colorimetric detection of a stoichiometric reaction involving the reduction of iodine by sulfur dioxide in the presence of water, have been proposed over the years, leading to the commercial availability of titration units that automatically dispense the required proportions of reagents and titrants for conductometric or coulometric assay, and provide digital displays of the calculated moisture content.

5. Physical Methods

Physical methods of moisture determination are based on the measurement of various physical properties of food samples, such as dielectric constant, conductivity, specific gravity or density, refractive index, freezing point, or absorption of energy in the mid- or near-infrared spectrum, followed by comparison to the corresponding properties of standards with known moisture content (22). For example, hydrometry using a calibrated lactometer is applied to determine the total solids content of milk

(AOAC Official Method 925.23B), while refractometry is used to determine solids in syrups (AOAC Official Method 932.14C). Near-infrared spectrophotometry is used for water content in dried vegetables (AOAC Official Method 967.19), while mid-infrared spectroscopy forms the basis for using IRMA (Infrared Milk Analyzers) for proximate analysis of milk, including solids, fat, lactose, and protein (AOAC Official Method 972.16).

Physical methods often provide rapid analysis of large numbers of samples, but it is important to bear in mind that the relationship between the measured physical property and the moisture content of the specific food sample must be known, either by reference to published tables of standard composition for that food, or by construction of standard curves by the analyst.

B. Ash

Ash is defined as the inorganic material remaining after oxidation of organic matter, and is used to refer to the total minerals in food. The ash content of unprocessed fruits and vegetables typically ranges from about 0.4% in raw tomatoes (23) to 4% in beans (14). Pure fats and oils contain practically no minerals, while the ash content of salted butter is about 2.1%. Similarly, fresh meat and poultry contain about 1% ash, while dried and salted beef may contain as high as 12% ash (14). Milling of wheat yields white flour with 0.47% ash, or whole wheat flour with 1.60% ash (7). The determination of ash content may thus be used as an indicator of the extent of processing of a food commodity, or of the addition of salt to foods.

1. Overview of and Considerations for Ash Determination

Minerals in foods may occur as complexes with other minerals, or with macromolecules such as proteins. The incineration or oxidation of organic matter during ashing may result in volatilization of some minerals, or formation of new complexes of other minerals, as summarized by Pomeranz and Meloan (14). Both the amount and the composition of ash that remains after incineration or oxidation therefore depend on the nature of the food and the method of ashing. This is an important consideration in selection of the ashing method and conditions, especially if further analysis of specific minerals (e.g., Ca, Zn, Fe, and so on) is required (24).

Since minerals often constitute 1% or less of the total wet weight of a food sample, it is critical that contamination of the food with metals or their salts be avoided. Potential sources of trace metal contaminants include glassware, grinders or metal blades used for sample preparation, and the crucibles used to hold the samples during ashing.

The two main methods of ashing, which are termed dry ashing and wet ashing, are described in the following sections.

2. Dry Ashing

Dry ashing involves the incineration of samples in a muffle furnace at high temperatures ranging from 400–700°C and typically around 525 or 550°C for 12–18 hours, until a light gray or white powder remains (14). The residue after incineration is weighed as a direct measure of the ash content.

Some modifications of the basic dry ashing procedure are required depending on the sample. High fat or moisture content may cause smoking or spattering during ashing of samples. Therefore, liquid samples may be pre-dried, and fat from high fat samples should be extracted with a solvent, prior to ashing. In most cases, dry ashing can be performed using the solids remaining after oven-drying or solvent extraction conducted for moisture or fat determination, respectively. A few drops of ashless olive oil may be added to animal products, syrups, and spices, to allow steam to escape as a crust is formed on the product (23). Incomplete combustion, especially in high sugar samples, is manifested by the appearance of black or carbon residues in the ash, and requires re-suspension in water or acid, followed by re-ashing (e.g., see AOAC Official Method 900.02, for ash of sugars and syrups). Acceleration of dry ashing may be achieved by the addition of an ethanol solution of magnesium acetate. The magnesium acetate method for ash content of flour (AOAC Official Method 936.07) uses a temperature of 700°C for ashing, compared to 550°C for the direct method (AOAC Official Method 923.03). New microwave muffle furnaces with temperatures reaching up to 1200°C can also reduce ashing time to minutes instead of hours (23).

Dry ashing is simple in both theory and practice, and simultaneous analysis of many samples is feasible. However, as noted in the preceding section, the composition of the minerals in the residue is not usually identical to that in the original food sample, and it is assumed that losses due to volatilization or other causes are compensated by gains due to formation of new complexes such as oxides. Formation of fusion complexes between some minerals means that the dry ash is not usually suitable for further analysis of specific mineral content. To address this, a method of dry ashing of different categories of foods for determination of individual contents of Na, K, Ca, Mg, Fe, Zn, Cu, and Mn was established by the Health Protection Branch Laboratories of Health Canada (25). The protocol involves dry ashing at 450°C for 16 hours, followed by addition of water and nitric acid, evaporation to remove the acid, and re-ashing at 375°C for another hour. Lanthanum and cesium solutions are added as ionization suppressors, to allow determination of Ca, Mg and Na, K, respectively.

3. Wet Ashing

Wet ashing is also referred to as wet oxidation or wet digestion. It involves the oxidation or digestion of organic matter by heating in the presence of concentrated acids such as nitric acid, sulfuric acid (usually with hydrogen peroxide) or perchloric acid, either singly or in combination. A typical wet ashing procedure involves heating or boiling of the sample with concentrated sulfuric and nitric acids, at about 200°C, until white fumes from decomposing sulfuric acid are observed; additional nitric acid is then added, and boiling or ashing of the sample is continued until a clear or light yellow solution is obtained (23).

Due to the lower temperatures and shorter times involved in wet ashing, less volatilization or fusion of minerals occurs, compared to dry ashing. The minerals usually stay in solution after wet ashing, and further analysis of the composition of individual minerals may be performed, for example, using atomic absorption spectrophotometry or inductively coupled plasma emission spectrophotometry. Despite these advantages of wet ashing for specific mineral composition, wet ashing is not usually preferred over dry ashing as the method for total ash content determination. This is because of the dangers of using corrosive acids, especially perchloric acid which is potentially explosive, specifically in the presence of undigested biological components, and the relatively limited number of samples which can be analyzed at one time. Combination dry-wet ashing methods have been proposed, for example, for analysis of minerals in infant formula (AOAC Official Method 985.35). Specially designed microwave ovens have also been proposed for safer and quicker wet ashing of sample, using either open-vessel or closed-vessel digestion systems depending on the amount of sample and the temperatures required for digestion (23).

C. Fat

The term "fat" is often used synonymously with "lipid" or "oil" to represent food components that are insoluble in water but are soluble in organic solvents (14). The fat content of foods varies widely, from less than 1% in many fruits and vegetables, to almost 100% in lard, shortening, or vegetable oils (7).

1. Overview of and Considerations for Fat Determination

The methods for fat determination may be generally classified into (i) methods that involve solvent extraction of fat from the food, followed by gravimetric, volumetric, or other means of measurement of the fat, and (ii) instrumental methods that measure the fat content based on its physical properties in the food, in comparison to standards of known composition. Other methods involving extraction of fat without the use of solvents have also been developed.

Methods using solvent extraction in fat analysis are based on the functional definition of fats, as substances that are insoluble in water but soluble in organic solvents. However, this functional definition of fat does not give the true picture of its heterogeneity in terms of chemical composition. Fat in foods consists primarily of highly non-polar or hydrophobic molecules classified as triacylglycerols, with smaller amounts of di- and mono-acylglycerols, sterols, and the somewhat more polar molecules such as phospholipids and sphingolipids. Minor components such as fat-soluble vitamins, pigments, or hydrocarbons are also included as "fat" when defined by the property of solubility, whereas free fatty acids, especially the shorter chain fatty acids, may be water-soluble and therefore not included as fat.

In addition to heterogeneity in the type of molecule, further diversity of fat composition exists as a function of the chain length as well as saturation or degree of unsaturation of the hydrocarbon chain of fatty acid constituents of fats. Depending on the exact chemical composition, the constituents of "fat" in a particular food sample may encompass a wide range on the polarity scale. Consequently, the composition as well as the efficiency of extraction of these different components of fat from food are dependent on the polarity of the solvent used for extraction. Furthermore, fats in foods frequently occur in bound form, for example, as non-covalent complexes with proteins or carbohydrates, or as lipoproteins or glyco-lipids. Organic solvents do not usually extract the fat molecules in these bound forms, unless they are released prior to extraction by pre-treatment with mild acid, alkali, or enzymatic digestion. The fat content determined by direct extraction with non-polar solvents is usually termed "crude fat," while that determined by extraction after a pre-treatment may be referred to as "total lipids."

It is worth noting that the "total lipid (fat)" content reported in the USDA Nutrient Database, and identified as "nutrient 204," was determined for most foods by gravimetric methods such as those using ether or chloroform-methanol solvent extraction, or by acid hydrolysis (7). However, "Nutrient 204 may not be identical to the fat level declared on food labels under the Nutrition Labelling and Education Act of 1990 (NLEA). Under NLEA, fat is expressed as the amount of triglyceride that would produce the analytically determined amount of lipid fatty acids" (7). Similarly, the fat content reported in the "Nutrition Facts Table Core Nutrition Information" on food labels in Canada (Table 42.3) is also based on the sum of fatty acids, expressed as triglycerides, analyzed by capillary gas chromatography (AOAC Official Method 996.06).

2. Solvent Extraction Methods

Solvent extraction may be continuous (e.g., the Goldfish method), semi-continuous (e.g., the Soxhlet method for cereals AOAC Official Method 920.39C), or discontinuous

(e.g., Mojonnier method for milk fat AOAC Official Method 989.05).

In the continuous method of solvent extraction, evaporating solvent from a boiling flask continuously condenses onto the dried sample held in a thimble. The solvent, carrying fat extracted as solvent drips through the sample, is collected back in the boiling flask. After completion of extraction, typically 4 hours to overnight (depending on the rate of solvent dripping through the sample), the solvent is evaporated from the extraction flask by air-drying overnight followed by brief oven drying, and the fat remaining in the flask is weighed. The semi-continuous solvent extraction method is similar except the extraction apparatus is constructed to allow solvent to remain with and soak the sample for 5–10 minutes, prior to returning to the boiling flask. In this manner, the sample is surrounded by solvent, thus avoiding channeling of solvent and providing for a more complete extraction of fat from the sample. For this reason, the semi-continuous methods, particularly the Soxhlet method, are often considered the standard methods for fat analysis of dried samples (26, 27).

For efficient extraction by both the Goldfish and the Soxhlet methods, it is important that samples are dried and ground to small particle size to maximize the surface area for extraction. Efficient extraction by organic solvents can only be achieved on dry samples, due to the inability of the organic solvents to penetrate the water phase of wet samples. Ethyl ether and petroleum ether are the most commonly used solvents for extraction by these methods. Ethyl ether is slightly more polar than petroleum ether and is a better solvent for fat. However, sample drying becomes essential to avoid extraction of non-fat components by ethyl ether; in addition, ethyl ether has a tendency to form peroxides and is more flammable than petroleum ether. Petroleum ether is cheaper, less dangerous and preferred over ethyl ether if a more selective solvent for hydrophobic lipids is desired (26).

The Roese-Gottlieb and the Mojonnier methods (AOAC Official Methods 905.02 and 989.05, respectively) are official methods for analysis of fat in milk, involving the release of bound fat by alkaline digestion with ammonium hydroxide, addition of ethanol, followed by sequential, discontinuous extraction of fat using ethyl ether and petroleum ether. The extractions are repeated three times and carried out in flasks designed to facilitate decanting of the fat-containing organic solvent (top layer) from the aqueous solution (bottom layer) during extraction. The fat-containing solvents from the repeated extractions are pooled, the solvent is removed by evaporation, and the weight of the fat is measured to determine the fat content. The Mojonnier method, using acid instead of alkali pre-treatment, has been modified for determination of fat content in flour (AOAC Official Method 922.06) and pet food (AOAC Official Method 954.02).

As an alternative method to gravimetric measurement (i.e., by weight), the measurement of refractive index has been proposed as a method to determine fat that has been extracted by solvent (14, 26). Fat is extracted using a discontinuous method with a solvent such as bromonaphthalene, which has a refractive index that is different from the fat to be extracted. The fat content is calculated by comparing the refractive index measured for the solvent containing the extracted fat, to the refractive index of solvent alone and that of the standard fat. The refractive index method has been reported to yield values of fat content comparable to the crude fat content measured gravimetrically.

For all of the solvent extraction-based methods, the content of fat analyzed depends on whether or not pretreatments such as addition of acid or alkali to release bound fat have been performed, as well as the polarity of solvent used for extraction. For example, the content of "fat (crude) or ether extract in flour" (AOAC Official Method 920.85) would be expected to differ from that of "fat in flour – acid hydrolysis method" (AOAC Official Method 922.06). Many researchers have reported that the amounts of extracted lipid as well as non-lipid material increase with the polarity of solvents used for extraction. The binding of lipids to other molecules such as carbohydrates and proteins, and the differing abilities of solvent or solvent mixtures to solubilize lipid classes has led to the concept of "total lipid extract" and "extractable lipid" (28). Even with ammonia pretreatment to release bound lipids, the Roese-Gottlieb method was reported to grossly underestimate the total lipid content of samples such as chocolate powder, liquid milk, and eggs (28); this could be due to the use of relatively non-polar solvents, ethyl and petroleum ethers, for extraction after hydrolysis. More polar solvent mixtures such as dichloromethane-hexane (1:4) or acetone-hexane (1:4) have been suggested to improve the efficiency of extraction from dry solid samples using the Soxhlet method (28). For wet or liquid samples, specific ratios of chloroform and methanol are used in combination with water in the Bligh and Dyer method (29) and in AOAC Official Method 983.23 for determining "fat in foods" after enzymatic hydrolysis. In a modified Bligh and Dyer procedure, methanol is replaced by propan-2-ol, and chloroform is replaced by cyclohexane, with a ratio of 11:8:10 for water:propan-2-ol:cyclohexane; the modified procedure has the advantage that the extracted lipid is in the top (cyclohexane) layer of the extraction mixture, compared to the bottom layer when chloroform is used (28).

3. Non-Solvent Separation Methods

The Babcock method for milk fat (AOAC Official Methods 989.04 and 989.10) is the best-known example of a non-solvent wet extraction or separation method for fat analysis. Concentrated sulfuric acid (with specific gravity of 1.82–1.83 at 20°C) is added to a specified weight of milk sample in the Babcock bottle, digesting protein and generating heat, and thus releasing bound fat from the sample. The acid also functions to increase the

density of the aqueous layer. Subsequent centrifugation at 55–60°C and addition of hot water at that temperature cause the fat layer to float on top of the aqueous layer into the calibrated neck of the Babcock bottle, where the percentage of fat content is read directly from the volumetrically calibrated markings.

The Babcock method has been adapted for determination of fat in other dairy products such as cream and cheese, as well as for essential oil in flavor extracts (AOAC Official Method 932.11) and fat in seafood (AOAC Official Method 964.12) (26). Similar to the Mojonnier method, the Babcock method can be applied to wet or liquid as well as dried samples, and includes a pre-treatment to release bound fat. However, it should be noted that fat components with high specific gravity, such as phospholipids, will not float to the top layer and therefore will not be included in the volumetric measurement for fat after centrifugation.

4. Instrumental Methods and Comparison to Standard Solvent Extraction Method

An automated turbidimetric method (AOAC Official Method 969.16) has been developed to determine fat in milk. In this method, EDTA is added to dilute the sample and to eliminate turbidity due to the casein protein. Homogenization is then used to form uniform fat globules, which may then be determined by measurement of turbidity, which is related to fat content through comparison to a standard curve.

Fat content of foods can also be analyzed using various other instrumental methods measuring such properties as density, nuclear magnetic resonance, x-ray absorption, dielectric constant, or infrared spectra (26). The differences in these properties between fat molecules and other food components form the basis for relating the measurement of these properties to the fat content. These methods are usually rapid and do not require extraction of fat from the food prior to analysis. However, it is important to construct standard curves for the specific food being analyzed, in order to determine the quantitative relationship between the particular physical property being measured by the instrumental method, and the fat content of standards with known composition, usually determined by solvent extraction methods such as the Soxhlet method.

Vogt et al. (27) compared four rapid methods to the standard Soxhlet extraction method for fat measurement in fish herring. The four methods were (i) the Torry Fatmeter based on dielectric properties of water, and intercorrelations between fish water and fat contents; (ii) microwave drying and calculation of fat from water content; (iii) near-infrared reflectance (NIR) spectroscopy with partial least-squares regression analysis; and (iv) fexIKA Soxhlet solvent extraction instrument modified to include filtration under reduced pressure. The NIR method gave the best prediction of the standard method (Soxhlet), while other methods gave lower fat content values. However, the NIR instrument is relatively expensive. In comparison, the microwave method is low cost, requiring only a microwave oven, and the Torry meter is moderately priced. The Soxhlet and fexIKA were also both considered to have the disadvantages of being time-consuming and requiring solvents.

D. Protein

Proteins are macromolecules composed of amino acids linked together through amide or peptide bonds to form polypeptide chains, which can range in molecular mass from a few thousand to over a million daltons. Proteins contribute to the nutritional value as well as textural and sensory properties of foods, and they also perform structural and biologically important functions. The protein content of foods ranges from less than 1–2% in fruits and vegetables, to 20–30% in meat, legumes, and dairy products (30).

1. Overview of and Considerations for Protein Determination

The most common official method for determination of protein content in food is based on measurement of total nitrogen content using the Kjeldahl method, followed by multiplication by a conversion factor to calculate the protein content. The Dumas (nitrogen combustion) method is also based on the principle of nitrogen determination and conversion to protein content. A number of other methods, mostly colorimetric or spectroscopic methods, are based on quantifying either the peptide bonds or particular side chains of the amino acid residues, and may be useful as rapid methods for quality control or research. These latter methods require calibration of the measured property, such as absorbance or color intensity, using standards of known composition, usually determined by nitrogen analysis, or sometimes by gravimetric analysis.

Many factors can affect the accuracy of analyzing protein content in food through measurement of its nitrogen content. Proteins are composed of amino acids whose chemical structures include hydrogen, carbon, nitrogen, oxygen, and sulfur atoms. Of these elements, nitrogen is considered most distinctive for proteins in comparison to other components considered in proximate analysis, since each of the twenty amino acid building blocks contains a nitrogen-containing amino (or imino) group. However, the side chains of these amino acids differ greatly, ranging from hydrocarbon chains containing primarily carbon and hydrogen atoms, to aromatic groups and polar or ionic groups that also contain sulfur, oxygen, or nitrogen atoms. Since proteins contain different combinations of the amino acids, each of which contains a different percentage of nitrogen in its chemical structure, the percentage of nitrogen can vary greatly between different proteins. Use of the correct conversion factor is required if an accurate estimation of protein is to be expected.

A nitrogen-to-protein conversion factor of 6.25 is commonly used to calculate the protein content of a food from the nitrogen content determined by Kjeldahl or combustion methods. This factor assumes an average of 16% (= 100 / 6.25) nitrogen content in proteins, i.e., 16 grams of nitrogen per 100 grams of protein. However, depending on the amino acid composition of the particular protein, the actual conversion factor may deviate from 6.25. For example, the conversion factors are 6.38, 5.70, and 6.25 for dairy products, wheat, and almonds, respectively (30), and 4.74, 5.3, 4.38, and 5.7 for chocolate and cocoa, coffee, mushrooms, and yeast, respectively (7). The conversion factor and source of information for the factor should be stated in listing protein content, as illustrated by some of the tagnames listed in Table 42.1C.

The presence of non-protein nitrogen in foods is another important consideration that may affect the accuracy of protein determination that is based on nitrogen measurement. Foods may contain varying levels of free amino acids or small peptides, ammonium salts, urea, uric acid, vitamins, amino sugars, nucleic acids, phospholipids or other constituents that contain nitrogen in their chemical structure. If unaccounted for, the contribution of nitrogen from these non-protein nitrogen sources will result in an over-estimation of protein content. Methods have therefore been established, using trichloroacetic acid or other protein precipitant, to enable distinction between protein and non-protein nitrogen. For example, AOAC Official Methods 991.20, 991.21, 991.22, and 991.23 describe methods for milk total nitrogen, non-protein nitrogen, protein nitrogen by direct method, and protein nitrogen by indirect method, respectively.

Due to the long period of time to perform Kjeldahl analysis and the necessity to determine the difference between non-protein nitrogen and total protein nitrogen, spectrophotometric or colorimetric methods for total proteins are commonly used as rapid methods suitable for research or quality control. However, there are potential interferences and other considerations that must be kept in mind when using these rapid methods (30–32).

An overview of the main methods for protein analysis based on total nitrogen analysis, and spectrophotometric, colorimetric, or other instrumental methods for protein analysis, are described in the following sections. For more details, the reader should refer to the chapter on protein analysis in this Handbook, and to an excellent book on this topic written recently by Owusu-Apenten (31).

2. Methods for Total Nitrogen Analysis

In the Kjeldahl method for total nitrogen analysis, the protein and other organic molecules in foods are digested by concentrated sulfuric acid in the presence of catalysts. The nitrogen is present in the acid digest in the form of ammonium sulfate, and may be analyzed either by an acid-base titration of the nitrogen after neutralization and distillation of the resulting ammonia, or by other techniques including nesslerization or colorimetric reaction with a phenol hypochlorite reagent (30). The Kjeldahl method is described in AOAC Official Method 920.87 for protein (total) in flour or AOAC Official Methods 928.08 and 981.10 for nitrogen or crude protein, respectively, in meat. Various modifications of the original method have been proposed over the years, implementing copper as an alternative catalyst to mercury (AOAC Official Methods 984.13 and 2001.11), semi-automation or automation (AOAC Official Methods 976.05, 967.06, and 990.02), and analysis of microgram quantities of nitrogen (AOAC Official Method 960.52).

In the Dumas (also known as nitrogen combustion or pyrolysis) method, the samples are subjected to very high temperatures up to 1000°C. Nitrogen that is freed by pyrolysis and subsequent combustion at high temperature in pure oxygen, is then quantitated by gas chromatography and thermal conductivity. Official methods based on combustion have been established, for example, for animal feed, meats, cereal grains and oilseeds, and fertilizers (AOAC Official Methods 990.03, 992.15, 992.23, and 993.13, respectively).

Both the Kjeldahl and the combustion methods determine total nitrogen, so the correct nitrogen-to-protein conversion factor and the contribution of non-protein nitrogen to the total nitrogen content must be considered for an accurate determination of protein content. The analyte is referred to as "crude" protein in the AOAC Official Methods, when total nitrogen is determined without correcting for non-protein nitrogen. Combustion methods have the advantages of speed of analysis, and avoidance of corrosive and toxic reagents, compared to the Kjeldahl method, but the expenses of the equipment and high-purity oxygen must be considered.

3. Spectrophotometric Methods

Aromatic amino acids (tryptophan, tyrosine, and phenylalanine) and peptide bonds absorb electromagnetic radiation in the ultraviolet (uv) region near 257–280 nm and 190–205 nm, respectively (33). The intensity of uv absorbance can be related to the content of those groups and, therefore, to the protein content of a solution.

Spectrophotometric methods are simple in principle, but only applicable to samples that are non-turbid solutions of relatively pure protein composition. Since the content of aromatic amino acids differs between proteins, and since the extinction coefficient and wavelength of maximum absorbance are characteristic for each of the three aromatic amino acid types, this method for protein analysis requires standard curves or tables, such as those compiled by Fasman (33), relating the absorbance at a particular wavelength to the concentration of the specific protein. The uv absorbance of the peptide bond is less dependent on the nature of the amino acid side chains.

However, the absorbance of ultraviolet radiation in this wavelength region by other food components, such as organic acids, nucleic acids, triacylglycerols, etc., may result in considerable interference and inaccuracy in relating the absorbance directly to protein content in complex foodstuff.

4. Colorimetric Methods

A number of colorimetric methods have been established for determination of protein content, based on the development of color upon reaction with either the peptide bonds or with particular functional groups of the proteins. Colorimetric methods based on reaction with peptide bonds, such as the biuret, Lowry, and bicinchoninic acid (BCA) methods, show relatively low protein-to-protein variability in the relationship between colorimetric intensity (absorbance) and concentration for different proteins. Protein-to-protein variability is much greater for methods that are based on reaction with specific functional groups on the amino acid side chains, since the amino acid composition of the protein as well as the protein content will affect the resulting colorimetric response. The Bradford or Coomassie Brilliant Blue method is presently the most common example of the latter class of methods, although Acid Orange 12 and Amido Black 10B were established as official dye-binding methods for protein in milk in 1967 and 1975 (AOAC Official Methods 967.12 and 975.17, respectively).

The Bradford method is based on a change in the wavelength and intensity of absorbance (color) of the reagent dye Coomassie Brilliant Blue G-250, when it is bound to proteins, particularly at basic amino acid side chains and enhanced by hydrophobic interactions. The biuret method is based on the development of a blue color upon complex formation of cupric ions with peptide bonds in alkaline solution, while the Lowry method combines the biuret reaction with reduction of the Folin-Ciocalteau phenol reagent by tyrosine and tryptophan residues in proteins, and the BCA method involves the reduction of cupric to cuprous ions by peptide bonds under alkaline solution, followed by development of a purplish color upon formation of cuprous ion complexes with the BCA reagent. The absorbance is read at 595, 540, 700, or 562 nm for the Bradford, biuret, Lowry, and BCA reactions, respectively, and the protein content is determined using a standard curve. As noted above, due to protein-to-protein variability, the selection of the appropriate protein for the standard curve is important, especially in the case of the Bradford method. The Bradford, Lowry, and BCA methods have greater sensitivity and lower limit of detection than the biuret reaction. Selection of the most appropriate method depends on considerations with regard to potential interferences from other constituents in the sample, availability of the appropriate protein standard for calibration, and the sensitivity that is required (30, 31).

5. Infrared Spectroscopy

Infrared spectroscopy may be used to determine the protein content of foods by relating the absorption of infrared radiation at wavelengths assigned to the peptide bond of proteins. This technique is rapid, may be applied to solid as well as liquid samples in the presence of other food constituents, and is not affected by non-protein nitrogen or amino acid composition. However, calibration must be conducted using standard curves relating the infrared absorption to protein content. Examples of mid-infrared and near-infrared spectroscopy for protein content include the official methods for protein (crude) in forages (AOAC Official Method 989.03) and for protein in milk (AOAC Official Method 972.16).

E. Carbohydrate

Carbohydrates in foods include monosaccharides (particularly D-glucose and D-fructose), disaccharides (e.g., sucrose, lactose, maltose), higher oligosaccharides (e.g., raffinose, stachyose and fructo-oligosaccharides) and polysaccharides (e.g., starch, food gums and hydrocolloids, pectin, hemicellulose, cellulose) (34, 35). The sugar alcohols, such as sorbitol, mannitol, xylitol, lactitol, and maltitol, are also considered as carbohydrates (34). Carbohydrates are important from a nutritional point of view, whereby metabolic energy is provided by digestible carbohydrates including simple sugars (monosaccharides, starch) while dietary fiber is obtained from the indigestible fraction. Polysaccharides also play a crucial role in textural properties of foods, while mono- and disaccharides may take part in reactions such as Maillard browning or caramelization, thereby imparting characteristic flavor and color to foods.

The total carbohydrate content of foods ranges from negligible (e.g., in chicken breast meat) to over 80% (e.g., in honey and breakfast cereals such as corn flakes) (35).

1. Methods and Considerations for Total Carbohydrate Determination

In proximate analysis for nutrition labeling, the total carbohydrate content of a food is usually calculated by subtracting the weights of moisture, ash, total fat, and crude protein from the total weight of the food (8, 35). When alcohol is present, it is also subtracted from the total weight in the calculation of carbohydrate by difference (7). It should be noted that protein calculated from total nitrogen, which may contain non-protein nitrogen, is used in determining carbohydrate by difference (7).

Although the calculation of carbohydrates by "difference" has a long history of usage as the method for determining total carbohydrates reported in food tables or nutrition labels, there are several problems with this

approach (34). Firstly, it includes a number of non-carbohydrate components such as lignin, organic acids, tannins, waxes, and some Maillard browning products. Secondly, it incorporates the sum of all of the analytical errors from determination of the other analytes in proximate analysis. Thirdly, a single value for "total carbohydrates" is not very informative with regard to nutritional value, as it fails to distinguish between the distinct physiological properties of different classes of carbohydrates (34).

The phenol-sulfuric acid method may also be used to estimate total carbohydrates (35). Heating of carbohydrates in the presence of strong acids produces furan derivatives and their polymers, which condense with various phenolic substances, including phenol itself, to yield a yellow-orange color. The absorbance at 490–500 nm is related to the concentration of carbohydrate using a standard curve. Although the phenol-sulfuric acid method is applicable to different classes of carbohydrates from monosaccharides to polysaccharides, the relationship between absorbance and concentration, and even the wavelength of maximum color intensity, are dependent on the chemical composition of the carbohydrates. Therefore, accuracy is dependent on selecting the appropriate reference carbohydrate or carbohydrate mixtures to prepare the standard curve, which is a difficult task in reality since most foods are composed of complex mixtures of carbohydrates. Incorporation of additional sample purification steps such as selective precipitation may be helpful to address this problem (e.g., AOAC Official Method 988.12E for dextran in raw cane sugar).

Finally, rather than calculating total carbohydrates by "difference," or by chemical methods for total carbohydrate determination such as the phenol-sulfuric acid method, an alternative approach involves the direct measurement of the individual components, which are then combined to give a value for total carbohydrates (34). In addition to information on total carbohydrate content, the various classes or sub-classes of the individual components may be reported, such as total simple sugars, starch, dietary fiber, etc. Mono- and disaccharides may be analyzed specifically by enzymes, gas-liquid chromatography (GLC), or high performance liquid chromatography (HPLC). Polyols and oligosaccharides are also usually determined by GLC or HPLC methods. Starch analysis is based on enzymatic degradation, followed by determination of the liberated glucose. Non-starch polysaccharide-analysis involves removal of starch enzymatic hydrolysis products and other low-molecular-weight carbohydrates, followed by hydrolysis of the non-starch polysaccharides to its monomeric constituents for analyisis. Although a number of methods have been established in the past for determination of crude fiber, acid-detergent fiber, neutral detergent fiber, etc. (e.g., see Table 42.1D), it is recommended that dietary fiber be determined by the enzymatic-gravimetric methods of Prosky and co-workers or Lee and co-workers, or the enzymatic chemical methods, such as that of Englyst and co-workers (34). Examples of the enzymatic-gravimetric method are AOAC Official Methods 985.29, 991.42, 991.43, and 993.19, for determining insoluble, soluble, and total dietary fiber.

III. OTHER COMPONENTS

As shown in Tables 42.2 and 42.3, in addition to conducting proximate analysis for the major food components described in Section II, further analysis is required to provide information on nutrition labels in the United States and Canada, respectively, and similar regulatory requirements are found in many countries internationally. This additional information includes the energy or caloric content, the contents of subclasses of fatty acids and carbohydrates, and the contents of a number of other components that may be minor in quantity but are of major importance as nutrients.

The specific methods recommended for analysis may vary between different countries. International standards are described in the FAO/WHO Codex Alimentarius Methods of Analysis and Sampling (19). The list of methods used by the Canadian Food Inspection Agency or CFIA (Table 42.3) to verify nutritional information is illustrative of the use of a combination of sources for the methods. As stated at the CFIA website: "The methods of analysis recommended are those published in the most recent version of the 'Official Methods of Analysis of AOAC International' wherever possible. Other collaboratively studied methods such as those published by the American Oil Chemists' Society, American Association of Cereal Chemists, ISO, etc. would also be considered appropriate. In house or journal methods with adequate method validation data are another possible option for method selection" (8). More detailed information on some of these methods is described in various chapters in this Handbook, including those on gas chromatography, HPLC, and mass spectrometry.

IV. TRENDS IN FOOD COMPOSITION ANALYSIS

Some of the trends in the analysis of chemical composition of food, with regard to methods validation, components analyzed, and new techniques, are outlined in the following sections.

A. Validation of Methods of Analysis and Validity of Food Composition Data

Nutrient values in food composition databases may be collected from various sources of information generated by chemical analysis of food samples, by calculations, or by

expert estimation or "imputation" (36). Furthermore, the analytical data may be obtained from chemical analysis of food samples from the food industry, from government agencies, from the scientific literature, or by analytical laboratories that may or may not be ISO-accredited. Since the data are gleaned from various sources and may be of uneven quality and detail of supporting documentation, it is crucial to assess whether or not the data are in fact reliable for inclusion in databases (36). For example, the USDA Nutrient Data Laboratory has been working to establish software for data acquisition, compilation, and dissemination, as well as to facilitate the evaluation of analytical data quality based on five categories – sampling plan, number of samples, sample handling, analytical method, and analytical quality control, leading to a combined rating represented by a quality index and confidence code (36).

There is a continuing need for reliable analytical methods that can be used to determine compliance with national regulations as well as international requirements in all areas of food quality and safety. Some form of validation procedure must be used to determine the reliability of a method. The Codex Alimentarius Commission, for example, requires that in order for a method of analysis to be included in a Codex commodity standard, certain method performance information should be available. This includes specificity, accuracy, precision (repeatability, reproducibility), limit of detection, sensitivity, applicability, and practicability, as appropriate. However, "It is not practical or necessary to require that all analytical methods used for food control purposes be assessed at the ideal level … Limiting factors for completing ideal multi-laboratory validation studies include high costs, lack of sufficient expert laboratories available and willing to participate in such studies, and overall time constraints" (20).

A joint FAO/IAEA expert consultation on "Validation of Analytical Methods for Food Control" was held in Vienna, December 2–4, 1997, to review existing schemes for validation of international methods, to identify requirements for validation of methods for analysis of veterinary drug and pesticide residues, food additives, and environmental contaminants in food, and to recommend alternative approaches which would be practical, cost effective, and considerate of time and human resource constraints (18). Although a collaborative study conducted according to generally accepted international protocols is always the preferred validation procedure, in some cases it is not feasible to do so. In these circumstances, the evaluations may be done in one laboratory, provided they are conducted according to five principles addressing competence and third party review of the testing laboratory, appropriate criteria assessment of the analytical method, careful documentation in an expert validation report, and evidence of transferability (18).

B. The Impact of Health Issues on Analysis of Chemical Composition

Increasing numbers of reports on the associations between consumption of certain foods or nutrients with improved health or reduced risk of disease, have led to an explosion of literature on food composition information on these nutrients, nutraceuticals, and functional foods. However, the validity of the measurements for specific bioactive analytes has not been adequately assessed in many cases. There is a need to apply the quality indices for methods validation described in Section IV.A., and to initiate an informatics approach to developing nutrient databases for these components. Recent trends in this direction include the initiation of a flavonoid database (37) and databases for several bioactive food components including carotenoids, six classes of flavonoids, omega-3 fatty acids, and plant sterols (38).

Increasing interest in the physiological roles of dietary fiber and resistant starch has also led to a renewed need to assess the methods for their determination. Resistant starch is considered to be that starch which resists digestion and absorption in the small intestine and escapes into the colon, where it may be fermented by bacterial microflora. The enzymatic-gravimetric and enzymatic-chemical methods for dietary fiber analysis include protocols for determining the content of resistant starch (35), but it has been reported that some data on resistant starch have only estimated retrograded amylose, which is only one of the 3 or 4 components of resistant starch in the diet (34). Similarly, data on dietary fibre intake around the world are difficult to compare because of methodology differences (34). In fact, a debate is ongoing at the present time on what should be included in the definition of dietary fiber. At the heart of the controversy is the issue of whether total fiber should be classified into dietary fiber (i.e. sources of fiber that are intrinsic or intact in plants) versus functional fiber (i.e., fiber that has been isolated and then incorporated as an ingredient in food products), with associated concerns of how these two classes of fiber might be analytically distinguished (39, 40).

C. Trends in Methodology for Food Analysis

There is a continuing need to explore the possibilities and limitations of rapid methods for analysis of food, and of equipment that will enable their successful application for quality control (41, 42). As reviewed by Ibañez and Cifuentes (43) in an excellent article, there have been many advances in applying new analytical techniques in food science, with an increasing focus on sophisticated techniques. These include nuclear magnetic resonance, capillary electrophoresis, mass spectrometry, and infrared spectroscopy, as well as coupled techniques and new approaches to sample

preparation (43), mass spectrometry, and hyphenated mass-spectrometry techniques (44, 45) and the vibrational spectroscopic techniques of near-infrared, mid-infrared, and Raman spectroscopy (46). Other recent trends include the increased application of enzymes as indicators of food quality, biosensors, immunochemical techniques, DNA probes, the polymerase chain reaction (PCR), rapid methods for microbio-logical analysis, and authentication of foods using isotopic methods (1, 43). There has also been great interest in methods for the detection of genetically modified foods. For example, Dahinden et al. (47) described the application of real-time PCR technology for quantification of the genetically modified organism (GMO) content of soybean (Roundup Ready soybean-RRSoybean) or corn (Bt176, Bt11, Mon810, and T25), and for demonstrating the amplification capacity of DNA from corn (invertase) and soybean (lectin).

V. CONCLUSIONS

This chapter has provided an outline of the basic principles and considerations for proximate analysis of food, and briefly described the analysis of other constituents that are of interest from the viewpoint of nutrition and health. A multitude of techniques based on different principles are available or being developed for the analysis of the chemical composition of foods. Due to the diversity and heterogeneity of these food constituents, and the dependence of the measured content of each constituent on the method used for its analysis, it is imperative that reports on food composition be accompanied by sufficient description of the analytical methods used for obtaining those data, and that these methods have been validated by officially recognized associations. Only then can the data on chemical composition of food analyzed by different sources or agencies be meaningfully compared, interpreted, and applied.

CONTENTS

I. INTRODUCTION TO SPECTROSCOPY

Spectroscopy is the study of the interaction of matter with electromagnetic radiation by absorption, emission, or scattering. Spectroscopic techniques are invaluable for obtaining both structural and quantitative information about atoms and molecules, and are used extensively in the analysis of foods and individual components.

Electromagnetic radiation has a dual nature and acts as if it is a particle (a photon) travelling through space with the characteristics of a wave, with oscillating electric and magnetic fields (Figure 43.1)(1). The energy of the radiation, E, is directly related to the frequency, ν (the number of oscillations per second), by Planck's constant ($h = 6.63 \times 10^{-34}$ J-s),

$$E = h\,\nu \tag{43.1}$$

The frequency, ν, is inversely related to the wavelength, λ, by

$$\nu = c/\lambda \tag{43.2}$$

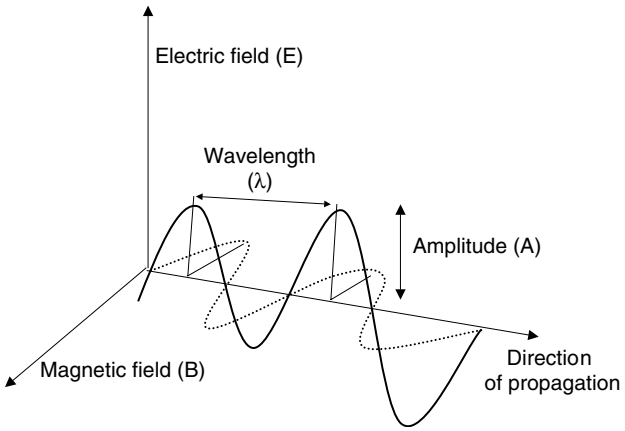

FIGURE 43.1 The characteristics of electromagnetic radiation, with electric and magnetic fields perpendicular to each other.

where c is the velocity of the radiation. The frequency of radiation is determined by the source, and does not change as the wave propagates through different media. However, the velocity, and therefore the wavelength, is affected by the medium. Wavelength is inversely related to energy, so ultraviolet radiation with short wavelengths has more energy than visible light. It should be noted that only those wavelengths that are visible to our eye, from about 400 to 800 nm, are referred to as light. Radiation is the general term used for electromagnetic radiation that ranges from cosmic rays with wavelengths of 10^{-12} m, to radio waves with wavelengths of 10^{4} m.

The charged particles of matter, the nucleus and the electrons, can interact with specific wavelengths of radiation, and the energy from the radiation can be transferred to, or absorbed by, the material. This absorption of energy excites the atom or molecule from a lower energy state (often the ground state at room temperature) to a higher energy state, and is observed as an absorption spectrum. Alternatively, the emission of radiation when the atom or molecule moves from a higher energy state to a lower, more stable, energy state can be monitored as an emission spectrum. There are a limited number of discrete energy levels that a particular atom or molecule can achieve, based on its structure. Therefore, only wavelengths of radiation with the precise amount of energy that exists between two different energy states can be absorbed or emitted. This allows atoms and molecules to be identified by their unique absorption or emission spectra.

The absorption and emission spectra of atoms are less complicated than those of molecules. Atoms can undergo electronic energy transitions, in which electrons (usually valence electrons) move to higher or lower energy states. Electronic transitions associated with excitation of valence electrons can occur with the energy of ultraviolet or visible radiation. Molecules also undergo electronic transitions, but have rotational and vibrational motions as well. For each electronic state, there are several rotational states,

and for each rotational state, there are several vibrational states (Figure 43.2). Vibrational motion occurs from the bending or stretching of bonds between nuclei. The energy required for vibrational motions is much smaller than for electronic transitions, and vibrational transitions are typically excited by infrared radiation. Rotational motion arises from movement of a molecule about its axes or center of gravity. Transitions between rotational states require even less energy than vibrational transitions, and can occur with the energy found in the far infrared to microwave regions of the electromagnetic spectrum.

In addition to absorption and emission, radiation can also be re-directed through scattering, reflection, or rotation due to its interaction with matter. This can occur with or without the transfer of energy, and therefore after interacting with a sample, the radiation may have a different or the same wavelength as the original radiation.

While many forms of spectroscopy are based on the interaction of electrons with electromagnetic radiation, the interaction of nuclei with radiation can also be detected under certain conditions. The nuclei of many elements have magnetic properties, and when they are placed in a strong external magnetic field, they will populate different magnetic states. If the nuclei are then exposed to radiation of an appropriate frequency, they will absorb the radiation and undergo transitions between magnetic states. The energy difference between these magnetic states varies with the strength of the external magnetic field and the chemical environment, but occurs in the radiowave region of the electromagnetic spectrum.

A summary of the spectroscopic techniques that will be explored in this chapter is given in Table 43.1. Spectroscopic techniques of fluorescence, infrared, and mass spectroscopy are discussed in other chapters of this book.

II. ULTRAVIOLET-VISIBLE SPECTROPHOTOMETRY

A. Introduction

Spectrophotometry is based on the ability of valence electrons of molecules to absorb specific frequencies of radiation, from the ultraviolet range (200 to 400 nm) through the visible range (400 to 800 nm). The absorption of the radiation can be detected using a spectrophotometer and will yield an absorption spectrum. Spectrophotometry can be used to obtain qualitative information regarding the compounds that are present in a sample extract, but it is not possible to obtain detailed structural information. In molecules, there are simultaneous transitions between different vibrational, rotational and electronic states, resulting in rather broad absorption bands. Spectrophotometry is more commonly used to quantitate the amount of a compound in solution. It is an extremely versatile technique, and spectrophotometric methods of detection and quantitation have been developed for hundreds of compounds. The technique can also be used to detect enzyme activity, and spectrophotometric detectors are commonly used for high performance liquid chromatography (HPLC). Some selected applications of spectrophotometry in food science are given in Table 43.2.

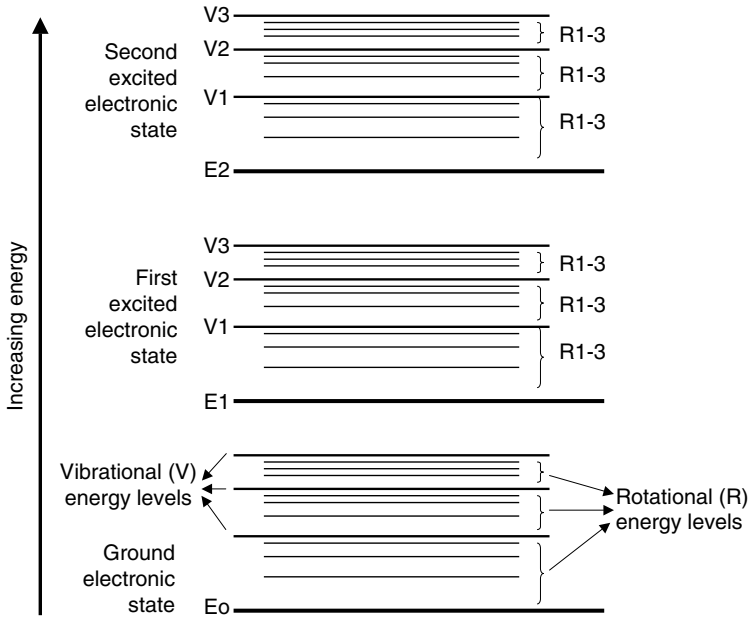

FIGURE 43.2 A partial energy diagram of a molecule, showing the relationship between electronic, vibrational, and rotational energy levels.

TABLE 43.1
Selected Characteristics of Some Spectroscopic Techniques

Spectroscopic Technique	Interacting Radiation	Transition	Interaction
Near Ultra-Violet Spectroscopy	200–400 nm	Valence electrons of molecules	Absorption
Visible Spectroscopy	400–800 nm	Valence electrons of molecules	Absorption
Tristimulus Colorimetry	400–800 nm	—	Reflection
Atomic Absorption Spectroscopy	160–900 nm	Valence electrons of atoms	Absorption
Atomic Emission Spectroscopy	160–900 nm	Valence electrons of atoms	Emission
Polarimetry/			
Optical Rotary Dispersion	200–800 nm Circularly Polarized	Valence electrons of molecules	Rotation
Circular Dichroism	170–700 nm Circularly Polarized	Valence electrons of molecules	Absorption
Nuclear Magnetic Resonance	Radiowaves $>$ 1 mm	Nuclear spin transitions	Absorption and Emission

B. Principles

The energy associated with ultraviolet and visible wavelengths of radiation varies from about 150 to 36 kcal mole^{-1} (15). Energy of this magnitude corresponds to the energy differences between electronic states of valence electrons of molecules. Therefore, electromagnetic radiation in this region absorbed by molecules can promote valence electrons to an excited orbital. The types of electronic transitions that occur with absorption of ultraviolet and visible radiation include sigma bonding (associated with single bonds) to sigma antibonding orbitals (σ-σ^*), non-bonding electrons to sigma antibonding orbitals (n-σ^*), or more commonly, pi bonding orbitals (formed by parallel overlap of p-orbitals) to pi antibonding orbitals (π-π^*) and non-bonding electrons to pi antibonding orbitals (n-π^*). The σ-σ^* and n-σ^* transitions require higher amounts of energy, and therefore usually involve absorption of ultraviolet radiation below 200 nm. These transitions cannot be monitored in commonly used instruments. A π-π^* transition occurs with a carbon double bond and n-π^* transition requires a nitro or carbonyl group with a non-bonded electron as well as a double bond. The π-π^* and n-π^* transitions occur readily with the energy available in the ultraviolet and visible spectrum. Molecules in which these types of electron transitions occur are referred to as chromophores, from *chroma*, the Greek word for color, and *phoros* meaning producer. Many food colorants have these types of bonds, and therefore are capable of absorbing visible light, giving color to our foods. Some typical chromophoric groups are given in Table 43.3. An auxochrome is a compound that does not exhibit absorption itself, but alters the wavelength or the intensity of absorption of a chromophore. If a longer wavelength of radiation is absorbed, it is termed a bathochromic or red shift, while a shift to shorter wavelengths is referred to as a hypsochromic or blue shift.

In addition to excitation of valence electrons, absorption of radiation by a molecule can result in charge transfer reactions involving the movement of an electron from one atom to another. As well, transition metals, with unfilled d- or f-orbitals, can also absorb radiation in the ultraviolet-visible region of the spectrum, corresponding to transitions between different d- or f-electronic states.

TABLE 43.2
Selected Applications of Spectrophotometry

Application	Reference
Quantitation of chlorogenic acid in potatoes	2
Determination of protein and fat in milk	3
Determination of paraquat in food and other samples	4
Determination of sulfite in foods using HPLC and ultraviolet spectrophotometric detection	5
Ultraviolet spectra to assess oxidative stability of corn oils	6

Chemical Group	Structure	Transition
Acetylenic	- C $\equiv$ C -	π-π^*
Amide	- $CONH_2$	π-π^*, n-π^*
Carbonyl	- C = O	π-π^*, n-π^*
Carboxylate	- COO^-	π-π^*, n-π^*
Ester	-COOR	π-π^*, n-π^*
Ethylenic	- C = C -	π-π^*
Nitro	- NO_2	π-π^*, n-π^*
Oxime	- C = N -	π-π^*, n-π^*

Source: Ref. 15.

To obtain the absorption spectrum of a sample, a beam of radiation is passed through the sample, and the power of the incident beam, P_o, is compared to the power of the radiation passing through the sample, P, the transmitted beam (Figure 43.3). The power of the transmitted beam will be reduced from the incident beam due to reflection at the cuvette and sample interfaces, scattering within the sample, and absorption by the analyte. The transmittance of the sample, T, is the ratio of the radiant power transmitted by a sample to the power of the incident beam,

$$T = P/P_o \tag{43.3}$$

Transmittance values range from 0 to 1, or from 0–100% for percent transmission. There is a logarithmic relationship between transmission and concentration of a compound that makes it inconvenient to relate the two. Therefore, another term, absorbance, A, is used, defined as

$$A = \log (1/T) = -\log T \tag{43.4}$$

The relationship between transmission and absorbance with concentration can be seen in Figure 43.4.

It was established, independently by Bouguer in 1729 and Lambert in 1760, that absorbance was directly proportional to the thickness of a sample, when concentration was constant, while Beer in 1852 determined that if the sample thickness was constant, the absorbance was proportional to concentration (15). These observations are combined to derive what is commonly referred to as the Beer-Lambert Law, or simply Beer's law, as

$$A = a \cdot d \cdot c \tag{43.5}$$

where a is absorptivity, a proportionality constant for a molecule at a specific wavelength, d is the sample pathlength, and c is the concentration of absorbing molecules.

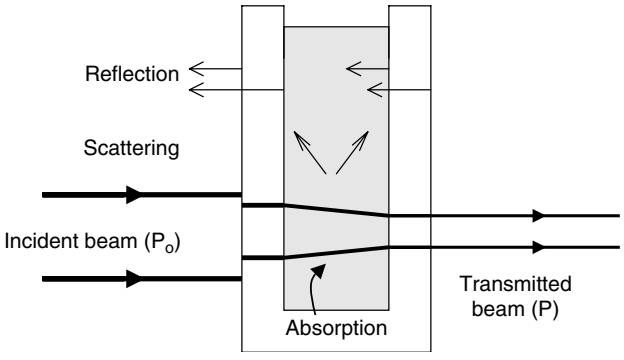

FIGURE 43.3 Attenuation of a beam of radiation by reflection at the cuvette and sample interfaces, scattering by particulates, and absorption by the analyte.

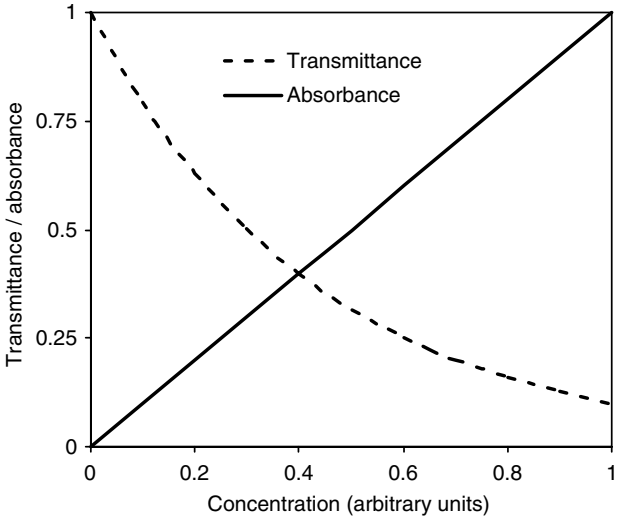

FIGURE 43.4 The relationship between transmittance, T, and absorbance, A, for a hypothetical compound.

The units of absorptivity vary, but reflect the units for concentration and sample pathlength. Molar absorptivity, or the molar extinction coefficient, ε, has units of $M^{-1}cm^{-1}$, while it is typical to give absorptivity constants of some compounds, such as proteins, in terms of a 1% solution at a specified wavelength and a 1 cm pathlength.

Beer's law is used in all absorptive spectroscopies, but is only valid if the following conditions are met: (1) the incident radiation is monochromatic, composed of a single frequency, since each wavelength will have its own absorptivity; (2) the solution is dilute enough that molecules absorbing the radiation act independently of each other; (3) the absorbing sample does not scatter or reflect the incident radiation (some unavoidable effects may be compensated by using a reference cell that contains all the sample components except the analyte); and (4) the absorption occurs in a uniform solution. Beer's law can also be applied to mixtures of molecules, as long as the components of the mixture do not chemically or physically interact. Therefore, absorbance of a mixture is additive, as follows,

$$A_{\text{compounds } 1-\iota} = \varepsilon_1 dc_1 + \varepsilon_2 dc_2 + \ldots. = d\,\Sigma\varepsilon_\iota c_\iota \tag{43.6}$$

C. Equipment

The basic elements of a spectrophotometer consist of a radiation source, a wavelength isolator, a sample container, and a detector.

1. Radiation Source

An ideal radiation source will produce stable, uniform, high intensity radiant energy over the wavelength spectrum of interest. A tungsten filament (or tungsten-halogen) lamp can be used from 320 nm into the infrared region to

2500 nm, but cannot be used in the ultraviolet region. The most common type of lamp for the ultraviolet region is a deuterium electrical discharge lamp with a quartz envelope, which can operate from about 180 to 370 nm.

2. Wavelength Isolator

A wavelength isolation device is an essential component of a spectrophotometer that enhances the selectivity of the analysis and the sensitivity of the instrument by eliminating most of the radiation that is not absorbed by the sample. The benefit of selecting radiation with a narrow range of wavelengths can be explained by the following example. Assume that a radiation source provides a constant 10 units of energy at *every* nm from 350 to 449 nm. A sample placed in the radiation beam absorbs 5 units of energy but only at 400 nm. If no wavelength isolation is used, the spectrophotometer must detect the difference between no sample (1000 units of radiation) and the sample (995 units), a 0.5% difference. However, if a crude wavelength isolation device is used which restricts the incident radiation to 10 nm around the wavelength of interest, 395–404 nm, the difference between the blank and the sample is now 100 versus 95 units of radiation. This is a difference of 5%, resulting in a 10-fold increase in sensitivity. A second important reason for using a wavelength isolation device is to enhance the selectivity of the analysis. If the radiation incident on the sample has a wide range of wavelengths, the observed absorption may be due to the interaction not only of the analyte of interest at the expected wavelength, but also from a contaminant which absorbs at another wavelength.

Using filters that only transmit radiation of certain wavelengths is one of the oldest methods of wavelength selection. Filters, however, have low selectivity and transmit relatively wide ranges of radiation. It is more common to use a monochromator, with a diffraction grating or a prism to separate wavelengths of radiation and focus them on the sample. The monochromator has an entrance slit to allow radiation to enter. The radiation is collected on a concave mirror and can be reflected to a prism or diffraction grating, which physically separates the different wavelengths of radiation. The diffraction grating is a reflective surface with 1200 to 1400 etched grooves per millimeter. The individual wavelengths of radiation are then reflected from another concave mirror to a focal plane aligned with the exit slit. By adjusting the exit slit, the desired wavelength of radiation is passed through the slit and can interact with the sample. In practice, it is not possible to select a single wavelength of radiation, but rather a narrow bandwidth of radiation, centered on the wavelength of interest, is obtained. Many instruments allow the entrance and exit slit widths to be varied, which affects the bandwidth of radiation selected. While a narrower exit slit results in a narrower bandwidth, the radiant power will be decreased. Usually, absorbance peaks in the ultraviolet-visible region are fairly broad, so a relatively wide bandwidth will give good results, and has the added advantage of giving a better signal to noise ratio.

3. Sample Holder

The sample holders used for spectrophotometric measurements are cuvettes. These are often sold in matched pairs that can be used in a dual beam spectrophotometer. Commonly used cuvettes have a pathlength of 1 cm, and may be constructed to hold either 4.5 or 1.5 mL volumes. Specialized cells are also available, with pathlengths varying from 1 mm to 10 cm, and volumes ranging from a few microliters to greater than 30 milliliters. Since the cuvette becomes part of the path that the radiation follows, it is critical that it does not contribute significantly to the absorption at the wavelengths of interest. The materials used for cuvettes vary depending on the wavelength of radiation that must be detected. For visible spectroscopy in the range from 340 nm to 800 nm, glass, quartz, polystyrene, or methacrylate cuvettes may be used. The polystyrene and methacrylate materials will give 75–90% transmission at the lower end of this range. For the ultraviolet region, only quartz or fused silica cuvettes must be used, as the other materials are opaque to ultraviolet radiation. It is important that the cuvette surface is free from scratches, material deposits, or other imperfections that can cause scattering or absorption of the incident radiation. Glass, quartz, or silica cuvettes can be cleaned periodically using 5M nitric acid or special detergents, designed to remove biological deposits, followed by rinsing with copious amounts of distilled-deionized, or reverse osmosis water. Ultrasonic baths for cleaning are not recommended by some manufacturers, as the cuvette may crack if it resonates with the bath frequency. Only lens paper or a soft cloth should be used to wipe the outer surface of the cuvette, as other papers with wood fibers can scratch the surface. The advantage of the plastic cuvettes is that they are inexpensive enough for single use, and therefore, maintenance is not an issue. An alternative to using cuvettes is to carry out analyses in microplates containing 96 wells. The absorbance of each well is obtained using a spectrophotometric reader designed specifically for such plates. Using this format, multiple assays can be performed quickly, with significant savings of precious samples or reagents since the volume of each well is only a few hundred microliters. However, the pathlength, and therefore the absorbance of the sample, varies with the total volume used for the assay and must be determined.

4. Detector

The radiation that is transmitted through a sample is quantified by conversion to an electrical signal by a detector. A

common type of detector is a photomultiplier tube. The photomultiplier tube is made up of a photoemissive cathode, coated with an easily ionized material, and several dynodes in a vacuum. A voltage of 400 to 2500 V exists between the cathode and the anode. When a photon strikes the cathode, electrons are ejected and strike the first dynode and release multiple secondary electrons. These accelerate toward the next dynode, which again multiplies the electrons released in a cascade, with an eventual gain of 10^4 to 10^7. These gains are very useful in detecting low levels of radiation. The amplified electrical signal can be displayed on an analogue meter, through the position of a needle on a meter, or converted to a digital signal and manipulated by a computer and displayed on a numerical read-out.

5. Dispersive Instruments: Single-Beam and Double-Beam Optics

In a single-beam spectrophotometer, the radiation follows a path through a single cuvette to a detector. This type of instrument is calibrated for 0% T by completely blocking all radiation from the detector, and 100% T using a reference sample that, ideally, contains all the components except the analyte. Because the calibration for 0 and 100% T is carried out independent of the sample readings, random fluctuations in lamp intensity, electrical power, and drift over time may introduce error into the sample readings. Repeated calibrations can be used to compensate for instrumental drift over time.

A double-beam spectrophotometer has a design advantage over a single beam instrument in that the radiation emitted by the source is split into two beams of equal intensity (Figure 43.5). This can be accomplished by a rotating sector mirror (chopper), which rapidly focuses the radiation beam sequentially through the sample cell, and then the reference cell, as it rotates. A single detector can receive alternating signals from the sample and the reference cells or there may be separate detectors for the sample and reference. With either approach, any minor fluctuations or drift in the radiation will affect the reference and sample beam identically, and can be ignored. A disadvantage of the double beam configuration is that the power of the incident radiation on the sample is decreased by splitting the beam, and therefore, the signal to noise ratio may be lower than with single-beam optics.

6. Diode Array Instruments

Diode array spectrophotometers have a very different design from dispersive instruments (Figure 43.6). In this type of instrument, the radiation covering all the wavelengths of interest is collimated, passed through the sample, and then separated into its component wavelengths using a fixed grating. The radiation is then projected onto hundreds of diodes that are present on a silicon chip,

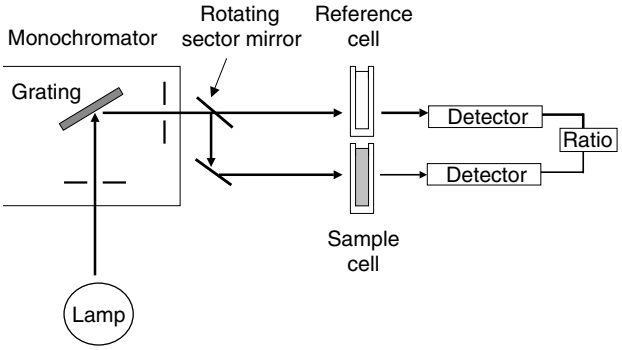

FIGURE 43.5 A schematic representation of a double-beam spectrophotometer.

termed the diode array. Each diode acts as a capacitor, and creates an electrical discharge proportional to the incident radiation. A photodiode is generally made up of a semiconductor and a capacitor to charge the semiconductor. As radiation hits the semiconductor, electrons flow through it, thereby lowering the charge on the capacitor. The intensity of radiation of the sample is proportional to the amount of charge needed to recharge the capacitor at predetermined intervals. This type of instrument allows an absorption spectrum to be obtained in less than a second, since each diode collects radiation at its unique wavelength at the same time; therefore, one of the major advantages of this type of instrument is the rapid analysis.

D. Quantitation

Quantitation is the most common use for spectrophotometry, and is typically carried out using a standard curve. A solution with a known concentration of the analyte is used to make up a series of dilutions. Then a plot of absorbance versus concentration at the appropriate wavelength is made. The slope of this plot can be used to determine the extinction coefficient of the compound. Alternatively, by knowing the extinction coefficient of the compound in the solvent, it is possible to calculate the concentration, using Beer's law, relating the concentration of an analyte in solution to the amount of absorbance of radiation.

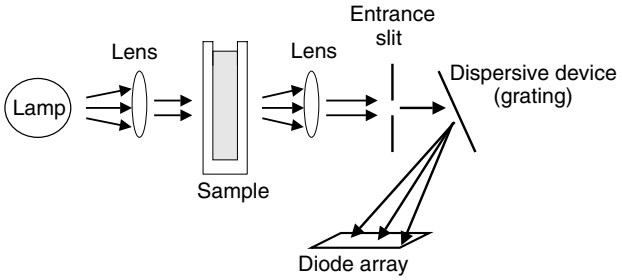

FIGURE 43.6 A schematic representation of a diode array spectrophotometer.

Care should be given to the selection of an appropriate reference sample. As noted above, the ideal reference sample contains all the sample components except the analyte. However, in practice, distilled water or even air is sometimes used to establish 100% transmission, which can cause erroneous absorbance measurements. If the refractive index of the reference and sample are not close, different amounts of reflective radiation loss will occur at the cuvette window. This failure to match the refractive index of the sample and reference can result in a shift of the baseline, with apparently greater than 100% transmission in the sample.

While many spectrophotometers are reported to give linear responses to 3 absorbance units, linearity of absorbance for any compound must be confirmed experimentally. At high concentrations of the analyte, one of the assumptions of Beer's law, the independence of the absorbing species, may not hold. At high concentrations, the analyte may interact with itself or other molecules, which can alter the absorption spectrum. As well, the design of the spectrophotometer dictates that the most accurate data will be obtained from absorbance values in the range from about 0.2–0.8 absorbance units. When sample concentration is very high, most of the radiation incident to the sample is absorbed, leaving only a small percentage traveling to the detector. Therefore, even a small error in determining the transmitted radiation power yields a large relative error, when compared to how much radiation is being detected. When the sample concentration is very low, on the other hand, most of the radiation falls on the detector. Again, a small error in radiation power at the detector translates into a large relative error in the amount of radiation absorbed by the sample.

Detection limits in spectrophotometry depend on the absorptivity of the compound being measured. A compound with a molar extinction coefficient of 10^4 to 10^5 $M^{-1}cm^{-1}$ can be detected in the micromolar concentration range. The wavelength of maximum absorbance (or minimum transmission) is the best to use for the analysis. This wavelength will yield the greatest sensitivity, with the greatest changes in absorbance as concentration changes. The accuracy and precision of a spectrophotometric assay depends on instrumental limitations, control over physical and chemical variables such as temperature, pH, and reagent purity, and operator skill.

In some analyses, the spectrum of the analyte of interest cannot be completely separated from interfering materials in the sample, or the baseline is shifted. In these cases, it may be beneficial to use the first, second, or higher order derivative for qualitative and quantitative analysis of absorption spectra (16). The derivatives can be easily calculated from the absorption spectra with the computers and programs that are standard with many modern instruments. The first derivative of a single peak spectrum is a plot of the gradient $dA/d\lambda$ versus wavelength, with a minimum that occurs at the λ_{max} and a maximum. The concentration of the analyte is proportional to the distance between these. The second derivative is $d^2A/d\lambda^2$ versus wavelength, and has two maxima with a minimum between them at the λ_{max}. The derivative spectra feature sharp bands, compared to the broader bands of the original spectra, which can enhance detection of minor spectral features. If Beer's law is valid for the original spectrum, then the derivative can be used for quantitation as

$$d^n A / d\lambda^n = d^n \varepsilon / d\lambda^n dc \qquad (43.7)$$

Another quantitative application of spectrophotometry is to determine reaction rates, rather than absolute absorbances. The rate of change in absorbance is determined just after mixing all the sample components and well before equilibrium is established. The concentration of the analyte is then proportional to the slope of absorbance as a function of time. Such procedures may be used for determining enzymatic activity. It should be noted that reaction rates can be very dependent on chemical and physical aspects of the reaction, such as pH and temperature, and these factors must be carefully controlled to obtain meaningful results.

Ultraviolet-visible absorption spectra can be used to qualitatively identify the presence of molecular species, by comparing the spectrum of an unknown with a library of possible compounds, or simply observing a characteristic absorption peak. Absorption is proportional to concentration, but spectra obtained at different concentrations can differ due to variations in absorptivity at different wavelengths, making comparisons difficult.

E. Sample Preparation

Clear solutions are required for spectrophotometry. If the analyte is in a suspension with some turbidity, rather than a clear solution, then a significant amount of radiation will be scattered, rather than absorbed, violating one of the assumptions of the Beer-Lambert law. A wide variety of solvents with various additives can be used to enhance solubility of the analyte of interest. The only limitation is that the solvent and additives must not themselves exhibit a significant amount of absorption in the region where the analyte will be monitored. All common solvents are suitable for use in the visible range of the spectrum, while fewer are transparent at the lower end of the ultraviolet range (Table 43.4). For optimal results, the absorbance of the cuvette and solvent should be no more than 0.05 absorbance units.

Turbid suspensions are deliberately used for some specific applications, not involving absorption. Microbial cell growth curves can be determined by monitoring the decrease in transmission of radiation through a sample caused by scattering of radiation, and with a standard

TABLE 43.4
Ultraviolet Absorption Cut-Off of Some Solvents

Solvent	Ultraviolet Cut-Off (nm)
Acetonitrile	190

Benzene	280
Acetone	330

curve, microbial cell density in a solution can be estimated. Alternatively, an increase in transmission, as a result of a decrease in the scattering of radiation, of a bacterial suspension can be used as a qualitative indication of cell lysis.

III. TRISTIMULUS COLORIMETRY

A. Introduction

Tristimulus colorimetry is the measurement of the perceived color of objects, based on the reflection of visible light from an object. Three components influence colorimetry readings: the radiant energy spectrum of the light source impinging on the object, the characteristics of the object itself, and the sensitivity of the detector, the human eye (17). A change to any of these three interacting components usually results in a change of perceived color. Color is not a strictly physical characteristic of an object, but is a psychophysical characteristic, since it depends on human perception of light reflected from an object. There are many factors that influence color perception by an individual including the light source, the viewing angle, the background, the size of the object, surface texture, particle size, number of receptors in the eye, and even aging or yellowing of the lens in the eye. These factors, and the ability of the human eye to distinguish subtle color differences, make reproducible color description and color difference estimation by people very difficult. Instruments have been developed that standardize the radiation source, the viewing conditions, and the detector, so that reproducible color parameters can be obtained. This allows color to be unambiguously defined for an object, and color differences between objects to be measured. Colorimetry can be used to establish color standards or color tolerances that are used for quality assessment, to determine the effects of physical and chemical conditions on the color of a sample, and to establish color parameters that can be used as rapid and non-destructive indices of other components in the sample, for example, the amount of a pigment in a sample or the loss of a reactive component. Applications of tristimulus colorimetry to foods are given in Table 43.5.

B. Principles

Colorimetry has the ultimate objective of being able to provide color coordinates that will enable different people to describe and visualize a color unambiguously. This is most easily achieved with a uniform color space, so that the distance between two colors in three-dimensional space correlates with their visual color difference. Numerous color appearance models, or color space models have been developed, and one well-recognized system is the CIE[1] L*, a*, b* system, which provides a reasonably uniform color space (Figure 43.7). The L* value represents lightness and ranges from 0 (black) to 100 (white), the a* value represents red to green (positive to negative values), and the b* value represents blue to yellow (positive to negative values). These values can be manipulated to yield the hue and chroma of the object. Hue is the name given to a color, such as red, blue, or yellow, while chroma is the saturation, or intensity of the color, relative to a white object viewed under similar illumination. The absolute value of a* and b* values indicates the chroma of the object, and can be defined as

$$\text{Chroma} = (a^{*2} + b^{*2})^{0.5} \tag{43.8}$$

while the hue is the angle defined by a point in color space joined to the origin and the positive a* axis. Hue can be calculated in positive degrees as

$$\text{Hue} = \tan^{-1}(b^*/a^*) \tag{43.9}$$

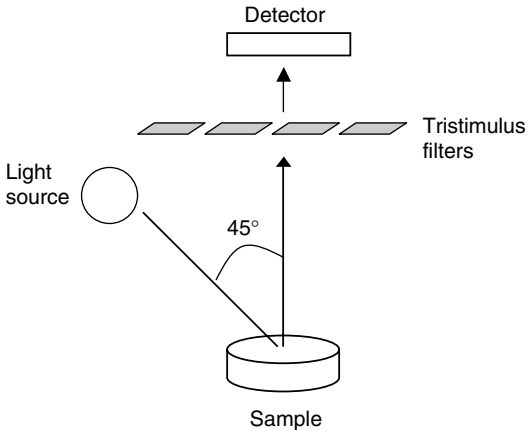

FIGURE 43.8 A tristimulus colorimeter with 45° illumination and 0° viewing geometry.

C. Equipment

Tristimulus colorimeters use a light source with a defined energy spectrum, standardized illumination and viewing conditions, and sensors that simulate the way the human eye perceives color. While different instruments use different color appearance models, values from each model can be interconverted using appropriate equations. Tristimulus refers to the concept that most colors can be matched by addition of different amounts of the three primary color lights—red, green, and blue. The components of a tristimulus colorimeter include a light source, a sample holder, a set of filters, and a detector (Figure 43.8).

1. Light Source

The light source has a significant effect on the perceived color of an object, since the reflected light is dependent on the intensity of the incident light. It is a common experience to observe that the color of an object differs when viewed under different lighting conditions. There are two light sources that are commonly used in tristimulus colorimeters, Illuminant A and D65. Each is defined by the CIE. Illuminant A represents incandescent illumination. D65 mimics daylight, and is characterized by a correlated color temperature of 6500 K. The correlated color temperature of an illuminant is derived from the concept of a black body radiator, a theoretical light source, in which the quantity and wavelengths of energy emitted increase with the absolute temperature. Therefore, as correlated color temperature increases, the emitted radiation becomes more intense, with more blue (shorter) wavelengths. Although D65 is a commonly used illuminant, there are other D illuminates used in colorimeters with different correlated color temperatures.

The angle that the light illuminates the object, coupled with the angle that the reflected light is viewed will also influence the perceived color. Therefore, the CIE has defined two sets of geometries for illumination and viewing that are commonly used in tristimulus colorimeters. In the first set, the sample is illuminated from all angles, using a sphere light source, and viewed at 0° to the surface. Alternatively, the sample can be illuminated at 0°, and the reflected light collected from all angles. Both of these configurations will yield the same tristimulus values. The second set of geometries includes illumination at 45° and viewing at 0° (shown in Figure 43.8), or alternatively, illumination at 0° and viewing at 45°. Again, both configurations will yield the same result. This design eliminates all components of gloss from the color parameters.

2. Filters and Detector

The filters used in a tristimulus colorimeter mimic the color sensitivity of an average person, based on the spectral responsiveness of the three types of cones in the human eye. The response curves are known as the standard observer curves. The concept can be understood as the amounts of red, green, and blue primary lights that are needed to match the colors of an equal energy spectrum by a person with average color vision. However, for calculation purposes, the red, blue, and green primary colors are mathematically converted to X, Y, and Z primaries, as some yellow hues cannot be matched by adding red, green, and blue light. Tristimulus colorimeters may use four filters, rather than three, for the same reason. Phototubes that monitor the light transmitted through each filter are used for detection.

An alternative system to the use of filters is a scanning spectrocolorimeter that uses a monochromator, coupled with diodes for detection. The reflectance data for every 5 or 10 nm are multiplied by the color-matching function of

the standard observer curves, and then integrated across the spectrum to yield values for the color appearance model used by the instrument.

The specification of absolute color of an object requires careful calibration of the light source and detectors of a tristimulus colorimeter, and it is difficult to obtain identical readings between two different instruments. However, very reproducible results can be obtained from determinations of color differences between two objects, and this is a more common and reliable application of a colorimeter. It is important to remember that some color differences, measured instrumentally, may not be distinguished visually. Therefore, instrumental results must always be related to human perception.

D. Sample Preparation

The ideal material for determining surface color is uniform in color, flat, smooth and does not exhibit gloss; however, few food materials have all of these characteristics. Therefore, the characteristics of each sample must be considered to obtain useful color information. Color measurements may be obtained on liquid, solid, or powder samples, and may require very little preparation prior to analysis. The main objective is to evaluate a sample as it would be normally viewed. Color parameters will vary with depth, surface characteristics, and particle size of the sample. Smaller particles will cause more scattering of light, and be perceived as brighter but less colorful than the same material with larger particles. Since color may vary within the sample, on the top or bottom, or depending on orientation, it may be appropriate to take several instrumental readings, turning or moving the sample between readings. The average color parameter can then be calculated. For translucent or transparent samples, a consistent sample depth must be used since color will change with the sample thickness. As well, some light may be transmitted through translucent or transparent samples, and therefore it is necessary to use a consistent background such as a white plate, and to avoid stray light that might be transmitted through the sides of the container holding the sample.

IV. ATOMIC ABSORPTION SPECTROSCOPY

A. Introduction

Atomic absorption spectroscopy (AAS) is a technique used to detect or quantitate the presence of elements, usually metals, at the sub part per million concentration. It can be used to detect elements in almost any solid, liquid, or gaseous sample, although most samples are converted into homogeneous solutions prior to analysis. Usually, only a single element is quantitated in each analysis. AAS is based on the absorption of radiation by ground state atoms, rather than molecules, but obeys the same general principles described for spectrophotometry. Two common types of AAS are flame AAS, and graphite furnace or electrothermal AAS. These methods differ in the way that ground state atoms are produced. Some applications of AAS to determine metals in food samples are given in Table 43.6.

B. Principles

There are two key steps involved in AAS (27,28). The first step is the production of free atoms of the analyte from the sample material, produced by heating the sample using either a flame or a furnace. During heating of a sample, the solvent is evaporated, water of hydration is removed, oxides may be produced, and finally free atoms of the metal are generated. The second step is the excitation of the atoms to a higher electronic energy state, mediated by the absorption of radiation by the valence electrons. The energy associated with the absorbed radiation corresponds to the difference in energy between the ground state and an excited state of the valence electrons, and is characteristic of each atom. There are multiple excited states that an atom can achieve, and therefore the absorbance spectrum of an atom is composed of several absorption lines. However, the resonance transition state, from ground state to the first excited state, is the most intense and therefore used most often as it offers the best sensitivity. Alternative resonances may be used if there is interference at the wavelength of the first excited state. Absorption lines for the different elements occur in the wavelength range from about 160 to 900 nm. The lines of the atomic absorption spectrum are very narrow compared to the absorption spectrum of a molecule obtained in the ultraviolet and visible range because there are no vibrational or rotational transitions for free atoms.

C. Equipment

1. Flame Atomic Absorption Spectroscopy

The basic components of a flame AAS are the radiation source, flame atom cell with a burner, sample introduction system, monochromator, and the detection system (Figure 43.9). A computer is usually used for control of the instrument, and manipulation of the data.

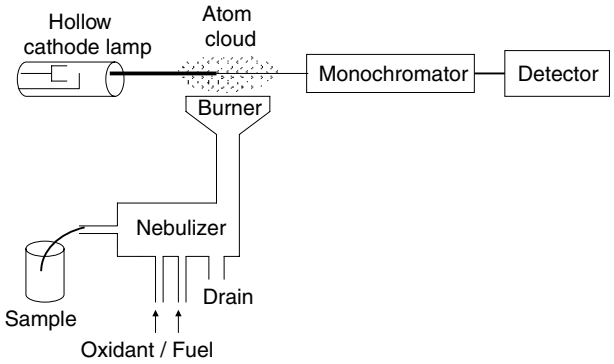

FIGURE 43.9 A schematic representation of a flame atomic absorption spectrometer.

a. *Radiation source*

The most common radiation source is the hollow cathode lamp (HCL), where the cathode is composed of the same metal as the analyte of interest. The HCL contains a glass envelope with a silica window for use in the ultraviolet spectrum. The glass envelope is filled with an inert gas such as neon or argon, at a low pressure between 1 to 5 torr. A voltage applied between the anode (positively charged) and the metal cathode causes the gas to ionize at the anode. The positive ions are accelerated toward the cathode, strike it, and cause some of the metal ions from the cathode to be released in an excited state. The excited ions produce an intense spectrum of radiation, characteristic of the metal when they return to the ground state. These metal atoms then diffuse back to the cathode or deposit on the glass envelope. Therefore, the HCL emits very narrow spectral lines of radiation, some of which are identical to the absorption lines of the analyte (Figure 43.10). The spectral width of atomic absorption lines is about 10^{-5} nm. There is some broadening of these lines to about 0.001–0.005 nm, but even these 'broader' absorption lines are much narrower than the resolution limits of the conventional spectral wave band selector. Therefore, the specific emission lines of the HCL eliminate a large background signal, and inherent loss of sensitivity, that would result from using a broad spectrum radiation source with a monochromator.

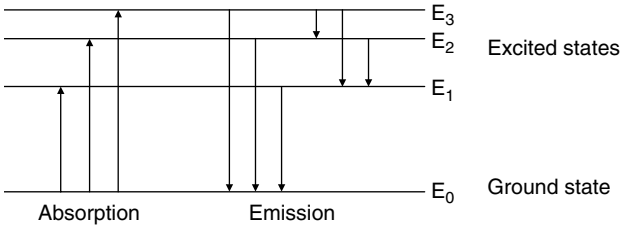

FIGURE 43.10 A comparison of the absorption and emission transitions corresponding to spectral lines for a hypothetical metal with three electronic excitation states. The emission transitions include those for absorption and additional transitions.

Typically, single element lamps are used but there are some multi-element lamps that can generate the absorption spectra of several metals simultaneously. However, usually one element is more volatile than the others, and tends to cover the surface of the other metals, reducing the intensity of radiation from these elements. The advantage of these multi-element lamps is that a single sample may be used to quantitate several elements, which is more time- and cost-efficient. An example of a multi-element lamp is the calcium and magnesium HCL, which has been used extensively for analysis of dairy products, plant extracts, and other samples.

b. *Flame atom cell*

The flame atom cell is where the sample is converted into free atoms by heating in a flame held in the burner. The flame therefore acts as the sample holder. A typical flame uses air as the oxidant and acetylene as the fuel. The ratio of oxidant and fuel can be varied to produce an oxidizing or reducing flame, which is optimized for each element. This flame is hot enough (~2500 K) to dissociate molecules of the sample into atoms for approximately 50 of the elements. However, there are approximately 10 to 20 elements that require a hotter flame, obtained using nitrous oxide-acetylene flame (~3200 K). These include elements that form very stable oxides such as aluminum, barium, and boron, and others such as lanthanum, the rare earth metals, molybdenum, silicon, and vanadium (29). A relatively long flame, several centimeters in length, is used to maximize the pathlength of the sample, and the amount of radiation absorbed by the atoms.

c. *Sample introduction system*

The sample is usually introduced into the flame as a fine mist with an ideal droplet size of 2 to 6 μm. The system should introduce the sample reproducibly, with no interferences, and no cross contamination between samples. Pneumatic nebulizers are the most common method of sample introduction. A jet of compressed air aspirates and nebulizes the solution. In a concentric nebulizer, the oxidant gas surrounds the sample as it emerges from a capillary tube, causing reduced pressure at the tip, and a suction of the sample solution from the container. The high velocity of the sample as it exits from the capillary tube creates a pressure reduction that causes the drop to break into a fine mist. Larger aerosol droplets are removed through a drain tube as the sample passes through an expansion chamber, and the remaining sample is mixed with the gases. Typically only 5 to 10% of the sample is nebulized and flows to the burner. Ultrasonic nebulizers, using high frequency sound between 0.1 to 10 MHz, have also been developed. These have a higher efficiency (~30%) than the pneumatic systems and can generate homogeneous aerosols with droplets smaller than 5 μm. They also allow the aerosol generation rate and gas flow rate to be varied independently. Because the sample is fed into the flame in a steady stream, a steady state signal is produced for each sample, depending on the flow rate.

d. Monochromator and detector

The monochromator is used to isolate the wavelength of interest. However, the inherent selectivity of the hollow cathode lamp means that only a low resolution monochromator is needed. A typical monochromator is composed of entrance and exit slits, and a prism, or gratings, similar to that used for a spectrophotometer. There has been some development of more complex optical systems for multi-element sensing. A photomultiplier tube, similar to those used in spectrophotometry, can be used for detection.

2. Graphite Furnace Atomic Absorption Spectroscopy

Furnace AAS differs from flame AAS in the way that atoms are generated and the sample is introduced into the system. Most designs are based on a heated graphite atomizer, commercially developed by the Perkin-Elmer Corporation. This system is a graphite tube, 50 mm long with a 10 mm diameter, heated by electrical resistance. An inert gas such as argon or nitrogen flows through the tube at a constant rate, and the system is enclosed in a water jacket. Discrete microlitre volumes of sample are deposited through an injection port onto a platform in the center of the tube, and are heated in three stages by applying a variable current. In the first stage, the solvent is evaporated, then the sample matrix is ashed, and finally the elements are atomized. The atom cloud then absorbs radiation from the HCL, and a single signal peak is produced from each sample application. Samples can be manually introduced to the graphite tube with micropipettes, but automatic sample introduction is also used. The technique requires from 2 to 200 µl volume, or a few milligrams of solid sample. While the technique is attractive because of the enhanced sensitivity and the small sample size, it is much more difficult to obtain reproducible results than with flame AAS. Furnace AAS is more prone to physical and chemical interferences that require more complex procedures to correct. As well, the instrumentation is more complex than flame AAS and requires more skill to operate and maintain.

D. Quantitation

Quantitation is achieved with a standard curve, where the relationship between signal intensity and the known concentration of analyte is determined. Usually, at least four concentrations of the analyte and a blank are used to establish the standard curve. The concentration of the unknown sample must fall within the upper and lower limits of the standard curve. The accuracy of the results will decrease, however, if atomization of analyte occurs differently in the standard solution compared to the samples. In cases where the matrix of the unknown cannot be matched with the standards, the method of standard addition may be used to compensate for interferences in the analysis. The signal from an unknown is determined, and then increasing amounts of the standard are added to the sample, and the signal is determined for each addition. The concentration of the original sample can then be determined by back extrapolation.

Flame atomic absorption produces a steady-state signal, depending on how rapidly the sample is introduced into the flame, and has a detection limit of 100 ppb for many elements. Graphite furnace AAS can have detection limits 10 to 100 times lower than flame AAS, achieving sub-ppb detection, and produces a transient signal, similar to a chromatographic peak. Therefore, peak area (recommended for more accurate results) or peak height may be used for quantitation.

E. Sample Preparation

Almost any solid, liquid, or gas sample can be analyzed by AAS, with the appropriate pre-treatment to obtain a homogeneous solution. Liquid samples may be used directly, sometimes only with dilution to an appropriate metal concentration range. For flame AAS, solid samples are dissolved, or digested using a wet or dry ashing procedure, prior to analysis. Care must be taken to avoid losses of volatile metals during dry ashing. Solid samples may be analyzed directly by graphite furnace AAS. Metals can be extracted from a gas sample by passing the gas through a scrubber, followed by solvent extraction. Solvents and chemicals used to prepare the samples may be a source of contamination, so ultra-pure reagents should be used, and possible contamination must be accounted for by analyzing a blank. The actual measurement of a prepared sample may take approximately 10 seconds for flame AAS or 2 minutes for furnace AAS.

During AAS, there can be chemical or physical factors inherent in the sample that interfere with or enhance the production of atoms, causing errors in quantitation. A well-documented case of reduction in volatility occurs with calcium in the presence of phosphate. When these two metals are present together, calcium phosphate forms, reducing the atomization of calcium compared to that achieved from calcium chloride. Releasing agents, or ionization suppressors, are added to samples with this problem, to minimize interferences caused by incomplete or slow breakdown of a molecule to atoms or the formation of ions. Lanthanum and strontium are examples of release agents that release calcium from phosphate interference. Formation of complexes that enhance volatility are less common, although fluoride may have this effect.

V. ATOMIC EMISSION SPECTROSCOPY

A. Introduction

Atomic emission spectroscopy (AES) is used for the qualitative and quantitative analysis of metals, similar to atomic absorption spectrophotometry. While there are some common features between the two techniques, there

are also important differences. Both techniques require the formation of atoms, followed by their excitation to a higher energy state. However, AES monitors the specific wavelengths of radiation emitted by excited atoms or ions, as the excited electrons fall back to lower states. Therefore, the *sample itself* creates the radiation signal in AES, and an external lamp is not required. Because a specific radiation source is not required, multiple elements can be detected in a single AES analysis. Examples of the application of AES to detect elements in food samples are given in Table 43.7.

B. Principles

AES uses thermal energy to form free atoms from a sample matrix, and to promote valence electrons of the atoms into an excited state (28). When the electrons fall back to the ground state, the excess energy is emitted as radiation that can be detected and quantified. Similar to AAS, emission lines occur from about 160 to 900 nm, and are typically very narrow. Each ion or atom will emit a distinct set of spectral lines dependent on the electron structure of the material and the permitted energy states of the electrons that are used for identification. Qualitative analysis can be achieved by monitoring the presence of a spectral line with intensity greater than the background. The intensity of the spectral line is proportional to the concentration of the element, allowing for quantitative analysis.

The emission spectral lines are more complicated than the absorption spectral lines. With atomic absorption, the electronic transitions are usually from the ground state to the first excited state (the resonance transitions), while in atomic emission, more intermediate transitions are detected. However, because of the very narrow and characteristic emission lines from the gas-phase atoms, each element can be detected relatively free of interferences from other elements. Most elements exhibit several spectral lines that have reasonably similar sensitivities. Therefore, if one spectral line exhibits interference, an alternative may be chosen. There are several commonly used variations of atomic emission spectroscopy, depending on the energy source used to excite the samples, including flame AES (also termed flame photometry), arc/spark AES, and inductively coupled plasma (ICP) AES.

TABLE 43.7
Selected Applications of Atomic Emission Spectroscopy (AES)

Application	Reference
Trace element (Ca, Cu, Fe, Mg, Mn, Zn, K, Na) food composition data for 32 different fruits by flame AAS and flame atomic emission spectroscopy	30
Selenoamino acids determined in garlic, onion, and broccoli using gas chromatography with atomic emission detection	31
ICP-AES to determine Al, As, B, Ba, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, Ni, P, Pb, Se, Sr, Tl, V, and Zn contents of food samples	32
ICP-AES of nickel, iron and copper in margarine samples	33
Simultaneous ICP-MS determination of 34 trace elements in the wines (Li, Be, Mg, Al, P, Cl, Ca, Ti, V, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Br, Rb, Sr, Mo, Ag, Cd, Sb, I, Cs, Ba, La, Ce, Tl, Pb, Bi, Th, and U)	34
Double focusing ICP-MS analysis of Sr, Cd, Hg, and Pb, and Na, Al, Ca, Mg, Cr, Mn, Fe, Ni, Cu, Zn, and Se in milk whey	35

C. Equipment

The instrument used for AES requires an energy source to atomize and excite the analyte, a sample nebulizer and introduction system, a monochromator to select the emission wavelengths, a detector to record the radiation intensity, and data manipulation/readout device. Therefore, except for the radiation source (the HCL), the components are similar to those of an atomic absorption spectrometer (Figure 43.9), and some instruments can be used for both techniques. The liquid sample is aspirated into the energy source, using pneumatic or ultrasonic nebulizers, similar to those used for AAS. As previously described, only a small percentage of the sample reaches the energy source while the rest is lost through droplet condensation. In the energy source, the solvent is evaporated, the sample matrix (if present) is ashed, and the analyte is atomized and electronically excited. The emitted photons are passed through a narrow entrance slit, dispersed using a mono- or poly-chromator, and detected with a photomultiplier. The energy sources and the specific characteristics and applications of the different types of AES are described below.

1. Flame Atomic Emission Spectroscopy

Some of the flames used for flame AES include air-hydrogen (~2300 K), oxygen-hydrogen (~3000 K), and oxygen-acetylene (~3400 K). The flame must supply enough energy to atomize the analyte and to excite the atoms to higher energy states. The alkali metals and alkali earth metals (sodium, potassium, lithium, cesium, calcium, strontium, and barium) are easily excited and amenable to analysis by flame AES. The flame provides relatively low amounts of energy, however, and may result in low intensities of radiation for other metals that require more energy to reach higher excited states. Still, there are more than 70 elements, and some metal oxides, that can be detected and quantitated using flame AES. In theory, using a hotter flame should produce a stronger emission, but this is not always the case since atoms may ionize at higher temperatures. Ionization creates new spectral emission lines, reducing the intensity of the atomic lines.

Because of the low energy flame, resonance spectral lines, arising from the transition between the first excited state and the ground state, are used for quantitation. However, at high concentrations, these spectral lines can self-absorb (i.e., atomic absorption occurs), causing a reduction in intensity and making it difficult to obtain reliable results. In addition, corrections to background emissions must be made for organic solvents which will yield spectral lines from products of complete or incomplete oxidation, and from the combustion fuel of the flame itself.

2. Arc/Spark Atomic Emission Spectroscopy

This type of AES utilizes an electrical discharge to excite the sample of interest. These sources can achieve temperatures of 4000 to 6000 K. Arc/spark emission spectroscopy has several advantages over flame AES. It is more universal in its application in that the higher temperature source can excite most elements, and therefore most metals can be analyzed. As well, the greater energy used in excitation causes transition beyond the first excited state, and allows transitions between two upper excited states to be used for analysis. This can improve quantitation since the number of atoms in the upper excited states is relatively low; therefore there is little self-absorption of these spectral lines, and a linear response between concentration and line intensity can often be obtained. Arc/spark AES is 10 to 1000 times more sensitive than flame AES. However, intense spectral lines that can cause interference can be produced from materials in the air near the electrical discharge.

3. Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES)

A plasma is an ionized gas that is neutral in charge. A plasma can be created starting with a stream of gas (typically argon) that flows through an open tube surrounded by a metal coil, such as copper. The coil transfers power from the radio frequency generator, acting as an inducer, and therefore the source is referred to as an inductively coupled plasma (ICP). The coil sets up an oscillating electromagnetic field. A few charged argon ions are introduced by an igniting device, and are caught in the oscillating field. These ions move rapidly with the field, generating more ions and free electrons from collisions with gas atoms. These secondary ions, in turn, create even more ions and free electrons, resulting in the plasma. Another stream of argon is used to carry the aerosol sample from the nebulizer into the plasma. The aerosol must be dried to remove the large amounts of solvent that would cool or extinguish the plasma. This is accomplished by passing the sample through a heated tube, and then a cooled condenser. When the atoms of the sample are introduced into the plasma, they collide with rapidly moving gas ions, become excited, and then relax to a lower energy state, emitting distinct spectral lines. The plasma source is extremely hot—estimates range from 6500 to 10,000 K—and therefore it is capable of breaking virtually all chemical bonds in the sample, resulting in independent ions and atoms. The method has high sensitivity since a large proportion of most elements will be excited, with little self-absorption and little chemical interference. Linearity can be achieved over four to six orders of magnitude. There are two configurations, radial and axial, for collecting radiation from the plasma. In the radial configuration, radiation is collected from the side of the plasma, across a narrow emitting central channel. An axial configuration views the plasma end-on. This configuration increases the pathlength of the sample, and increases the detection limits 5 to 10 times.

4. Detection Systems

An advantage of AES over AAS is that multiple elements can be detected in a single analysis. There have been several different detection systems designed to accommodate this characteristic (36).

a. Sequential spectrometers

Sequential instruments are the least expensive and most flexible types of emission spectrometers. Most include a single photomultiplier tube that receives wavelengths of emitted radiation in sequential order from a monochromator. This configuration is good to use when the metals to be determined, their concentration, and the sample matrices vary. The major disadvantages of the sequential instruments are the relatively long analysis times, since only one element may be determined at a time, and the greater sample volume required.

Two methods are used to obtain reproducible wavelength selection with this type of instrument. One approach is to rely on the analyte to produce the largest spectral line near the expected wavelength. This can result in selection of an erroneous line if an interfering element is present at relatively high concentrations. Alternatively, a known spectral line, such as the carbon line at 193 nm, can be used for reference, and the wavelength of interest is identified as a predefined number of steps from the reference. This method is less likely to lead to selection of the wrong spectral line, but increases analysis time.

b. Simultaneous spectrometers

Simultaneous spectrometers use multiple detectors, with one or more photomultiplier tubes for each analyte of interest, so that the instrument is configured for a set number of analytes, with known interferences. The radiation of different wavelengths emitted by the sample is dispersed through a monochromator onto the detectors. Because detectors and grating are stationary, there is no need for a peak search routine. Matrix-dependent interferences can be overcome by installing multiple detectors for

a single element, and selecting the one that is most sensitive and interference free. The major disadvantage of these instruments is the lack of flexibility, as they are configured for specific spectral lines of analytes, and the installation of additional detectors after the instrument has been configured can be expensive.

c. Solid-state array detector spectrometers

To overcome the limitation of both the sequential and simultaneous instruments, charge-injection device (CID) or charge-coupled device (CCD) detectors have been introduced to give very high sensitivity and resolution. These detectors can monitor 250,000 or 5,000 spectral lines simultaneously, respectively. These instruments with a CID or CCD can be obtained for the same price as an instrument with a simultaneous configuration and 25 photomultiplier detectors, and therefore are likely to be the configuration of choice.

d. ICP-AES mass spectrometry

Mass spectrometry can be used in conjunction with ICP to detect the atoms and ions, rather than using the radiation they emit (28). The atoms and ions are produced by the plasma as previously described, extracted from the center channel of the plasma, and separated and detected using mass spectrometry, by their mass to charge ratio. The technique is extremely sensitive, with detection at the part per trillion level, and may require a clean room environment to eliminate background interferences. It is the only atomic absorption/emission technique that can separate and quantitate isotopes, but it is by far the most expensive type of AES.

D. Quantitation

AES can be used quantitatively, using a standard curve or by the method of standard addition, as described for AAS; however, careful calibration is required to obtain accurate results. Many different experimental variables affect the intensity of radiation emitted, including spectral line overlap from elements in the samples that cannot always be avoided. In these cases, correction factors are calculated, using pure solutions of each component.

Matrix effects are common for flame and arc/spark AES. If the matrix is more volatile than the analytes, it will cause the signal from the elements to be released over a longer time and with a lower intensity. Ideally, the matrix of the sample and the standards should be identical. If there are substantial differences in the matrix between the samples and standards, background correction must be used.

It is difficult to compare the different atomic absorption or atomic emission techniques for sensitivity and detection limits, since factors such as the equipment configuration, slit width, the sample matrix, and the spectral line used influence the signal obtained. For a particular analysis, a literature search can be carried out to determine the best method. However, some general comparisons of the techniques can be made. Flame AES can detect elements at sub-ppm levels, while arc/spark-AES and ICP-AES have detection limits that are 10 to 1000 times lower, at sub-ppb to several hundred ppb. As mentioned above, ICP-AES mass spectroscopy has a detection limit that is several orders of magnitude lower than this, often at ppt to the sub-ppt level. In relationship to atomic absorption techniques, ICP-AES is between that of flame and furnace atomic absorption spectrophotometry, with flame AAS being the least sensitive method of detection.

E. Sample Preparation

Sample preparation for AES is similar to that required for AAS. Only liquid samples can be applied to AES, and therefore solid samples must be solubilized in an appropriate solvent, and may require wet or dry ashing.

VI. POLARIMETRY

A. Introduction

Anisotropic materials, those that have a lack of symmetry in their molecular or crystalline structure, and nonracemic samples, those containing unequal concentrations of enantiomers of a chiral molecule, have the ability to rotate a plane of polarized radiation. Such substances are said to have optical activity. The measurement of the rotation of plane polarized radiation by an optically active material is called polarimetry. Polarimetry is a nondestructive technique that can be used for studying the structure of anisotropic materials, for checking the concentration and purity of chiral mixtures in solutions, and as an aid in identifying unknown compounds. Chemical or enzymatic reactions may be monitored by the change in optical rotation over time. The technique is used extensively for the analysis of carbohydrates in the sugar refining industry. Some selected applications of polarimetry in food science are given in Table 43.8.

B. Principles

Linearly or plane polarized radiation is made up of equal intensities of left- and right-circularly polarized radiation (40). Optical rotation occurs because the electrical component of left- and right-circularly polarized radiation interact with the asymmetric centers of chiral molecules, differently. This differential interaction causes the two circularly polarized components to travel at different velocities. Therefore, they are not in phase when they exit the sample, and exhibit an overall rotation. Optical rotation occurs for both visible and ultraviolet radiation. The rotation is said to be dextrorotatory (d) if the radiation is rotated clockwise when viewed by an observer looking toward the radiation

TABLE 43.8
Selected Applications of Polarimetry

Application	Reference
Polarimetry in sugar analysis	37
Polarimetry as a quantitative tool for the determination of collagen content of isinglass finings	38
Laser-based polarimetry for the detection of gentamicin analogues separated by reverse phase ion pair chromatography in whole milk	39

source, and the enantiomer is given the (+) designation. Similarly, the enantiomer that rotates radiation to the left, or counterclockwise, is called the levorotatory (l) or the (−) enantiomer. It should be noted that the direction that polarized light will be rotated by a chiral compound cannot be predicted by its stereochemistry (designated *R* or *S*), and must be determined experimentally.

C. Equipment

The simplest polarimeter consists of a monochromatic radiation source, a polarizer, a sample cell, a second polarizer, which is called the analyzer, and a radiation detector (Figure 43.11). The analyzer is oriented 90° to the polarizer so that no radiation reaches the detector. When an optically active substance is present in the beam, it rotates the polarization of the radiation reaching the analyzer so that there is a component that reaches the detector. The angle that the analyzer must be rotated to regain the minimum detector signal is the optical rotation.

D. Quantitation

The amount of optical rotation depends on the number of optically active species, through which the radiation passes, and is therefore dependent on both the sample pathlength and the analyte concentration. Specific rotation, $[\alpha]$, accounts for these factors, and is defined as:

$$[\alpha]_{\lambda} = \alpha / (l \cdot d) \qquad (43.10)$$

where α is the measured optical rotation in degrees, l is the sample pathlength in decimeters, and d is the density if the sample is a pure liquid, or the concentration if the sample is a solution. In either case, the units of d are g/cm^3. As well, optical rotation depends on the wavelength of radiation, λ, and the temperature, t, so both are specified. A sodium lamp that has a spectral emission D-line at 589 nm is often used as a monochromatic source, and the specific rotation is designated as $[\alpha]_D$ to denote this. It can be noted that the specific rotation, $[\alpha]_{\lambda}$, and the measured optical rotation, α, of Equation 43.10 are analogous to the absorptivity, *a*, and the absorbance, A, respectively, of the Beer-Lambert law (Equation 43.5). Therefore, similar to spectrophotometry, the concentration of an analyte can be determined knowing the specific rotation of the compound, and determining the optical rotation at the specified wavelength and temperature. Alternatively, a standard curve relating optical rotation to concentration of a standard compound may be used for quantitation.

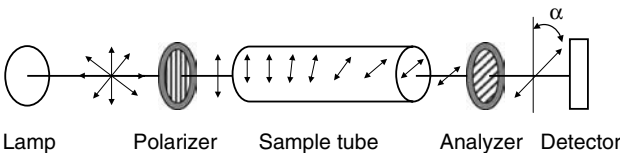

FIGURE 43.11 A schematic representation of a polarimeter.

The optical rotatory dispersion (ORD) is the optical rotation as a function of wavelength. It is recorded using a spectropolarimeter, which has a broad-spectrum radiation source and a scanning monochromator. This technique has largely been replaced by circular dichroism spectroscopy. Additional information on ORD may be found in (40).

E. Sample Preparation

Samples must be liquids or dissolved in an appropriate solvent for analysis by a polarimeter. The solvent used must be specified since it will affect the specific rotation of the analyte.

VII. CIRCULAR DICHROISM SPECTROSCOPY

A. Introduction

Circular dichroism (CD) can be observed when optically active matter both absorbs and rotates left- and right-handed circular polarized radiation slightly differently (40). If the left- and right-circularly polarized radiation has the same amplitude and wavelength, the resultant radiation is observed as plane polarized radiation. However, when the plane polarized radiation passes through a sample that absorbs the two circularly polarized components to different extents, the radiation rotates along an ellipsoid path (Figure 43.12). The difference in the left- and right-handed absorbance, *A*(l)- *A*(r), is very small and will cause an ellipticity of the radiation, ψ, of a few 1/100ths to 1/10ths of a degree. This small ellipticity can be measured accurately, and recorded as a function of wavelength to yield a CD spectrum. CD spectroscopy can be a more informative method than ultraviolet-visible spectrophotometry since it reflects not only the absorption of radiation, but also the chiral centers of the analyte through features termed Cotton bands. CD spectroscopy can be used to establish the stereochemistry of a chiral molecule or confirm chiral purity, and is very useful for obtaining information about the secondary structure of chiral macromolecules such as proteins, peptides, polysaccharides, and nucleic acids. For example,

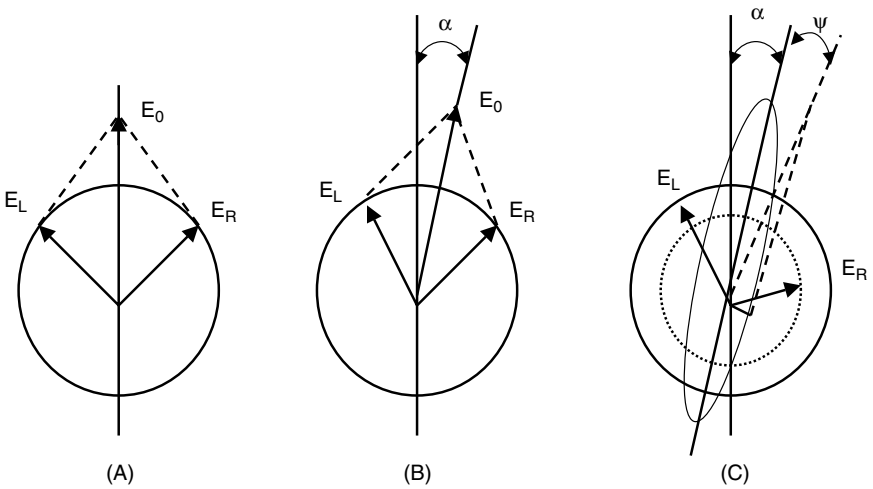

FIGURE 43.12 A. A sample that is not optically active does not preferentially interact or absorb left (E_L) or right (E_R) circularly polarized radiation. The radiation leaving the material is linearly polarized, with no rotation and ellipticity (E_O). B. The preferential interaction of one type of circularly polarized radiation passing through an optically active sample will cause a rotation in the detected radiation of α. C. The preferential absorption of one type of circularly polarized radiation will cause the transmitted radiation to follow an ellipse, with an ellipticity of ψ.

each of the three basic secondary structures of a polypeptide chain (helix, sheet, and coil) shows a characteristic CD spectrum from about 180 to 260 nm (41). Therefore, the spectrum of a protein will be the sum of the helix, sheet, and coil components, and can be deconvoluted to yield the proportion of the protein that is in each secondary structure. Examples of the application of CD spectroscopy in food analysis are given in Table 43.9.

B. Principles

The CD spectrum is recorded in radians of ellipticity, ψ, as a function of wavelength, and can be expressed as

$$\psi = [2.303c \cdot d(\varepsilon_L - \varepsilon_R)] \quad (43.11)$$

where c is the concentration in mol/l, d is the optical pathlength in cm, ε_L and ε_R are the molar absorptivity coefficients of the sample for the left and right hand circularly polarized radiation at each wavelength. It is more convenient to convert ellipticity from radians to degrees, as

$$\theta = \psi(360/2\pi) = [32.09c \cdot d(\varepsilon_L - \varepsilon_R)] \quad (43.12)$$

Molar ellipticity, [θ], can then be calculated to obtain an intrinsic quantity, as

$$[\theta] = (\theta \cdot M)/(l \cdot c' \cdot 100) \quad (43.13)$$

where M is the molecular weight, l is the pathlength in decimeters, and c′ is the analyte concentration in g/ml. For work with proteins, ellipticity is normalized to a mean residue ellipticity, $[\theta]_p$ with units of degree cm^2/decimol residue, to allow comparison between samples, calculated as

$$[\theta]_p = (\theta \cdot M)/(10 \cdot c \cdot d \cdot n_r) \quad (43.14)$$

where n_r is the number of residues in the protein.

C. Equipment

The components of a CD spectropolarimeter include a radiation source, a monochromator, a polarizer and modulator, a sample holder, and a detector (Figure 43.13). The radiation from the monochromator is first linearly polarized and then passed through a dynamic quarter wave plate that modulates it into left- and right-circularly polarized forms that pass through the sample. One type of quarter wave plate is an isotropic (uniform) crystal that is made to

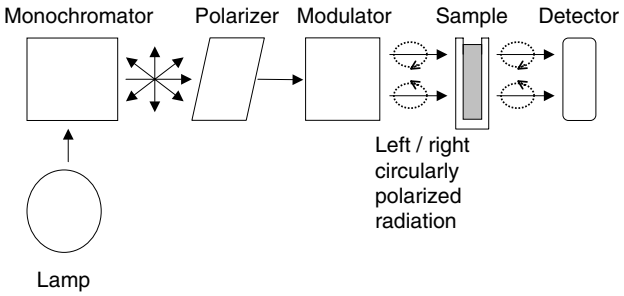

FIGURE 43.13 A schematic representation of a circular dichroism spectrometer.

be anisotropic through the application of an alternating current at high voltage. The signal intensity obtained in CD spectroscopy is small, and therefore the incident power of the radiation source must be high, and a 500 W xenon lamp is often used. As well, oxygen must be removed from the instrument by purging with pure nitrogen to eliminate the production of ozone that would interfere with absorbance at the lower wavelengths, since CD spectra are recorded from ~170 nm.

D. Sample Preparation

The requirements for a compound to be amenable to CD spectroscopy are that it must have ultraviolet or visible absorption bands and be optically active. It should be remembered that a molecule that is chiral may not be optically active if it is present as a racemic mixture. As well, samples that are not optically active may be derivatized with a chiral material prior to analysis. The detection limits for CD spectroscopy can be around the ppm range. Unfolded protein and particulate matter act as scattering particles, and add significant noise to the CD spectrum. Therefore, passing sample solutions through a 0.45 to 0.2 μm filter may improve the signal to noise ratio.

The CD spectrum of a protein can typically be obtained using 20 to 50 μl of a 0.1 to 0.5 mg/ml protein in a low ionic strength buffer (5 to 10 mM), in a cuvette with a 0.1 to 1.0 mm pathlength. Protein concentration has a significant effect on the spectrum, and therefore accurate determination of protein concentration is required. Any compound that absorbs in the region of interest (190 to 250 nm), such as chloride ions, should be avoided, and only additives in the minimum concentration essential to maintaining the solubility of the protein should be present in the sample.

VIII. NUCLEAR MAGNETIC RESONANCE (NMR) SPECTROSCOPY

A. Introduction

Nuclear magnetic resonance (NMR) spectroscopy is one of the most powerful, non-destructive analytical tools. It uses low energy radio frequency radiation to induce transitions between different nuclear spin states of a sample in a magnetic field. A single type of nuclei (e.g., ^{1}H, ^{13}C, or ^{31}P) is observed in one analysis. The most common nuclei detected are protons, which have a high natural abundance, and high inherent sensitivity, and carbon-13, which has a low natural abundance (~1.1% of naturally occurring carbon) and a low sensitivity. However, other nuclei of potential interest in food systems, such as ^{14}N, ^{23}Na, and ^{43}Ca, can also be detected. The utility of NMR spectroscopy arises because the same nuclei in different chemical environments experience slightly different magnetic fields. This causes spin state transitions for the same nuclei in different functional groups to occur at slightly different resonance frequencies. NMR spectroscopy can be used for determining the detailed structural features of molecules, quantitative measurement of sample components, and for two- and three-dimensional imaging of solid materials (46). Some selected applications of NMR spectroscopy in food science are given in Table 43.10.

B. Principles

Nuclei with an odd number of protons, neutrons, or both will have an intrinsic nuclear angular momentum or nuclear spin (60). This causes the nucleus to have magnetic characteristics including a magnetic moment and a magnetic dipole. When such a nucleus is placed in a static magnetic field, B_o, the nuclear spin can align in the same direction as the external field, in a low energy state, or in the opposite direction as the external magnetic field, in a less favorable high energy state (Figure 43.14). The difference in energy (ΔE) between the two states increases with the strength of the magnetic field. When the nuclei are exposed to radio frequency radiation that has the same energy as the difference between the two states, they will absorb it and the population of the high energy state will increase slightly, by only a few nuclei for every 10^5 nuclei. This small excess of nuclei in the higher energy state accounts for the relatively low sensitivity of NMR compared to some other spectroscopic techniques. The frequency of radiation that causes the transition is referred to as the chemical shift, δ, and is expressed in parts per million (ppm), calculated relative to a reference signal as

$$\delta = [\nu_{\text{signal}} - \nu_{\text{reference}} / \nu_{\text{reference}}] \times 10^6 \quad (43.15)$$

Using chemical shift allows spectra obtained from instruments with different magnetic strengths to be compared directly. After absorbing energy, nuclei re-emit the radio frequency radiation and return to the lower energy state in a process termed relaxation. There are two types of relaxation, spin-lattice (T_1) that involves energy exchange with the environment, and spin-spin relaxation (T_2) that involves energy exchange between similar molecules. The relaxation times are a characteristic of the chemical and physical environment of the nuclei.

There are several parameters of the NMR spectrum that can yield information about the sample. Different chemical structures can be inferred from specific chemical shifts. Characteristic splitting patterns of the NMR signals known as spin-spin coupling that occur from interactions between nuclei close to each other and the size of the splitting, the J coupling constant, are also indicative of specific structures. The area under the NMR signal peaks is proportional to the number of nuclei causing the signal. As well, the relaxation times, T_1 and T_2, have been used to determine the mobility and physical state of sample components.

Low resolution NMR spectroscopy utilizes magnets with a field strength up to ~2.0 tesla (85 MHz)[2]. An advantage of this technique is the relatively low cost of the equipment, since the magnet strength is low and the magnetic field does not need to be extremely uniform. Low resolution NMR spectroscopy can be used to determine the proportion of the sample that is moisture or lipid, the physical state of a component, and to follow chemical reactions such as crystallization, gel formation, or protein denaturation. It is not possible to obtain detailed structural information using low resolution NMR spectroscopy, as spin-spin coupling and the coupling constants may not be well resolved.

High resolution techniques use magnets of 2.3 to 21 tesla (100 to 900 MHz), with high magnetic field homogeneity. The more powerful the magnet, the greater the resolution between resonance signals. High resolution techniques are used to yield detailed structural information about molecules, and while not routine, it is possible to carry out structural analysis of macromolecules that are greater than 100 kDa (61). High resolution NMR spectroscopy has an advantage over other structure-determining techniques such as x-ray crystallography as the molecule can be analyzed in a more natural state, without the need for crystallization. High resolution NMR spectroscopy has also been used to detect sample adulteration by a technique known as site specific natural isotope fractionation (SNIF) that determines isotope ratios in specific chemical structures.

An extension of NMR spectroscopy is magnetic resonance imaging (MRI) (62). MRI yields two- and three-dimensional images of the internal structure of objects, using proton resonances. Linear radio frequency gradients are applied to the sample, in addition to the static magnetic field, B_o. This makes the resonance frequency of a nucleus dependent on its location in the gradient, and a position-dependent spectrum is obtained. By applying linear radio frequency gradients in several directions, an image based on proton density within a sample is obtained. MRI can be used to understand heat and mass transfer in a sample, water mobility, food stability, and processes such as ripening, drying, crystallization, and gelation.

C. Equipment

The basic components of a NMR spectrometer are a magnet and shim coils, the probe, the radio frequency receiver, and a computer (Figure 43.15). The magnet can be the most expensive component, and produces the principal magnetic field. Magnets greater than 4.7 tesla (200 MHz) are surrounded by liquid helium and liquid nitrogen to maintain the super-conducting conditions. There may be a number of shim coils to modify the magnetic field around the sample so that it is very homogenous, a requirement to obtain high resolution. The NMR probe is positioned in the shim coils, and generates the radio frequency radiation that causes the nuclear spin transitions. Radio frequency coils also act as the receiver to detect the relaxation signals from the sample. The sample is positioned within the radio frequency coil of the probe and is spun to minimize heterogeneity in the sample and the magnetic field. A computer is an integral part of NMR spectrometers, and controls the settings of the components, and data storage and manipulation.

[2] Although magnet strength is measured in tesla, it is common to refer to instruments in terms of the resonance frequency for a proton at the specified magnet strength, expressed in MHz.

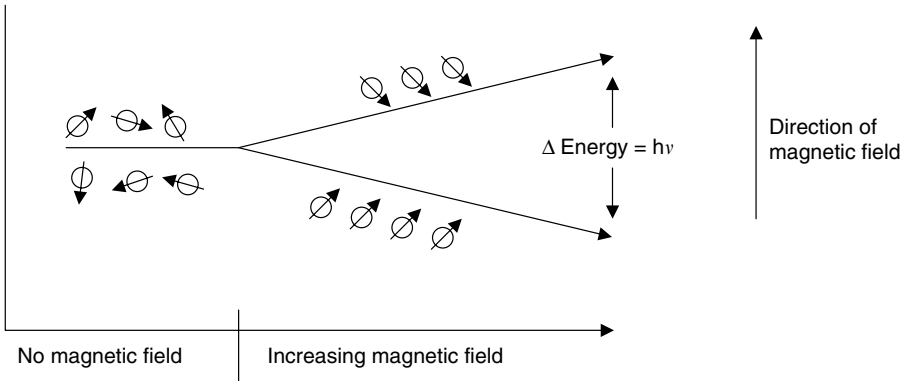

FIGURE 43.14 A schematic illustration of nuclei with a magnetic moment in the absence or presence of an applied magnetic field. The energy difference between the magnetic states of the nuclei (ΔE) is related to the strength of the magnetic field, and is a function of the radiation frequency (ν) and Planck's constant (h).

Fourier transform spectrometers are the most common type of instrument. They emit a short pulse of radiation over a broad range of frequencies, so that the spin state of all the nuclei of interest (i.e., all the protons in a sample) is altered. All of the resulting relaxation signals are also received at the same time, and can be separated mathematically yielding the NMR spectrum. An alternate approach is the continuous wave instrument that emits the range of radio frequencies sequentially, and also received the signal sequentially. Therefore, data collection with a continuous wave instrument takes a significantly longer time.

D. Sample Preparation

Solutions and solid samples may be analyzed by high resolution NMR spectroscopy. Pure samples are dissolved in an appropriate solvent (usually one in which all the hydrogens have been replaced with deuterium) to yield a homogeneous solution and filtered to remove particulate matter that will affect resolution. With the application of more powerful magnets, the resolution between the resonances increases and the amount of sample required for analyses decreases. A few micrograms to milligrams of sample may be required, depending on the instrument, and the molecular weight of the analyte. The ideal solid for high resolution NMR spectroscopy is a uniform powder compacted into a sample holder, that is subjected to 'magic-angle spinning'—a 54.44° angle between the sample spinning axis and the external magnetic field that is used to improve signal resolution.

For low resolution NMR applications, samples can be analyzed without extraction or solubilization because radio frequencies can penetrate solid materials. The sample must only be manipulated to fit in a sample tube. Therefore, valuable information relating to the intrinsic structure and composition of a sample can be determined based on the relaxation parameters, T_1 and T_2. Large samples with no modification can be monitored by MRI, the only limitation being the size of the probe cavity.

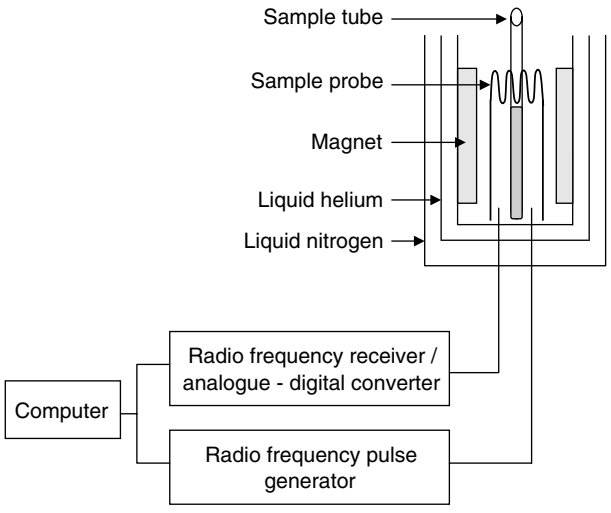

FIGURE 43.15 A schematic representation of a nuclear magnetic resonance spectrometer.

IX. CONCLUSION

This chapter has briefly highlighted the essential features of some commonly used spectroscopic techniques and provided examples of how each technique can be applied to food-related analyses. These techniques are fundamental analytical tools that have allowed us to better understand the individual components of food and foods as complex systems. They have played a key role in the maintenance of food quality and safety. Improvements in instrumentation and advances in the application of these techniques will continue to provide food scientists with more sensitive and informative methods of analysis.

44 Infrared and Raman Spectroscopy in Food Science

Ashraf A. Ismail, Robert Cocciardi, Pedro Alvarez, and Jacqueline Sedman
Department of Food Science and Agricultural Chemistry, McGill University

CONTENTS

I. INTRODUCTION

Infrared (IR) and Raman spectroscopy provide detailed information about both the composition of foods and the molecular structure and the functionality of the components in food systems. Both techniques are based on molecular interactions with electromagnetic radiation that result in transitions between the vibrational energy levels of the ground electronic energy state of the molecule, corresponding to the excitation of various stretching and bending vibrations. However, the nature of these interactions is fundamentally different in these two types of vibrational spectroscopy, and hence they are regarded as complementary techniques. In general terms, as well as specifically in regard to applications to food systems, IR spectroscopy has found much more extensive use than Raman spectroscopy owing to the greater simplicity and lower cost of the instrumentation as well as the greater utility of IR spectroscopy as a quantitative analysis tool. On the other hand, Raman spectroscopy offers certain advantages in relation to sample handling, the study of aqueous systems, and possibilities for on-line process monitoring. Thus, the selection of IR or Raman spectroscopy, or the combined use of both techniques, depends on the nature of the application. Near-infrared (NIR) spectroscopy combines the sample-handling advantages of Raman spectroscopy with the powerful multicomponent analysis capabilities of IR spectroscopy and thus has found widespread application for quality control and process monitoring in the food industry for several decades. However, by comparison with (mid-) IR and Raman spectra, NIR spectra are fairly uninformative, and NIR analysis is largely based on statistical treatment of the spectral data. Entire books have been devoted to NIR

analysis of foods (1, 2) and NIR spectroscopy will not be considered in this chapter.

In the following sections, the principles of IR and Raman spectroscopy and the instrumentation and sample-handling techniques employed to acquire spectra will be briefly described. The utility of these two techniques for investigations of the individual components of food systems will then be illustrated by considering the information that can be extracted from the IR and Raman spectra of food proteins. Finally, a survey of the applications of IR and Raman spectroscopy in the analysis of foods will be presented.

II. FUNDAMENTAL PRINCIPLES OF IR AND RAMAN SPECTROSCOPY

IR and Raman spectroscopy are both based on the excitation of molecular vibrations by interaction with electromagnetic radiation. A nonlinear molecule made up of N atoms possesses $3N - 6$ vibrational modes, each of which has a specific frequency; the number of vibrational modes is reduced by one in the case of linear molecules. The factors determining the frequencies of molecular vibrations can be illustrated by considering the simplest case, a diatomic model AB, which has a single vibrational mode involving the stretching of the bond linking atoms A and B. The frequency at which this bond vibrates can be calculated from the model of a harmonic oscillator, whereby the restoring force (F) on the bond is given by Hooke's law:

$$F = -kx \tag{44.1}$$

where k is the force constant of the bond and x is the displacement from the equilibrium internuclear distance. Under this approximation, the vibrational frequency, ν, is given by

$$\nu = (1/2\pi)(k/\mu)^{1/2} \tag{44.2}$$

where μ is the reduced mass of the system, as defined by the following equation:

$$\mu = m_A \cdot m_B / (m_A + m_B) \tag{44.3}$$

where m_A and m_B are the individual atomic masses of A and B. By convention, vibrational frequencies are given in wavenumbers ($\overline{\nu} = \nu/c$, where c is the speed of light), expressed in units of reciprocal centimeters (cm^{-1}), rather than in units of frequency (s^{-1}), although in older literature, band positions are often reported in units of wavelength (λ), i.e., microns (μ). The frequencies of molecular vibrations fall primarily in the mid-IR region of the electromagnetic spectrum (4000–400 cm^{-1}; 2.5–25 μm).

The quantum-mechanical treatment of molecular vibrations leads to modifications of the harmonic oscillator model as the vibrational energy levels are quantized:

$$E = (\nu + 1/2)h\nu \tag{44.4}$$

where ν is the vibrational quantum number, h is Planck's constant, and ν is the fundamental vibrational frequency. The quantum-mechanical theory predicts that at room temperature, only transitions from the ground-state vibrational level ($\nu = 0$) to the first excited vibrational level ($\nu = 1$) will occur; however, experimentally this is not the case as weak overtone bands, corresponding to transitions to higher energy levels, can be observed, especially in the NIR spectral region.

IR spectroscopy is based on the measurement of molecular absorption of IR radiation of frequencies that match those of the molecular vibrations. However, all of a molecule's vibrational modes do not give rise to IR absorption bands because a vibration will only be IR-active if it results in a change in the dipole moment of the molecule. For example, the stretching vibration of a homonuclear diatomic molecule, such as N_2 or O_2, is not IR-active because the equal displacement of the two atoms from the center of mass does not change the dipole moment of the molecule. However, this is no longer the case when the two atoms in the diatomic molecule have different masses, and hence the stretching vibrations of molecules such as CO are IR-active. Similarly, the symmetric stretching vibration of the CO_2 molecule illustrated in Figure 44.1 is IR-inactive because of the molecule's linear geometry while the corresponding vibration of a nonlinear triatomic molecule such as H_2O is IR-active, as are the asymmetric stretching vibrations of both linear and nonlinear triatomics.

Raman spectroscopy is based on the inelastic scattering of light by the molecules in a sample rather than their absorption of IR radiation. When a sample is irradiated with light, most of the photons are elastically scattered; that is, the wavelength of the scattered photons is unchanged. However, a small fraction (~1 in 10^6 photons) will show a shift in wavelength from that of the incident light. This phenomenon was theoretically predicted by Adolf G. Smekal in 1923 but was first observed experimentally by Sir Chandrasekhara V. Raman in 1928 and hence is called

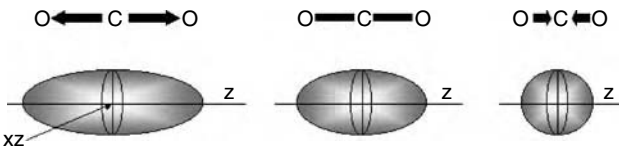

FIGURE 44.1 The symmetric stretch of the CO_2 molecule is a Raman-active but not an IR-active vibration because it results in a change in the molecule's polarizability but does not involve a change in its dipole moment.

the Raman effect. Detection of the inelastically scattered photons requires that the sample be irradiated with monochromatic (i.e., single-wavelength) light. Furthermore, since the Raman effect is very weak, an intense monochromatic light source is required. For these reasons, Raman spectroscopy only became practicable in the 1960s with the development of lasers and highly sensitive photon-counting devices, such as photomultiplier tubes.

In Raman spectroscopy, a sample is irradiated with a laser line of frequency $\overline{\nu}_0$, and the intensity of the scattered light as a function of frequency is then measured, yielding a Raman spectrum (Figure 44.2). Although most of the elastically scattered light is filtered out prior to reaching the detector, the spectrum is still predominated by a broad signal centered at the frequency of the incident light (referred to as the Rayleigh line). The remainder of the spectrum is composed of much weaker bands at lower frequencies, $\overline{\nu}_0 - \overline{\nu}_i$ (referred to as Stokes lines). The frequency shifts $\overline{\nu}_0 - \overline{\nu}_i$ (referred to as Raman shifts) are independent of $\overline{\nu}_0$, the frequency emitted by the excitation source, and correspond to the vibrational frequencies of the molecules in the sample. Even weaker bands occur at higher frequency, $\overline{\nu}_0 + \overline{\nu}_i$ (referred to as anti-Stokes lines). The Stokes and anti-Stokes lines are equally displaced from the Rayleigh line; however, the anti-Stokes lines are rarely observed owing to their very low intensity.

For a molecular vibration to be Raman-active (i.e., show a Raman effect), it must result in changes in the polarizability of the molecule, which is represented by an ellipsoid, and therefore must result in changes in the shape of the electron density cloud around the molecule. For example, as illustrated in Figure 44.1, in the symmetric stretching vibration of CO_2 the shape of the electron cloud is different between the minimum and maximum internuclear distances. Therefore, the polarizability of the molecule changes during the vibration and this vibrational mode is Raman-active. In the asymmetric stretch, the change in the polarizability ellipsoid as one of the bonds extends is cancelled by the opposite change due to the compression of the other bond, and hence there is no overall change in polarizability and the asymmetric stretch is Raman-inactive.

It is important to note that the criteria (referred to as "selection rules") for an IR-active vibration (i.e., a change in the dipole moment of the molecule) and a Raman-active vibration (i.e., a change in the polarizability of the molecule) are different. In fact, for any molecule that possesses a center of symmetry (such as the CO_2 molecule considered above), vibrations that are IR-active are Raman-inactive, and vice versa. In general, vibrations that give rise to weak IR bands often produce intense Raman bands, and vice versa. Hence, IR and Raman spectroscopy are complementary techniques, and it is usually necessary to apply both types of vibrational spectroscopy to obtain the full spectral profile of a sample.

III. INSTRUMENTATION

A. Infrared Spectroscopy

IR spectrometers essentially consist of a broad-band source of IR radiation, a means for resolving the IR radiation into

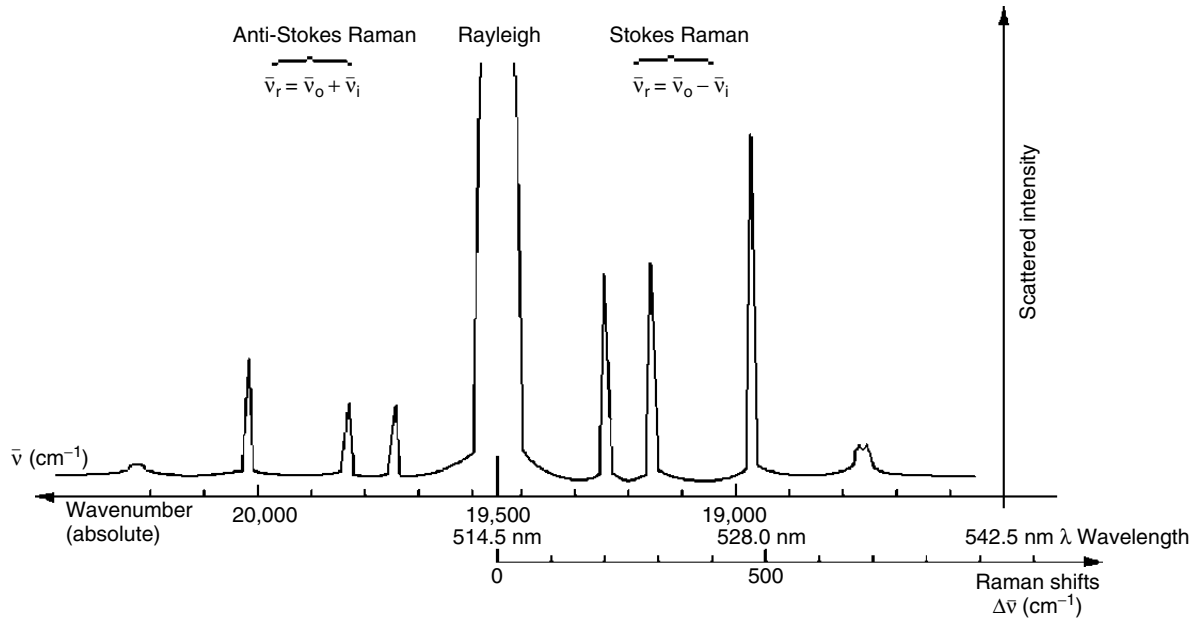

FIGURE 44.2 Schematic representation of a Raman spectrum excited with the 514-nm line of an argon ion laser. Most of the laser light is elastically scattered with the same frequency (ν_0) as the incident light. However, a small proportion is inelastically scattered with frequencies of ($\nu_0 + \nu_i$) and ($\nu_0 - \nu_i$), where ν_i is the frequency of one of the fundamental vibrations of the molecules in the sample.

its component wavelengths, and a detector. Generally speaking, an IR spectrum of a sample can be represented mathematically by the following equation:

$$T(\overline{\nu}) = I(\overline{\nu})/I_0(\overline{\nu}) \quad (44.5)$$

where T is defined as transmittance, I is the intensity of IR radiation reaching the detector when it passes through the sample, I_0 is the intensity of IR radiation reaching the detector with no sample in the beam, and $\overline{\nu}$ is the wavenumber of the radiation. Usually, transmittance is converted to absorbance (A) using the following relationship:

$$A = -\log T \quad (44.6)$$

In the early years of IR spectroscopy, prisms were used to resolve IR radiation from the source into its component wavelengths but they were subsequently replaced by diffraction gratings. In the 1970s, the field of IR spectroscopy was revolutionized when these dispersive IR spectrometers began to be replaced by Fourier transform infrared (FTIR) spectrometers. FTIR spectroscopy is based on interferometry and makes use of a beamsplitter to divide the IR radiation into two beams, with one beam being directed to a fixed mirror and the other to a moving mirror (Figure 44.3). When these two beams are reflected back to the beamsplitter and recombine, they undergo constructive and destructive interference due to the path difference between the two mirrors, yielding an interferogram. The path difference, known as retardation δ, is proportional to time t because the moving mirror travels at a constant velocity, v, i.e., $\delta = 2vt$. Through the use of a fast Fourier transform (FFT) algorithm, the time domain interferogram, $I(\delta)$, is converted into the frequency domain, $I(\overline{\nu})$, according to the following relationship:

$$I(\delta) = 0.5H(\overline{\nu})I(\overline{\nu})\cos 2\pi\overline{\nu}\delta \quad (44.7)$$

where $H(\overline{\nu})$ is a single wavenumber-dependent correction factor that accounts for instrumental characteristics. The interferogram decoded into the frequency domain is in the form of an energy curve called a single-beam spectrum (Figure 44.4). The ratio of the single-beam spectrum of the sample against a background single-beam spectrum recorded with no sample in the optical path results in a transmittance spectrum, in accordance with Equation [44.5], which is then normally converted into an absorbance spectrum by carrying out the mathematical transformation represented by Equation [44.6].

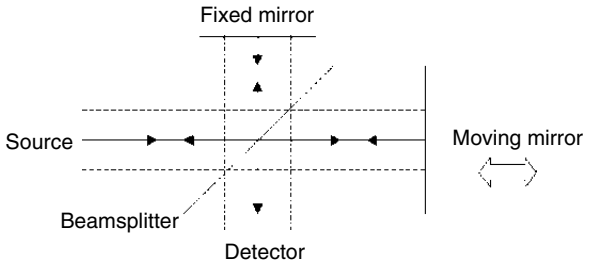

FIGURE 44.3 Schematic diagram of a Michelson interferometer. The IR radiation from the source is split into two beams by a beamsplitter and directed to the fixed and moving mirrors. The two IR beams recombine at the beamsplitter and are directed to the sample and the detector.

FTIR spectrometers have several advantages over conventional dispersive IR instruments, including a dramatic improvement in the signal-to-noise ratio (S/N) obtained by multiplexing (simultaneous detection of all frequencies), reduction in scan time, and higher energy throughput. Another important advantage is the excellent wavelength reproducibility of FTIR spectrometers, owing to the use of an internal reference laser, which allows spectral data manipulations such as spectral subtraction, addition, and ratioing to be performed with a very high degree of accuracy. The advancement of FTIR spectroscopy has been greatly assisted by the availability of increasingly powerful personal computers, which have facilitated the use of sophisticated software packages for both qualitative and quantitative applications.

B. Raman Spectroscopy

The design of traditional dispersive Raman spectrometers differs markedly from that of IR instruments. However, FT-Raman spectrometers, which have become increasingly common in recent years, are similar in design to FTIR spectrometers, and combined FTIR/FT-Raman systems are available from most major FTIR vendors. In dispersive Raman spectroscopy, the source is a high-power laser emitting visible radiation at several discrete frequencies, with filters being employed to select a single laser line; commonly employed laser lines are the 488.0-nm (blue) and 514.5-nm (green) lines of an argon-ion laser. After this monochromatic radiation impinges on the sample, a portion of the scattered radiation is directed to a monochromator to resolve it into its component frequencies and then to a photomultiplier tube. The resulting signal as a function of frequency is plotted as intensity versus Raman shift, yielding a Raman spectrum.

The major drawbacks of traditional Raman spectrometers originate with the use of high-power visible lasers as excitation sources. Samples that are susceptible to either thermal or photochemical degradation may be destroyed by the laser radiation, although various experimental approaches can be taken to minimize such damage. However, a more pervasive problem is the fluorescence that results when species present in the sample are electronically excited by the visible laser radiation. Because the Raman effect is weaker than fluorescence by many orders of magnitude, even the fluorescence from a trace

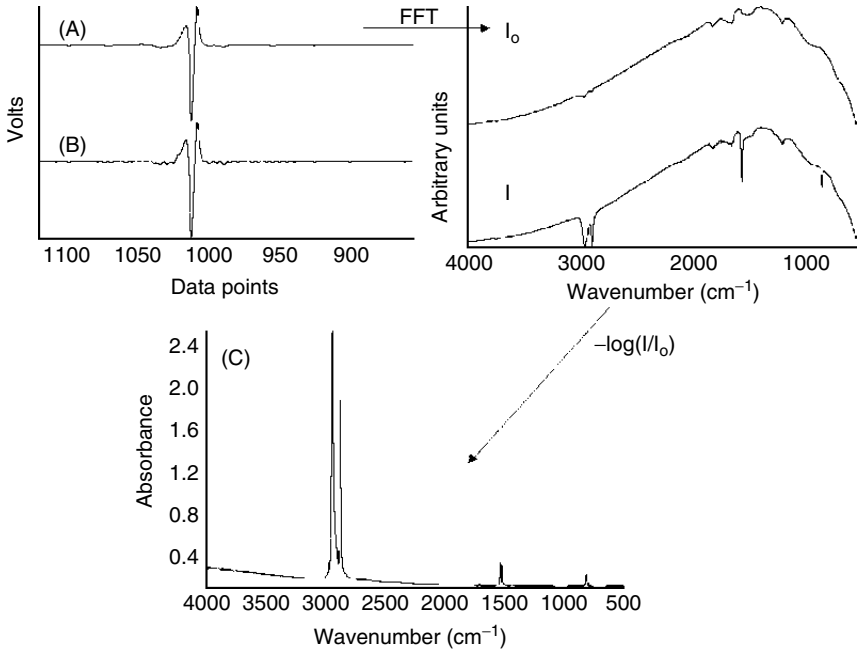

FIGURE 44.4 (A) Interferogram recorded with no sample in the path of the IR beam; (B) interferogram recorded with a thin film of polyethylene (PE) placed in the path of the IR beam. Fourier transformation of the interferogram A and B by a fast Fourier transform (FFT) algorithm yields, respectively, the open-beam spectrum (I_0) and the single-beam spectrum (I) of PE. (C) Absorbance spectrum of PE obtained by the mathematical transformation shown on the figure.

impurity can completely mask the Raman spectrum of the sample. In the past, this phenomenon severely restricted the scope of Raman spectroscopy, particularly in relation to samples of biological origin. However, it has been substantially alleviated by the use of laser excitation lines in the NIR instead of the visible region of the electromagnetic spectrum, such as the 1064-nm line emitted by neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers. Because the use of NIR lasers as excitation sources in conventional dispersive Raman spectrometers is not technically feasible, this option only became practicable with the development of FT-Raman spectrometers (3), which, like FTIR spectrometers, are based on interferometry. In fact, FTIR spectrometers can be modified to acquire Raman spectra by incorporating a Nd:YAG laser and using beamsplitters and detectors appropriate for the NIR region. The availability of these dual-purpose instruments has greatly facilitated comprehensive vibrational spectroscopic studies, although their high cost remains a disadvantage.

IV. SAMPLING METHODS

A. Infrared Spectroscopy

Infrared sample-handling accessories include transmission cells, attenuated total reflectance (ATR) accessories (both multiple- and single-bounce crystals and fiber-optic probes), as well as diffuse reflectance infrared Fourier transform (DRIFT) and photoacoustic spectroscopy (PAS). The latter two techniques, reviewed previously (4), will not be considered here, as they have had limited application in mid-IR food analysis, although DRIFT is widely used in NIR food analysis.

1. Transmission Mode

The transmission mode is the most common and oldest mode of IR sample analysis. The sample is placed in the optical path of the IR beam, and the amount of light transmitted through the sample is inversely proportional to the sample thickness, which can vary from meters for gas samples to microns for condensed-phase samples. The spectra of liquids and solutions are recorded in a transmission cell, composed of two optical windows separated by a spacer that determines the pathlength. The optical windows commonly employed are polished salt crystals (e.g., NaCl or KBr), because all materials containing covalent bonds, including glass, do not transmit IR radiation. There are also severe restrictions on the pathlength that can be employed because of the limited energy available from IR sources. For instance, aqueous solutions are typically measured in cells having pathlengths of 15–40 μm, owing to the intense absorption of IR radiation by water; beyond this thickness, virtually no IR radiation reaches the detector.

Transmission cells can be demountable or sealed, and the use of flow-through cells such as that shown in Figure 44.5 facilitates sample handling. Sealed transmission cells

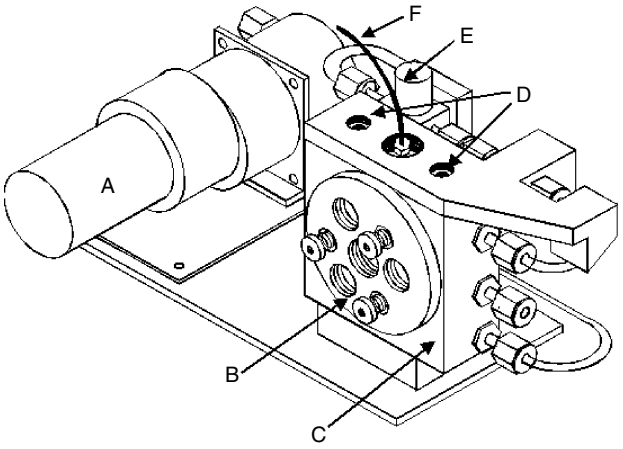

FIGURE 44.5 Schematic diagram of a transmission flow-through cell: (A) micropump, (B) demountable cell insert (transmission cell), (C) cell block, (D) heat cartridges, (E) solenoid valve, (F) thermocouple. The accessory slides horizontally so that the cell can be moved out of the path of the beam to record an open-beam background spectrum.

are preferred for quantitative analysis because a constant pathlength is required to obtain reproducible results. However, if a demountable cell is used because the sample is too viscous to inject or pump through a sealed cell, or the cell cannot be effectively cleaned between samples by simply rinsing with a solvent or detergent solution, an internal standard with a distinct absorption band can be introduced into the sample to compensate for pathlength variations.

In the case of solid samples, light scattering effects are a problem when particle dimensions are comparable to or exceed the wavelengths of mid-IR radiation and, as such, particles must be ground to <3 μm prior to analysis. The sample can then be diluted with KBr, KCl, or NaCl and pressed to form a pellet. An alternative procedure for analyzing solid samples is to make a liquid dispersion using oils, such as mineral oil (Nujol) or paraffin oil. Both the pellet and the dispersion method have the disadvantage of destroying the sample.

2. Attenuated Total Reflectance

The restrictions on sample thickness and particle size imposed by the nature of transmission measurements represent major sample-handling limitations. Attenuated total reflectance (ATR) spectroscopy, developed in the 1960s, provides a more versatile sample-handling approach. ATR spectroscopy is based on total internal reflection of the IR beam in an ATR crystal, which is made of a high-refractive-index material and serves as an internal reflection element (IRE). Total internal reflection gives rise to an evanescent wave that emerges from the surface of the ATR crystal at each point of internal reflection and decays as it propagates away from the surface (Figure 44.6). The

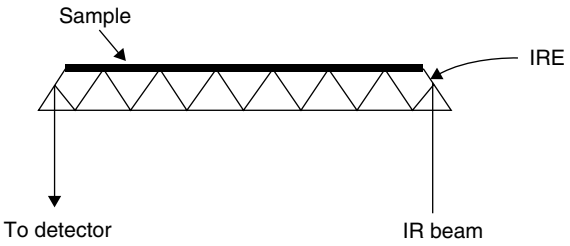

FIGURE 44.6 Schematic of a horizontal multiple-bounce attenuated total reflectance (MB-ATR) accessory.

evanescent wave is attenuated by the absorption of the IR radiation by species on or near the surface of the ATR crystal, and measurement of this attenuation as a function of wavenumber yields the IR spectrum of a sample placed on the surface of the ATR crystal.

The effective pathlength of an ATR accessory is calculated by multiplying the number of internal reflections by the depth of penetration (d_p), which is defined as the distance at which the intensity of the evanescent wave decays to $1/e$ of its value at the surface as given by the following equation:

$$d_p = \lambda/\{2\pi n_1[\sin^2\theta - (n_2/n_1)^2]^{1/2}\} \qquad (44.8)$$

where λ is the wavelength of IR radiation, n_1 is the refractive index of the IRE material, n_2 is the refractive index of the sample, and θ is the angle at which the IR radiation strikes the ATR crystal. Owing to the variation of the depth of penetration as a function of wavelength, the relative intensities of the bands in an ATR spectrum will differ from those in a conventional transmission spectrum, but this effect can be corrected for mathematically.

For a typical ATR accessory, the effective pathlength ranges from a few microns at the high-wavenumber end of the IR spectrum to several tens of microns at the low-wavenumber end. Thus, the ATR technique provides an inherently short effective pathlength without any physical restriction on the sample thickness, such that samples can be simply poured or spread on the surface of the ATR crystal and then wiped off after analysis. In addition, particle size in solid samples is not a concern as, unlike transmission spectra, ATR spectra are not affected by light scattering, and even the spectra of opaque samples can be recorded. The ATR technique is particularly advantageous for analyzing aqueous solutions, because the pathlength is sufficiently short and the common IRE materials (e.g., germanium and ZnSe) are water-insoluble, unlike most of the materials suitable for use as transmission cell windows.

The evident advantages of the ATR sample-handling technique are accompanied by certain disadvantages. The inherently short effective pathlength limits sensitivity. In addition, because the depth of penetration is on the micron scale, any surface contamination on the ATR crystal will

make a major contribution to the spectrum. Furthermore, a spectrum representative of the entire sample will be obtained only if the sample is homogeneous on this scale. In the case of powdered and solid samples, intimate contact between the sample and the ATR crystal is required, and although various clamping devices are available to press the sample against the ATR crystal, it can be difficult to obtain reproducible spectra. Another drawback that limits the utility of ATR spectroscopy is the need for precise temperature control, because the depth of penetration is dependent on the refractive indices of the IRE material and the sample, which in turn are dependent on temperature.

Many of the disadvantages described can be alleviated by employing a single-bounce (SB-ATR) accessory because of the much smaller dimensions of the ATR crystal as compared to those in multiple-bounce (MB-ATR) accessories (Figure 44.7). Although such accessories were rarely employed in the past owing to their very short effective pathlengths, which severely limited sensitivity, improvements in the optical design of SB-ATR accessories in recent years have compensated for this limitation. Because of the small surface area of the ATR crystal, precise temperature control and good optical contact between solid samples and the crystal (particularly with diamond IREs, which can withstand a strong clamping force) can be more readily achieved than with MB-ATR accessories. In addition, only very small amounts of sample are required to cover the ATR crystal (e.g., for liquid samples, <50 μL), and thus cross-contamination between samples can be virtually eliminated by wiping the crystal with the next sample prior to applying it onto the crystal to record its spectrum, provided that the samples are miscible with each other. These advantages make this type of accessory very promising for quantitative analysis of foods, although potential applications are restricted by the short effective pathlength and hence limited sensitivity.

B. Raman Spectroscopy

In terms of sample handling, Raman spectroscopy is a much more versatile and flexible method than IR spectroscopy because it does not suffer from restrictions on sample thickness (or pathlength), the need for specialized sample-handling accessories, or problems caused by light scattering. Thus, Raman spectra can be recorded directly from solid samples, even if opaque, with no sample preparation, and samples can be contained in ordinary glass vials. Thin glass capillaries are ideal for recording Raman spectra of solids or liquids because the laser is a highly focused energy source, allowing spectra to be obtained from samples as small as 100 μm in diameter. The main sample-handling difficulty encountered in Raman spectroscopy is excessive heating of the sample if an intense visible laser is employed as an excitation source. To alleviate this problem, the laser beam may be defocused, or various accessories that are available to prevent heating of the sample may be employed; these range from devices that continuously rotate the sample, which can effectively reduce sample heating in the case of fluid samples, to expensive helium-cooled cryostats, which may be required to prevent burning in the case of thermally unstable solids. The need for such measures has been reduced, however, with the use of NIR lasers in FT-Raman spectroscopy.

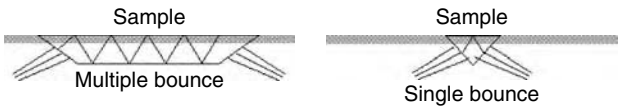

FIGURE 44.7 Illustration of the relative sample dimensions in multiple- and single-bounce horizontal ATR accessories.

V. IR AND RAMAN SPECTROSCOPY OF FOOD COMPONENTS AND FOODS

The vibrational spectra of foods are the superposition of the spectra of all the individual components present and are thus generally very complex. The IR spectra of aqueous systems are dominated by the intense absorptions of water (Figure 44.8A), which can obscure the spectral features of other components in broad regions of the spectrum, as illustrated by the transmission spectrum of milk in Figure 44.8B. Although the spectral contributions of water can be removed digitally by spectral subtraction (Figure 44.8C), information cannot be obtained from regions of intense IR absorption by water except when very short pathlengths are employed; this limitation is often addressed by taking advantage of the inherently short effective pathlengths of ATR accessories (Figure 44.9). This difficulty is absent in Raman spectroscopy because water is a weak Raman scatterer.

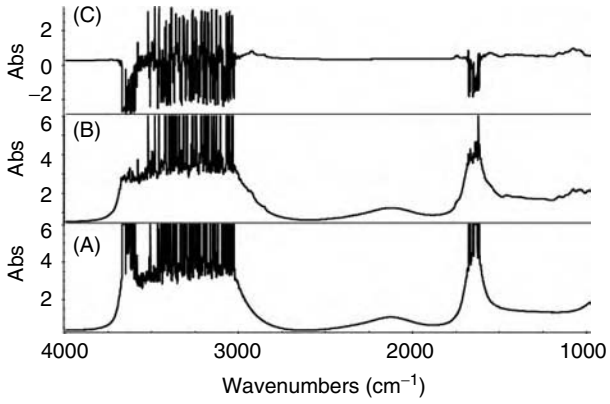

FIGURE 44.8 FTIR spectra of water (A) and milk (B) recorded using a 50-μm transmission cell and difference spectrum (C), obtained by subtraction of spectrum A from spectrum B.

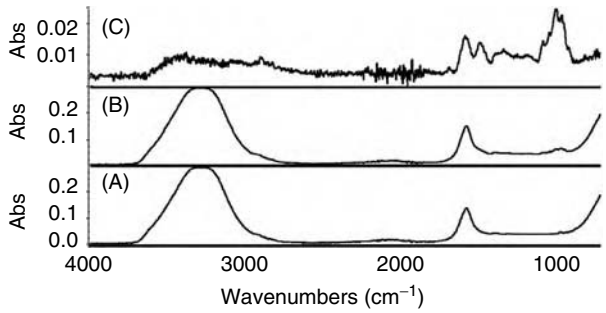

FIGURE 44.9 ATR/FTIR spectra of water (A) and milk (B) recorded using an SB-ATR accessory and difference spectrum (C), obtained by subtraction of spectrum A from spectrum B.

The other major components of foods—fats, proteins, and carbohydrates—give rise to strong bands in both IR and Raman spectra. Although many of the bands due to these individual components overlap with each other, fats, proteins, and carbohydrates each have certain characteristic bands that arise from particular functional groups. The band positions and assignments of some of the major bands of these components are summarized in Table 44.1. However, it should be noted that vibrational frequencies are sensitive to electrical effects, steric effects, the nature, size, and electronegativity of neighboring atoms, phase changes, hydrogen bonding, and solvent polarity. Although this sensitivity may complicate spectral interpretation, it also contributes to the high information content of vibrational spectra. Thus, IR and Raman spectroscopy are valuable techniques for the characterization of materials in terms of their chemical composition, detailed investigations of molecular structure and bonding, and studies of the interactions of molecules with their environment. Furthermore, IR and Raman spectra of substances serve as their "fingerprints," allowing for the identification of substances with a high degree of specificity by comparison of their spectra with those in a spectral database or "library."

The powerful qualitative analysis capabilities of vibrational spectroscopy can be applied to complex samples, such as foods, for purposes of classification and authentication. For such applications, multivariate analysis techniques such as principal component analysis (PCA) are commonly used to reduce the dimensionality of the spectral data (5). Because an FTIR or FT-Raman spectrum is produced by Fourier transformation of an interferogram, as described in Section III.A, the spectra inherently consist of digital data. The dimensionality of the data depends on the spacing between data points, which is a function of the instrument resolution at which the spectra were collected and the level of zero filling employed in the calculation of the Fourier transform. For example, the FTIR spectra of condensed-phase samples are typically collected at 4-cm^{-1} resolution between 4000 and 400 cm^{-1} and thus, with one level of zero filling, each spectrum contains ~1800 data points. Each of these data points is a variable that contains the absorbance at a particular wavenumber, but many of these variables are highly correlated since (a) the inherent width of the bands is usually much greater than the resolution so that a given band contributes to several contiguous data points and (b) any given species present in the sample usually has multiple bands and the intensities of these bands thus change collinearly as a function of change in concentration. By using PCA, most of the variation in the data can be described by a few orthogonal principal components (PCs), or latent variables, which are linear combinations of the original variables. The data are characterized by scores, which are projections of the spectra onto each PC, and loadings, which represent the contributions of the variables to each PC. Cluster analysis based on PCA

TABLE 44.1
Selected Vibrational Bands of Major Food Components[a]

Food Component(s)	Frequency (cm^{-1})	Band Assignment(s)
Water, carbohydrates	3600–3200	O-H stretching vibration; strong water IR absorption band
Fats	3012–3004	C-H stretching of *cis* double bonds
Fats, carbohydrates, and proteins	3000–2800	C-H stretching of CH_2 and CH_3 groups
Fats	1745–1725	C=O stretching, ester linkages in triacylglycerols
Proteins	1700–1600	Amide I band, peptide linkages of proteins
Fats[b]	1678–1665	C=C stretching of *trans* double bonds
Fats	1662–1648	C=C stretching of *cis* double bonds
Water	1650	H-O-H bending vibration; strong IR absorption band
Proteins	1560–1520	Amide II band, peptide linkages of proteins
Proteins	1300–1190	Amide III band, peptide linkages of proteins
Carbohydrates	1250–800	C-O stretching and C-O-H bending vibrations
Fats[b]	971–965	C=C-H bending of isolated *trans* double bonds

[b] Predominantly hydrogenated fats and oils.

scores may then be performed to group samples according to their degree of spectral similarity, which in turn reflects their degree of compositional similarity. Alternatively, with the application of supervised pattern recognition techniques (e.g., discriminant analysis), the PCA scores may be employed to assign samples to particular classes for purposes of authentication. The capability of distinguishing between different classes of samples on the basis of differences in their vibrational spectra has led to investigations of the potential utility of IR and Raman spectroscopy as a means of detecting adulteration of foods.

Both IR and Raman spectroscopy can also be employed for quantitative analysis. However, although Raman scattering intensity is directly related to concentration, quantitative analysis by Raman spectroscopy has generally been regarded as problematic, and relatively few applications in the area of food analysis have been reported. On the other hand, the scope of reported applications of quantitative IR spectroscopy in food analysis has increased substantially in recent years owing to the advantages of FTIR spectrometers and the new sample handling technologies available combined with the development of a range of sophisticated multivariate analysis methods. As in other types of absorption spectroscopy, IR quantitative analysis is based on the linear relationship between absorbance and concentration, as expressed by the Bouguer-Beer-Lambert law, commonly known as Beer's law:

$$A_\nu = \varepsilon_\nu bc \tag{44.9}$$

where A_ν is the absorbance measured at frequency ν, ε_ν is the absorption coefficient of the absorbing species at the same frequency, b is the pathlength of the cell, and c is the concentration of the absorbing species. Therefore, a calibration curve can be developed by relating changes in absorbance to changes in concentration of a species at a fixed pathlength. It is important to note that IR spectroscopy is a secondary method of analysis, so the development of a calibration requires a set of standards of known composition, prepared gravimetrically or analyzed by a primary reference method. Once a calibration has been developed, it can be used to predict the concentrations of unknowns, provided that the spectra of the unknowns are recorded under the same conditions as the calibration standards and the spectra of the standards are representative of those of the unknowns in the spectral region(s) employed for quantitation. IR spectroscopy can also be employed to directly predict various physical properties and quality attributes of samples, provided that they are dependent on the chemical composition of the substance.

Although simple in theory, implementation of quantitative IR spectroscopy can be complicated by underlying absorptions due to other components as well as inter- and intramolecular interactions. However, these effects can usually be modeled by the application of multivariate analysis methods, such as multiple linear regression (MLR), partial-least-squares regression (PLS), or principal component regression (PCR). A full discussion of the mathematical basis of these multivariate analysis methods is available elsewhere (6) and is beyond the scope of this chapter.

A detailed review of IR and Raman spectroscopic studies of the major components of foods has recently been published (7). Thus, in the following section, the information that can be extracted from the IR and Raman spectra of individual food components will be illustrated by considering only a single class of food components, namely, proteins. In the subsequent section, reported applications of IR and Raman spectroscopy in the qualitative and quantitative analysis of various types of foods will be surveyed. This section will highlight the most significant research findings and practical applications and will focus mainly on IR spectroscopy, owing to its more widespread use in food analysis as well as the much larger amount of research activity in this area. However, certain specific applications for which Raman spectroscopy is particularly well suited will also be discussed.

A. IR and Raman Spectroscopy of Food Proteins

IR and Raman spectroscopy have found extensive application in the study of proteins and are particularly useful techniques for the elucidation of protein secondary structure. The spectra of polypeptides and proteins exhibit nine amide bands that represent different vibrations of the peptide linkage. The wavenumber positions of these bands and their vibrational assignments are listed in Table 44.2 (8). Obtaining information pertaining to protein secondary structure from IR and Raman spectra is based on empirical correlations between the wavenumbers of certain of these bands and the various conformations adopted by the polypeptide chain. The amide I band (in the range of 1700–1600 cm^{-1}) is the most frequently employed in IR spectroscopy, and characteristic amide I band positions have been identified for α-helices, 3_{10}-helices, parallel or antiparallel β-sheets, turns, and unordered or irregular structures (Table 44.3). Using these band assignments, secondary structures of proteins can be deduced, although it is generally advisable to confirm the results with a second technique such as circular dichroism. The amide III band (in the range of 1300–1190 cm^{-1}) can similarly be employed for the estimation of the relative proportions of the secondary-structure components. However, in some cases, the amide III band can be overlapped by bands due to side-chain vibrations of particular amino acid residues—or absorptions from other biomolecules present, for example, in a food matrix—and consequently one must be cautious when assigning bands in this region. In IR spectra, the amide III band is much weaker than the amide I band and hence is much less frequently employed in secondary-structure investigations. However,

TABLE 44.2
Amide Bands of Proteins[a]

Designation	Nature of Vibration
A	N-H stretching
B	N-H stretching
I	80% C=O stretching; 10% C-N stretching; 10% N-H bending
II	60% N-H bending; 40% C-N stretching
III	30% C-N stretching; 30% N-H bending; 10% C=O stretching; 10% O=C=N bending; 20% other
IV	60% O=C-N bending; 60% other
V	N-H bending
VI	C=O bending
VII	C-N torsion

[b] Assigned to antiparallel β-sheet structure when it is accompanied by a high-wavenumber component (1695–1675 cm^{-1}); otherwise assigned to parallel (or extended) β-sheet structure.
[c] Indicative of protein aggregation.

both the amide I and amide III bands are commonly employed in Raman spectroscopy (Table 44.4) (9), as their Raman intensities are comparable.

The IR spectra of proteins are most commonly recorded in aqueous solution in a transmission cell, although ATR accessories have also been employed to study the spectra of protein films and powdered samples (Figure 44.10). The Raman spectra of proteins can also be recorded in aqueous solution but the spectra obtained from solid samples are generally of much higher quality and exhibit sharper bands (Figure 44.11). For IR studies involving examination of the secondary-structure-sensitive amide I band, proteins are commonly dissolved in D_2O because H_2O has a strong band in the amide I region. Since D_2O has no absorptions that overlap with the amide I band (which, by convention, is termed the amide I′ band when D_2O is the solvent), the use of D_2O solutions allows the protein absorptions to be observed without the need

TABLE 44.4
Approximate Positions (cm^{-1}) of Amide I and Amide III Band Components in Raman Spectra of Proteins[a]

for subtraction of the spectrum of the solvent. More importantly, it also makes it permissible to use much longer pathlengths (40–80 μm vs. 10 μm for aqueous solutions), thereby yielding a higher signal-to-noise ratio. An additional advantage of dissolving proteins in D_2O is the resulting ability to study the rate at which the hydrogens of the amide groups exchange with the D_2O solvent due to the ~100-cm^{-1} shift of the amide II band (from 1560–1520 to 1460–1420 cm^{-1}) that occurs upon H-D exchange. This rate is indicative of the compactness of the protein since amide groups exposed to the solvent undergo H-D exchange faster than those in the interior of the protein. Thus, increases in the rate of H-D exchange as a result of variations in physicochemical parameters such as pH, temperature, and pressure can be interpreted in terms of the extent of protein unfolding.

Because of the inherent overlap between the amide I′ band components of the various conformations of the polypeptide backbone, computational band-narrowing techniques such as Fourier self-deconvolution (FSD) and derivative spectroscopy are routinely employed. It should be noted that caution must be exercised in applying these techniques because they can distort the shapes of the

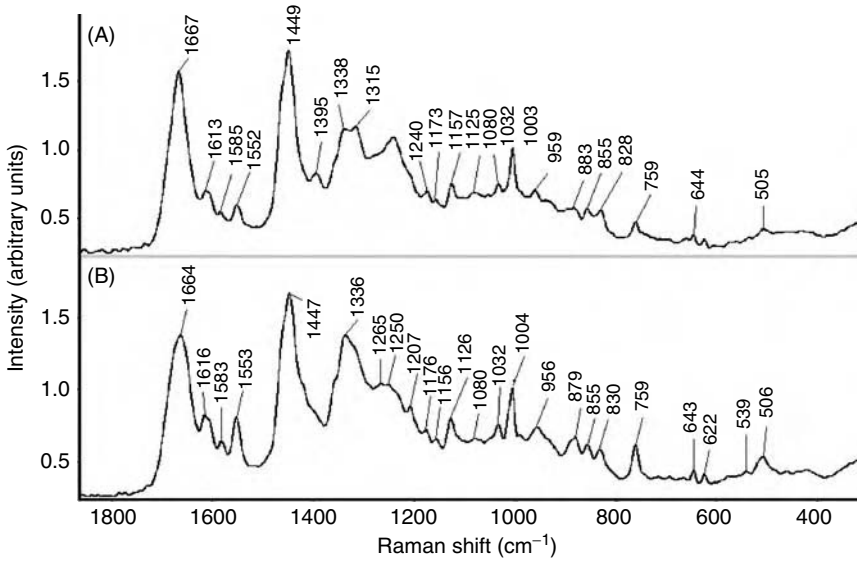

FIGURE 44.11 FT-Raman spectra of powdered β-lactoglobulin (A) and α-lactalbumin (B) in 1-mm glass capillaries recorded with 1064-nm excitation. (Nd:YAG laser). For band assignments, see Ref. 10.

bands and can also decrease the signal-to-noise ratio (11). Furthermore, the relative band intensities in derivative spectra are affected by the inherent widths of the bands, whereas deconvolution has the advantage of preserving the true relative band intensities (11). On the other hand, the results of deconvolution depend strongly on the values of the adjustable deconvolution parameters and are thus more subject to artifacts. For example, as illustrated in Figure 44.12, the selection of inappropriate deconvolution parameters that result in "overdeconvolution" amplifies the spectral noise, which may lead to spurious peaks. Similarly, atmospheric water vapor gives rise to very weak narrow peaks in the amide I region of IR spectra that can also be misinterpreted as amide I′ band components in deconvolved spectra. The latter pitfall is best avoided by thoroughly purging the spectrometer, including the optical compartment, with dry air or nitrogen. Other possible sources of artifacts are absorptions of buffers or contaminants in the protein solution (12).

Additional information about protein structure can be obtained from bands due to side-chain vibrations of amino acid residues, such as aspartic acid, glutamic acid, tyrosine, and tryptophan. For example, the ratio of the intensities of the Raman bands of tyrosine at 850 and 830 cm^{-1}, attributed to ring-breathing and out-of-plane bending vibrations, respectively, provides the following information about the polarity of the microenvironment of tyrosine residues (13):

- High I_{850}/I_{830} (>2.5): Tyr acts as H-bond acceptor
- Low I_{850}/I_{830} (<0.5): Tyr acts as H-bond donor
- $I_{850}/I_{830} \sim 1$: Tyr is exposed to an aqueous environment (i.e., Tyr near or at the protein surface)

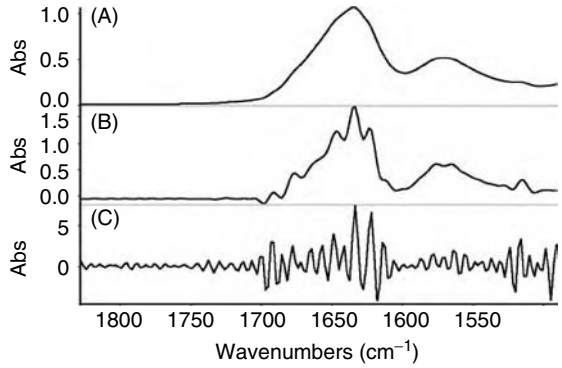

FIGURE 44.12 Raw FTIR spectrum (A), spectrum after Fourier self-deconvolution (FSD) (B), and "overdeconvolved" spectrum (C) of β-lactoglobulin in D_2O (5% w/v). FSD parameters: (B) bandwidth factor of w = 27 and resolution enhancement factor of k = 2.4; (C) w = 27 and k = 4.

Raman spectroscopy is also a very useful tool for probing the formation and rupture of disulfide linkages because the S-S and S-H stretching vibrations can be clearly discerned in the Raman spectra of proteins. The FT-Raman spectra of the amino acids L-cysteine and L-cystine are presented in Figure 44.13 and show, respectively, a band at 2552 cm^{-1} assigned to the S-H stretching vibration and a band at 498 cm^{-1} assigned to the S-S stretching vibration. In the Raman spectra of proteins, these bands are shifted to 2580–2550 and 550–500 cm^{-1}, respectively (14). The corresponding IR bands are not readily discernible, making Raman spectroscopy the technique of choice for the observation of disulfide linkages and examination of thiol-disulfide exchange. For example, in Figure 44.11, the higher content of disulfide linkages in α-lactalbumin as compared

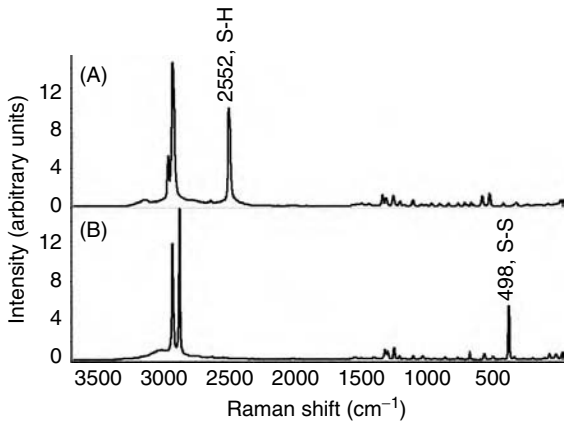

FIGURE 44.13 FT-Raman spectra of L-cysteine (A) and L-cystine (B). The spectra were recorded from solid samples in 1-mm glass capillaries, with 1064-nm excitation (Nd:YAG laser). Laser power was 500 mW; 1024 co-added scans were collected at 8-cm^{-1} spectral resolution.

to β-lactoglobulin is evident from the stronger intensity of the ν(S-S) band at ~ 505 cm^{-1}.

Although many of the proteins that have been studied by FTIR and Raman spectroscopy may be categorized as food proteins, such as whey, soy, and egg proteins, the majority of these studies have not been specifically concerned with the behavior of the proteins as food components. However, some detailed investigations of food proteins have been conducted to gain a better understanding of protein stability and structure-functionality relationships, with the overall objective of obtaining information that can assist the food industry in making more effective use of food proteins (7). Figure 44.14 shows an example from our studies on the thermal denaturation of whey proteins by variable-temperature FTIR spectroscopy (15–18). The spectra in the amide I region (Figure 44.14A) were recorded during heating of a 7% (w/v) solution of β-lactoglobulin in D_2O in a temperature-controlled transmission cell from 25 to 95°C and have been deconvolved by Fourier self-deconvolution. A plot of the changes in intensity of several of the amide I′ band components as a function of temperature is shown in Figure 44.14B. The decreases in band intensity at 1648 (▲) and 1635 cm^{-1} (●), assigned to α-helical and intramolecular β-sheet structures, respectively, and indicative of protein denaturation, occur prior to a sharp increase in the band intensity at 1618 cm^{-1} (■), assigned to intermolecular β-sheet formation and characteristic of protein aggregation. Similar experiments have been performed with the use of a diamond-anvil high-pressure IR cell to monitor denaturation of whey proteins under conditions of applied hydrostatic pressure, similar to those utilized in high-pressure processing, and provided information on the nature of the differences between thermal and pressure-induced denaturation (19, 20). In addition,

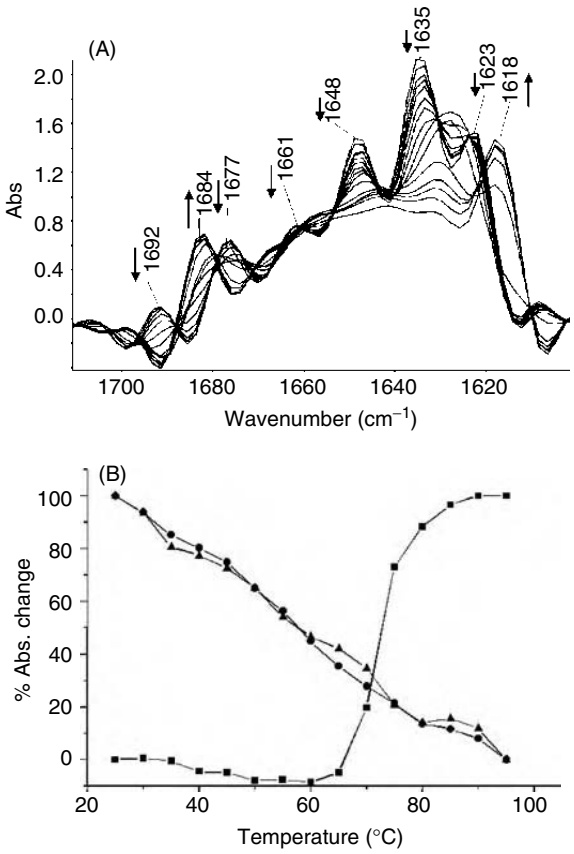

FIGURE 44.14 (A) Spectral overlay plot of the deconvolved amide I′ band in the FTIR spectrum of β-lactoglobulin (7% w/v) as a function of increasing temperature (25–95°C). FSD parameters: w = 27 and k = 2.4. (B) Plot of changes in intensity at 1648 (▲), 1635 (●), and 1618 cm^{-1} (■) as a function of increasing temperature.

multivariate analysis techniques have been employed to correlate FTIR spectral changes observed as a function of changes in physicochemical parameters, such as pH, ionic strength, temperature, and pressure, with rheological data collected under the same conditions (7). Such studies provide a better understanding of the structural changes at the molecular level that govern rheological behavior.

B. Analysis of Foods by FTIR and Raman Spectroscopy

1. Milk and Dairy Products

To date, the utility of IR spectroscopy in the quantitative analysis of foods has been most clearly exemplified by milk analysis. The determination of fat, protein, and lactose in milk by IR spectroscopy is an official method of the Association of Official Analytical Chemists (AOAC) and is used extensively as a basis for milk payment, dairy herd recording, and routine quality control in the dairy industry. High-volume automated instruments allow for

the analysis of 100–500 samples per hour. Dispersive spectrometers and subsequently filter-based instruments were originally employed in commercial IR milk analyzers, but FTIR milk analyzers are now on the market (21). The accepted IR milk analysis methodology employs a 37-μm CaF_2 transmission flow cell, which is kept at a constant temperature (40 ± 0.1°C) to obtain reliable, stable, and accurate measurements. Typically, IR milk analyzers incorporate a high-pressure (150–200 kPa) homogenizer to reduce the size of the fat globules to <1 μm to avoid light scattering effects. The pressure is maintained in the system throughout the analysis to avoid formation of air bubbles in the cell, and the cell is flushed with the next sample at extremely high velocity (30 m/s), eliminating the need for rinsing of the cell. Whereas filter-based IR milk analyzers were restricted to the analysis of fat, protein, and lactose, because the filters employed were specifically selected for the measurement of these components, commercial FTIR milk analyzers can be calibrated to measure other components in a wide range of dairy products, such as infant formula, ice cream, yogurt, and whey and whey concentrates (21).

In transmission measurements of dairy products, light scattering by fat globules must be eliminated in order to obtain quantitative analytical results. In the case of fluid products, this requirement can be addressed, albeit at some cost, by the use of high-pressure homogenizers, as described above. Because ATR measurements are not affected by light scattering, ATR accessories would appear ideal for the analysis of dairy products, including non-fluid products such as butter and cheese. However, the presence of fat globules in dairy products is, in fact, highly problematic because it results in sample inhomogeneity on the scale of the depth of penetration, which is in the order of a few microns or less, and thus the spectrum obtained is not truly representative of the sample composition. In a study of the effect of fat globule size in cream on ATR/FTIR measurements, a nonlinear relationship was found between absorbance at 1744 cm^{-1} (commonly used as a measurement peak for fat) and fat content over the range of 0–48% (by volume) (22). The authors of this study proposed the use of a nonlinear calibration curve for samples having fat globules > 1 μm. In a study of assessing the feasibility of employing ATR/FTIR spectroscopy for fat, protein, and moisture determination in cheese (23), large variations in the ATR/FTIR spectra of replicate samples taken from the center of a cheese were observed owing to both variations in the diameter of the fat globules and inhomogeneous distribution of fat within the cheese. Based on the fairly poor accuracy of PLS calibrations that were developed for the determination of fat, protein, and moisture contents, the authors concluded that the utility of the ATR/FTIR method for the analysis of cheese was quite limited but might be improved by homogenization of the samples prior to analysis; however, this requirement would significantly complicate the procedure. Another approach to overcoming the problem was employed in the development of a rapid FTIR quality control method for fat and moisture determination in butter employing an ATR sample-handling accessory (24). Samples were dissolved in 1-propanol and warmed to 40°C, thereby solubilizing the fat without causing separation of an aqueous phase, and applied to a heated ATR crystal (40°C) for spectral recording. A calibration was developed by employing gravimetrically prepared mixtures of anhydrous butterfat and water in 1-propanol as calibration standards. Analysis of 20 butter samples by this ATR/FTIR method yielded good agreement with reference values obtained by the Mojonnier method (24).

The speed of FTIR analysis (typically, <2 min/sample) is particularly advantageous in a processing environment since it allows the manufacturing process to be monitored and adjusted as it proceeds. A method for the simultaneous determination of sucrose, lactose, total solids, and fat in chocolate milk by FTIR spectroscopy for use in a production environment has been described (25). An ATR/FTIR method for fat and solids determination was developed for quality control purposes during manufacture of sweetened condensed milk (26). The ATR sample-handling technique is highly suitable for this type of viscous product, which would be very difficult to handle if a transmission cell were used, and highly reproducible results were obtained when samples were homogenized at 65°C prior to ATR/FTIR analysis. More recently, an SB-ATR/FTIR method has been developed for monitoring enzymatic hydrolysis of lactose during the production of lactose-reduced milk (27).

2. Beverages

Aside from milk analysis, numerous FTIR methods for the analysis of different types of beverages have been developed. Determination of sucrose, glucose, fructose, and total sugars in juices and soft drinks by ATR/FTIR spectroscopy was investigated by Rambla and co-workers (28, 29). Sinnaeve et al. analyzed apple juice using a 16-μm temperature-controlled transmission cell and successfully quantified malic acid, total sugars, glucose, fructose, sucrose, and specific gravity (30). Flow injection analysis coupled with transmission FTIR spectroscopy was used in the determination of sucrose in fruit juices (orange juice, apple juice, and sports drink) (31). Acetate buffer was used as the carrier solvent, and samples were passed through an enzyme reactor containing β-fructosidase prior to FTIR spectral acquisition. In another study, flow injection analysis/FTIR spectroscopy was employed to quantify malic acid, tartaric acid, and citric acid in juices and soft drinks using pH modulation to eliminate matrix effects (32). In a flow injection analysis/FTIR method for the determination of caffeine in soft drinks, caffeine was extracted by passing

the samples through a solid-phase extraction column (C_{18}), using chloroform as the eluent (33). A rapid ATR/FTIR method was developed for the determination of caffeine in soft drinks without extraction (34). This method allowed caffeine quantitation in soft drinks at levels as low as 0.5 mg/100 mL and was found to produce results similar to, but slightly higher on average than, those obtained from the conventional ultraviolet (UV) method.

Various publications have described methods for ethanol determination in distilled liquors, wines, and beers. Dilution of beverages having ethanol contents of >15% (v/v) is often required for analysis in a transmission cell, but this step can be eliminated when an ATR accessory is employed (35). The use of ATR fiber-optic probes in the quantitation of alcohol in liqueurs has been reported (36).

Recently, commercial FTIR wine analyzers, employing a flow-through transmission cell similar to that incorporated in FTIR milk analyzers, have been marketed (21). Patz et al employed an FTIR wine analyzer to analyze for alcohol, tartaric acid, malic acid, lactic acid, total acidity, pH, volatile acidity, reducing sugars, fructose, glucose, total SO_2, total phenols, and glycerol (37). The calibration and test sets comprised 165 wine samples, preanalyzed by standard methods; because the concentration ranges for glycerol and volatile acidity in these samples were too narrow, standards prepared in water were added to the calibration set. The authors reported that results were acceptable for all parameters except total SO_2 and total phenols. Comparable results were obtained with a standard benchtop FTIR spectrometer equipped with an SB-ATR accessory in a similar study conducted by the McGill IR Group to demonstrate the feasibility of employing SB-ATR/FTIR spectroscopy for the routine analysis of distilled liquors and wines (27). Dubernet and Dubernet used a commercial FTIR wine analyzer to analyze for alcohol, reducing sugars, total acidity, pH, malic acid, tartaric acid, lactic acid, total phenols, volatile acidity, CO_2, glycerol, gluconic acid, and saccharose content in 200,000 wine samples (38). These authors reported that not all wines could be analyzed accurately using the same calibration due to matrix effects and therefore developed separate calibrations for dry and sweet wines as well as for wine musts. Because calibration development may require the accurate analysis of several hundred representative wines for multiple components, which is clearly a major undertaking, an alternative approach based on synthetically prepared mixtures of the major components present in wine has been investigated (39). It was demonstrated that the preparation of large numbers of calibration standards that are often required for multivariate calibration and the acquisition of their spectra may be automated by sequential injection, a form of flow injection analysis. However, when calibrations based on model solutions of nine common components as a substitute for preanalyzed wines were applied to the analysis of wine samples, only limited agreement was obtained between the IR-predicted values for organic acids and sugars and results obtained by high-pressure liquid chromatography (HPLC) (39).

In a different type of application related to wine production, SB-ATR/FTIR spectroscopy in combination with PCA and cluster analysis was used to discriminate between phenolic extracts of different wine cultivars (40). Phenolic extracts were obtained by solid-phase extraction of the wine samples and subsequent elution of the phenols with methanol. Only 1 μL of the methanolic extract was required to cover the SB-ATR crystal and the methanol was allowed to evaporate prior to spectral recording. Almost complete discrimination of all cultivars investigated was achieved. SB-ATR/FTIR spectroscopy was also used in the analysis of white wine polysaccharide extracts to identify the type of wine-making process employed (must clarification versus maceration) based on the polysaccharides present (41).

3. Edible Oil Analysis

In the past decade, a large amount of work has been done on both FTIR and FT-Raman analyses of edible fats and oils. These included the development of both qualitative applications, involving the characterization and classification of oils, and numerous examples of quantitative analysis applications. The literature in this area has been surveyed in a recent review (42), and only selected applications will be highlighted in this section.

Typical FTIR and FT-Raman spectra of an edible oil are presented in Figure 44.15. The FTIR spectra of edible oils and premelted fats in their neat form can be recorded with the use of either a heated transmission flow cell or a heated ATR accessory, making these types of samples fairly ideal from a sample-handling perspective. On the other hand, dispersive Raman spectroscopy is generally unsuitable for the analysis of edible oils owing to background fluorescence arising from colored components present in oils. However, with the recent advent of FT-Raman instrumentation employing NIR excitation sources, the problem of background fluorescence has largely been eliminated, as can be seen from the high quality of the FT-Raman spectrum in Figure 44.15, and thus the potential for practical implementation of Raman analysis of fats and oils has been greatly enhanced.

The most noteworthy application of IR spectroscopy in the analysis of fats and oils is the determination of isolated *trans* isomers, which is an official method of the AOAC, the American Oil Chemists' Society (AOCS), and IUPAC. In the original IR *trans* analysis method, which was developed over 50 years ago with dispersive IR spectrometers, samples were dissolved in carbon disulfide before recording their spectra in a fixed-pathlength transmission cell (43). This dilution procedure was necessary

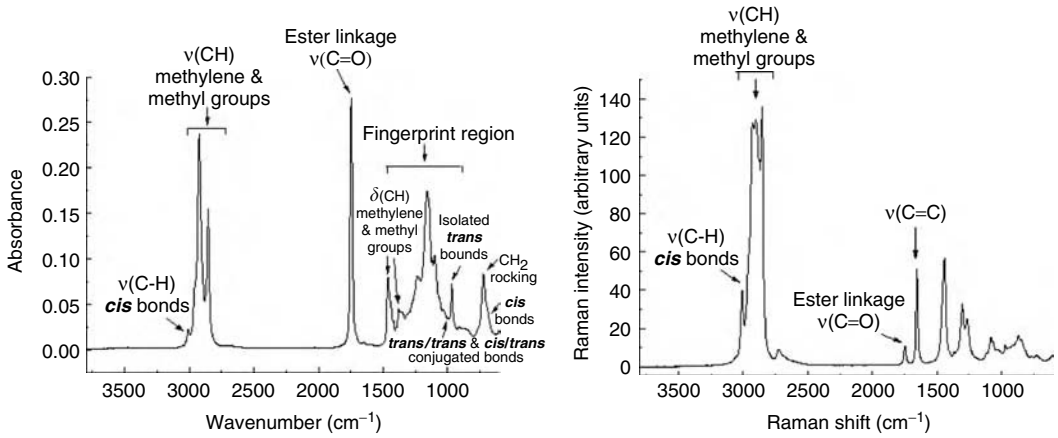

FIGURE 44.15 FTIR spectrum (left) and FT-Raman spectrum (right) of an edible oil. The spectra contain bands characteristic of *trans* double bonds because the sample is a partially hydrogenated oil.

because the analysis of oils in their neat form would require a cell pathlength of 10 μm or less due to the high absorptivity of the major absorption bands. With the development of FTIR spectrometers, however, it became possible to employ transmission cells with somewhat longer pathlengths (25–100 μm) or ATR accessories for the analysis of oils in their neat form. In 1996, Mossoba et al. described a rapid and simple ATR method for the determination of isolated *trans* isomers at levels down to 1% (44), and this method was subsequently adopted as an official method by both the AOAC and the AOCS. The use of an SB-ATR accessory for this analysis is advantageous because the small surface area of the ATR crystal allows for more precise temperature control and minimizes sample cross-contamination (45). Furthermore, the small volume of sample required (<50 μL) is advantageous in the analysis of fats extracted from foods, especially low-fat food products. This sample-handling technique was employed for the determination of *trans* content in hydrogenated vegetable oils in a collaborative study (46). The relative standard deviation between five labs was 1.62% for a sample having a *trans* content of 39.12% and 18.97% for a sample having a *trans* content of 1.95%. The relatively high error at low *trans* levels is attributable to the poor signal-to-noise ratio resulting from the very short effective pathlength of the SB-ATR accessory. Another factor limiting the accuracy of the method is the need for a *trans*-free reference oil that closely matches the fatty acid composition of the sample. If an appropriate reference oil is not available, as generally would be the case in the analysis of fats extracted from foods, the accuracy of the method may be poor, particularly at low *trans* levels (47).

The McGill IR Group extended the SB-ATR method for *trans* analysis to allow simultaneous determination of iodine value (IV), a measure of total unsaturation (45). Calibration models for the prediction of both IV and *trans* content were developed using PLS regression and a calibration set consisting of 9 pure triacylglycerols. Good agreement was obtained between the results obtained by gas chromatography (GC), the FTIR/PLS method, and the AOCS FTIR method for *trans* analysis and between a GC method and the FTIR/PLS method for IV determination (45). Much better precision and accuracy were achieved with the SB-ATR accessory than in previous work with an MB-ATR accessory (48). The McGill IR Group has also done extensive work on edible oil analysis using the custom-designed transmission flow-through cell shown in Figure 44.5, heated to 80°C to avoid fat crystallization during analysis (49). Methods have been developed for the determination of *trans* and *cis* content (50), free fatty acids (51), solid fat index (52), iodine value (53), saponification number (53), anisidine value (54), and peroxide value (PV) (55). While most of these methods are based on the spectral features of neat fats and oils, the PV method employs the stoichiometric reaction of triphenylphosphine with hydroperoxides to produce triphenylphosphine oxide, which has a strong absorption band at 542 cm^{-1} that is used for PV quantitation. Ruiz et al. automated this method through the application of flow injection analysis to allow on-line PV analysis, without the need for manual sample manipulation (56).

The complementary nature of IR and Raman spectroscopy is well illustrated by the spectra of edible fats and oils. By comparison of the spectra in Figure 44.15, it may be noted that the relative band intensities in the IR and Raman spectra differ markedly. Of particular significance in relation to the measurement of unsaturation is the 1700–1600 cm^{-1} region, in which strong C=C stretching absorptions are the dominant features in the Raman spectra of unsaturated oils whereas the corresponding bands in IR spectra are extremely weak. Because the C=C stretching absorptions of *cis* and *trans* double bonds are observed at different wavenumbers (1656 and 1670 cm^{-1}, respectively), Raman spectroscopy allows for the determination of both the degree

and type of unsaturation (57, 58). Thus, the potential utility of Raman spectroscopy, in conjunction with fiber optics, to monitor hydrogenation processes has been suggested (59). Raman spectroscopy has also been reported to provide information about the relative proportions of saturated, monounsaturated, and polyunsaturated fatty acids in a variety of fats and oils of both plant and animal origin (60).

As reviewed in Ref. 42, there have also been many studies during the past decade on the classification of edible oils by vibrational spectroscopy. Although the spectra of most pure fats and oils appear fairly similar visually, they reflect the differences in fatty acid composition that exist among different types of fats and oils. Thus, with the use of chemometric techniques such as PCA and discriminant analysis, different types of oils can be distinguished on the basis of differences in their IR or Raman spectra. The powerful capabilities of these techniques are exemplified by the successful use of FTIR spectroscopy, in conjunction with discriminant analysis, to differentiate between extra virgin and refined olive oils, despite the strong similarities between the spectra of these two types of oils (61). In another study, SB-ATR/FTIR spectroscopy was employed to detect adulteration of sunflower oil in olive oil down to a level of 20 mL/L of extra virgin olive oil (62). Similarly, Raman spectroscopy was shown to allow for the detection of adulteration of virgin olive oil with hazelnut oil, a very chemically similar oil type, at levels down to 5% (63). These examples are illustrative of fairly extensive research that has demonstrated the potential utility of FTIR and Raman spectroscopy for the authentication of edible oils.

Another important qualitative analysis application involves the dynamic monitoring of oil oxidation by FTIR spectroscopy to evaluate the oxidative stability of oils. For example, by monitoring the FTIR spectra of a thin film of oil spread on the heated surface of an ATR sample-handling accessory (64, 65) or on a polymer film (66) and subtracting the fresh oil spectrum ($t = 0$) from those taken subsequently over time, the resulting differential spectra reveal subtle spectral changes that can be employed to track changes in oxidation via "indicator bands" such as the *cis*, isolated and conjugated *trans*, hydroperoxide, and aldehyde absorptions. This approach allows one to develop a "dynamic" oxidation profile (peak height vs. time) based on these indicator bands and evaluate the relative stability of oils in a simple and rapid manner.

4. Syrups and Semi-Solids

ATR/FTIR spectroscopy is particularly useful for the quantitative analysis of viscous samples that cannot be easily introduced into a sealed transmission cell. The potential utility of ATR/FTIR spectroscopy for continuous on-line process monitoring of the conversion of corn starch to corn syrup has been demonstrated (67). Another study used a ZnSe ATR accessory to determine dry substance (glucose, maltose, and fructose) in glucose syrups after sample dilution (1 g/2 mL) (68). Determination of fruit content and detection of adulteration in strawberry jam by ATR/FTIR spectroscopy was investigated (69) but the accuracy of the method was limited by the overlapping of the 1725 cm^{-1} band used for fruit quantitation with the strong water absorption band at ~1650 cm^{-1}. In a later study, 36 jam samples were classified by ATR/FTIR spectroscopy according to their fruit content as "strawberry" or "nonstrawberry," with a correct classification rate of 91% (70). In a similar but much larger study, 95% of over 1000 fruit puree samples were correctly classified as "raspberry" or "nonraspberry," and it was shown that adulteration with sucrose or with apple and plum could be detected at levels of 4% (w/w) and 20% (w/w), respectively (71). The detection of inverted cane sugar adulteration in honey (72) and beet and cane sugar adulteration in maple syrups (73) by ATR/FTIR spectroscopy has also been reported.

5. Solids

Classification and detection of adulteration of solid food products by ATR/FTIR spectroscopy has been investigated. Instant coffee samples were dissolved in distilled water at 50°C at a concentration of 30% (w/v) and applied onto the surface of a horizontal ATR accessory (74). Spectra were recorded immediately to avoid settling out of a small insoluble fraction. Discrimination of *Arabica* and *Robusta* instant coffees was achieved by applying linear discriminant analysis (LDA) to the scores obtained by PCA of the spectral data, and the composition of *Arabica* and *Robusta* blends was determined by multivariate analysis. A similar methodology was employed for the detection of adulteration of instant coffees with glucose, fructose, and xylose, and the carbohydrate profile was also successfully quantified (75). The capability to distinguish between minced chicken, pork and turkey meats as well as fresh and frozen-thawed samples by ATR/FTIR spectroscopy has also been described (76).

For quantitative analysis of solid samples, IR transmission measurements are unsuitable owing to light scattering effects whereas an ATR/FTIR spectrum may not be fully representative of the sample owing to inhomogeneity on the scale of the depth of penetration associated with ATR measurements. In a study of protein-starch mixtures (77), samples were prepared by mixing dry gluten and starch or casein and starch and then adding a gram of water per gram of sample to produce wet mixtures, which varied in consistency from a moist powder at high starch content to an elastic mass at high gluten content. These samples were spread evenly on the ATR crystal to ensure uniform coverage and a constant pressure was applied to achieve good optical contact between the ATR crystal and the sample. However, poor reproducibility was obtained, especially for the casein-starch mixtures due to large particle size of casein.

In general, IR quantitative analysis of solid food products with the use of transmission or ATR sample-handling techniques requires some prior sample preparation. For example, quantitative analysis of sugar powders (glucose, fructose, sucrose) by ATR/FTIR spectroscopy was performed by impregnating the powders with an organic solvent (acetone), thereby forming a film on the surface of the ATR crystal after evaporation of the acetone (78). Determination of total fat and protein in meat by FTIR spectroscopy was carried out on meat samples prepared by suspension in 0.1N NaOH solution at 67°C and homogenized using a high-pressure valve homogenizer, prior to injection into a 37-μm CaF_2 heated (65°C) flow-through cell (79). Total fat determination in food products by transmission FTIR spectroscopy has been performed by extracting the fat in a chloroform/methanol (2:1) solvent (80) or 1-propanol (81).

The need for such sample preparation steps can potentially be eliminated through the use of alternative sample-handling techniques. One technique that has been investigated is photoacoustic (PAS) spectroscopy, which is based on the detection of IR absorption by using sound (82, 83). However, PAS has poor S/N relative to transmission and ATR techniques because the efficiency of energy transfer (absorbance to sound) is poor, and thus it is a relatively insensitive technique. In addition, water vapor gives rise to strong photoacoustic signals, requiring that the sample be very dry during analysis. Finally, the photoacoustic signal is dependent on several factors, such as incident energy, absorption coefficient, surface morphology, and thermal diffusivity, which, in part, are sample dependent. Accordingly, PAS does not appear to have general applicability for quantitative food analysis.

Raman spectroscopy is better suited to the analysis of solid samples than IR spectroscopy. In the area of food analysis, this suitability is best illustrated by various studies on modified starches, in which the degrees of acetylation and succinylation were determined from the FT-Raman spectra of solid samples contained in glass capillary tubes (84). However, no examples of the use of Raman spectroscopy in the analysis of processed foods have been reported.

CONTENTS

I. INTRODUCTION

Gas chromatography (GC) has been widely used in various applications involving the qualitative and quantitative analyses of foods (1) for several decades. In order to improve food safety and quality, GC techniques and methods have been developed and evaluated for many diverse applications. GC has been an excellent tool for the separation and determination of trace level, thermally stable, volatile organic analytes in complex food matrices.

Many food matrices are analyzed by GC in order to determine nutritional and palatability needs, check food adulteration, engineer novel food products, or meet process-control, quality assurance, food labeling, or other requirements. The widely different components include natural constituents, contaminants, and additives of foods, as well as products that arise from natural reactions and/or industrial processing. Food constituents are primarily water, lipids, proteins, carbohydrates, vitamins, and minerals, and components such as fatty acids, sterols, alcohols, aroma components, and off-flavors, are determined by GC. Contaminants in food products include residues of pesticides, veterinary drugs, and industrial pollutants (such as polyhalogenated hydrocarbons and polycyclic aromatic hydrocarbons), as well as toxins from spoilage, vegetative bacteria, endospores, or fungi (mycotoxins). Additives usually consist of components that are added to food products (such as preservatives, colors, or flavors).

Auto-oxidation and food processing (for example, frying, catalytic hydrogenation, or irradiation) also lead to the production of components (such as cyclic or *trans* fatty acids, histamine, urethane, nitrosamines, or 2-alkylcyclobutanones irradiation markers) that can be identified by GC.

In the past decade, GC advances have been achieved including the development and/or optimization of GC instrumentation components (injectors, detectors) and of portable, miniaturized, high-speed GC systems in which retention times are very short due to high flow rates, short and narrow bore columns, low film thickness, increased diffusivity of a solute in the gas phase, and faster temperature programming. GC detectors with greater selectivity and sensitivity such as mass spectrometers (MS), pulsed flame photometric detectors, and halogen specific detectors proved to be advantageous in food-analysis applications. Fast-GC/MS analyses (1) have been carried out by using micro-bore columns with time-of-flight (TOF)-MS (2–4), low pressure (LP)-GC/MS (5–7), and supersonic molecular beam (SBM)-MS (8–10).

In this chapter, three different areas of research selected from a large field of issues related to food analysis by GC techniques are addressed. The sections describe the instrumentation and applications of fast-GC to the study of food contaminants, the application of high resolution (HR) GC to the analysis of polyhalogenated contaminants in foods, and the GC analysis of foodborne bacterial lipids. Reasons for selecting fast-GC include its future potential in the analysis of many GC-amenable food additives and contaminants. Polyhalogenated aromatic compound determination in foods provides an excellent example of the continued application of gas chromatography to one of the most intractable analytical problems with food analysis. Without the advances in column design, both size and phase, the isomer specific analysis of PCDD/Fs and PCBs would be a much longer and more difficult process. Finally, GC-based methodologies are important analytical chemical tools that have been used increasingly for the speciation of microorganisms.

II. FAST GAS CHROMATOGRAPHY AND FOOD ANALYSIS

A major breakthrough in gas chromatography occurred in 1957 with the introduction of open tubular columns (11). This was followed in 1962 by an infamous demonstration of very fast gas chromatography (12). Utilizing a 120 cm $\times$ 0.035 mm squalene-coated column, H_2 carrier gas, and a hammer to depress the syringe, Desty and coworkers (12) obtained near-baseline separation of 15 hydrocarbons and isomers in under 2 s. In addition to such demonstrations of very fast analysis times, early work in open tubular columns also led to the development of columns with extremely high plate numbers (10^6). In spite of these early breakthroughs, open tubular columns were not rapidly accepted for chromatographic analysis. Small sample capacity, fragile, rigid glass capillaries, difficulty of incorporation into existing instruments and irreproducible column characteristics, attributed to slowing the implementation of open tubular columns. It was not until the late 1970s that the introduction of fused silica columns (13) and improvements in GC instrumentation led to the wider use of capillary columns.

The greater use of capillary columns was not accompanied by a large reduction in analysis time or sudden interest in fast chromatography. Instead, the greater efficiency of capillary columns was used to analyze and separate increasingly more complex mixtures. To ease in the transfer of methods from packed columns, developers chose capillary columns with large diameters, thick films, and excessive lengths. The concept of "killing it with plates" (14) and "over separating" (15) are often used to describe these early methods. Indeed, many of these methods became official or standard methods and the "over separation" still persists. Recently, with the increased cost of analysis, the interest in process control and the desire to develop rapid field-deployable test methods for environmental and security monitoring, there has been a renewed interest in rapid gas chromatographic analyses. The availability of fast chromatographic instrumentation (16) and method translation software will undoubtedly expand the use of the technique.

The terminology "fast gas chromatography" can be extremely subjective. If an analysis normally takes 70 minutes, then a 40-minute run time could be considered "fast." Dagan and Amirav first attempted to quantify the terminology used for Fast, Very Fast, and Ultra-Fast Gas Chromatography by identifying a "speed enhancement factor" (SEF) (17). SEF, the product of column length reduction factor and carrier gas linear velocity increase, constitutes a reduction factor in the flow time of the carrier gas compared to conventional GC. Dagan and Amirav defined a 30-m narrow bore column with a 1 ml/min gas flow rate (34 cm/s helium linear velocity) as the reference conditions for conventional GC-MS. Although SEF is quantitative in nature we find the classifications based on peak widths and total analysis time introduced by van Duersen et al. (1) to be more useful. According to the classification, "fast GC" separations happen in minutes and have peak widths of several seconds. "Very fast GC" describes seconds range separation with 30–200 ms peak widths and "ultra fast GC" is sub-second separations with 5–30 ms peak widths. Hinshaw (18) also "quantified" analysis speed by dividing methods into four levels based on relative speed, column dimensions, and inlet pressures. Hinshaw used the terminology of conventional, rapid, high-speed and very-high-speed for levels 1 through 4, respectively. This discussion will apply the van Duersen criteria for describing applications and will primarily focus on fast GC and the application in food analysis.

A. Chromatographic Theory

Prior to reviewing the practical aspects of fast gas chromatography, a brief review pertaining to resolution and efficiency in chromatographic separation is in order. It should be noted that the following discussion is a brief summary and is not intended as a thorough discussion of chromatographic theory. For the interested reader more in-depth and complete discussions of the equations and theory relating to sample introduction, speed of separation and detection in gas chromatographic analysis can be found in a number of sources (14,19–22).

In chromatographic analysis the goal is to separate the analytes of interest, denoted as the "critical pair," and to do so in the shortest amount of time. By definition, when the pair is separated, all of the peaks in the chromatogram will also be separated. The degree of separation is called the resolution (R_s), which is commonly defined by

$$R_s = \frac{\Delta t_R}{4\sigma_c} \tag{45.1}$$

where Δt_R is the difference in retention time between a critical pair and σ_c is the standard deviation of chromatographic peak broadening. Baseline separation is achieved when peaks of equal size show a resolution of >1.5; however a resolution of > 1.0 is often sufficient. The number of theoretical plates required to produce a given resolution is expressed as:

$$N = 16R_S^2\left[\frac{1+k}{k}\right]^2\left[\frac{\alpha}{\alpha-1}\right]^2 \tag{45.2}$$

where k is the solute capacity factor of the second eluting peak of the critical pair and α is the relative retention or selectivity factor for the two components.

Once resolution of the critical pair is achieved, the time for the chromatographic separation is minimized. The run time can be determined by the column length (L), average linear gas velocity ($\bar{\mu}$), and the solute capacity factor (k) of the last eluting peak using the following equation:

$$t_R = (L/\bar{\mu})(1+k) \tag{45.3}$$

where t_R is the retention time of the last eluting compound. Equation 45.3 exhibits the relationship between analysis time, column length, and linear gas velocity, but is more instructive when written in terms of the number of theoretical plates (N) and the height equivalent to a theoretical plate (H).

$$t_R = N(H/\bar{\mu})(1+k) \tag{45.4}$$

Equation 45.4 demonstrates the direct relationship between run time, plate number, and plate height. By combining equations 45.2 and 45.4 the relationship between analysis time and resolution becomes evident:

$$t_R = 16R_S^2\left(\frac{\alpha}{\alpha+1}\right)^2\frac{(1+k)^3}{k^2}\frac{H}{\bar{\mu}} \tag{45.5}$$

B. Reduction of Chromatographic Analysis Time

Using narrow bore columns is one of the easiest and most common methods for reducing the analysis time, while maintaining resolution. Schutjes et al. (23), although not the first to utilize narrow bore columns, derived the expressions relating a decrease in column diameter to a decrease in analysis time. They also experimentally confirmed the relationships for isothermal and temperature programmed conditions using 30 and 50 μm diameter columns. Klee and Blumberg (13) report nearly a 10-fold increase in "relative speed" by reducing the column diameter from 530 to 100 μm, while keeping "separation power equivalent." These studies demonstrated that decreasing column diameter effectively increases the number of plates per unit length of column (24). However, there are practical limits to the column diameter, Schutjes et al. (23) used 30 and 50 μm columns in their studies; however, due to potential problems with sample capacity, inlet pressure limitations, and maintaining injection efficiency it has been recommended that columns with diameters ≥ 100 μm (13) and ≥180 μm (24) be used in routine analysis.

Along with reducing column diameter, the choice of carrier gas can also impact speed of analysis, without decreasing resolution. By switching from helium to hydrogen as a carrier a 30% reduction in analysis time can be achieved, while switching from nitrogen gives a >3-fold reduction in analysis time (25). Finally, reduced outlet pressures through vacuum-outlet conditions have also been shown to be a useful method for decreasing analysis time at constant resolution (26). However, under certain conditions Cramers et al. (26) did report a 12.5% reduction in column efficiency when using vacuum outlet conditions. Although vacuum outlet conditions are only applicable when utilizing mass spectrometric detectors, an understanding of the effects of high pressure drops is important when developing fast chromatographic methods. A thorough study of the effect of high pressure drop commonly seen in fast chromatography, performed by Blumberg (27–29) and summarized by Klee and Blumberg (13), shows the complex relationship of pressure drop, column efficiency, analysis speed, column length and diameter, and film thickness.

A number of methods are available to the analyst for shortening analysis time through a reduction in resolution. Many of these, shortening column length (30), adjusting carrier gas velocity, and increasing temperature program rates (30), are familiar options during traditional method development. However, as was mentioned previously,

many of the current "official" methods are over separated, and some estimates suggest that up to 75% of the chromatogram contains no useful information (14). Even if that value overstates the extent of "lost time," the analyst should not overlook the ability to gain analysis speed through the optimization of resolution reducing parameters (14,19–21).

The reduction of peak widths and separation times achieved in fast chromatography begin to place stringent requirements on other instrumental parameters, often referred to as "extra-column sources." The Golay model (10), assumes that band broadening occurs only in the column, which is an accurate assumption when describing systems with long columns and low linear gas velocity. However, given the short column and/or high gas velocity in fast chromatography, this assumption is not always valid (20). Therefore, "extra-column sources" in general, and sample introduction specifically, can become an extremely important part of the analysis. The need to introduce the sample, without overloading the column or introducing band broadening, is critical to maintaining fast, highly resolved chromatograms. For fast chromatography conventional split/splitless injectors can be utilized, although the ratio or timing must be adjusted to avoid overloading column capacity (13). A number of other sample introduction systems have been developed for use in fast, very fast, and ultra-fast GC (21,22,31–33). The best method of introduction depends on the application of the chromatographic method.

As with sample introduction, sample detection mechanisms must maintain chromatographic efficiency by limiting band broadening. Additionally, detectors must have a sampling frequency fast enough to provide 15–20 data points across a peak (22). Many of the commonly used detectors including electron capture (EC), photoionization (PI), and thermal conductivity (TC), are sufficiently fast, but traditionally have large dead volumes, which leads to band broadening. The use of make-up gas to offset the large detector volume and limit band broadening leads to a loss of sensitivity with EC, PI, and TC detection (21). Small volume cells have been utilized to reduce band broadening and limit or eliminate the need for make-up gas (22). The use of mass-flow-sensitive detectors such as flame ionization, photometric, and thermionic detectors offer satisfactory data acquisition and sensitivity for use in fast GC (21). Along with the selection of a detection mechanism that has adequate sensitivity and maintains chromatographic efficiency, it is also beneficial to choose a selective detector that does not respond to co-extracted matrix components. Such selectivity will assist in shortening analysis time by reducing the need for increased chromatographic resolution. Perhaps the most common example is the use of mass spectrometric detectors to separate compounds not fully resolved by the chromatographic system (34). Wu and coworkers (35) utilized an element selective detector to assist in decreasing analysis time in their method. Additionally, Mastovska et al. (36) described the benefits in using a flame photometric detector compared to FID when analyzing for organophosphate pesticides in wheat.

Column selectivity changes can also be used to alter the analysis and subsequently gain speed. The choice of stationary phase can have a profound effect on elution order and elution time. Additional changes in temperature rates, gas velocity, or column length can then be used to further increase analysis speed. An extension of the use of a selective stationary phase is the use of two columns (GC × GC) with different retention properties (14). Unfortunately, specialized instruments, data systems, and experience are required to utilize these methods.

C. Applications of Fast Chromatography

In general, our interest in fast chromatography is not concentrated on a specific sub-discipline of the technique, but is in the overall potential benefits offered by the methods. As in any laboratory, the ability to analyze more samples in less time would represent a significant cost and time savings. Conversely, the shortened analysis time would enable us to investigate more samples in a given time period, allowing for a greater cross section of the food supply to undergo analysis. We are also intrigued by the application of fast chromatography to rapid field sampling. Such instrumentation would be useful in greater monitoring of the food supply, or in assisting manufacturers with process control as part of additional QA/QC procedures.

Although there has been an improvement in instrumentation and methods development associated with fast GC, food analysis can pose difficult challenges. Fortunately, the increase in interest in fast GC has produced a number of recent promising publications, which have application in our area of research. The research of Chen and coworkers (37) on the residual solvents is related to the work performed in our laboratories analyzing food and food packaging for volatile compounds (38–40). They were able to shorten the analysis of 40 organic solvents from 45 to less than 5 minutes using a short, narrow bore capillary column. Additional decreases in time were realized, by implementing temperature and pressure programming and limiting the list of analytes. Sample introduction was carried out by headspace analysis and direct injection. Although both showed acceptable reproducibility, the impact of the rapid method and sample introduction on detection limits was not evaluated.

Wang and Burleson (41) reported the development of a fast GC method used in the analysis of pyrolysis products from synthetic polymers. Pyrolysis GC has been shown to be useful in identifying low level additives in synthetic polymers (42) and a fast GC method could be useful in our analysis of polymer packaging materials (43,44). Wang and Burleson successfully transferred the traditional method to a fast GC, achieving a 10-fold increase in analysis speed. They also investigated the effect of head pressure and/or oven temperature on analysis time in conventional GC. Their

findings indicate that pyrolysis-fast GC is a useful method for analyzing synthetic polymers in short time periods.

Although the applications mentioned above have direct implications in the analysis of food and food packaging, they do not represent the same challenges often encountered with direct food analysis. Food is an extremely complex matrix, with a variety of interferences, often at concentrations significantly higher than the analyte of interest. Therefore, the ability to analyze foods by fast GC represents a particular challenge. Reed and coworkers (45) used a 5 m × 330 μm column, combined with fast temperature programming, to analyze for 2,6-di-(tert-butyl)-4-methylphenol (BHT) in chewing gum, breakfast cereal, and granola bars. Realizing that the extraction of BHT is often the rate limiting step in these analyses, Reed et al. utilized microwave assisted extraction (MAE) to further increase the overall processing time (45). Chromatographic analysis of each of the three sample matrices was completed in about 3 minutes with acceptable resolution and reproducibility reported for all samples.

Sandra and David (46) reported a fast gas chromatographic method for the determination of polychlorinated biphenyls (PCBs) in food matrices, and the fatty acid composition (as fatty acid methyl esters, FAME). The method was developed in response to the need to analyze a large number of samples (4000) in as short a time as possible. Initial development and validation was carried out in side-by-side studies using the official method. For the PCB method a shorter, narrow bore column was implemented to achieve a 4-fold increase in analysis speed without sacrificing resolution. Sandra and David (46) also applied a splitless injection to the fast GC, improving the limits of detection. It should be noted that the splitless liner was replaced after every 100 samples. A shorter, narrow bore column was also used for the FAME analysis and it also produced a reduced analysis time. This study was extremely successful at demonstrating the utility of fast GC; additionally, it represents one of the most extensive uses of fast GC that has been reported to date.

Lloyd and Grimm (35) increased the temperature program rates in order to increase analysis speed for sugars and FAMEs in food. For the sugar analysis they report a >7-fold increase in speed, but do note a loss in chromatographic resolution. Such a loss in resolution is to be expected when using temperature program rates as the driving force behind faster separations (22). However, the resolution of the fast separation was still acceptable for this analysis. The FAME analysis showed an increase in speed similar to the sugar analysis; however, separation of several of the compounds was incomplete. The mass selective detector did help distinguish co-eluted analytes, except in the case of positional (*cis, trans*) isomers. Lloyd and Grimm concluded that fast GC was successful in reducing analysis time, but had reservations about the loss of resolution.

Mastovsak et al. (36) evaluated the impact of reducing column length and temperature program rates in their analysis of 15 organophosphate pesticides in wheat. They also compared the performance of conventional and fast GC with flash GC, a commercially available resistive heating device. By reducing the column length from 30 to 5 m, increasing their temperature program rate, but maintaining column diameter and film thickness, Mastovsak and coworkers were able to reduce their analysis time 10-fold. Splitless injections with different splitless timing were used for the conventional, fast, and flash analysis. The researchers found that the narrower peak widths produced in flash GC experiments produced better detection limits, despite the smaller quantities of analyte being introduced to the column. The comparison of fast GC and flash GC methods showed similar run times, but the flash GC produced better retention time reproducibility. Additionally, the flash GC runs had faster cooling rates, leading to faster overall analysis times. The only drawback of the fast and flash GC was the loss of some resolution and subsequent coelution of analytes. However, some of the lost resolution could be attributed to the less selective stationary phase used for the flash GC analysis.

D. Method Translation Software

In creating methods for fast GC, the analyst has two choices; either redevelop the entire method or translate the method from traditional chromatography. Klee and Blumberg (13) offer an in-depth discussion of principles and practices of method translation. Method translation is often the easier of the two choices, especially if retention indices or "fingerprint" patterns need to be retained. To assist in the transfer, it is helpful to use method translation software, which is currently available on Agilent Technologies' internet site (www.chem.agilent.com/cag/servsup/usersoft/main.html#mxlator). A number of researchers (24,47) have evaluated the software's capabilities. David et al. (47) utilized the method translation software in transferring analysis of essential oils, bacterial fatty acids, and other complex mixtures from traditional to fast gas chromatography. By using a shorter, narrow bore column, and switching to hydrogen carrier gas they were able to analyze nutmeg and lemon oils in <13 min, a 6-fold decrease in analysis time. Additionally, the shorter analysis exhibited comparable retention indices and peak area ratios as the longer runs, allowing the "fingerprint pattern" of the separations to be maintained. Wool and Decker (24), by implementing a shorter, narrow bore column and using hydrogen as the carrier gas, observed a 50% reduction in time for analysis of 22 pesticides. Their conclusion was that "Method Translator should be a standard tool for analysts interested in speeding up the analyses done in their laboratories."

Fast gas chromatography is not a new concept, but the research and use appear to be undergoing a recent

renaissance. This renewed interest is probably due to a number of factors, including cost of analysis, interest in field sampling, and availability of adequate instrumentation. Whatever the reasons it is clear from past and recent publications that there are real benefits in developing fast gas chromatographic methods. These benefits will apply to laboratory sampling, process control, and field sampling, and will have an impact on the analysis of food and food packaging.

III. HIGH RESOLUTION GC AND THE ANALYSIS OF CONTAMINANTS IN FOODS

A. Scope of the Problem

This discussion will not be a review of the more than 25-year history of research involving high resolution gas chromatography (HRGC) and its application to the analysis of poly-halogenated contaminants. Rather than be a review, this treatment will examine the current approaches and future directions. The poly-halogenated contaminants of great interest in foods fall into several classes based on their carbon skeleton. A common feature of all the classes is the large number of isomers with similar physical and chemical properties, while conversely possessing widely varying effects on biological systems. These compounds exhibit very similar chemical properties to the analyst needing to detect and identify them, but nevertheless the individual isomers must be identified to determine their potential importance to a biological system. Table 45.1 lists some classes of poly-halogenated aromatic contaminant studied as a result of food contamination incidences or occupational exposures.

Table 45.2 provides a list of some of these classes along with a few chemical properties and their toxic equivalency factors (TEFs) values where known. Estimated toxicities often vary by many orders of magnitude for chemicals with fairly similar boiling points, melting points, vapor pressures, and octanol/water partitioning coefficients.

TABLE 45.1
Classes for Poly-Halogenated Aromatic Compounds, Synthetically and Environmentally Derived Contaminants

Chemical Class	Range(X)	Possible Congeners
Polychlorinated dibenzo-p-dioxins (PCDDs)	1–8(Cl)	75
Polychlorinated dibenzofurans (PCDFs)	1–8(Cl)	135
Polychlorinated naphthalenes (PCNs)	1–8(Cl)	75
Polychlorinated biphenyls (PCBs)	1–10(Cl)	209
Polybrominated biphenyls (PBBs)	1–10(Br)	209
Polybrominated diphenylethers (PBDEs)	1–10(Br)	209
Polychlorinated diphenylethers (PCDEs)	1–10(Cl)	209
Polybrominated dibenzo-p-dioxins (PBDDs)	1–8(Br)	75
Polybrominated dibenzofurans (PBDFs)	1–8(Br)	135

B. HRGC Column Stationary Phases

During the past 20 years, high resolution capillary GC columns have become the standard approach to separation difficulties presented by complex mixtures of polyhalogenated contaminants. Greater toxicological understanding of these chemicals has required increasing amounts of analytical data that report isomer-specific quantifications of these compounds in foods. Column lengths used in these procedures are typically at least 50 m, but most often 60 m, in length. PCDD/Fs provide a good example of separation difficulties with these compound classes. No single column could effectively separate all the isomers with largest TEFs from all others.

Ryan et al. (48) published the separations of all 136 tetrachloro- to octachloro-PCDD/Fs on nine different stationary phases and reported retention times on all the nine column phases. The column stationary phases covered a range of polarity from purely non-polar methyl silicone and the widely used 95% methyl, 5% phenyl polysiloxane (DB-5, RTX-5, equivalent, etc.) to the most polar 90% biscyanopropyl/ 10% 1:1 phenyl/ cyanopropyl polysiloxane (SP-2331) and 100% biscyanopropyl (CP-Sil-88) and the more recently introduced SB-smectic liquid crystalline methyl (80%) diphenyl carboxylic ester (20%) phase. Polar phases generally separated more of the 2,3,7,8-substituted isomers with the fewer numbers of congeners co-eluting, especially with 2,3,4,7,8-PeCDF and 2,3,7,8-TCDF, while leaving some HxCDFs or HxCDDs unresolved. Columns containing DB- 210 (50% methyl/ 50% trifluropropyl polysiloxane) or DB-225 (50% cyanopropylphenyl/50% methyl polysiloxane) equivalent phases are used for resolving the multiple co-elutions with 2,3,7,8-TCDF found on non-polar columns, but also produce co-elutions with 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, and certain HxCDFs such that they must be used with a second, usually non-polar, column.

Two medium polarity columns tested produced separations comparable or better to some more polar phases. A DB-17 column (50% phenyl/ 50% methyl polysiloxane) separated 2,3,7,8-TCDF completely and separated most other 2,3,7,8-substituted congeners except 1 isomer co-eluting with 2,3,7,8-TCDD, 1,2,3,7,8-PeCDF, and an incomplete separation of 1,2,3,6,7,8-HxCDF. An OV-17 column still contained an isomer co-eluting with 2,3,7,8-TCDF and with 1,2,3,7,8-PeCDD, while producing more complete separation for HxCDFs. While some column phases performed much better than others, a combination of at least two columns was needed to identify all isomers of the 2,3,7,8-chlorine substituted dibenzo-p-dioxin and –furan isomers in complex mixtures. The polar phases provide separation for all but a few of the 12 2,3,7,8-substituted tetrachloro-hexachloro-DD/Fs, but require hour-long GC run times leaving significant overlaps between chlorination levels. Often the performance of these polar phases

TABLE 45.2
Some Physical Properties for Poly-Halogenated Pollutants and Associated TEFs

Class or Member	MP [a]	BP [a]	VP	log(Kow)	TEF [b]

will deteriorate faster than non-polar ones which significantly alter the quality of the separation and increase maintenance time and costs. Some phases have been marketed specifically to produce a near-complete separation of the critical 12 2,3,7,8-substituted tetrachloro- through hexachloro-DD/Fs. The "DB-Dioxin" separates all 2,3,7,8-substituted congeners except for 1,2,3,4,7,8-HxCDF, although some congeners were not 100% resolved from other isomers.

Fraisse et al. (49) reported an improved separation using a non-polar phase initially developed for low bleed requirements of ion trap mass spectrometers. The "DB-5ms" phase

used the same composition (95% methyl-5% phenyl polysiloxane) as a DB-5 or RTX-5 equivalent phase, but with phenyl groups pendant on as well as inserted as aryl inclusions in the polysiloxane chain. The resulting phase could easily separate 2,3,7,8-TCDD and 2,3,7,8-TCDF from the other 21 or 37 isomers, respectively, compared with an ordinary DB-5 which could not resolve 2,3,7,8-TCDF from 5 other isomers and produced only a slight separation of 2,3,7,8-TCDD from several closely eluting isomers. In addition, all the hexachlorinated isomers were also separated, except for a poor separation of 1,2,3,7,8,9-HxCDF, compared with separating only 4 of the 7 congeners on DB-5. The 1,2,3,7,8-PeCDD was still resolved well enough, but not to baseline as with DB-5. This column effects a separation for PCDD/Fs from food extracts with near-complete isomer specificity with a very durable high temperature column. There are almost no circumstances (e.g., an old DB-5 ms column measuring high levels of TCDF in a shellfish sample containing all TCDF isomers or where the cleanup was poor) where a second or alternative column is necessary for food analysis in a regulatory setting.

Isomer-specific PCB methods have recently focused on the unique GC separation and mass spectrometry determination of the PCB congeners with established TEFs (see Table 45.2). Frequently, the PCBs are fractionated before GC separations are attempted using non-polar columns (DB-5 equivalent, etc.). The separations greatly simplify the task of the GC so that a single non-polar capillary column with high durability can separate the remaining congeners. PCB congeners with no orthochlorine substitutions are isolated for analysis with the dioxins. Other PCB congeners are analyzed separately or further fractionated by the number of orthochlorine substitutions (e.g., mono-orthochloro and di-orthochloro-). Some methods attempt to determine all of the PCB congeners with TEFs with a single GC injection. EPA 1668 Rev. A has the purpose of separating PCBs 77, 81, 105, 114, 118, 123, 126, 156, 157, 167, 169, 189 from all other congeners in an environmental sample using an SPB-octyl column (Supelco 2-4218). This method requires retention time of decachlorobiphenyl to be greater than 55 minutes (quite long) and analyzes PCB 156 and 157 as a summed peak. The combination of the SPB octyl column and a DB-1 is reported in the method to uniquely separate 180 PCB congeners. Garrett et al. (50) reported that the SPB octyl column produced high bleed, producing unstable retention times within a few days. Some new columns could not meet the specifications of EPA 1668 Rev. A. An RTX-5 sil MS column was suggested as an alternative. Covaci et al. (98) reports separating PCBs in human adipose using a 50 m × 0.22 mm id HT-8 column made with 8% phenyl methyl silicone and dicarbaclosododecarborane that SGE has claimed will separate 192 of the 209 PCB congeners at least partially.

The separation and retention behavior of all 72 polychlorinated napthalenes isomers was investigated on six different HRGC columns phases by Järnberg et al. (51). No column could separate all congeners at any chlorination level from dichloro- to hexachloro-. A pair of hexachloronapthalene isomers (1,2,3,5,6,7 and 1,2,3,4,6,7) known to strongly bioaccumulate, were not separated on any phase. More recently, a complete separation of all 14 pentachloro- and 10 hexachloronapthalene isomers was demonstrated using a proprietary column phase made by Restek that used per-methylated β-cyclodextrin (52).

C. HRGC Column Dimensions

The efficient separation of isomeric mixtures has required relatively long columns (50 m or 60 m). Some better separations are accomplished on polar stationary phases with lower temperature maxima, further slowing the elution of highly chlorinated congeners. Hayward et al. (53,54) demonstrated that a shorter and narrower "minibore" 40 m × 0.18 mm ID DB-5 ms column could produce nearly identical separations as the wider and longer 60 m columns in 40 min and was durable enough for analysis of large numbers of food samples for PCDD/Fs. MacPherson et al. (55) optimized the conditions for PCDD/Fs, coplanar PCBs, and chlorinated pesticides on 40 m × 0.18 mm and 20 m × 0.1 mm DB-5 columns by adjusting temperatures ramps and using higher inlet pressures enabling comparable separations and quantifications using either 60 m, 40 m, or 20 m DB-5 columns. On 20 m columns, PCDD/Fs were eluted in as little as 14 min. This same approach using 20 m columns and fast temperature ramps was applied to a mixture of 56 PCBs and to PAH mixtures (56). Microbore columns have also been tested in dual column applications for determining target PCB congeners and dioxins in the same GC run. MacPherson et al. (57) recently reported the sequential acquisition by HRMS of mono-ortho PCBs (PCBs 105, 118, 156 etc.) eluting from a 20 m × 0.1 mm ID column while PCDD/Fs and non-ortho-PCBs 77, 81, 126, and 169 were being separated on a 40 m × 0.18 mm ID column in the same GC injected immediately after the injection on the 20 m column of the PCB fraction. This way separate PCB fractions could be determined with the same acquisition and into the same data file for processing. Worrall et al. (58) used a similar approach, but delay the injection of the PCDD/F containing fraction on the 40 m column for 2.4 min to help avoid co-determination of chlorinated diphenylethers that would be present in the mono-ortho PCB fraction eluting on the 20 m column.

Dimandja et al. (59) demonstrated a very fast separation of 38 PCBs found in human serum in 5 min using a short 15 m column using time-of-flight (TOF) mass spectrometry for detection. The high spectral acquisition rates inherent in TOF have been used to reduce the time of separations on standard sized columns allowing simultaneous PCB and pesticide determinations in as little as 9.5 min (60).

D. Multi-Dimensional GC (GC^2)

Multidimensional GC or GC^2 refers to the separation of chemicals using two or more independent migrations for a chemical during the same fixed distance (GC) experiment. Multidimensional separations increase the capacity and resolution of a given GC system. The concepts for multidimensional separations are aptly described by Giddings (61). Liu and Phillips (62) reported achieving two-dimensional gas chromatography through use of an on-column thermal modulator system. A narrow bore column of standard length (20 m) is connected through the modulator (short section of column rapidly heated and cooled) to a short (~0.5 m) microbore column that produces a second fast separation of components pulsed to it by modulator from the first column. Two dimensional gas chromatograms could be generated on complex mixes of hydrocarbons using this system. The same approach was reported for pesticides in human serum by Liu et al. (63). Rapid separations of pesticides, PCBs or PCDD/Fs require fast mass spectral acquisition of a TOF instrument for mass spectrometric detection. More recent work has focused on robust modulator designs. Vreuls et al. (64) compared the performance of 4 modulator systems and report separating 91 PCB congeners and all 17 2,3,7,8-PCDD/Fs with the GCxGC/microECD with an ultimate goal of using TOF for the determination of PCBs and dioxins.

IV. APPLICATION OF GC TO THE IDENTIFICATION OF FOODBORNE BACTERIA

Among the U.S. population, it is estimated that millions contract foodborne illnesses each year (65). Currently, there is active surveillance for laboratory-diagnosed cases of 10 foodborne diseases resulting from infection with *Campylobacter, Escherichia coli* O157, *Listeria monocytogenes, Salmonella, Shigella, Vibrio* spp.*, Yersinia enterocolitica, Cryptosporidium parvum, Cyclospora cayetanensis,* and hemolytic uremic syndrome (HUS) (66). Since September 2001, there has been an additional need to identify select agents such as toxins (botulinum toxin and staphylococcal enterotoxin), chemical agents (sarin nerve gas and mustard gas), viruses, and particularly pathogenic bacteria including *Bacillus anthracis*, *variolla* (small pox), *Clostridium botulinum*, and *C. perfringens* (67). This requirement has led to a sudden surge in demand for routine rapid tests as well as fast and accurate microbiological assays and analytical methodologies for bacterial identification.

The most common techniques used for identifying bacteria include polymerase chain reaction (PCR), immunoassay biochemical reaction tests, and classical microscopy (67). Analytical chemical methods such as infrared spectroscopy (IR) (68–71), mass spectrometry (MS) (71,72), and gas chromatography (GC) (72–80) have been also used increasingly for bacterial speciation in research laboratories.

A. Gas Chromatography and Cellular Membrane Components

Early reports demonstrating that GC analysis of cellular fatty acid could be used successfully to identify bacteria were published in the 1960s (74,75). Whole bacterial cells are usually treated with sodium hydroxide and alcohol to cause hydrolysis and release of cellular membrane fatty acids. Sodium salts are formed and subsequently esterified. The resulting mixture of volatile fatty acid methyl esters (FAMEs) are separated by GC, identified and quantified. Derivatization increases volatility and improves chromatographic resolution. It was later recognized that further application of sophisticated multivariate statistical analyses to GC fatty acid profiles would facilitate the identification of microorganisms (75,76). The resulting new chemotaxonomy (75,76) based on multivariate statistical strategies such as principal component analysis differed from traditional microbial taxonomy that did not involve any statistical treatment.

The structures and names of cellular fatty acids are often complex (80). The structures of fatty acids can vary widely and include saturated, unsaturated, and branched fatty acids as well as those with hydroxy groups (e.g., 3-OH-C14:0) and rings. Branched fatty acids include the *iso* series, $(CH_3)_2CH(CH_2)_aCOOH$, and the *antiso* series, $CH_3CH_2CH(CH_3)(CH_2)_bCOOH$ or $CH_3(CH_2)_cCH(CH_3)(CH_2)_dCOOH$ with branching at a carbon in the middle of the fatty acid chain. Using a simplified nomenclature, examples include *iso*-C15:0, *antiso*-C15:0, and 10-Me-C19:0. An example of a fatty acid with a saturated 3-membered cyclopropane ring would be *cis*-11,12-methy- lene-octadecanoic acid (C19:0cyc11,12).

The primary source of cellular fatty acids is the lipid component of the cell membranes (including phospholipids) or the lipid A component of lipopolysaccharides in Gram-negative bacteria and lipoteichoic acid in Gram-positive bacteria (77). Most bacteria synthesize fatty acids with chain lengths having between 10 and 19 carbon atoms, and those with highest frequency are fatty acids with 16 to 18 carbons. Distinctive properties that allow identification of various microorganisms originate from differences in fatty acid composition, a characteristic that includes fatty acid distribution and quantity. Branched structures predominate in some Gram-positive bacteria, while cyclopropane-containing fatty acids and hydroxy fatty acids are often characteristic of lipopolysaccharides of Gram-negative bacteria. Gram-negative bacteria tend to have a greater proportion of saturated and monounsaturated fatty acids with an even number of carbon atoms than Gram-positive bacteria. The latter usually have a larger proportion of saturated branched-chain fatty acids

with an odd number of carbon atoms and low levels of saturated straight-chain fatty acids.

With the advent of long fused silica capillary columns, the application of GC to the determination of cellular FAMEs has become more widely used since the 1980s. An automated commercial system, Microbial Identification System (MIS) (79), that applies a GC procedure with flame ionization detection (FID) and multivariate analysis to the profiling of fatty acids ranging in length from 9 to 20 carbon atoms has been used increasingly by research, government, and commercial laboratories because it offers a FAME database for more than 2000 bacteria. The generally recommended GC-FID procedure (79) is outlined below. GC procedures have been widely used to identify bacterial species and strains primarily from clinical, environmental, plant, and soil, but only to a limited extent from food matrices (80).

A full understanding of this chemical type of bacterial identification requires that analysts and researchers in different disciplines collaborate and/or acquire expertise in all three microbiological (bacterial growth), chemical/analytical (GC), and biometric/chemometric (multivariate analysis) techniques.

B. Microbiological, GC-FID, and Multivariate Procedures

The analytical chemistry of bacterial identification depends on the comparison of the chemical composition of whole cells or their constituents (such as lipids or carbohydrates) that exhibit differences in microbiological characteristics. For the analysis to be reproducible, the various species and strains must be grown strictly under identical conditions to minimize variability.

Before any "fingerprinting" procedures can be used to analyze bacterial samples, the microorganisms must be cultured in order to produce sufficient biomass (*ca.* 40 mg) (79) for GC-FID analysis.

The accurate identification of unknown bacteria using a particular FAME database requires the use of microbiological conditions identical to those used to create that database. These conditions are primarily the temperature used in the cultivation of bacteria, the age of the culture, and the nature of the growth medium (79). It has been well documented (81) that differences in these factors will lead to large variations in the lipid content and composition of bacteria. Most aerobic bacteria are grown on trypticase soy broth agar (TSBA) medium that consists of 30 g trypticase soy broth and 15 g agar. Other common media are also used for aerobic bacteria and depend on the nature of the organism investigated. A temperature of 28°C would allow the growth of a wide range of microorganisms on TSBA. For anaerobic bacteria, agar cultures are grown at 35°C on brain heart infusion (BHI) with supplements. To minimize variability due to age, broth cultures are harvested at a given turbidity, and plate cultures are grown for 24 (aerobes) or 48 hours (anaerobes). Longer incubation times may be used for slow-growing bacteria. Approximately 40 mg of the bacterial cells are needed per test sample. For plate cultures, the physiological age is usually standardized by selecting a particular sector from a quadrant-streaked plate. Bacterial colonies are harvested with a 4-mm loop (or spatula) from the third quadrant. For a slow-growing organism, other quadrants may be used. Oftentimes, more than one quadrant must be harvested to collect as much as 40 mg. The weighed cells are placed in a culture tube with a teflon-lined screw cap and their membranes are prepared for GC analysis.

The preparation of FAMEs from cellular membranes for GC analysis involves several steps that include saponification, methylation, and extraction (79,80). Lipids from approximately 40 mg (79) of bacterial cells are first saponified with 1 mL of a sodium hydroxide (NaOH) solution prepared from 45 mg NaOH, 150 mL H_2O, and 150 mL methanol. Tubes containing bacterial cells and NaOH solution are securely capped, vortexed for 5–10 sec, heated in a boiling water bath for approximately 5 min, vortexed for 5–10 sec again, and returned to the water bath for 25 min. The tubes are allowed to cool down to room temperature and the fatty acids are methylated with 2 mL of an acidic methanol stock solution prepared from 6N HCl (325 mL) and methanol (275 mL). The tubes are vortexed for 5–10 sec, recapped, carefully heated at 80°C ± 1°C for 10 ± 1 min, and rapidly cooled. The resulting FAMEs are poorly soluble in the aqueous phase and are extracted with 3 ml of a 1:1 solution of hexane:*tert*-butyl ether by gently shaking the tubes for 10 min. The lower aqueous phase is pipetted out and discarded. Sample clean up consists of washing the remaining organic phase with 3 mL NaOH solution prepared from 10.8 g NaOH in 900 mL H_2O. This is carried out by gently shaking the recapped tubes for 5 min. Two-thirds of the top organic phase is pipetted into a GC vial that is capped and saved for subsequent GC analysis.

The remaining analytical steps include computer-controlled automation (79). A GC autosampler allows test samples to be chromatographed unattended. GC separation is usually carried out on a 25-m and 0.2-mm-ID phenyl methyl silicone fused silica capillary column. A temperature program that consists of ramping the temperature from 170°C to 270°C at 5°C/min is followed. GC peaks are electronically integrated and fatty acid composition data are stored. GC-FID profiles of FAME test samples are compared to those in the MIDI commercial databases and analyzed by proprietary pattern recognition algorithms. Multivariate algorithms apply statistical techniques to reduce the dimensionality of multivariate data while preserving most of the variance (82).

C. Application of GC-FID Methodology to Foodborne Pathogens

While the vast majority of GC studies involve the identification of clinical, environmental, and other microorganisms (83–86), there is a paucity of publications on the analysis of fatty acid GC profiles of foodborne pathogens (87).

In a validation study (87), the performance of the GC-FID-based MIS was compared to four other commercially available automated microbial identification systems. These four microbial identification systems are based on substrate utilization and bacterial growth; these processes lead to changes in pH, which in turn trigger changes in the color of indicators. All five systems were evaluated for their ability to identify six of the most common foodborne pathogens. The sensitivities, specificities, and repeatabilities of the MIS, the MicroScan WalkAway 40 system (Dade Diagnostics Corp., Mississauga, Ontario, Canada), the MicroLog system (Biolog, Inc., Hayward, CA), the VITEK system (bioMerieux Vitek, Hazelwood, MO), and the Replianalyzer system (Oxoid Inc., Nepean, Ontario, Canada) were tested by identifying food isolates of *Bacillus cereus, Campylobacter jejuni, Listeria monocytogenes, Staphylococcus aureus, Salmonella* spp., and verotoxigenic *Escherichia coli* (VTEC).

In the GC validation study by Odumeru et al. (87), 40 reference positive isolates (RPIs) and 40 reference negative isolates (RNIs) of these six microorganisms were used. Of the 40 RPIs, 35 were obtained from food samples and 5 from the American Type Culture Collection (ATCC). Of the 40 RNIs, 5 were ATCC strains, and 35 were cultured from food, clinical, or environmental samples and consisted of laboratory isolates that were related to but not identical to the bacteria of interest; RNIs showed similarities regarding their biochemical reactions and Gram staining results to those of the microorganism of interest. Sensitivity was defined in this study as the proportion of the RPIs that were correctly identified with an acceptable identification confidence level specified by the system's manufacturer. Specificity was determined by the proportion of RNIs that were not identified as the pathogen of interest with an acceptable confidence rating. Repeatability tests consisted of performing replicate analyses for 20 randomly selected ATCC strains and laboratory isolates from the RPIs and RNIs. Repeatability of identification was defined as the proportion of replicate analyses that generated the same result at similar confidence levels.

Odumeru et al. (87) reported that the sensitivities of the five systems used for the identification of microorganisms ranged from 42.5 to 100%. In particular, the sensitivity of the MIS was 90% for *Listeria* spp., 47.5% for *S. aureus*, 55% for *B. cereus*, 72.5% for *C. jejuni*, 85% for *Salmonella* spp., and 52% for *E. coli.* The authors attributed the lower sensitivities found for some of these pathogens with the MIS to the fact that they were based on fatty acid composition while the reference systems for these species were based on biochemical reactions. The specificities were usually close to 100%; those of the MIS were 100% for *Listeria* spp., 100% for *S. aureus*, 97.5% for *B. cereus*, 32.5% for *C. jejuni*, 100% for *Salmonella* spp., and 97.5% for *E. coli.* The repeatabilities of the MIS for the identification of test organisms were generally lower (30 to 90%) than those of the remaining four systems (60–100%). The repeatability of the MIS for RPIs was 30% for *Listeria monocytogenes,* 60% for *S. aureus*, 90% for *B. cereus*, 90% for *C. jejuni*, 90% for *Salmonella* spp., and 70% for *E. coli,* while the repeatability of the MIS for RNIs was 55% for *Listeria monocytogenes,* 90% for *S. aureus*, 80% for *B. cereus*, 75% for *C. jejuni*, 65% for *Salmonella* spp., and 65% for *E. coli.* According to Odumeru et al. (87), the selection of an automated system for the identification of foodborne bacteria depends on many factors including the nature of the available range of organisms in the system's database and the ability of the system to correctly identify the pathogen of interest.

In a GC-FID application study (88), the sources of *Bacillus cereus* in pasteurized milk were investigated. The MIS was used to determine the incidence and distribution of *B. cereus* vegetative cells and spores in raw and pasteurized milk. The presence of *B. cereus* in pasteurized milk is a concern for the dairy industry because it may lead to off-flavors, sweet curdling, and even outbreaks of food poisoning. *B. cereus* is a Gram-positive, spore-forming microorganism that can produce toxins in pasteurized milk at refrigeration temperatures. In pasteurized milk, *B. cereus* may originate from spores that are present in the raw milk or from the dairy plant environment.

In the study by Lin et al. (88), a total of 232 milk samples from sampling points along milk processing lines and 122 environmental swabs were collected in two dairy plants over several months. The fatty acid composition of each *B. cereus* isolate was determined by GC-FID. Using MIS, a database of *B. cereus* FAME profiles for 229 *B. cereus* isolates from milk samples and environmental swabs was created and used to determine the relationships between *B. cereus* isolate test samples.

Less than 10% of samples were positive for *B. cereus* vegetative cells in raw milk. The average *B. cereus* count in positive samples was less than 50 cfu per ml after enrichment at 8°C for 3 days. The incidence of *B. cereus* spores in raw milk samples was measured by the presence of *B. cereus* in heat-treated (75°C for 20 min) milk and was found to be very high. Of the heat-treated raw milk samples, more than 80% were found to contain *B. cereus,* and the average *B. cereus* count in positive samples was more than 1.1×10^5 cfu per ml after enrichment at 8°C for 14 days.

In pasteurized milk the incidence of *B. cereus* was high. After enrichment at 8°C for 14 days, 76–94% of these samples were contaminated with *B. cereus* and the average count reached 3.7×10^5 cfu per ml. Of the final products (pasteurized milk in cartons or plastic bags) more than 90% contained *B. cereus* and the average count reached 5.5×10^6 cfu per ml after enrichment. Most *B. cereus* isolates obtained from the pasteurized milk and final products belonged to the same sub-groups as the *B. cereus* strains germinated from spores in raw milk. Therefore, the authors (88) concluded that *B. cereus* spores in raw milk were the major source of *B. cereus* contamination in pasteurized milk.

The environmental swabs contained no *B. cereus* vegetative cells after enrichment at 8°C for 14 days. However, the heat-treated swabs had a low incidence (5%) of *B. cereus,* and the positive ones had a low average count for *B. cereus* of 30 cfu per ml after enrichment at 8°C for 14 days. According to Lin et al. (88), the presence of *B. cereus* in environmental swabs suggested that the dairy plant environment was a potential minor source of *B. cereus* in pasteurized milk.

Sundhein et al. (89) studied the contamination and spoilage of cold-stored chicken carcasses by *Pseudomonas* species. The shelflife of fish, red meat, and poultry in air is limited due to the presence of psychrotrophic pseudomonads that cause the formation of slime and production of off-odors. GC-FID traces of cellular FAMEs were analyzed by the MIS and used as an effective complementary technique to carbon source assimilation tests for the identification of pseudomonads from fresh and chill-stored chicken carcasses. Hundreds of bacterial strains were isolated from 18 chicken carcasses and based on results of carbon assimilation tests they were assigned to one of 17 defined groups of chicken pseudomonads. Isolates that had carbon assimilation patterns that could not be matched to any known species exhibited FAME profiles that corresponded to *P. fluorescens, P. lundensis* or *P. fragi.* The *P. fluorescens* biovars had greater levels of *cis* 9–16:1 (21–37%) and *cis* 9–18:1 (10–19%) relative to those of 17:0 cyclo (1–17%) and 19:0 cyclo (0–1%), while the opposite was found for *P. lundensis* and *P. fragi*. The authors concluded that none of the species was dominant and that the relative incidence of the various species may vary with flock or even individual birds.

D. Optimization of Analytical Methodologies

In research facilities, scientists have introduced minor refinements or major modifications to GC-FID analytical procedures, have added to existing commercial databases or created their own databases, and have applied and compared different analytical methodologies and pattern recognition algorithms.

A major drawback of using GC-based methods for fatty acid profiling is the requirement of laborious fatty acid derivatization procedures. To eliminate this manual step, researchers have used supercritical fluid derivatization/extraction and GC-MS (90), *in situ* thermal hydrolysis methylation (THM)-GC-MS (91), and *in situ* THM-MS (72) for the determination of cellular FAMEs. With *in situ* THM-MS, the 60-min extraction/methylation and the 20-min GC separation steps are eliminated, and this approach may potentially be amenable to rapid, single-step, automated analysis (72).

Muller et al. (86) used trimethylsulfonium hydroxide (TMSH) pyrolysis to complement the MIS procedure for the identification of FAMEs. This optimized TMSH procedure was used to transesterify bound fatty acids in phospholipids and triacylglycerol molecules to FAMEs in a rapid single step that can be carried out at room temperature. This reaction also released secondary alcohols and, for mycobacteria, mycolic acid cleavage products with chain lengths of C22 to C26 that were also amenable to GC-FID analysis. A pyrolysis-GC-atomic emission procedure (92) has also been used for identification of microorganisms.

Alternatively, the carbohydrate composition of bacterial cell hydrolysates may be analyzed by using a fully automated alditol acetate derivatization procedure and GC-MS and GC-MS-MS (78).

Selective detectors that require sophisticated instrumentation such as GC-MS/MS have provided high specificity and sensitivity in detecting trace amounts of chemical markers from clinical and environmental bacterial samples (78). However, the profiling of cellular fatty acids from vegetative cells and spores by GC-FID has been a more widely used analytical procedure (88,93). No single technique is suitable for all applications, and the full potential of analytical microbiological methodologies has yet to be reached.

46 Modern Thin-Layer Chromatography in Food Analysis

Bernd Spangenberg
Umweltanalytik Fachhochschule Offenburg

CONTENTS

I. INTRODUCTION

Thin-layer chromatography (TLC) is a well-established and widely used separation technique. Most undergraduate students of chemistry or food science used TLC as a primitive separation tool, which does not need more than small pieces of TLC plates, a glass jar and some solvents. TLC has evolved from a simple separation method of the past into an instrumental technique that offers automation, reproducibility and accurate quantification for a wide variety of applications [1]. The use of modern 10*10 cm TLC plates with narrow particle size distribution is called high performance thin layer chromatography (HPTLC), to distinguish the method from the use of traditional 20 × 20 cm TLC plates.

Numerous applications of TLC in the areas of food analysis, especially food composition, artificial additives, and contaminants have been reported. An excellent overview of modern thin layer chromatography is given by C. F. Poole [1,2], Sz. Nyiredy [3], J. Sherma and B. Fried [4], and also by N. Grinberg [5]. TLC analysis methods of agricultural products, foods, beverages, and plant constituents is comprehensively reviewed by J. Sherma for the period 1995–2000 [6].

There is strong competition among the different separation systems in food analysis. Widely used are GC (gas chromatography), IC (ion chromatography), and CE (capillary electrophoreses). HPLC (high performance liquid chromatography), which is often called the direct competitor of TLC [7], is especially common. The question here is not whether we need TLC beside HPLC but whether it is necessary to discuss how far thin-layer chromatography can be employed as a pilot technique. It is important to determine to what extent TLC can be used for optimization of separation selectivity. New developments show that TLC is not obsolete but has its niche in separation science and that niche is even still expanding. In this sense TLC and HPLC are competitors (S. Ebel from [7]).

II. THEORY OF TLC

HPLC and TLC separations are similar because nearly identical stationary and mobile phases are used. In HPLC reversed phase separations are preferred whereas in TLC the normal phase conditions dominate (the mobile phase is more lipophilic than the stationary phase). TLC has often been used as a pilot method for HPLC because TLC with various mobile phases can be performed much faster. Thin-layer chromatography in general has the advantage

of higher sample throughput by performing separation in parallel. TLC can handle cruder extracts than column techniques because the separation medium is used only once. The experience of the analyst is important in TLC separations because some steps have to be performed by hand. HPLC, in contrast, is fully automated with regard to the sample application, separation, and detection. But nevertheless, pre-cleaning of the analyte is mostly done by hand.

There are principal differences in TLC compared to commonly used column techniques like HPLC, GC, CE, or IC. In all the column techniques mobile and stationary phases have to be in equilibrium conditions before samples are injected. In TLC the sample is applied on the dry plate before the solvent contact starts the separation. It is worth noting that the solvent used in TLC is not identical with the mobile phase of the separation. The mobile phase arises from the equilibrium formation between solvent and TLC plate. When a plate is immersed under capillary flow-controlled conditions in a tank containing a few milliliters of the solvent, the distance moved by the solvent front z_f is related to time by the following equation:

$$z_f = \sqrt{\chi t} \tag{46.1}$$

$$\chi = 2k_0 d_b \frac{\gamma}{\eta} \cos\delta \tag{46.2}$$

t = separation time
χ = velocity constant
k_0 = permeability constant
d_b = particle diameter
γ = surface tension
η = viscosity of the solvent
δ = contact angle

To increase layer efficiency, high performance thin layer plates have been commercially available since the mid-1970s. The layers of these plates consist of fine particles with a very narrow particle distribution [8]. Assuming a narrow particle-size distribution, the velocity constant increases linearly with the average particle size. For coarse-particle layers of TLC plates the solvent front velocity is greater than for HPTLC layers. The velocity of the solvent front depends linearly on the ratio of surface tension and viscosity of the mobile phase. Although for silica gel layers the contact angle of all common solvents is close to zero, for reversed-phase layers containing bonded lipophilic groups the contact angle of the solvent increases rapidly with increasing water content of the mobile phase and cos(δ) will become very small, even zero. In this case the solvent is virtually unable to ascend the plate surface.

The nature of the sorbents, which is fixed as a layer of 100 μm to 250 μm thickness on glass, aluminum, or plastic plates, crucially influences the kind of separation. In TLC mainly strong polar sorbents like silica gel or Al_2O_3 are used. These sorbents have active centers, where sample molecules can be reversibly fixed. During the separation, an equilibrium is established between sample molecules, active centers of the stationary phase, and the solvent. If molecules remain primary in the stationary phase, they will move less than molecules staying mainly in the mobile phase.

The definition of the relative spot movement in comparison to the movement of the solvent front is given by the following formula:

$$R_f = \frac{z_S}{z_f - z_0} \tag{46.3}$$

R_f = retardation factor
z_S = movement distance of the sample spot
z_f = movement distance of the solvent front
z_0 = difference between starting position of solvent and spot

Two extreme situations are possible. If the sample does not pass into the mobile phase, it will not move. The R_f-value of this sample will be $R_f = 0$. If the sample stays constantly in the mobile phase, it will move with the solvent front and will not have any interchange with the stationary phase. In this case the R_f-value will be 1. It is obvious that a sample spending the same time adsorbed at the stationary phase as dissolved in the mobile phase will show an R_f-value of 0.5. If k is the equilibrium factor (often call the capacity factor), which represents the distribution probability between stationary and mobile phase, the expression (1) is valid.

$$R_f = \frac{m_m}{m_s + m_m} = \frac{1}{k + 1} \tag{46.4}$$

m_s = mass of sample in the stationary phase
m_m = mass of sample in the mobile phase
k = capacity factor

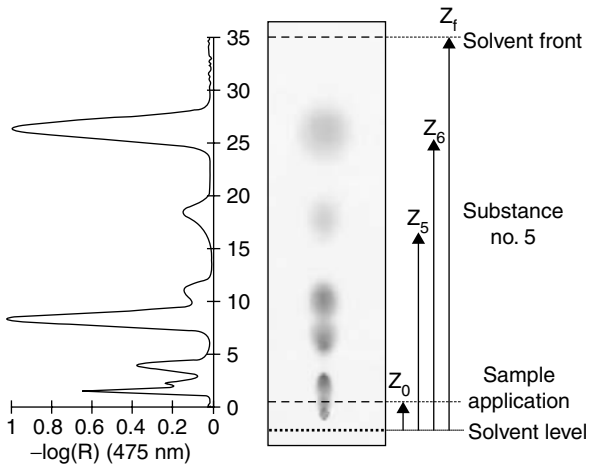

FIGURE 46.1 Separation of a dye mixture (CAMAG dye III, Switzerland) with densitogram (left).

If a sample stays at the point of application, obviously no separation can have taken place. The same situation is valid when all samples move with the solvent front. A sample separation is only possible if the samples change phases to different extents. In formulas, the appropriate k-values of substances must be different for them to separate. Chromatography is a separation technique where molecules can be separated because of their distinctive attraction to mobile and stationary phase. During the time of separation, all molecules in the mobile phase show a randomized diffusion movement. This diffusion causes a gaussian shaped peak with the variance σ_S. Diffusion effects are responsible for peak-broadening, which can be described with the following expression:

$$N' = \left(\frac{z_S - z_0}{\sigma_S}\right)^2 = NR_f' \qquad (46.5)$$

σ_S = variance of the sample spot (peak width)
N' = number of measurable plates
N = number of theoretical plates
R_f' = average R_f-value of all separated substances

The number of theoretical plates (N) is be corrected by an averaged R_f-value of all separated spots, because not all sample spots will, like in column separations, move over the same distance. The product of the theoretical plates number and the averaged R_f-value of all separated substances is a measure for layer efficiency. The basic evidence of the formula is that the squared quotient of the passed distance and the peak width is a constant value for all separated spots.

The baseline width (W_B) of a peak is virtually the spot diameter and this is easy to measure on the plate. In contrast, the peak width at half peak height in a densitogram is much easier to determine than the baseline peak width. The baseline width of a chromatographic peak can be assumed as $W_B = 4\sigma_S$ and the peak width at half peak height ($W_{1/2}$) is $W_{1/2} = 2.354\sigma_S$. For this, the chromatographic law can be expressed as follows:

$$N' = 16\left(\frac{z_S - z_0}{W_B}\right)^2 = 5.545\left(\frac{z_S - z_0}{W_{1/2}}\right)^2 \qquad (46.6)$$

W_B = baseline peak width
$W_{1/2}$ = peak width at half peak height
N' = number of measurable plates

It is worth mentioning that increasing separation distances are gained proportional to the square root of time. To double the separation distance it needs four-fold time! Unfortunately, diffusion is a matter of time and will increase over-proportionally with increasing distance. This is a definite disadvantage of TLC in comparison to column techniques, where the flow velocity is constant. This disadvantage of planar chromatography strongly affects the separation of two substances. The resolution (R_S) of two neighbourhood peaks is defined as the distance between both peak maximums and the averaged baseline width of the peaks.

$$R_S = \frac{z_{S2} - z_{S1}}{\frac{w_{B1} + w_{B2}}{2}} = 2\frac{z_{S2} - z_{S1}}{w_{B1} + w_{B2}} \qquad (46.7)$$

The resolution can be expressed in terms of capacity factors, the number of effective plates, and the R_f-value.

$$R_S = \frac{1}{4}\sqrt{N'}(1 - R_{f2})\left(\frac{k_1}{k_2} - 1\right) \qquad (46.8)$$

$N'(1 - R_{f2})^2$ = number of effective plates
R_{f2} = retardation factor of peak 2
k_1, k_2 = capacity factors of peak 1 and peak 2

The change in resolution of two closely migrated spots as a function of different R_f values is shown in Figure 46.3. Resolution increases only by square root of measurable plate number, which is a measure of layer quality and

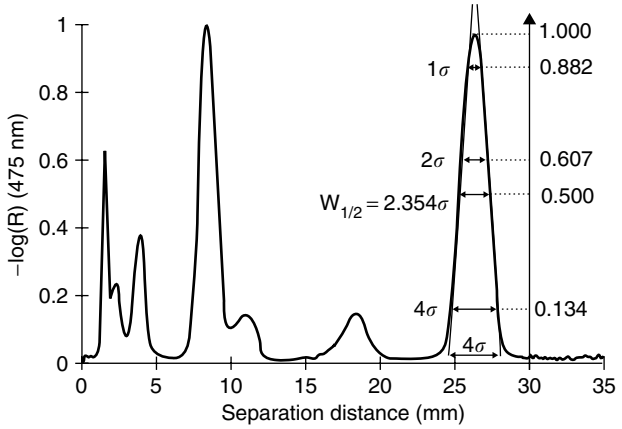

FIGURE 46.2 Gaussian peak of dye no. 6 in a densitogram of several dye spots.

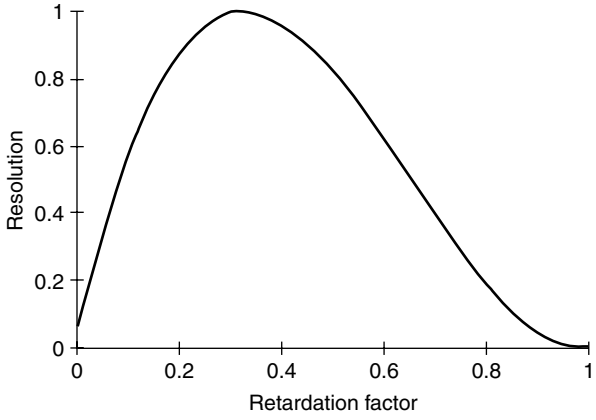

FIGURE 46.3 The plot shows the change in resolution of two peaks, plotted as a function of R_f-values.

efficiency. The influence of peak position on resolution is the opposite behavior to that of the layer quality. At larger values of R_{f2} the term $(1 - R_{f2})$ decreases and in the case of $R_{f2} = 1$ the resolution will become zero [9]. This is reasonable and agrees with the statement that phase changes are essential for separation. Figure 46.3 indicates that a resolution optimum of two closely migrating peaks can be observed at a R_f value of 0.33.

In summary, the selectivity $(k_1/k_2 - 1)$ can easily be increased by a factor of 10 or even 50 by solvent/sorbent changes, while it is difficult to change the layer quality factor $\sqrt{N'}$ by more than 2–3. Therefore, for resolution enhancement it is most rewarding to invest time in solvent optimization and to a lesser extent in sorbent optimization and least in the improvement of layer quality [10].

If the separation system is perfectly chosen, baseline separation of the desired substance can be done even on a few centimeters. In Figure 46.4 the separation of caffeine is shown, separated over a distance of only 11 mm. Samples from coffee, tea, or even strong sugar-containing beverages can be applied without further cleaning steps directly on the plate, after removal of CO_2.

The separation power of TLC or HPTLC plates is normally not sufficient to separate more than ten spots in one run. For the separation of more complicated mixtures, more than one solvent system must be used. However, the planar chromatographic separation power can be increased if a two-dimensional separation mode is used. Several AOAC (Association of Official Analytical Chemistry) methods, for instance, recommend a two-dimensional separation of aflatoxin samples to avoid overlapping spots [80]. For a two-dimensional HPTLC separation, samples have to be spotted at all four edges of a 10 × 10 cm HPTLC plate and four standards are also spotted on each of the four plate sides exactly between the sample spots. After simultaneous development from both plate sides to a distance of 45 mm the plate is dried and, after a turn of 90°, developed once again to a distance of 45 mm by use of a different mobile phase. The separation in two directions using different mobile phases extends the TLC separation power dramatically. A separation of a dye mixture in two dimensions is plotted in Figure 46.5.

In Figure 46.5 a dye mixture consisting of six dyes is shown, which can be separated only by two-dimensional separation using different solvent phases. One spot in the two-dimensional separation is not in a rectangular position between the two single separations. This indicates a compound, which changed its chemical property during the separation. Two-dimensional developments can be beneficially used to check sample decomposition during the separation.

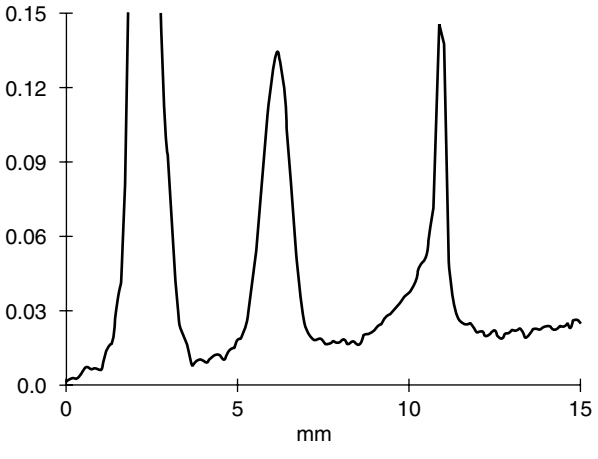

FIGURE 46.4 Plotting the caffeine peak at 6 mm from a well-known sparkling and sugar-containing black beverage. The solvent system isopropanol-cyclohexane-aqueous NH_3 (25%) (7+2+1) has been used in combination with a Si_{60} plate [11].

III. STATIONARY PHASES

TLC and HPLC plates are commercially available as pre-coated layers supported on glass, plastic sheets, or aluminum foil. The classic TLC plates are 20 × 20 cm in size whereas the modern HPTLC plates are smaller (10 × 10 cm or 10 × 20 cm). Compared with TLC, HPTLC-phases provide better separation efficiency, faster separations over shorter distances, and lower detection limits. In Table 46.1 the parameters of both plate types are listed.

The choice of the layer and the development solvent depends on the nature of the sample. In general, more than 75% of all HPTLC separations are done using silica gel as the stationary phase [5]. Silica gel, silica, or kiesel gel are various names for a polycondensation product of orthosilicic acid. It is prepared from silica solution by precipitation with acids. The improvements of HPTLC-plates are still under development. Macherey-Nagel company (Düren, Germany) developed especially hard and waterproof silica gel plates. These materials are commercially available

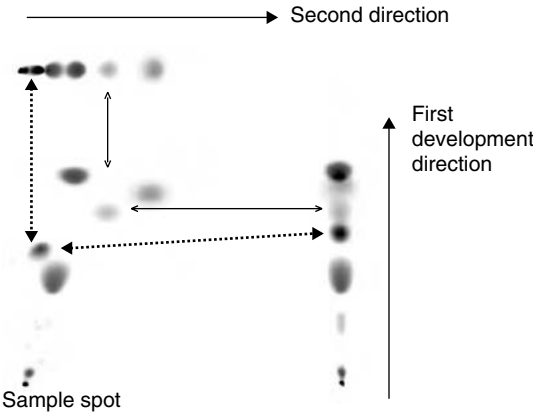

FIGURE 46.5 The plot shows a two-dimensional HPTLC separation of a dye mixture, with two one-dimensional standard separations right and on top.

TABLE 46.1
Comparison of Conventional TLC and Modern HPTLC Parameters

Parameter	TLC	HPTLC
Plate size (cm)	20×20	10×10
Layer thickness (μm)	100–250	100
Particle size (μm)	20	5–15
Sample volume (μl)	1–5	0.1–5
Application distance from plate side (mm)	10–15	5–10
Solvent migration distance (cm)	6–15	3–7
Starting spot diameter (mm)	3–6	1–1.5
Time of development (min)	30–200	3–20
Detection limits in remission (ng)	10–50	5–50
Fluorescence (pg)	500–1000	20–100

under the labels DurasilR and Nano-DurasilR. Merck (Darmstadt, Germany) sells HPTLC-plates with regular, ball-like particles under the name LiChrospher^R. The company claims a shorter developing time and better resolution in comparison to irregular articles. The use of Al_2O_3 as a stationary phase is restricted to mainly pesticide separations. Aluminia and silica gel plates form typical normal phase adsorption systems in retaining substances by active centers of the stationary phase.

Cellulose phases are more often used as aluminia, especially for amino acid separations and basic reacting substances like nucleotides. Polyamides as stationary phases are not often used. This very interesting material is well suited for the separation of acid-reacting substances like phenols, nucleotides, or dansyl derivatives. Bonded phases, based on silica gel, are becoming increasingly important in food analysis. These sorbents are typical for reversed phase separations. HPTLC is mostly performed on chemical bonded C-18, C-8, C-2, C-NH_2, C-CN, and C-$CHOHCH_2OH$ (diol phase) material. Cellulose and chemical bonded stationary phases are typical materials for distribution chromatography.

The flexibility of planar chromatography is a consequence of the absence of restrictions on the choices of mobile and stationary phases. Usually, TLC and HPTLC plates are obtained from commercial suppliers, but home-made layers are recommended for special purposes. Plates containing silver ions, for example, are able to separate compounds differing only in the position of one double bond [12]. The plates are difficult to store and are made by hand, mostly for research purposes. Other customers prefer home-made plates.

Although TLC is an inexpensive separation method, industrial produced plates must be purchased or may not be available everywhere. In developing countries cost and availability might be strong reasons to be independent of plate suppliers. A versatile TLC-layer can be made by mixing 27 g of corn starch with 3 g gypsum in 20 mL water and 10 mL ethanol. Nada Perišić-Janjić et al. [13] published the determination of organic acids like malic acid, citric acid, tartaric acid, and ascorbic acid in fruit juice using the solvent mix ethanol-n-butanol-water-conc. ammonia (40+30+15+15) in combination with the TLC-layer just described. A separation of amino acids with the solvent system 2-propanol-formic acid-water (40+2+10) is also possible as well as the separation of fat-soluble vitamins. For the separation of vitamin E and D_2 a solvent system containing acetone-conc. acetic acid (3+2) was used. Fructose, glucose, sucrose, and galacturonic acid are perfectly separated with the solvent system n-propanol-benzylalcohol-water-formic acid-dioxan-benzene (10+27+5+4+10+20) and anthocyanins from fresh cherries and cherry juice were separated on this unconventional layer using n-butanol-glacial acid-water-benzene (30+20+10+0.5).

IV. MOBILE PHASES

In planar chromatography the mobile phase is not restricted to a special kind of solvent. This makes it possible to separate a wide range of different analytes using only a single plate layer. In HPLC solvents are restricted to substances with low absorption values because analyte and mobile phase both have to pass the on-line detector. In planar chromatography even strong light absorbing solvents can be used because the mobile phase is removed before plate scanning. Nevertheless carcinogenic substances should be avoided. In the older literature (and even modern methods) benzene is often recommended as a solvent, but in this case toluene should be used.

Sometimes it is necessary to use chlorinated substances like chloroform or CH_2Cl_2. The leftover solvents should be collected separately to protect the environment. The mobile phase in planar chromatography is commonly chosen by trial and error, guided by literature descriptions of similar separations. On the basis of a sufficient substance movement in the R_f-range between 0.2 and 0.8, fine-tuning of the mobile phase should be done using different solvent mixtures with nearly the same solvent strengths (P'). The solvent strengths of a mixture can be calculated as the sum of the appropriate solvent strengths of the different mixture shares. A change in selectivity can be achieved if solvents with various selectivity parameters (x_e, x_d, x_n) are used. In Table 46.2 the most important solvents for planar chromatography are listed.

To create a new solvent system, one solvent should be tested from at least each selectivity class. While the velocity of the solvent front depends linearly on the ratio of surface tension and viscosity, this quotient should also be taken into account. Small values indicate fast separations, little peak diffusion, and therefore narrow peaks.

TABLE 46.2
Solvent Parameters for Different Solvents (the Values in Brackets Refer to RP Conditions; the Polarity Index (*P′*) Refers to the R_f-Value, Whereas (x_e, x_d, x_n) Influences the Selectivity of a Separation (+ γ/η[m/s]))

Sample Pre-Treatments, Application and Plate Development. In food analysis a pre-treatment step prior to separation is usually necessary. The pre-cleaned analyte is then applied on the plate, separated, and either visually detected or scanned by use of appropriate items. The determination of α-solanine and α-chaconine in potatoes is a typical example of a complete HPTLC determination. Solanines are toxic substances because they inhibit cholinesterases and cause gastrointestinal necrosis. An undamaged potato tuber contains 20–150 mg/Kg total solanines. Exposure to light or mechanical damage can increase the content. A routine analytical method to determine solanines is useful [14].

For preparation of potato samples 2 g dehydrated potatoes were extracted with three 15 mL portions of boiling methanol-acetic acid (95+5). The solution is filtered and evaporated under vacuum. The residue is dissolved in 4 mL methanol-acetic acid (99+1). In modern methods very often pre-columns, containing a stationary phase, are used in pre-cleaning. The analyte is accumulated on the stationary phase, cleaned by washing with appropriate solvents, and eluted by a solvent with high solvent strength. This pre-treatment increases the analyte concentration and removes contamination.

The sample application for qualitative purposes is mostly done by use of glass capillaries. If the same capillary is used, even quantitative measurements are possible. Glass capillaries in the size 0.5 μm, 1.0 μm, 2.0 μm, and 5.0 mm are commercially available. The disadvantage of this kind of application is the rather large spot diameter of the starting spots, which restrict the chromatographic resolution. For better resolution an automated application item should be used which is able to bring the sample bandwise on the plate. If a band length

of 7 mm is chosen, even 20 µl analyte can be applied on an HPTLC-plate. In general, an automated application is recommended if low measurement uncertainties are desired. Prior to separation the plates should be pre-washed by development at best with the mobile phase. In the case of solanine separation, the authors recommend pre-washing with methanol, pre-equilibration with the separation solvent for 1 h in a twin-trough chamber, and development up to a distance of 85 mm [14]. The separation conditions are very important, especially with respect to the vapor phase to obtain reproductive results [10]. The use of vapor dry chambers without mobile phase pre-equilibration should be avoided, and therefore the use of twin chamber or a linear chamber is recommended. The linear chamber for sandwich developments (Figure 46.6) is ready to use without time-consuming pre-equilibration because the very small vapor volume, in contrast to trough chambers, is responsible for reliable development conditions. If TLC plates are to be used, the separation distance should not be above 15 cm. For HPTLC-plates the separation optimum is 4.5 cm.

After solanine separation the plate is dried and dipped in a modified Carr-Price reagent containing 70 g antimony (III) chloride in 280 mL acetic acid-CH_2Cl_2 (1+3). After dipping the plate is subsequently heated for 5 min at 105°C [14]. One of the most important advantages of planar chromatography is the huge number of different staining systems [15], which makes planar chromatography very specific. The Carr-Price system, for example, reacts most specifically and sensitivly with the double bond of steroids. If staining is recommended, the plate should be automatically dipped for a defined time instead of spraying with reagent because sprayed plates are useless for quantification purposes.

The solanine peaks are quantified by densitometric reflectance measurement at 507 nm. The range of linearity for α-solanine is 100–2000 ng per spot. The limit of detection (LOD) is 50 ng and the limit of quantification (LOQ) is 100 ng. The LOD is the smallest quantity of the target substance that can be detected as peak, but not precisely quantified in the sample. The LOQ is the smallest quantity of the target substance in the sample that can be assayed under experimental conditions with well-defined precision and accuracy. The analytical precision is determined by measuring the repeatability at different concentrations. The repeatability for 5 determinations within 3 days for 500 ng α-solanine is 3.2%. Accuracy is a measure of agreement between a conventionally accepted value or a reference value and a mean experimental value. The extraction recovery for 900 ng α-solanine is calculated to 98.9% [14]. All these data are necessary to present a complete TLC or HPTLC method in food analysis.

Separations without complicated pre-cleaning steps are superior to those which need a lot of practical work prior to detection. The application of "dirty" samples on the separation medium is only possible in planar chromatography because disposable plates are used. This is a real advantage in comparison to HPLC because the pre-cleaning is simplified and the overall precision can be increased. C. F. Pool and co-workers [16] describe an elegant method to quantify vanillin in chocolate. Although chocolate is a difficult matrix it is only necessary to extract 5–8 g chocolate with 15 ml 70% ethanol in an ultrasonic bath for 15 minutes. After extraction the sample is centrifuged and separated on silica gel HPTLC-plates with chloroform-ethyl acetate-1-propanol (94+2+4) to a distance of 6 cm. Quantification is done by remission measurements at 280 nm.

V. DENSITOMETRIC MEASUREMENTS

In situ densitometry offers a simple way of quantifying by measuring the optical density of the separated spots directly on the plate [17]. During densitometric measurements the illuminating light is either absorbed or scattered. Only the scattered light is reflected from the plate and this light provides the desired information. This reflected light is called remission light. Quantitative evaluation of thin-layer chromatograms by optical methods is based on a differential measurement of light, emerging from the sample-free and sample-containing zones of the plate, although the relationship between detector response and sample concentration is not simple [18–20]. At first approximation a parallel light beam with the intensity I is used for illuminating the HPTLC-plate. To get a lamp-independent spectrum it is recommended to use the quotient of the sample spectrum and the spectrum of the clean HPTLC-plate. Usually the remission values (I_{rem}) are

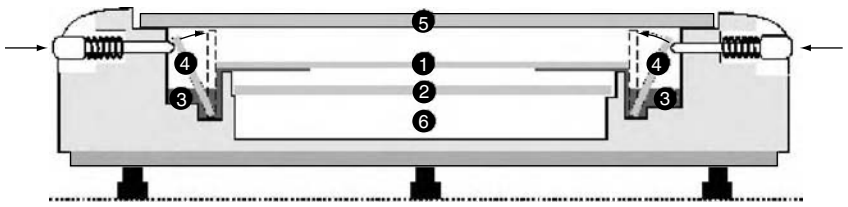

FIGURE 46.6 Sketch of a linear chamber. 1. HPTLC plate; 2. counterplate used only for sandwich development; 3. troughs for eluents; 4. glass strip to regulate eluent flow; 5. covering glass plate. (Reproduced with permission from CAMAG, Switzerland.)

calculated from the measurement values of the HPTLC-track divided by reference values (I_0).

$$R(\lambda) = \frac{I_{rem}(\lambda)}{I_0(\lambda)} \tag{46.9}$$

$R(\lambda)$ = corrected remission light spectrum
$I_{rem}(\lambda)$ = remission light spectrum
$I_0(\lambda)$ = reference spectrum

The proper choice of the reference spectrum $I_0(\lambda)$ is a very effective method for baseline corrections. A convenient way to transform remission data into mass-dependant signals is to use the folowing formula:

$$A(I_{rem},\lambda) = -\ln R(\lambda) \tag{46.10}$$

The logarithm expression sets all intensities smaller than I_0 to positive values. Theoretical predictions indicate that the Kubelka/Munk-equation is the only transformation formula which shows linearity between the remission data and the sample mass (m) [11].

$$KM(I_{rem},\lambda) = \frac{(1 - R(\lambda))^2}{2R(\lambda)} = const.m \tag{46.11}$$

In principle, all light absorbing substances are detectable because a modern diode-array TLC-scanner covers the range from 200 nm to 1100 nm. In Figure 46.7 a typical contour-plot of a dye mixture is shown, which comprises 450 single spectra, evaluated with Equation (46.10). Within less than 1 minute the diode-array scanner measures the track over the distance of 45 mm in the wavelength range of 200 to 600 nm with a spatial resolution of 0.1 mm.

There are numerous examples for *in situ* densitometric determination in food matrices. For example, the quantification of methyl and propyl parabens, benzoic acid, and sorbic acid at 228 nm and 254 nm are published in [21]. Fruit juices and jams are extracted and separated on silica gel TLC-plates, using the solvent mix ethanol-NH_3 aqueous-ethyl acetate-acetone (1+3+3+28) for the parabens and ethyl acetate-acetic acid-hexane (1+4+16) for both acids. The AOAC Official Method Polycyclic Aromatic Hydrocarbons (PAHs) and Benzo[a]pyrene in Food, describes a PAH separation using isooctane on cellulose plates. After separation the spots have to be scraped out and measured externally in UV [22]. In contrast, a modern TLC-scanner can separate 16 PAHs in one run, using the different absorption maxima of the PAHs spectra for quantification. Even spots not separated on the plate can be quantified, because spots can be spectrally distinguished [20].

The Kubelka/Munk equation is the only theoretically founded expression describing all remission processes. If a substance absorbs more light than the clean part of a

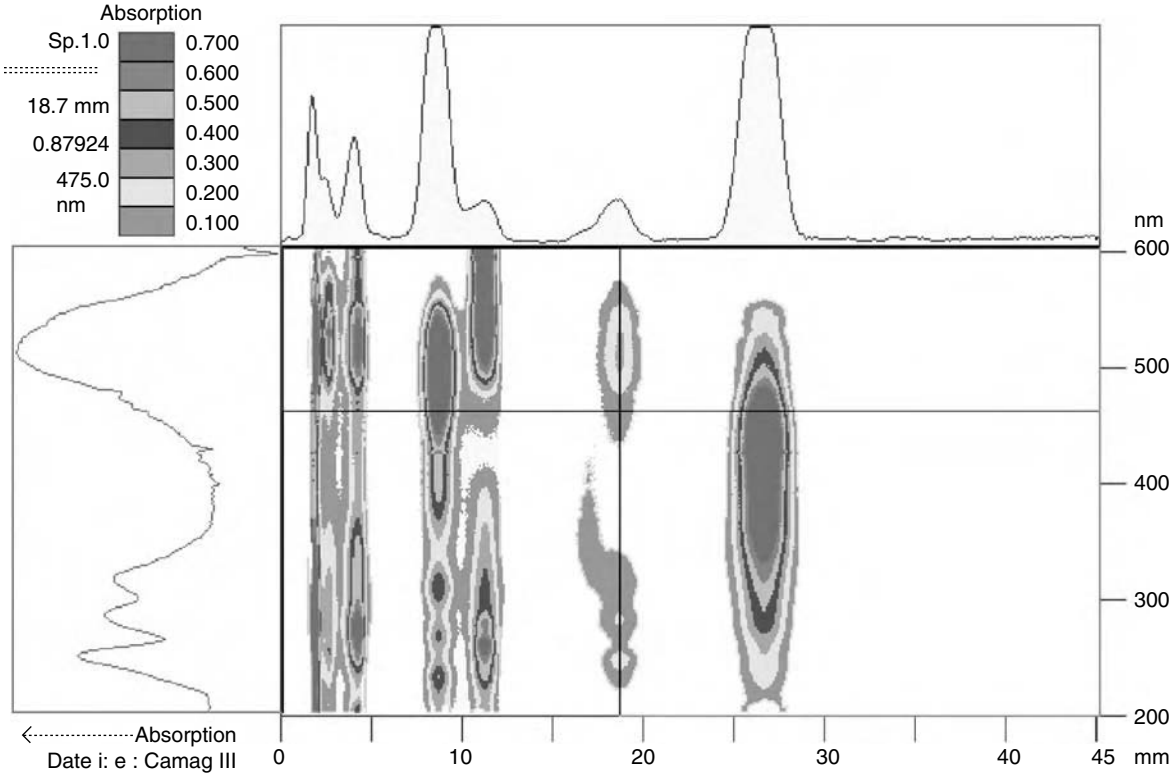

FIGURE 46.7 The plot shows the contour-plot of a CAMAG-III dye mixture. The dyes are separated with toluene over a distance of 45 mm. The spectrum at 18.7 mm (peak 5) is plotted left and the densitogram, taken at 475 nm, is shown on top.

plate, the comparison of sample and reference spectrum using Equation (46.10) or (46.11) can be used for quantification purposes. If the spot emits more light than the reference, the sample shows fluorescence. The fluorescence spectrum is derived from sample and reference spectrum using either Equation (46.11) or Equation (46.12).

$$F(I_{rem},\lambda) = [I_{rem}(\lambda) - I_0(\lambda)]/1000 \qquad (46.12)$$

Quinine is a fluorescent compound which emits light which was absorbed below 380 nm. In Figure 46.8 the densitogram of a beverage sample, applied undiluted on a silica gel HPTLC-plate, is plotted. The mobile phase (the same as shown in Figure 46.4) cannot separate quinine completely from sugars. The absorption densitogram (lower plot in Figure 46.8, evaluated using Equation (46.10) shows an irregular baseline and the quinine signal cannot be used for quantitative determination. If the same data set is evaluated using Equation (46.12) (upper plot in Figure 46.8), the quinine peak can be easily integrated [11].

The AOAC Official Method No. 969.27 [23] describes the separation of the non-nutritive sweeteners calcium cyclamate, sodium saccharin, and dulcine in non-alcoholic beverages on silica-gel plates using n-butanol-alcohol-NH_3-H_2O (40+4+1+9). Saccharin (R_f = 0.5) shows fluorescence at shortwave UV and can be quantified using the fluorescence mode of a diode-array scanner. In the AOAC method, color reagents for cyclamat and dulcine are recommended. These substances are detectable by direct remission measurements.

TLC scanners for *in situ* remission measurements are modern computer-controlled, high-sensitivity instruments that measure absorption and fluorescence. Modern diode-array TLC scanners are able to measure simultaneously at different wavelengths. They allow quick peak identification and peak purity investigation, using the registered spectra. Furthermore, the simultaneous registration at different wavelengths opens the way for chemo metric evaluations, like peak purity monitoring, to improve accuracy and reliability in HPTLC analysis. Diode-array scanners make fluorescent measurements possible without use of edge-filters or other facilities. Even a separate run for fluorescent measurements is not necessary, because the required information can be extracted from the remission data [11, 17–20].

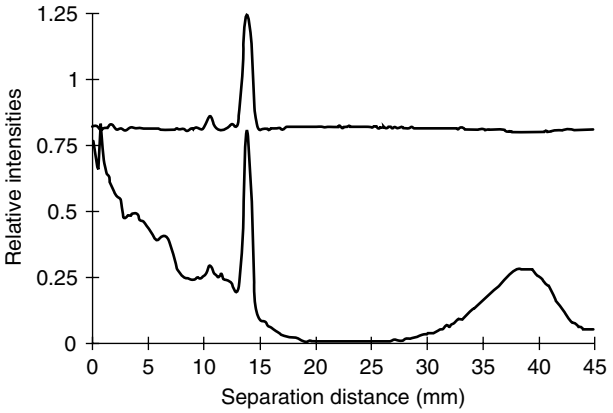

FIGURE 46.8 Densitogram of a bitter lemon sample in absorption (lower graph) and fluorescent mode (upper graph).

VI. SUGAR ANALYSIS AND SEPARATION OF DYES AND FOOD LIPIDS

Planar chromatography offers a wide range of different reagents for specific staining of analytes. The recommended handling of mostly hazard reagents eliminated many TLC methods from official method collections. To avoid plate dipping with mostly hazard reagents, specific plate coatings can be used for staining purposes. In the past, sugars had to be transformed into colored products by use of 4-aminobenzoic acid in glacial acetic or similar reagents [24]. The AOAC official method for glucose in honey or fructose starch sirup in honey recommends sugar detection by spraying with aniline/diphenylamine reagent after separation with n-butanol-acetic acid-water (2+1+1) on silica gel [25, 26]. In modern HPTLC amino phases are used for sugar separation [27, 28]. The separation is possible by using CH_3CN-H_2O solvent systems. After separation the amino plates are placed at 150°C for 15 minutes. All carbonyl-group containing substances will react with the NH_2-group to form colored, strong fluorescent products. Sample pre-treatments usaully are not necessary. In Figure 46.9 the separation of the artificial sweeter Sucralose® after amino plate derivation is shown. The detection limit is 10 ng/spot of Sucralose® [29], which is a typical value for what is termed thermochemical activation in sugar analysis.

Dye separation is one of the basic TLC applications because no scanner and staining reagent are necessary. Companies like CAMAG sell dye mixtures to check the layer quality of TLC and HPTLC plates. In [30] a rapid clean-up procedure for FD&C color additives in foods by use of reverse phase C_{18} cartidges is given. The color additives are separated on silica gel G TLC plates with n-butanol-methyl ethyl ketone-NH_4OH-H_2O (5+3+1+1). Similar systems are used to quantify colours from non-alcoholic and alcoholic beverages [31] and from raw sausages [32]. Detection of natural pigments from red pepper, paprika, and tomato is performed by using different hexane-aceton solvents or by using a mixture of CH_2Cl_2-ethyl ether (9+1) on silica gel [33].

Beside dyes, food lipids are a classic field of TLC analysis. A review of planar chromatography separations of food lipids is given in [34]. An AOAC official method describes the separation of some fatty acids in oils and fats. Erucic acid, cetolic acid, and trans-isomers of docosenoic acid are converted to methyl ester and separated by use of silver impregnated silica gel TLC plates.

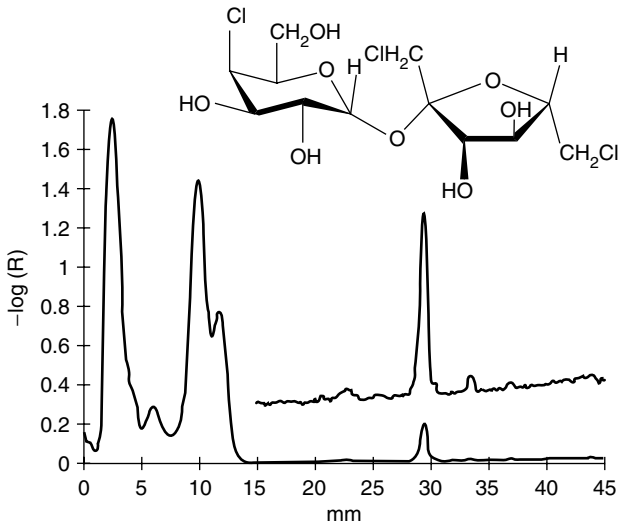

FIGURE 46.9 Densitogram of a "Cola" type softdrink in the absorption mode (1 µl spotted) containing 48 mg/L Sucralose® (peak at 29 mm). The upper signal line is plotted 5-fold enhanced.

The development of the plates is performed at −22°C with toluene-n-hexane (9+1) as mobile phase [35]. For spot visualization the plate is dipped in sulfuric acid-ethanol-hexane (1+35+64) for 2 seconds and then heated to 110°C for 45 min. This treatment turns lipids into fluorescent compounds [36]. Animal fat in vegetable fats and oil is identified by analyzing cholesterol with ether-petrol-ether (1+1) on silical gel. In the AOAC official method, cholesterol is scraped off at R_f: 0.2–0.3 and quantified by use of GC [37]. Charring with 50% sulfuric acid can be used to visualize cholesterol as well as all carbon-containing substances [38]. In this sense sulfuric acid acts as a universal detector in planar chromatography. To visualize oils and fats, plates are often sprayed (or dipped) in 2′7′-dichlorofluorescein reagent (0.5 g/L in 50% aqueous methanol), because the fluorescence in a lipophilic surrounding is mostly enhanced. This can either be used to visualize fats with fluorescing substances, or to enhance fluorescent intensity by dipping in non-polar reagents like Triton-X or parafine.

VII. DRUGS IN FOOD AND FEED

TLC or HPTLC methods are widely used in the screening of drugs in food and feed. The following examples show that in planar chromatography quantification can be done without a special column pre-cleaning. Coccidostats like aklomide or buquinolate are incorporated in the broiler feed as additives to prevent coccidiosis in poultry. To check the legal limits of aklomide in feeds [39] the sample is extracted with methanol and separated on a silica gel G TLC plate in ether [39]. The plate is sprayed with 1 ml 20% $TiCl_3$ to 25 ml p-(dimethyl-amino)cinnamaldehyde (DMC) (0.1 g in 100 ml 1.0 N HCl) solution. Aklomide forms reddish pink spots. Buquinolate can be identified after extraction from feeds with $CHCl_3$, concentrated and separated by TLC with $CHCl_3$ as mobile phase. Busquinolate shows fluorescence under short wavelength UV light with excitation at 265 nm and emission wavelength at 375 nm (R_f: 0.4–0.6) [40]. For quantification purposes the busquinolate TLC zone is transferred to a vial, extracted with 80% alcohol and measured with a spectrophotofluorometer [40]. The busquinolate fluorescence makes the method very specific.

Invermectin is a highly potent antiparasitic drug that is active at extremely low dosage against a wide variety of nematodes and arthropod parasites. The drug is widely used for antiparasitic control in cattle, horses, sheep, and swine. An HPTLC method using UV detection after reaction with acetic anhydride in pyridine was able to detect 5 µg/Kg in cattle blood or plasma [41]. With an improved derivative step (fluoroacetic anhydride instead of acetic anhydride) and a separation on silica gel HPTLC Si60 plates using $CHCl_3$-ethyl acetate (75+25) as the solvent, a visual fluorescence detection of the drug in liver, muscle, and fat as low as 5 µg/Kg was achieved [41]. AOAC methods in particular, often prefer visual detection to keep the method simple. For qualification the spot color and R_f-values are accepted as sufficient. Quantification is done by comparison of sample and standard spot intensity or zone transfer to spectrometric devices. By use of a diode-array scanner, food and feed additives can be easily identified and quantified using *in situ* measured UV/vis-spectra in combination with spectral libraries. Time-consuming transfer steps can be avoided. If fluorescence signals can be used, HPTLC methods are very specific and show detection limits comparable to HPLC.

There are several official AOAC methods for sulfonamide residues in animal tissues. The screening method for sulfabromomethazine, sulfadimethoxine, sulfamethazine, sulfapyridine, sulfaquinoxaline, and sulfathiazole recommends a tissue extraction with ethyl acetate after addition of sulfapyridine as internal standard and a cleanup step by seperating organic and aqueous solvents. Spotting zones on silica gel TLC-plates are focused by developing 1 cm in ethanol followed by 2 developments, 6 cm and 12 cm, in $CHCl_3$-tert-Butanol (8+2). Compounds are derived by dipping the plate in fluorescamine solution (25 mg fluorescame in 250 ml acetone) and scanned in UV [42]. To identify sulfamethazine the plate is sprayed with 1% sodium nitrite, dried at 100°C, and sprayed with NEDA (0.4% 1-naphthyl-ethylendimine in methanol) to form pink spots [43]. The AOAC method for trisulfapyrimidines determination in drugs recommends separation with $CHCl_3$-methanol-NH_4OH (30+12+1) on silica gel. The substances are located under shortwave UV [44]. A simple HPTLC

method to quantify thiamphenicol in bovine plasma has been published by P. Corti. Different phases like NH_2, CN-, and Si_{60} plates are used to increase determination specificity. A detection limit of 180 μg/Kg thiamphenicol is achieved whereas the HPLC detection limit is calculated to 70 μg/Kg [45].

The multiclass and multiresidue qualitative detection of chloramphenicol, nitrofuran, and sulfonamide residues in animal muscle was published by J.-P. Abjean [46]. The identification is done with the help of a specific reaction either with pyridine to identify nitrofurans or with fluorescamine to identify chloramphenicol and sulfonamides. Furans appear as blue spots on Si_{60} plates and were visually quantified. The limit used by the U.S. Food and Drug Administration for enforcement purposes for nitrofurans in 1989 was 100 μg/Kg. The expected limit of sensitivity with the method described is 1 μg/Kg [46]. The HPTLC method allows screening of residues in food with a sample throughput of about 20 samples per analyst per day without requiring expensive apparatus.

The identification and determination of oxytetracycline, tiamulin, lincomycin, and spectinomycin in veterinary preparations separated by two solvent systems is described in [47]. After separation on TLC silica gel aluminum sheets the absorption spectra of the separated substances were recorded by densitometry. The spots are visualized with Ehrlich's reagent (1 g 4-dimethylaminobenzaldehyde in 36% HCl-ethanol, 25+75) or 16% sulfuric acid and heated at 105°C for 10 min. The stained spots were scanned again to confirm the identification. Quantitative analysis achieved quantification limits per spot of 40 ng for tiamulin, 200 ng for lincomycin, 280 ng for oxytetracycline, 500 ng for spectinomycin, and 630 ng for oxytetracycline [47]. All antibiotic determination methods mentioned use specific post-separation reactions, which can be easily performed on the plate. Nearly all compounds can be identified using the R_f-values in combination with appropriate staining reactions. Hundreds of different staining reactions have been published and all act as specific TLC detectors [15].

Most specific is the use of enzymes for detection purposes. Oxytetracycline and chlortetracycline hydrochloride are antibiotics incorporated into feeds, either individually or in combination with other drugs, at concentrations ranging from 10 mg/Kg to 500 mg/Kg [48]. P. K. Markakis developed a simple, reliable, and precise TLC method for both these tetracyclines in animal feeds in the presence of other drugs. He used HPTLC Si_{60} plates and $CHCl_3$-methanol (10+1) as the developing solvent. After separation the appropriate HPTLC-zones were scraped out and the material was incubated for 11 h at 30°C in the presence of *Bacillus subtilis*. A detection limit of 0.625 mg/Kg for chlortetracycline hydrochloride and 1.25 mg/Kg for oxytetracycline was achieved, using the diameter of *Bacillus subtilis* inhibition zones for quantification [48].

The combination of TLC and very specific biology detection shows the great flexibility of planar chromatographic methods; nevertheless, scraping the TLC plate and incubation are time-consuming preparation steps that are difficult to automate. Much more elegant is the paper by H. E. Hauck [49] where an *in situ* bioautography of antibiotics is presented. Methanolic extracts of foods and feeding stuffs are subjected to HPTLC plates und separated using different solvents. After separation the plate is dipped in a bacteria culture (*Bacillus subtilis*) and incubated at room temperature for 19 h. The plate is sprayed with a tetrazonium salt as a reagent to detect active bacteria as purple color. The inhibition zones are recorded with a video system. Detection limits down to 100 μg/Kg were obtained [49]. This kind of detection is useful not on special compounds but on special attributes, for example, antibiotic quality. Attribute identification is also used to identify free radical scavenger capacity (RSC) of foodstuff [50]. Extracts of samples were separated on silica gel plates and after separation the plates were stained with a methanolic solution of 2,2-diphenyl-1-picrylhydrazyl radical. Dots of separated foodstuff extracts with RSC turn yellow, with color intensity depending on the RSC compounds present in the extract. This test is sensitive enough to detect differences of RSC between varieties and brands of water- or methanol-soluble products [50].

VIII. PESTICIDES

Attribute analysis is particularly useful for pesticides which inhibit the enzyme cholinesterase. This is the case for all organophosphates and carbamates [51]. For quantification, pre-cleaned samples were separated on Si60 HPTLC plates using tetrahydofurane-hexane (7+25) as a solvent. The plates were dipped in a solution containing cholinesterase, 1-naphthyl acetate, and Fast Blue salt B. If the enzyme is not inhibited, it will cleave the acetate to 1-naphthyl phenol. The substance will react on the plate surface with Fast Blue salt B to form a violet color. The inhibition spots of organophosphates and carbamates become visible as white zones on a violet background. The spots can be quantified by reflectance spectrometry at 535 nm. Detection limits for different substances were in the range of 13–800 pg per spot [51].

The AOAC standard test to detect organochlorine pesticide contaminations like aldrin, DDT, dieldrin, chlordane, strobane, and toxaphen [52] recommends n-hexane as the solvent and silica gel as the stationary phase. The stationary phase is either mixed with $AgNO_3$ or dipped in 0.1% aqueous $AgNO_3$ after separation. When the plate is radiated with shortwave UV in the presence of chlorine substances, AgCl will be formed, which reacts with light to elementary silver. Reduced silver forms black spots, which can be used for a very sensitive chlorine pesticide screening.

For determination of carbaryl pesticide residues in apple and spinach the samples are extracted with CH_2Cl_2 and separated on Al_2O_3 TLC plates with aceton-benzene (1+4) [53]. The plate is sprayed with 1.0 N alcoholic KOH and then with a solution of diethylene glycol-alcohol solution (1+9) with p-nitrobenzene-diazonium fluoborate (25 mg/100 mL). The diazonium salt forms blue spots in the R_f-range between 0.52–0.6. For semi-quantitative estimation size and intensity of sample and standard spots have to be compared. For the determination of biphenyl pesticide residues in citrus fruits [54] no derivation step is necessary. Biphenyl is extracted from blended peel or pulp by steam liquid-liquid extraction. The extract is separated on a silica gel TLC plate with heptane. Viewed under UV light, biphenyl appears as a blue spot on a yellow background.

TLC or HPTLC is in general well suited to separate a few compounds from a complicated matrix. The resolution in TLC becomes maximal for R_f-values around 0.3. If a special phase system separates substances in the optimal R_f-range of 0.1 and 0.8, only compounds with k-values between 9 and 0.25 will move (4). This is a very narrow polarity window. All other substances outside this window will stay at the point of application or will move with the solvent front. Therefore, only few substances of similar polarity can be separated in one run. But in samples like water or food, pesticides of a wide polarity range can be present. To cover a wide range of polarity a special gradient mode, the automated multiple development (AMD) technique, can be exploited using a great variety of solvents [54, 55]. The principle of AMD is simple. The TLC plate is developed at first only over a very short distance using a solvent of great elution strengths to move all substances. After plate drying another separation step takes place, but now the solvent strength is slightly reduced whereas the separation distance is slightly increased. During the first separation cycle all substances of the sample will move because the highest elution power of the solvent is working. When the solvent front reaches a sample spot the sample will be concentrated in a narrow band because the molecules in the sample zone start their upward moving earlier than those in the upper part of the spot. During every cycle the zones will be concentrated to a narrow band if the substances are moving. Between the developments the solvent is completely removed from the developing chamber and the plate is dried under vacuum. For the next development the layer is conditioned with the vapor phase of the next solvent. Cycle for cycle, the solvent strength is reduced and more and more substances will remain at their plate positions. At the end of the last cycle only the compound with the largest mobility will move. Usually the number of cycles is between 10 and 40 for a separation distance of not more than 8 cm. All the steps in AMD are computer controlled and fully automated. A development of 40 cycles needs between 2 and 4 h. The AMD technique brings substances of a large polarity range to move and compresses substances in very narrow zones. This technique, like all gradient developments, increases the chromatographic resolution dramatically. It should be mentioned that a commercially available AMD system is able to separate more than 40 samples in parallel.

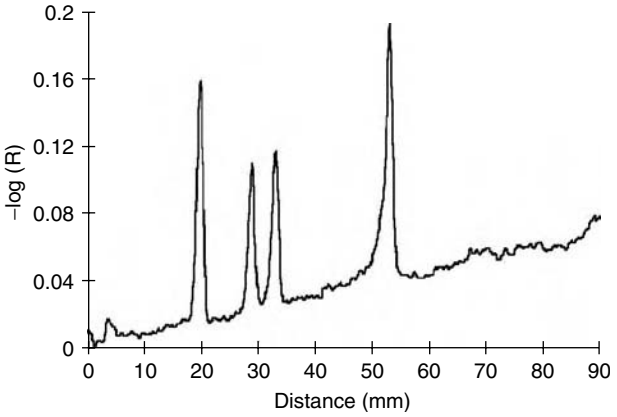

FIGURE 46.10 AMD separation of four pesticides, separated by use of a "universal" gradient [56]. Separated are 2,4-D (Aryloxyalkanoic acid), Methoxuron, Atrazine, and Parathion-ethyl.

The AMD technique is especially suited for pesticide monitoring because several pesticides can be simultaneously determined in the same sample [55–57]. An overview of AMD methods for the determination of pyrethrin and pyrethroid pesticide residues in crops, foods, and environmental matrices is given by Z.-M. Chen [57]. The combination of AMD and diode-array TLC-scanner is a powerful tool especially for pesticide monitoring because the photodiode array technique substantiates the analytical result by providing spectral confirmation for the appropriate substances.

IX. MYCOTOXINS

Mycotoxins are fungal metabolites, which are of great concern as toxic contaminants in food and feeds. Among a number of other techniques, planar chromatography is still very popular in the determination of certain mycotoxins. Sample preparation is necessary and is mostly an extraction step to clean up the sample and to concentrate the mycotoxins is proposed. In general, TLC can cope better with more crude extracts than HPLC where the clean-up step is more important to save the column. An important feature of TLC is its off-line operating principle. For instance, Leming Lin et al. [58] employed two development systems for the determination of zeraleone and patulin in maize. In the first step the lipids in the sample were isolated, and the second development is used to separate the mycotoxins. For mycotoxin visualization on plate two

different methods are frequently applied: the examination under UV light if the mycotoxins show naturally fluorescence and the spraying or dipping with chemical reagents that produce colored or fluorescent products. The spot colors and the R_f-values in combination with *in situ* measured spectra are used for mycotoxin identification. The natural fluorescence of aflatoxins, citrinin, and ochratoxin A makes its identification much more certain. A review from 1998 sums up more than 10 different mycotoxin TLC methods compared with other techniques [59]. The high sample throughput of TLC and HPTLC makes it the most cost-effective analytical technique for mycotoxins screening routine. A drawback of TLC in comparison with HPLC is its untapped potential for automation.

Ochratoxin A is a mycotoxin with nephrotoxic, carcenogenic, teratogenic, and immunosuppressive properties. A review of chromatographic methods for determination of ochratoxin A is given by H. Valenta [60]. The official AOAC method for ochratoxin determination in barley [61] recommends silica gel plates and the solvent mix benzene-methanol-acetic acid (18+1+1) [61]. The solvent system toluene-ethyl acetate-formic acid (5+4+1) can be used as well [62]. The blue-green fluorescence of the ochratoxin A, brought out by long-wave UV light, is used for detection. For densitometric fluorescence measurements an exication wavelength range from 310–340 nm and an emission range from 440–475 nm should be used. A detection limit of 25 μg/Kg rice is achieved [63, 64], whereas the quantification limit for HPLC is 0.2 μ/Kg [61, 63, 64].

A review of the chromatographic determination of patulin in fruits and fruit juices is given by G. S. Shepard [65]. Patulin has no teratogenic or carcenogenic effects but shows embryo toxicity accompanied by maternal toxicity. The official AOAC method of patulin determination in apple juice [66] is that the juice is extracted with ethyl acetate and cleaned up on silica gel column. The silica gel TLC plate is developed with toluene-ethyl acetate-90%-formic acid (5+4+1) and sprayed with 3-methyl-2-benzothiazolinone hydrazone-HCl solution (0.5 g in 100 ml H_2O) before the plate is heated for 15 min to 130°. Patulin appears as yellow brown spots at R_f 0.5 with a detection limit of 20 μg/L whereas HPLC methods show a detection limit of 0.5 μg/L [67] and a quantification limit of 5 μg/Kg [64]. The quantification limit for patulin in HPTLC is 50 μg/Kg [64].

The AOAC official method for zearalenone in [68] corn recommends $CHCl_3$-acetone (9+1) as the mobile phase for separation on a Si_{60} HPTLC plate with a quantification limit of 100 μg/Kg and an overall recovery of 97% [64, 67–69]. The appropriate HPLC quantification limit is 35 μg/Kg [64]. The separation of deoxynivalenol (DON) in wheat on silica gel 60 TLC plates with the mobile phase $CHCl_3$-acetone-isopropanol (8+1+1) is published in [70]. The developed plates have to be sprayed with $AlCL_3$ solution and heated 7 min to 120° to see blue fluorescent spots under long-wave UV at R_f 0.6. The detection limit is 37.5 mg/Kg for TLC [71] and 20 μg/Kg for HPLC [72]. Using toluene-ethyl acetate-formic acid (6+3+1) nephrotoxic citrinin and ochratoxin A can be separated and viewed under UV [73]. Citrinin can be separated from patulin and aflatoxin B_1, B_2, G_1, and G_2 in one run, using oxalic acid impregnated silica gel TLC plates. A limit of detection of 35 μg/Kg for citrin is achievable [74].

Fumonisins B_1, B_2, and B_3 were isolated in 1988 from corn and have been associated with cases of leucoencephalomalacea in equines, pulmonary oedema in swine, and hepatic cancer in rats [75]. A great majority of reports on fumonisin determinations use fluorescent derivatives for sensitive detection [76]. Using an immunoaffinity column for extract purification and an RP-18 HPTLC plate with 4% aqueous KCL-methanol (2+3) as the mobile phase, a fluorescamine derivation detection limit of 2 ng per spot is achievable [74]. This is an overall detection limit of 100 μg/Kg. The appropriate detection limit for HPLC is 10 to 500 μg/Kg [75].

Aflatoxins are considered to play an important role in the high incidence of human hepatocellular carcinoma in certain areas of the world [77]. There are official AOAC methods for aflatoxins in peanut products, corn, milk and cheese, liver, green coffee, and cotton seed. Mostly these methods refer to the TLC separation method for peanuts and peanut products using silica gel TLC plates and the solvent mixture acetone-$CHCl_3$ (9+1) [78]. Due to the natural fluorescence of all aflatoxins the overall detection limit for TLC methods is 5 μg/Kg [79] or better [80]. The HPLC overall detection limit for all four aflatoxins is published as better than 1 μg/Kg [59]. Quantification limits for aflatoxin B_1 are specified with 5 μg/Kg in corn [64] in comparison to 3 μg/Kg (in corn also) for HPLC [66]. Dell et al. [81] reports that for the aflatoxin determination in peanut butter the TLC method was more precise than HPLC. Tosch et al. compared TLC and HPLC methods and showed that TLC appeared to be equivalent to HPLC [82] with respect to precision, accuracy, sensitivity, recovery, and linearity of response.

One of the major advantages of TLC analysis is the simplicity of the separation step, which makes the method very cost effective. If densitometric quantifications are recommended, costs will arise. An interesting method to keep the analytical costs in densitometry low has been published by E. Anklam et al. [83, 84]. A simplified densitometer for the detection of aflotoxins was developed using a low-cost UV-light emitting diode (UV-LED) with a peak emission wavelength of 370 nm [83]. The resulting signal was further amplified by means of a commonly used operational amplifier integrated circuit and directly converted into a digital signal with a simple analogue-digital converter. The signal was recorded at the signal port (RS232) of a portable PC and processed with a widely used spreadsheet program.

The same working group developed a modified computer scanner by substitution of the scanner light tube with a black light tube and additional inclusion of a UV-filter. The modified scanner in combination with a personal computer can be used to determine aflatoxins at low nanogram levels, which, when used in combination with an appropriate TLC method, enables monitoring of the compounds in food and feed at the levels stipulated in European legislation [84]. Both systems are available for less than 2000 Euro and both methods can be expanded in combination with the appropriate TLC system to all mycotoxins that show long-wave UV fluorescence.

TLC is a well-established, easy-to-perform, fast, routine, cost-effective, and suitable method for analysis of a wide range of mycotoxins [59]. TLC will continue to play an important role in mycotoxin analysis because of the worldwide requirement for fungal metabolite control. Mycotoxins occurring in a matrix are usually very low quantity levels and the analysis method must be very sensitive. In general, all mycotoxin TLC methods show detection limits or quantification limits 10-fold higher than HPLC values. Nevertheless the FDA regulatory level for aflatoxin in human food and for feed for immature livestock is 20 μg/Kg. The appropriate value for deoxynivalenol is 1000 μg/Kg. HPTLC is able to check these levels in feed and food as well as HPLC. The advantage of HPTLC methods has been described by B. Renger [85]. An assay and purity testing of phospholipids HPTLC is only 38% of the HPLC costs, a value that can surely be adapted to TLC food analysis.

X. FUTURE OF PLANAR CHROMATOGRAPHY

What is the future of TLC and HPTLC? First of all, TLC methods that are able to check official regulatory levels without using technical equipment will of course remain in use. This simple and inexpensive way of doing analysis is too effective to discontinue. It must also be kept in mind that not all countries have or will have the resources to check official regulatory levels using expensive methods like HPLC. A low-cost flat-bed scanner in combination with a personal computer for documentation and quantification purposes will be used. HPTLC methods are strong in screening and will play an increasing role in the field of pesticides and drug monitoring in feed and food. The combination of AMD and diode-array scanner technology, using spectral libraries for sample identification and checking of regulatory levels, will increase in importance. The quantification ability of HPLC will be used for the determination of critical analyts like sugars, the quantification of which can be easily performed by NH_2 layers. The simple pre-cleanings of caffeine, quinine, and sucralose® in beverages or vanillin in chocolate will probably be used for quantification purposes to keep the overall standard deviation low. All in all, TLC and HPLC methods will find niches where the chromatography is more cost-effective than other methods or the performance is so outstanding that no other assays will show comparable results.

47 High Performance Liquid Chromatography

Antoine-Michel Siouffi
Université Paul Cezanne, Campus St. Jerôme

CONTENTS

I. GENERAL

According to the IUPAC definition (1) chromatography is a physical method of separation in which the components to be separated are distributed between two phases, one of which is stationary (the stationary phase) while the other (the mobile phase) moves in a definite direction.

The mobile phase is a fluid which percolates through or along the stationary bed. Chromatography is a differential migration technique where the flux of solutes to separate is perpendicular to the deplacement of the mobile phase (2).

Three types of fluid are in current use: liquid, gas, or supercritical. Chromatography is named principally by the nature of the fluid. We can distinguish liquid, gas, or supercritical fluid chromatography.

The stationary phase may be a solid or a liquid. The combination of mobile and stationary phases unambiguously names the chromatographic mode.

Mobile phase	Gas	Liquid	Supercritical
Stationary	Liquid	Liquid	Liquid
Phase	Solid	Solid	Solid

Gas-liquid chromatography (GC) and liquid-solid chromatography are by far the most popular types. A special type of stationary phase consists of bonding chemical moieties onto a solid surface by covalent bonds. It is a bonded phase. Liquid chromatography with alkyl (or any other) bonded phases is considered liquid-solid. Use of liquid-liquid chromatography is rapidly declining and reports on the technique in recent years are scarce.

According to the nature of the stationary phase a chromatographic mode is often named by the chemical species which governs the retention mechanism.

We can thus distinguish in liquid chromatography (LC):

Adsorption chromatography, often referred to as normal phase mode (NP)
Reversed phase chromatography (on alkyl bonded silica) (RP)
Ion chromatography (IC)
Affinity chromatography
Size exclusion chromatography (SEC)
Chiral chromatography
Micellar liquid chromatography

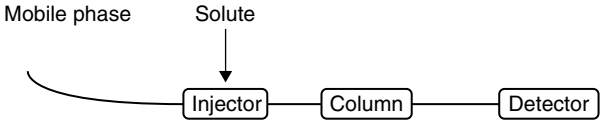
High performance liquid chromatography (HPLC) is a well-established method in modern analysis. The method is simple, robust, and applicable to the majority of components to be analyzed. Low efficiency and small peak capacity are of HPLC when complex mixtures have to be separated. In contrast to GC the diffusion coeficient of the analytes is small and that is the biggest obstacle to efficient separations.

II. BASIC CHROMATOGRAPHIC INSTRUMENTATION

The heart of the separation is the column. Solutes are injected onto the column where they partition between the mobile and the stationary phase. When a solute is flowing off the column it is eluted.

Typically a chromatograph is depicted as follows:

Solutes to separate are placed in an injector, they are driven to the separation column; when they elute, they are monitored by a detector.



There are two ways to perform chromatography: analytical mode and preparative mode. We shall only consider the analytical mode in which solutes are infinitely diluted.

Molecules of solute which do not interact with stationary phase are not retained. Molecules of solute that can partition between both phases are retained. Detection and recording of separated solutes yield a chromatogram (Figure 47.1). On the chart solutes appear as peaks, the shape of which is nearly gaussian.

III. DEFINITIONS

The column volume is Vcol; the volume of the stationary phase inside the column is Vs; the volume of the mobile phase is V_M, which can be divided in extraparticular volume Ve and intraparticular volume Vi according to the type of the packing; and the porosity is $\varepsilon = V_M / Vcol$.

t_M is the mobile phase hold-up time; this is not the same as the retention time of the unretained solute, written as t_0. In fact, t_0 and t_M are not equal (especially in packed columns) and the nature of the unretained (or inert) solute should be mentioned in any reported experimental conditions. t_{Ri} is the retention time of the solute i.

The volume of the mobile phase required to elute an unretained solute is called V_0.

$$t_0 = \frac{V_0}{F}$$

where F is the mobile phase flow rate. $F = u_o \varepsilon S$ where u_o is the linear velocity of the liquid; ε is the porosity; and S is the cross section of the column. $t_0 = L/u_o$. Similarly, V_{Ri} is the retention volume of solute i.

The mobile phase must flow through the column. In packed columns Darcy's law (3) is written

$$u_0 = B_0 d_p^2 \Delta P / \eta L$$

B_0 is the permeability of the column packed with particles of average size d_p; ΔP is the pressure difference between inlet and outlet of the column; η is the viscosity of the mobile phase; and L is the column length.

The retention factor is

$$k_i = \frac{(t_{Ri} - t_0)}{t_0} = \frac{(V_{Ri} - V_0)}{V_0} = \frac{(d_{Ri} - d_0)}{d_0}$$

where d_0, d_R are retention distances measured on the recording chart.

The retention factor is also equal to the ratio of amounts of a sample component in the stationary and mobile phases, respectively, at equilibrium.

$$k = \frac{\text{Number of solute molecules in stationary phase}}{\text{number of solute molecules in mobile phase}}$$

$k = K(Vs/V_M)$ where K is the partition coefficient and Vs/V_M is the phase ratio.

The adjusted retention time is $t'_{Ri} = t_{Ri} - t_0$ and $k = t'_{Ri}/t_0$. Similarly,

$$V'_{Ri} = V_{Ri} - V_0$$

$$d'_{Ri} = d_{Ri} - d_0$$

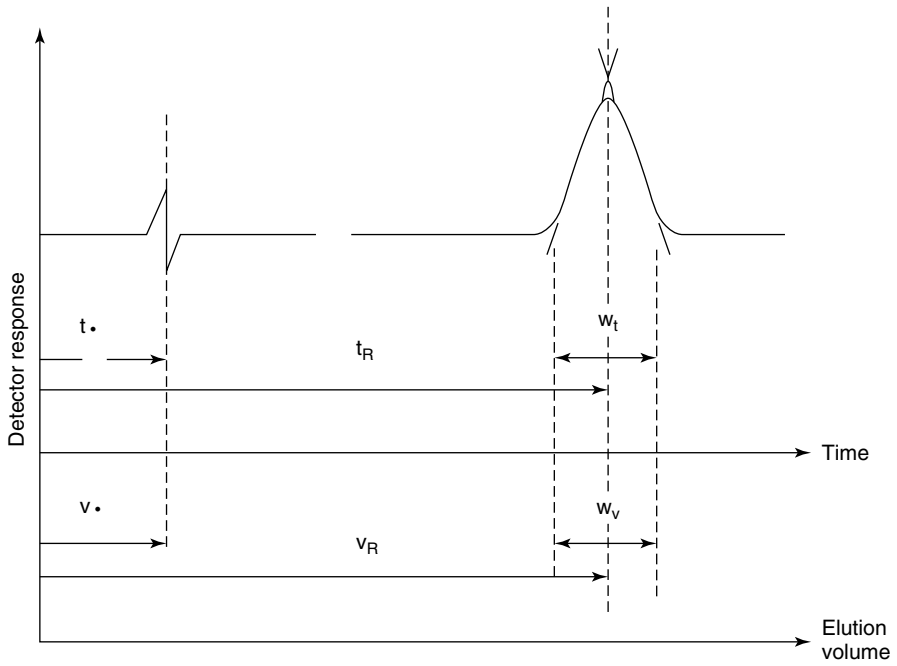


FIGURE 47.1 A chromatogram.

In analytical mode, peaks are presumed to be gaussian and retention parameters are taken at maximum peak heights.

When peaks are not truly gaussian, it is necessary to use statistical moments. The zero moment

$$M_0 = \int_b^a h(t) \cdot dt$$

where h(t) is the peak height at time t yields the peak area.

The first moment $M_1 = (1/M_0) \int_b^a t \cdot h(t) \cdot dt$ expresses the true retention time as it corresponds to the elution time of the center of gravity of the peak.

$$M_2 = \text{peak variance}$$

$$M_3 = \text{peak skew}$$

When two consecutive (i, j) gaussian peaks are close, the

$$\text{resolution is } Rs = 2\,(t_{rj} - t_{ri})/(\omega_i + \omega_j)$$

ω is the peak width in time units (see Figure 47.2).

When peaks are gaussian $\omega = 4\sigma$ (σ is the standard deviation).

When two peaks are well resolved then $Rs \geq 1.25$ (see Figure 47.2).

Resolution can be written $Rs = (\sqrt{N/4})(\Delta u/\bar{u})$ where Δu is the difference in velocity between two solutes i and j, $\bar{u}$ is the average velocity, and N is the efficiency.

Assymetry is determined by the A/B ratio (Figure 47.3).

Selectivity a is defined as $\alpha = k_j/k_i$. In this way $\alpha \geq 1$; when $\alpha = 1$ no separation occurs.

When solutes are late-eluting it is convenient to use gradient elution. The gradient retention factor is

$$k^* = t_G F/\Delta\%B V_M S$$

where t_G is the gradient time in min, F is the flow-rate in ml/min, $\Delta\%B$ is the gradient range (e.g., $\Delta\%B = 0.80$ for a 20–100% gradient), V_M is the column volume in ml, and S is a constant for a given compound (see below).

Sharp peaks are indicative of the efficiency of the chromatographic process since the variance is small. Efficiency is also called plate number.

$$N = \left[\frac{t_R}{\sigma_t}\right]^2 = \left[\frac{V_R}{\sigma_V}\right]^2 = \left[\frac{d_R}{\sigma_d}\right]^2$$

When peaks are gaussian $N = 16(t_R/\omega)^2$:

$$N = 5.54\left[\frac{t_R}{\delta}\right]^2$$

δ is the peak width at mid-height. When peak tailing occurs, it is convenient to use the Dorsey-Foley equation (4) from an exponentially modified gaussian equation.

The area of a gaussian peak is a function of its standard deviation and peak height according to the equation

$$A = \sqrt{2\pi\sigma h_p},\ h_p \text{ is the peak height}$$

$$\text{From } N = \left[\frac{t_r}{\sigma}\right]^2$$

and rearranging

$$N = \frac{2\pi(h_p t_r)^2}{A^2}$$

The plate height H is the column length divided by the plate number N = L/H

$$\text{Number of effective plates } N_{eff} = 16\left[\frac{t'_R}{\omega}\right]^2$$

The above equations can be combined. If $\bar{k} = \frac{(k_i + k_j)}{2}$ and assuming peaks are close enough,

$$Rs = \frac{\alpha - 1}{\alpha + 1} \frac{\bar{k}}{1 + \bar{k}} \frac{\sqrt{N}}{4}$$

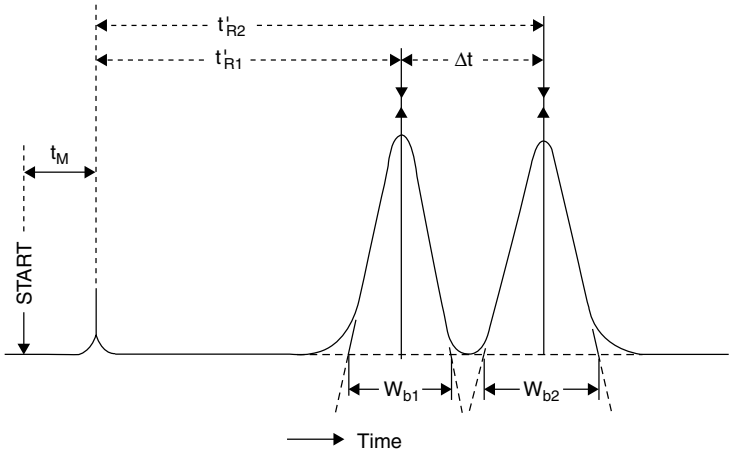

FIGURE 47.2 Resolution between two gaussian peaks: t is retention time, ω is peak width.

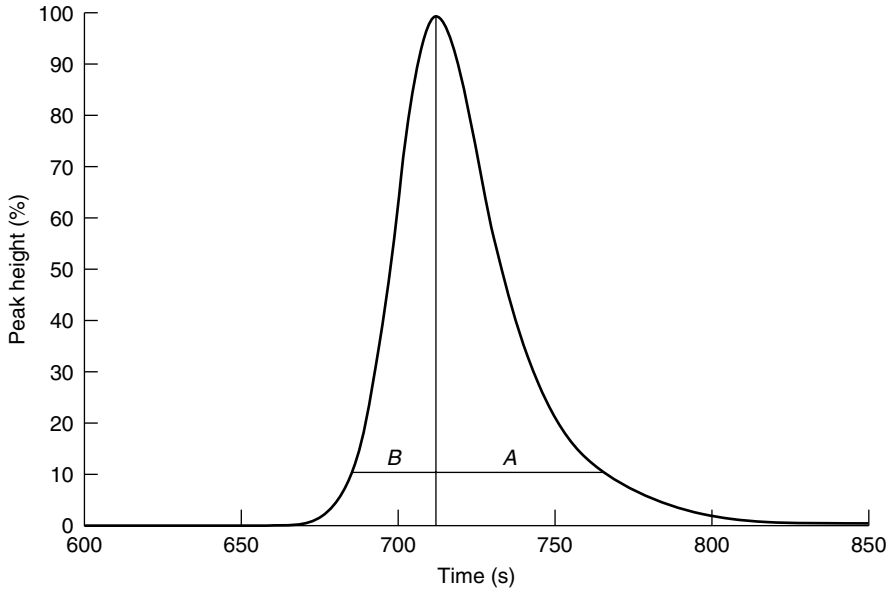

FIGURE 47.3 Asymmetry factor by determination of A/B ratio at 10% height.

A slightly different equation is written as

$$N = 16\,Rs\left[\frac{\alpha}{\alpha - 1}\right]^2\left[\frac{1 + \bar{k}}{\bar{k}}\right]^2$$

The equation permits us to determine the number of plates required to achieve the separation between two solutes of retention factors k_i and k_j, respectively, with a given Rs.

There are three factors in this equation which together determine the chromatographic resolution. The overall resolution is affected (assuming that the column length L is constant) by the selectivity term ($\alpha/\alpha-1$), the retention term factor ($k/1+k$), and the plate height H. Larger k values may lead to an increase in resolution at the expense of longer run times and wider bands. It is best to set k values between 1 and 6. The resolution power is the number of plates necessary to separate two solutes of relative retention α with a resolution Rs.

$$\alpha = [1 - 4Rs/\sqrt{N.1}+k/k]^{-1}$$

The height equivalent to a theoretical plate (HETP) is dependent on the flow rate of the mobile phase. A slightly different equation from the well-known Van Deemter Equation (5) is valid in LC, the Knox Equation (6).

$$h = A\nu^{1/3} + B/\nu + C\nu$$

where h is the reduced plate height $h = H/d_p$; ν is the reduced velocity, $\nu = u_0 d_p/D_m$ where D_m is the diffusion coefficient of the solute in the mobile phase; and d_p is the average particle diameter.

The peak capacity is the number of peaks which can be observed on a chromatogram with baseline resolution (sometimes with unit resolution) assuming the constant N.

$$n_p = 1 + \frac{\sqrt{N}}{4}\log\frac{t_{Rz}}{t_{r1}}$$

In this equation t_{Rz} is the retention time of the last eluted solute. t_{r1} is the retention time of the first eluted solute.

Capacity of a column is the maximum amount of sample that can be injected into a column before significant peak distortion occurs.

Peak distortion is measured by either peak skew or by asymmetry factor.

IV. INSTRUMENTATION

Despite the trend towards miniaturization, most instruments are "conventional." A scheme of a LC instrument is displayed in Figure 47.4.

It consists of:

Solvent reservoirs
A solvent delivery system
An injection device
The column
A detector
A data acquisition system.

A. Solvent Reservoirs

Solvent reservoirs are usually made of glass. They should be equipped with degassing device. Degassing with helium is usually performed but it may form slugs of helium in the tubing.

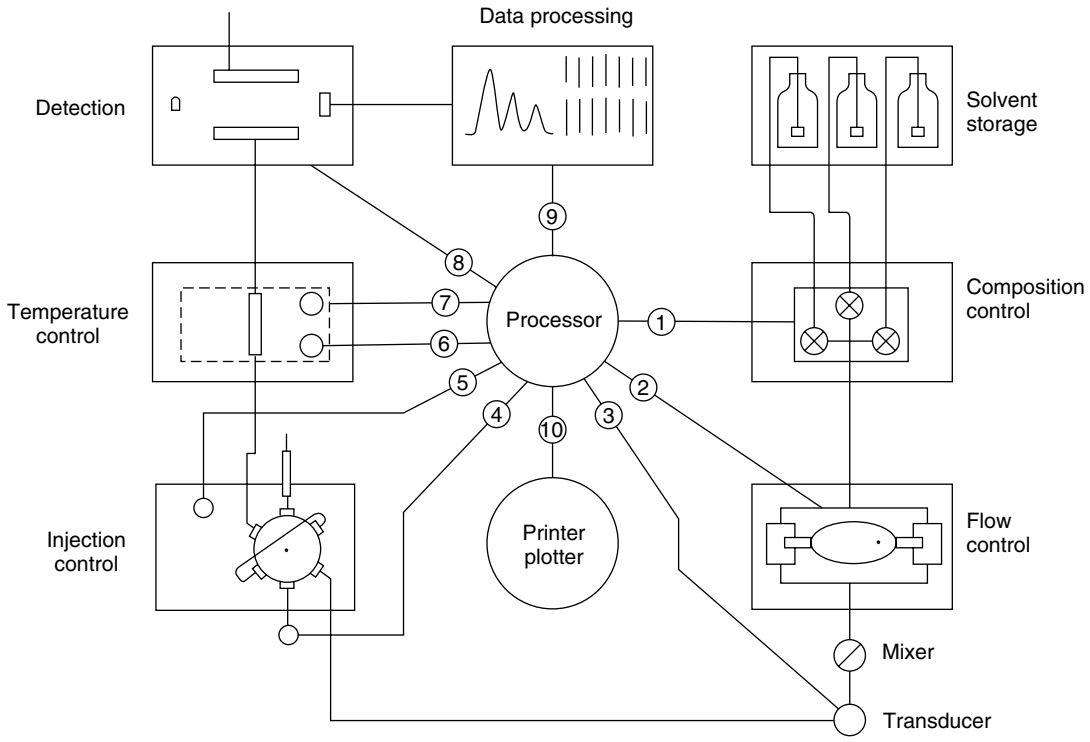

FIGURE 47.4 A scheme of a LC instrument.

Solvents are mixed in a mixing chamber. To account for the desired composition solenoid valves are actuated. Solvents should be HPLC grade. Careful attention should be paid to water and preparation of buffers.

B. Solvent Delivery System

Reciprocating pumps are almost exclusively utilized with conventional columns. They exhibit large column back pressure compensation abilities, flow rates in the 0.1–10.0 ml range with high precision. Precise control of flow rate is of primary importance to ensure reproducibility of retention times. In some cases titanium or ceramic head pumps ensure biocompatibility. With open tubular columns, split flow techniques are probably best. Flow splitting devices are based on the microflow processor concept.

At present, most commercially available pumping units for conventional HPLC are the single or multihead reciprocating piston type. There is a trend towards very high pressures (up to 1200 bar) but that is achieved by modifying a commercially available pump.

Requirements for solvent delivery systems are as follows:

Flow rate stability
Flow rate accuracy (usually ± 0.3%)
Flow rate reproducibility
Large flow rate range (from 0.1 to 10 ml/min in HPLC)
Compatibility with any liquid
Standing with high pressures

In capillary LC, syringe-style, positive-displacement, continuous delivery design delivers solvent at the low-microliter flow rates that are optimal for micro-LC-MS but eluent compressibility and mixing of microflows are serious drawbacks.

1. Gradient Formation

Increasing the solvent strength permits us to achieve elution of highly retained solutes. Moreover, optimization procedures such as Drylab G make use of two gradients.

Two methods can generate binary solvent gradients: low pressure mixing or high pressure mixing. Some manufacturers display both. In the low mixing method, two solvent reservoirs and one single pump are used. In high pressure mixing mode two pumps separately deliver the required volumes of solvents.

The most critical points are the electronic control units and the mixing chamber.

Linear or curved shape gradients are possible but linear gradients are used by the vast majority of chromatographers. There is obviously a time delay between the solvent composition programmed and the actual composition at the column inlet due to the dwell volumes. Gradient delay and rounding are observed. Blank runs are carried out with the injector directly connected to a UV detector. Mobile phase

A is UV transparent and mobile phase B contains a slight proportion of UV absorbing solvent (1% acetone in methanol, for example). The gradient is performed and the delay time is determined. This is of primary importance to obtain reliable retention times.

Gradient delay volume is the volume between the start of the gradient and the top of the column.

Gradient delay time is the time elapsed between the start of the gradient and the time it reaches the top of the column.

C. Column

Most commercially available columns are 4.6 mm inside diameter P (i.d.). They are made of stainless steel and the inner wall of the tubing is electropolished. Stainless steel tubing is easily machined and compression fittings can be affixed readily to ensure high pressure seals. Among the alternatives are polytetrafluoroethylene (PTFE)-lined stainless steel, polyetheretherketone (PEEK), hasteloy, and titanium. Metal-free systems are desirable for ion chromatography and the analysis of trace metals by ion exchange. Variable lengths are available (10-cm-long columns are most popular). Columns or cartridges can be serially connected to increase the plate number. Columns are packed with 3 μm or 5 μm particles either spherical or irregular shaped. Particles are either porous or non-porous. Silicagel is still the mainstay base material for most HPLC packings. Silicagel is rigid, provides excellent efficiency, is reasonably priced, and can be functionalized by virtue of the reactive silanols (SiOH). Most commercial silica-based analytical HPLC materials are made of ultra-pure monodisperse silica. In a porous particle solutes transfer from the moving mobile phase outside the particle into the stagnant mobile phase within the pores to interact with the stationary phase. The slow rate of mass transfer into and out of the porous particles is a major source of band broadening. The non-porous packings are less and less in use due to the limited sample capacity; on the one hand the thin layer allows faster mass transfer; on the other hand, the back pressures are high. Superficially porous packings (e.g., Poroshell from Agilent) are recommended for large biomolecules. Polymeric materials are used by approximately 15–20% of liquid chromatographers. Similar to silicagel, polymeric packings are also available with a variety of particle diameters. Polystyrene-divinylbenzene (PS-DVB) is the most popular with polymethacrylates. The PS-DVB polymers have a wide pH range, high cross-linking, withstand average pressure, and have no silanols to interact with the basic compounds. Conversely, the efficiency provided cannot compare with silica-based material since the rate of mass transfer is slower.

Copolymers of organofunctional silanes and tetraethoxysilane are a new means to synthesize of HPLC packings.

Zirconia provides some interesting features since it can be produced in monodisperse porous spherical particles, withstand a pH of 14, and has no silanols. However, it exhibits hard Lewis acid sites and consequently has a strong affinity towards Lewis bases (hydroxyls, phosphate). To overcome this drawback the analyst must use a competing anion or, even better, a polymer-coated, zirconia-based stationary phase.

Manufacturers provide a test chromatogram and ensure reproducibility from batch to batch.

An increase in column performances can be achieved by increasing the column permeability. The use of monolithic columns is a convenient way to overcome the drawback of the back pressure generated by small particles (see Darcy's equation above). Moreover, in the search for new stationary phase configurations with enhanced mass-transfer properties, the concept of monolithic stationary phases was established in which the separation medium consists of a continuous rod that has no interstitial volume but only internal porosity consisting of micro- and nanopores. Four approaches have been utilized to prepare continuous beds: polymerization of an organic monomer with additives, formation of a silica-based network using a sol-gel process, fusing the porous particulate packing material in a capillary by a sintering process, and organic hybrid materials. Polymer-based monolithic chromatographic supports are usually prepared by the *in situ* polymerization of suitable monomers and porogens within a tube that acts as a mold. Polymer monoliths are Polystyrene-divinyl benzene, polyacrylamide, or polymethacrylate (7–9). Silica-based monoliths were pioneered by Nakanishi and coworkers (10–12). Silica-based monolithic columns were released in 2000 by Merck. They consist of a single rod of silica-based material embedded in a PEEK tubing (13, 14). The new sorbent material consists of monolithic cylindrically shaped rods of highly porous metal-free silica. The defined homogeneous bimodal pore structure, produced during the manufacturing process, means that the columns possess a unique combination of a large internal surface area, over which quick chemical adsorption can take place, together with a significantly higher total porosity.

The pressure drop is dramatically decreased and longer columns can be used. These monolithic columns possess about 15% higher porosity as compared to particulate ones. Monolithic columns are 10 cm long and can be connected in series.

To reduce solvent consumption, there is a trend towards microcolumns, minicolumns, or true capillary columns.

Columns which exhibit internal diameter in the range 0.5–1.0 mm are called microcolumns (they were formerly called microbore). Good efficient microcolumns can be produced at the present time because the packing procedure has been optimized.

Capillary LC columns are of 10–500 μm internal diameter. It seems that 50 μm i.d. packed with 8 μm particles exhibit the best performances.

From theoretical papers published in the 1980s, open tubular columns in LC can only match performances of packed columns if the diameter of the column is of the same order of magnitude of the particle diameter in conventional columns. This conclusion has led to nanoscale LC with 5–11 μm i.d. open tubular columns which are used in research laboratories but not yet available for routine use.

The current trend of lab on a chip will result in new packing materials. Packing a stationary phase in microchannels looks impossible but microfabrication by ablation is promising (15).

Guard columns (1 cm long) must be connected to the analytical column to increase the lifetime, especially when dealing with complex samples. Guard columns, which fit between the injector and the analytical column, collect debris and stongly retained components. Two types of guard columns are available: those that are separate with their own holders and those that are integrated with the analytical column. A recent improvement is the use of guard discs that can be replaced periodically.

D. Injection

For manual and automated injection, the majority of the injection systems consist of injection valves. Sample loops are usually 10 μL for injection with a conventional column. In LC the analyst can increase the volume of injection without disturbing the separation efficiency. Conversely, the analyst must prevent any mass overloading. If so, partition of the solute is not performed in the linear portion of the isotherm with the consequence of peak tailing. Autosamplers are time-saving devices; design and associated problems were thoroughly discussed by Dolan (16,17).

E. Detectors

Some requirements of a LC detector are that it be of such a design that the separated components are not remixed while passing through the detector cell; have a low drift and noise level; have a fast response time; have a wide dynamic range; be relatively insensitive to changes in mobile phase flow rates and temperature; and be easy to operate and reliable.

There are three different types of detector noise: short-term noise, long-term noise, and drift.

1. Photometric Detectors

They rely on Beer's law. The Beer Lambert law is expressed as
where

$$A = \varepsilon \cdot l \cdot c$$

ε = molar absorptivity of the solute
l = path length through the sample
c = concentration of solute
A = absorbance

a. UV-VIS

These detectors measure changes in absorbance of light in the 190–350 nm region or 350–700 nm region.

Basic instrumentation includes a mercury lamp with strong emission lines at 254, 313, and 365 nm, cadmium at 229 and 326 nm, and zinc at 308 nm. Deuterium and xenon lamps exhibit a continuum in the 190–360 nm region which requires the use of a monochromator. A filter or grating is used to select a specific wavelength for measurement. Cut-off filters pass all wavelengths of light above or below a given wavelength. Band-pass filters pass light in a narrow range (e.g., 5 nm). In the single beam mode, the energy from the source lamp passes through the sample flow cell to a photocell via some wavelength selection device. The double beam system is preferred.

The flow cell is typically 8 μL with a 10-mm path length.

The photodiode array (see below) is currently the best sensor.

According to Beer's law, the higher the path length, the higher the transmitted light. For that purpose most cells are Z shaped.

With capillaries such as LC capillaries or CE capillaries there is only limited path length. A free portion of capillary is brought into the light path of a UV absorbance detector. When the aperture of the source is adjusted to the inside diameter of the capillary the effective light path is

$$l_{eff} = 1/2\pi r$$

where r is the radius of the capillary.

To improve the transmitted light a ball is placed after the capillary to focus the beams.

The limit of detection is highly dependent on the molar absortivity of the solutes ε (see Beer's law). UV-VIS detectors must be checked for wavelength accuracy, absorption accuracy, scattered light, and spectral resolution. Derivative spectra are obtained by differentiating the absorbance (A) spectra of the sample with respect to wavelength.

First, second, or higher-order derivatives may be generated. All the derivatives emphasize the features of the original spectra by enhancing small changes in slope.

Derivative spectra are generated optically, electronically, or mathematically. The usual optical method utilizes the wavelength modulation technique where wavelength of incident radiation is rapidly modulated over a narrow wavelength range. Electrically, derivatives are performed by analog resistance capacitance devices. Mathematical methods are obviously the best performing. The Savitsky Golay algorithm generates derivatives with a variable degree of smoothing.

Derivatives are used to

Enhance spectral differences
Enhance resolution
Selective substraction.

A photodiode array (PDA) is shown in Figure 47.5.

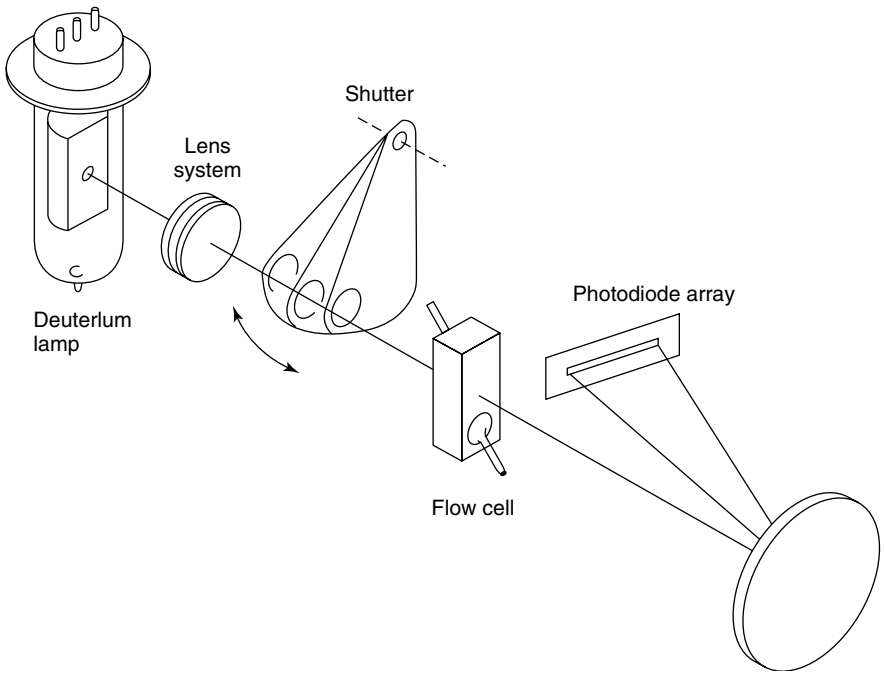

FIGURE 47.5 A photodiode array.

The detection of structurally similar impurities eluting simultaneously with the analytes of interest is a problem. The analyst must detect the existence of peaks of interest, determine the extent of their purity, and confirm their identity.

Photodiode operation relies on the photovoltaic effect. In the typical photodiode there are two components of semiconductor called P and N. P is a very pure silicon with low levels of three valent impurities such as boron or gallium. Each impurity atom can accept an electron from the valence bonds, giving rise to a hole that can take part in the electrical conduction process and an immobile negatively charged impurity ion. Since the hole is positively charged such a material is a P (positive) silicon crystal. If the impurity added is a pentavalent atom (As) the atoms behave as donors of electrons that can move through the entire silicon crystal. It is thus a N (negative) type. A photon of wavelength less than 1.1 nm is able to break a covalent bond between the silicon atoms. The free electron formed is free to move with the missing electron in the broken valence bond which induces electrical conduction by repeated replacement. The PDA detector passes the total light through the flow cell and disperses it with a diffraction grating. The dispersed light is measured by an array of photosensitive diodes. The array of photodiodes is scanned by the microprocessor (16 times a second is usual). The reading for each diode is summed and averaged. A PDA detector can simultaneously measure the absorbance of all wavelength versus time. The amount of data storage is a key feature in PDA. A run can easily take several megabytes of data storage. The dynamic range is usually 0.5 mAU–2.0 AU. Each pixel spans 1.25 nm. Noise is around + or − $1.5*10^{-5}$ absorbance units (AU) with a 2 sec time constant.

Peak purity is based on the proprietary spectral contrast algorithm which converts spectral data into vectors that are used to compare spectra mathematically. This comparison is expressed as a purity angle. The purity angle is derived from the combined spectral contrast angles between the peak apex spectrum and all other spectra within that peak. To determine peak purity, the purity angle is compared to the purity threshold. For a pure peak the purity angle will be less than the purity threshold.

Spectral deconvolution techniques are used when two peaks co-elute.

Identification of peaks is performed by comparison with spectra contained in a library of standards.

b. Fluorescence detection

The quantum yield ϕ is a fundamental molecular property that describes the ratio of a number of photons emitted to the number of photons absorbed.

$$\phi = \frac{k_f}{k_f + \Sigma k_d}$$

k_f is the rate constant for fluorescence emission. Σk_d is the sum of the rate constants for all the nonradiative processes which can depopulate S_1.

The signal intensity I_f is given by Beer's law:

$$I_f = I_o(1 - e^{\varepsilon lC})\phi k$$

When sample absorbance is small this expression is reduced to

$$I_f = I_0 \cdot 2 \cdot 3 \cdot \varepsilon \cdot 1 \cdot C \cdot \phi k$$

k is the instrumental efficiency for collecting the fluorescence emission. I_o is the intensity of the incident radiation.

Fluorescence emission provides more selectivity and increased sensitivity compared to UV absorption. Attomole detection is possible. Xenon lamps are far superior to Hg lamps or D_2 lamps as light sources. Selection of excitation or emission wavelength is done by a monochromator.

Laser-induced fluorescence is in current use. Various lasers are utilized (He-Cd diode, Argon ion). The diode laser seems the best choice. Due to the highly collimating nature of lasers most scattering sources are eliminated. Increased detection is carried out with pre- or post-column derivatization. A three-dimensional spectrofluorometer incorporating a charge-coupled-device has been described (18) that made possible the collection of fluorescence excitation-emission intensity data of polycyclic aromatic hydrocarbons in a flow stream in 0.05 s with ng/milliter limits of detection.

Chiroptical detection provides additional qualitative and quantitative information for photometric detection since only chiral compounds are monitored. A detector provides both the differential absorbance of the circular dichroism and the absorbance of the UV mode simultaneously as a function of time (19).

c. Chemiluminescence method

Oxidative combustion of nitrogen-containing compounds produce nitric oxide. Nitric acid when in contact with ozone produces a metastable nitrogen dioxide molecule

$$NO + O_3 \longrightarrow NO_2^* + O_2$$

which relaxes to a stable state by emitting at a wavelength of 700–900 nm

$$NO_2^* \longrightarrow NO_2 + h\nu$$

Chemiluminescence is used for specific detection of nitrogen.

d. Derivatization

Many solutes do not exhibit UV absorption or fluorescence; they can be converted into UV absorbing or fluorescent derivatives by pre- or post-column derivatization. When precolumn derivatization is carried out the chromatographic system is obviously different fom the one selected for the non-derivatized solutes. A large volume of literature deals with post-column reactions. They can be carried out in coils, in packed bed reactors, or by photolysis. The main requirement is not the completion of the reaction but the reproducibility. Reaction vessels should not produce excessive band broadening. Table 47.1 displays some derivatizing reagents for the fluorescence labeling of functional groups.

2. Electrochemical Detection

a. Conductivity

The detection method is based on the application of an alternative voltage E to the cell electrodes. The cell current is directly proportional to the conductance G of the solution between the electrodes by Ohm's law.

$$G = \frac{1}{k} = \frac{i}{E}$$

The measured conductivity is the sum of individual contribution to the total conductivity of all the ions in solution. Kohlrausch's law states that

$$k = \frac{\Sigma_i \lambda_i^0 C_i}{1000}$$

C_i is the concentration of each ion i, and λ_i^0 is the limiting equivalent conductivity which is the contribution of an ion to the total conductivity divided by its concentration extrapolated to infinite dilution.

Kohlrausch's law is only valid in dilute solutions (chromatography or electrophoresis). The magnitude of the signal is greatest for small high mobility ions with a multiple charge such as sulphate. The conductivity detector was the breakthrough in ion chromatography (IC).

Early IC systems detected ions eluted by strong eluents from high capacity ion exchange columns by measuring changes in conductivity. To achieve reasonable sensitivity, it was necessary to suppress the conductivity of eluent prior to detection in order to enhance the overall conductance of the analyte and lower the background conductance of the eluent. This was achieved by a "suppressor" column in which counter ions were exchanged with H^+ or OH^-. Due to excessive band-broadening column suppressors are no longer in use. Membrane based devices are utilized. The membrane suppressor incorporates two semi-permeable ion exchange membranes sandwiched between sets of screens. The eluent passes through a central chamber. Regenerant flows in a counter-current direction over the outer surfaces of the membranes providing constant regeneration. Electrolysis of water produces hydrogen or hydroxide ions required for regeneration. There is no contamination with carbonate (Figure 47.6).

In conductivity detectors the change in conductivity Δk depends on the concentration of the injected ion (A) and its equivalent ionic conductivity λ_A compared with that of the eluent ion λ_E.

$$\Delta k = (A) \cdot (\lambda_A - \lambda_E)$$

Conductivity detectors usually operate at 10 kHz; scale ranges are 0.01 to 5000 μS in 12 steps.

TABLE 47.1
Derivatizing Reagents for the Fluorescence Labeling of Functional Groups

Reagent	Abbreviation	Functional Group
Aminoethyl-4-dimethylaminonaphthalene	DANE	Carboxyl
4-(Aminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole	ABD-F	Thiol
Ammonium-7-fluorobenzo-2-oxa-1,3,diazole-4-sulfonate	SBD-F	Thiol
Anthracene isocyanate	AIC	(Amine), hydroxyl
9-Anthryldiazomethane	ADAM	Carboxyl (and other acidic groups)
Bimane, monobromo-	mBBr	Thiol
Bimane, dibromo-	bBBr	Thiol
Bimane, monobromotrimethylammonio-	qBBr	Thiol
4-Bromo-methyl-7-acetoxycoumarin	Br-Mac	See Br-Mmc
4-Bromo-methyl-7-methoxycoumarin	Br-Mmc	Carboxyl,imide, phenol, thiol
N-Chloro-5-dimethylaminonaphthalene-1-sulfonamide	NCDA	Amine (prim., sec.), thiol
9-(Chlormethyl)anthracene	9-CIMA	See Br-Mmc
7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole	NBD-Cl	Amino (prim., sec.), phenol
2-p-Chlorosulfophenyl-3-phenylindone	DIS-Cl	Amino acids, amino sugars
9,10-Diaminophenanthrene	9,10-DAP	Carboxyl
2,6-Diaminopyridine-Cu^{2+}	2,6-DAP-Cu	Amines (prim. aromatic)
4-Diazomethyl-7-methoxycoumarin	DMC	See ADAM
5-Di-n-butylaminonaphthalene-1-sulfonyl chloride	Bns-Cl	See Dns-Cl
Dicyclohexylcarbodiimide	DCC	Carboxyl
N,N′-Dicyclohexyl-O-(7-methoxycoumarin-4-yl)methylisourea	DCCl	Carboxyl
N,N′-Diisopropyl-O-(7-methoxycoumarin-4-yl)methylisourea	DlCl	Carboxyl
4-Dimethylaminoazobenzene-4′-sulfonylchloride	Dbs-Cl	See Dns-Cl
N-(7-Dimethylaminoazobenzene-4′-methyl-3-coumarinylmaleimide	DACM	Thiol
5-Dimethylaminonaphthalene-1-sulfonyl-aziridine	Dns-aziridine	Thiol
5-Dimethylaminonaphthalene-1-sulfonylchloride	Dns-Cl	Amino (prim., sec., tert.), (hydroxyl), imidazole, phenol, thiol
5-Dimethylaminonaphthalene-1-sulfonyl-hydrazine	Dns-hydrazine	Carbonyl
4-Dimethylamino-1-napthoylinitrile	DMA-NN	Hydroxyl
9,10-Dimethoxyanthracene-2-sulfonate	DAS	Amine (sec., tert.)
2,2′-Dithiobis (1-aminonaphthalene)	DTAN	Aromatic aldehydes
1-Ethoxy-4-(dichloro-s-triazinyl)naphthalene	EDTN	Amine, hydroxyl (prim.)
9-Fluorenyl-methylchloroformate	FMOCCl	Amine (prim., sec.)
7-Fluoro-4-nitrobenzo-2-oxa-1,3-diazole	NBD-F	Amine (prim., sec.), phenol, thiol
4′-Hydrazino-2-stilbazole	—	α-Oxo acids
4-Hydroxymethyl-7-methoxycoumarine	Hy-Mmc	Carboxyl
4-(6-Methylbenzothiazol-2-yl)-phenyl-isocyanate	Mbp	Amine (prim., sec.), hydroxyl
N-Methyl-1-naphthalenemethylamine	—	Isocyanates (aliphatic, aromatic)
1,2-Naphthoylenebenzimidazole-6-sulfonyl chloride	NBl-SO2Cl	See Dns-Cl
2-Naphthylchloroformate	NCF	Amine (tert.)
Naphthyl isocyanate	NlC	(Amine), hydroxyl
Ninhydrin	—	Amine (prim.)
4-Phenylspiro(furan-2(3H), 1′-phthalan)-3,3′-dione (fluorescamine)	Flur	Amine (prim., sec.), hydroxyl, (thiol)
o-Phthaldialdehyde (o-phthalaldehyde)	OPA	Amine (prim., sec.), thiol
N-(1-Pyrene)maleimide	PM	Thiol

b. Amperometric

Electrochemical detection is a concentration-sensitive technique. In amperometric mode compounds undergo oxidation or reduction reaction through the loss or gain, respectively, of electrons at the working electrode surface. The working electrode is kept at the constant potential against a reference electrode. The electrical current from the electrons passed to or from the electrode is recorded and is proportional to the concentration of the analyte present.

A thin layer cell is displayed in Figure 47.7.

A thin gasket with a slot cut in the middle is sandwiched between two blocks: one contains the working electrode, the other contains the counter electrode. The slot in the gasket forms the thin layer channel. The reference electrode is placed downstream from the working electrode.

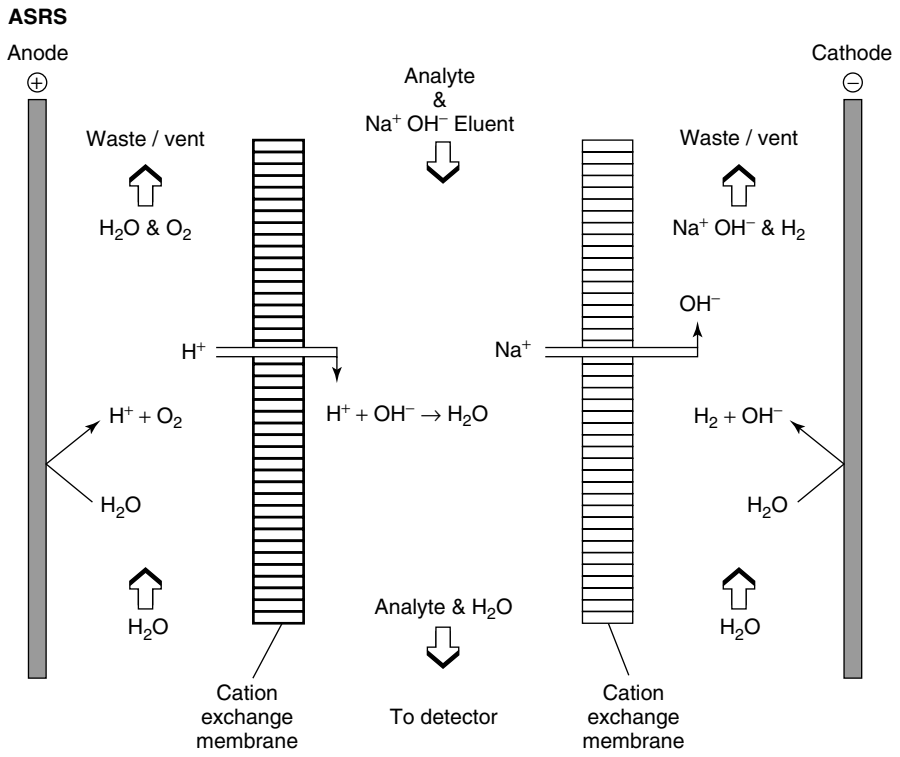

FIGURE 47.6 Anion self-regenerating suppressor for ion chromatography. (Courtesy of Dionex.)

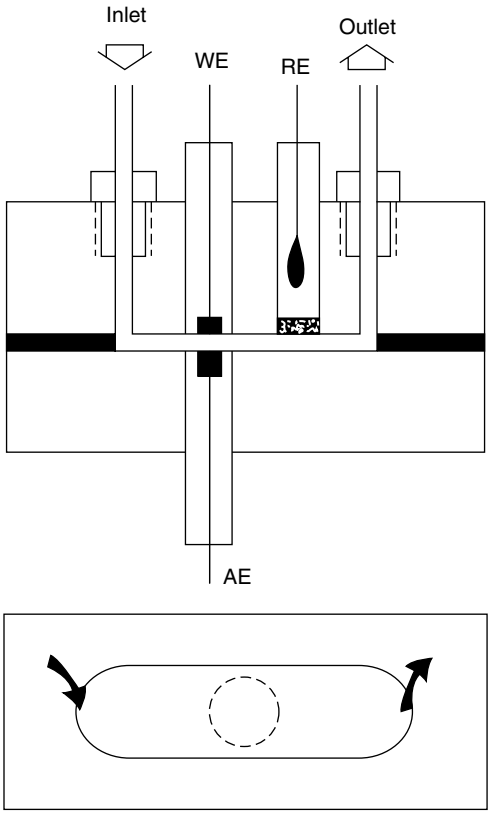

FIGURE 47.7 Electrochemical detector: a thin layer cell. WE: working electrode; AE: auxiliary electrode; RE: reference electrode.

The thin layer design produces high mobile phase linear velocity which in turn produces high signal magnitude.

The intensity of the current is

$$i = f \cdot n \cdot F \cdot u^{1/2} \cdot C \cdot D^{2/3} \cdot A$$

- n = the number of electrons
- F = the Faraday constant
- u = the linear velocity of the mobile phase
- C = the analyte concentration
- D = the diffusion coefficient of the solute
- A = the electrode surface
- f = the geometrical constant of the cell

The quality of the sample clean-up procedure often determines the detection limits. The instability of the reference electrode is the source of voltage noise.

A parallel dual electrode may be used for a number of reasons.

i. With one electrode at a positive and one electrode at a negative potential, oxidizable and reducible compounds can be detected in one single chromatographic run.
ii. When two solutes with different redox potentials co-elute from the column, the potential of one electrode can be selected such that only the most easily oxidized (or reduced) compound is detected while on the other electrode both compounds are converted. The concentration of

the second compound is evaluated by subtraction of the signal.

Series dual electrodes are set up in that one electrode is in oxidative and the other is in reductive mode. The downstream electrode measures the products of the upstream electrode. The second electrode only responds to compounds which are converted reversibly. The redox product is more selectively detected.

Voltammetric analysis is performed by scanning the potential or by applying triangular potential wave form to the electrode. Co-eluting peaks are distinguished if their voltagrams are significantly different.

3. Refractive Index Detector (RI)

This is one of very few universal detectors available. An RI detector monitors both the eluent and the analyte. The output reflects the difference in refractive index between a sample flow cell and a reference flow cell. The measured RI response is determined by the volume fraction of the analyte in the flow cell (x) and the volume fraction of the eluent in the other flow cell (1 − x).

$$\eta - \eta_2 = v_1 (\eta_1 - \eta_2)$$

where

v_1 = volume fraction of the analyte
η_1 = refractive index of pure analyte
η_2 = refractive index of pure solvent (contained in a reference cell)
η = refractive index of solution in sample cell.

$$\text{RI signal} = K_{RI} \cdot dn/dc \cdot C$$

where K_{RI} is an instrument constant, dn/dc is the refractive index increment, and C, the concentration.

There are four types of RI detectors.

- The deflection type is by far the most popular; it relies on Snell's law which governs the angles of incidence and refraction at an interface:

$$\eta_1 \sin \theta_1 = \eta_2 \sin \theta_2$$

where θ_1 is the angle of the beam with respect to the normal of the interface in the medium with RI of η_1.

- The eflection type according to Fresnel's law of reflection; measurement of Δn is a measure of change in reflectivity
- The interference type (utilized in capillary LC)
- The Christiansen effect type

The refractive index is very sensitive to temperature and pressure. For that reason the reference and the measurement cell are close since the difference in temperature between them is critical. Specifications of a RI detector are: refractive index range, linearity range, cell volume, maximum pressure in cell, and temperature control.

$$\frac{d\eta}{dt} \cdot 10^{-4} = 0.67 \text{ for water}$$
$$= 6.84 \text{ for dichloromethane}$$

$$\frac{d\eta}{dp} \cdot 10^{5} = 1.53 \text{ for water}$$
$$= 6.84 \text{ for dichloromethane}$$

He/Ne laser-based RI detection has been developed for nanoscale LC.

4. Light Scattering Detector

The principle of operation is a three-step process. The effluent of the LC column is vaporized in a nebulizer by means of a gas. The droplets pass through a drift tube at a temperature of 40–50°C, and the only particles left are the analyte and the solvent impurities. A laser (typically 1 mV He/Ne) irradiates the particles, and the scattered light is collected by a glass rod and transmitted to a photomultiplier tube (Figure 47.8). The light measured is proportional to the amount of sample in the light scattering chamber.

Parameters affecting the response are particle size, degree of nebulization (most critical), and nature of the solvent. When an LSD detector is used to detect thermally labile compounds the temperature used to evaporate the mobile phase is critical. If the temperature is too high, the compounds of interest can be thermally decomposed and reduce the sensitivity of the assay. The temperature range of the nebulizer is 40°–220°. The design of the evaporation tube is critical. The amount of scattered light depends strongly on the molar absorptivity of the solute. The light-scattering detector is universal detector but not a mass detector. Its response is nonlinear and the calibration curve is log-log. It can easily be used with a gradient. The benefits are low temperature evaporation of the mobile phase, and gradients can be used since the mobile phase is removed. The detector is suited for lipids and sugars. The signal of a light-scattering detector is proportional to the molecular weight of polymers.

V. HYPHENATION

Combining a chromatographic separation system on-line with a spectroscopic detector in order to obtain structural information on the analytes present in a sample has become the most important approach for the identification or confirmation of identity of target and unknown chemical species. In most instances, such hyphenation can be accomplished by using commercially available instruments. For most trace-level analytical problems the LC-MS combination is the accepted approach. However, more information is retrieved from concatenation of LC-MS with FTIR or NMR.

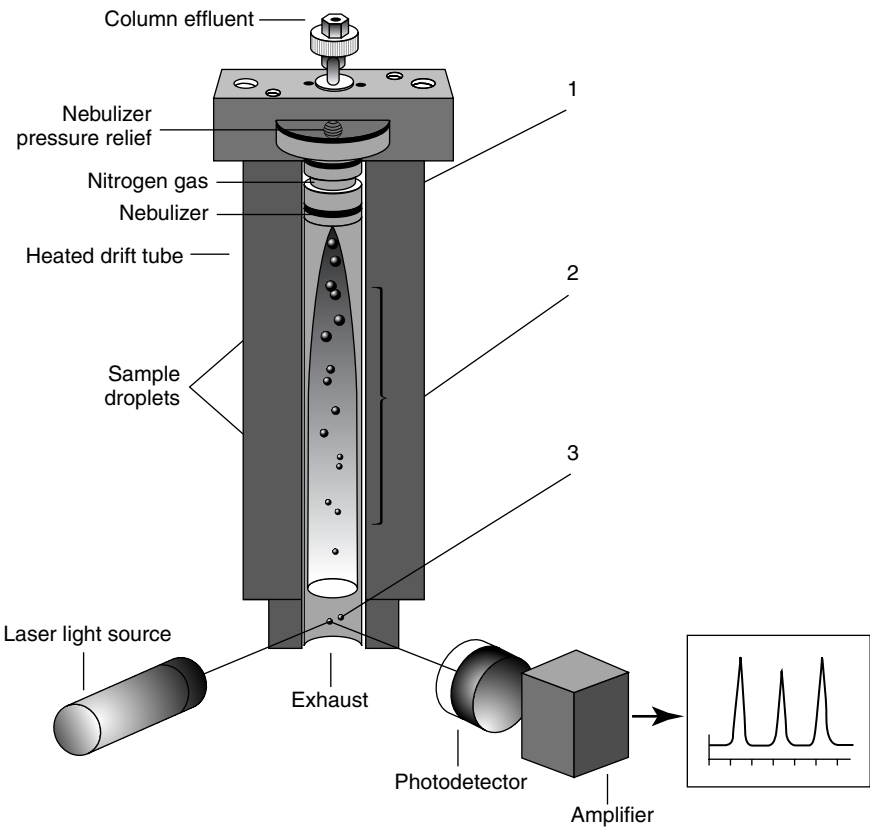

FIGURE 47.8 Light scattering detector: 1: nebulization; 2: mobile phase evaporation; 3: detection. (Courtesy of Alltech.)

The LC-UV-NMR-MS (hypernation) is the best example (Figure 47.9).

A. LC-MS

The mass spectrometer is becoming the detector of choice for many LC methods. In this case it is important in RPLC to select buffers that are MS-compatible such as 0.1% trifluoroacetic acid (pH ≅ 1.9) and ammonium formate for applications at higher pH values.

Interfaces have been developed to solve the problem of handling high LC flow rates (1 mL/min) and the high vacuum required by mass spectrometers.

The mass spectrometer is a mass flow sensitive detector. The enrichment factor is the ratio of the analyte concentration in the MS flow and that in the LC flow. The transfer yield is

$$Y = Q_m/Q_l$$

Q_m is the amount of solute transferred in MS and Q_l is the amount of solute from LC column.

LC is not nearly as compatible with MS as in GC.

Hyphenating LC and MS requires overcoming some difficulties.

- Conventional packed columns are operated at 1 mL/min; to overcome this drawback microbore columns are more and more frequently utilized.
- LC separations make use of non-volatile mobile phases and very often buffer solutions.
- Ionization of non-volatile or thermally labile solutes is difficult. However, difficulties have been overcome and LC-MS has become a robust and routinely applicable tool in environmental laboratories.

Electrospray (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric-pressure photoionization (APPI) are today the ionization techniques enabling robust interfacing of LC to (tandem) MS. Nowadays LC-MS-MS instruments are marketed within the chromatographic community as a laboratory workhouse requiring only basic knowledge about mass spectrometry from the analyst. A wide variety of atmospheric pressure ionization (API) source designs are available from the instrument manufacturers.

1. Ionization

a. Electrospray ionization(ESI)

A typical LC-MS with ESI interface is displayed in Figure 47.10. In ESI the ionization occurs in the liquid phase (in the spray) where ions might already be present or are created by application of a high electrical potential (3–5kV) to the sprayer tip. Evaporation of the liquid is assisted by

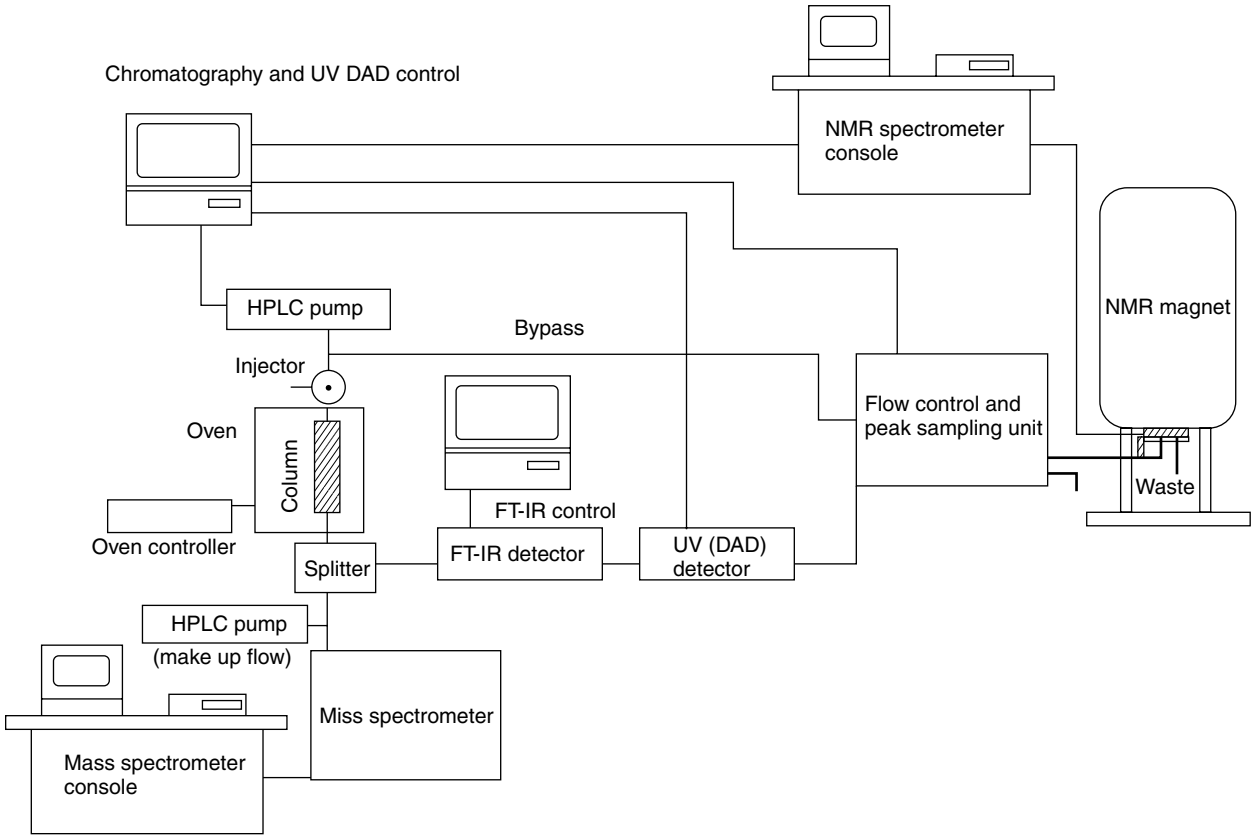

FIGURE 47.9 Hypernation: set up for LC-[DAD UV] –FTIR NMR/MS. (Reproduced from Journal of Chromatography A, Vol. 1000, p. 350. With permission from Elsevier.)

pneumatic pressure and by heat. Orthogonal spray orientation keeps the capillary and ion optics cleaner. The standard ESI sources cover the range from 0.1 to 2 $mLmin^{-1}$ and are therefore compatible with the average flow rate (1 mL/min) from 4.6 mm i.d. columns. ESI is a soft technique well suited to thermally labile molecules. The drawback is the occurrence of matrix effects. ESI is concentration dependent. A great deal of effort is focused on miniaturization of the system.

Two mechanisms have been proposed for the formation of ions by electrosray. The first is ion evaporation, which results in analyte ion desorption from a droplet due to high-field strength generated by charged droplets (20,21) The other relies on Rayleigh fissions to form very small charged droplets followed by solvent evaporation to result in a gas phase analyte ion (22). One characteristic of ESI instrumentation is the large pressure differential which is necessary for the combination of ionization at atmospheric pressure with the low pressures required for mass analysis and ion detection. The pressure differential is usually achieved either with a sampling cone/skimmer or capillary/skimmer arrangements. As the gas expands through the sampling cone into the lower pressure region, it forms a supersonic jet. The position of the skimmer in the source relative to the cone or capillary is extremely important for ensuring minimal ion losses in this region. Potentials applied between the skimmer and the cone/capillary serve both to focus the ion beam through the skimmer orifice and to accelerate ions through the intermediate pressure region.

Most manufactured electrospray interfaces attempt to negate the effects of the charged residues by using off-axis nebulizers, have an arrangement of off-axis skimmers or skimmer capillary sampling orifices, or use a shield in front of the sampling orifice. The disadvantage of ESI is its low tolerance to buffer salts. Nano ESI is more and more in use in protein analysis.

b. Sonic spray ionization (SSI)

In this technique (Figure 47.11), a sample solution is sprayed from a sample introduction capillary by a high speed nitrogen gas flow that is coaxial to the capillary, and ions of the chemical in the solution as well as charged droplets are produced at room temperature and atmospheric pressure. An electric field is applied to the solution in the capillary to increase the charge density of produced droplets, so that multiply charged ions are produced. The most important feature of SSI is that it does not require a heated nebulizer or the application of a high voltage to the sprayer. The range of solution flow rates in SSI is under

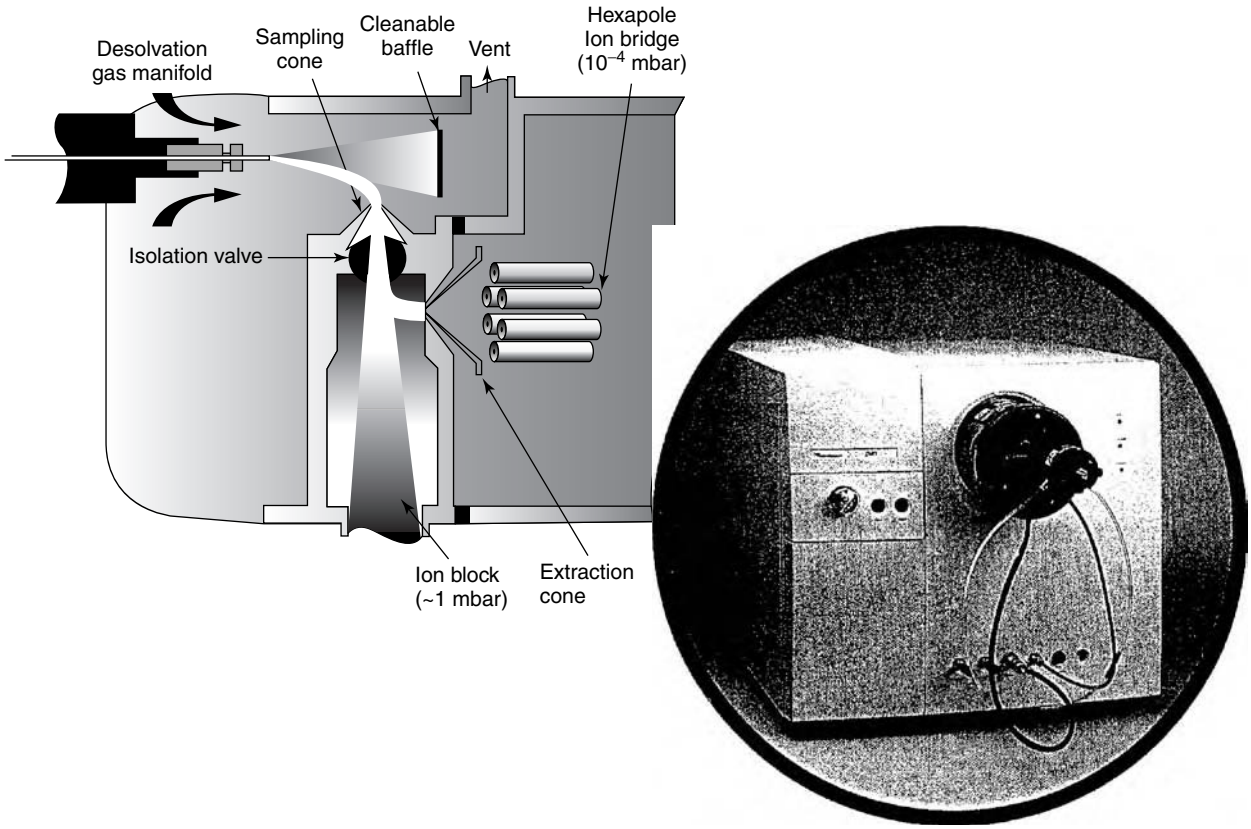

FIGURE 47.10 Schematic of the LC-MS electrospray interface with orthogonal electrospray system. (Courtesy of Agilent.)

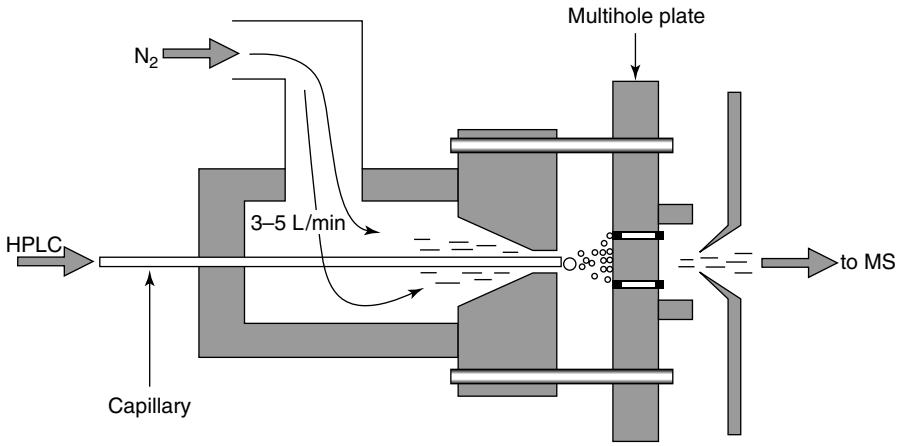

FIGURE 47.11 Schematic of a sonic spray ionization source. (Courtesy of Hitachi.)

0.2 mL/min; SSI is useful for semi-micro LC-MS but not well suited for conventional flow rates of 1mL/min.

c. Atmospheric pressure chemical ionization (APCI)

Atmospheric pressure chemical ionization (APCI) is a three-step process: the liquid flow from the LC is sprayed and rapidly evaporated by a coaxial nitrogen stream and heating the nebulizer to high temperature (350°–500°). Additional ionization is achieved by means of a corona discharge (3–6 keV) producing primary ions (N_2^+ and O_2^+ in positive mode). Interface consists of a concentric pneumatic nebulizer and a heated large-diameter, quartz tube. The primary ions react immediately with the solvent molecules of the mobile phase with the formation of reagent ions (e.g., H_3O^+, $CH_3OH_2^+$ in positive mode). The reagent ions react (e.g., proton transfer) with solute molecules yielding $[M+H]^+$ in positive ion mode or

$[M-H]^-$ in negative ion mode. Processes are separated in APCI which allows the use of some unfavorable solvents. Ionization occurs in the gas phase whereas it occurs in the liquid phase in ESI. APCI is mass dependent and less prone to matrix effects. APCI can withstand high flow rates but miniaturization is more difficult than with ESI.

d. Atmospheric-pressure photoionization (APPI)

Photoionization is induced by means of a xenon lamp (10 eV). A dopant species, with the ionization potential of <10 eV, such as toluene, is utilized. Covaporized dopant molecules are ionized by UV radiation. Photoions thus produced initiate ion molecule reactions with the solute molecules, yielding $[M+H]^+$ and M^+ by proton transfer or charge transfer. The solvents in the mobile phase must have a ionization potential >10 eV to prevent ionization from the xenon lamp with a resulting increase in background signal.

e. Maldi

Matrix-assisted laser desorption ionization (MALDI) is well suited for macromolecules such as peptides, proteins, oligosaccharides, and oligonucleotides. In a Maldi experiment a proper organic matrix (e.g., glycerol) is required for mixing with the analyte in a ratio typically 500/1. The mixture is dried and inserted in a MS. A laser beam will desorb and ionize the matrix species, thus ionizing the analyte. Most Maldi-MS systems are based on time of flight (TOF) mass analyzers. Ions produced by the laser beam are extracted from the source and expelled to the flight tube.

B. Mass Analyzers

The resolving power of a mass spectrometer is a measure of its ability to distinguish between two neighboring masses. Resolution is Δamu/amu (atomic mass unit). Spectrometers easily perform resolutions of 50,000 (i.e., distinguish Δamu = 0.01 when M = 500). Resolution is often written in ppm, Δamu $*10^6$ /M.

The quadrupole mass filter consists of four parallel hyperbolic rods in a square array (Figure 47.12). The inside radius (field radius) is equal to the smallest radius curvature of the hyperbola. Diagonally opposite rods are electrically connected to radio frequency/direct current voltages. For a given radio frequency/current voltage ratio, only ions of a dedicated m/z value are transmitted to the filter and reach the detector. Ions with a different m/z ratio are deflected away from the principal axis and strike the rods. To scan the mass spectrum, the frequency of the radio frequency voltage and the ratio of the ac/dc voltages are held constant while the magnitudes of ac and dc voltages are varied. The transmitted ions of m/z are then linearly dependent on the voltage applied to the quadrupole producing m/z scale which is linear with time. A triple quadrupole instrument uses two quadrupole MS analyzers for the actual MS experiments and a third quadrupole in RF mode which transmits all incoming ions from MS1 to MS2.

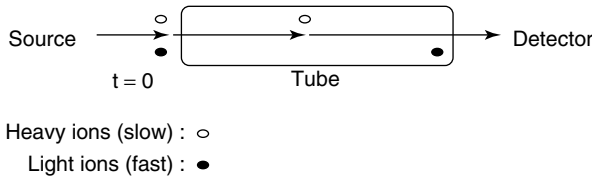
For quadrupole mass spectrometers, selected ion monitoring (SIM) yields significantly enhanced detection limits compared with scanning MS operation because of the greater dwell time for signal acquisition at each selected m/z values.

Ionization steps and ion separation are space separated in a quadrupole system whereas they are time spaced in ion traps. An ion trap (Figure 47.13) is a linear quadrupole bent to a close loop. Typically, three electrodes are a common design of an ion trap: a ring electrode and two end cap electrodes. The outer rods form a ring and the inner rod is reduced to a mathematical point in the center of the trap. End electrodes exhibit a hole in their center to allow for introduction of ions and ejection of these ions towards the detecting device. A radio frequency is applied to the ring electrode and consequently, a quadrupole field is produced which traps ions. Each ion is submitted to an oscillating motion, the amplitude of which depends on the RF and the m/z ratio. Ions of different masses are stored together in the trap and released one at a time by scanning the applied voltages. They can be ejected through the end caps and detected by applying a RF voltage with a frequency corresponding to the characteristic frequency of the ion moving through the ion trap or by scanning the amplitude of the applied RF voltage. With a reduced pressure of gas (He)(10^{-3} torr) the motion of ions in the trap is dampened and the ions move closely around the center of the trap. Ion traps are a powerful tool in elucidating fragmentation mechanisms since it allows stepwise and controlled fragmentation in multistage MS. Ion traps are small benchtop instruments.

Linear two-dimensional ion traps are now commercially available (23).

1. Time of Flight

A scheme is displayed below:



A small number of ions is extracted from the source in a few μseconds, accelerated with few kV, and directed to a tube. The process can be repeated 100,000 times per second. Kinetic energy is similar for every ion and ions with higher velocities (light ions) will reach the end of the tube before heavy ions. Instruments have two tubes with a mirror in the middle and resolution may reach 5000. A schematic diagram of an instrument is displayed in Figure 47.14.

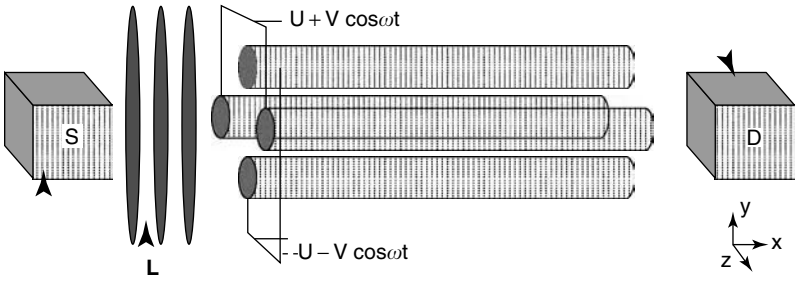


FIGURE 47.12 Scheme of a quadrupole instrument. (Coustesy of Micromass.)

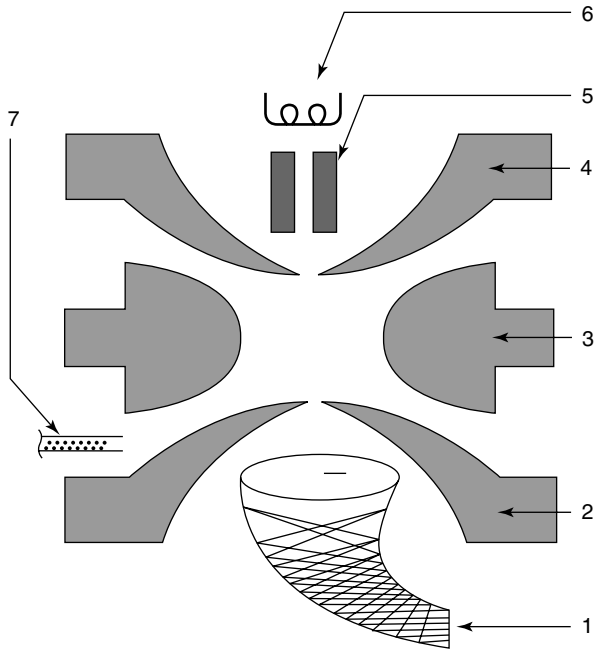

FIGURE 47.13 An ion trap. 1 = channeltron detection; 2 = cap electrode; 3 = ring electrode; 4 = cap electrode, 5 = electron gate; 6 = eletron emitting device; f = column. (Courtesy of Agilent.)

In a tube L the time of flight t is connected to the velocity v

$$t = L/v$$

Ions get a kinetic energy $E_k = 1/2\ mv^2 = 2V$ where V is the voltage, then $t = L[m/2Vz]^{1/2}$. The time of flight is proportional to the square root of the ion mass which allows discrimination according to the m/z ratio.

As an example, if 300V are used to accelerate the ions in the flight tube, an ion with m/z = 1000 needs about 200 μs to reach the detector.

The hybrid quadrupole time of flight mass spectrometer (Q-TOF) was introduced as a mass spectrometer capable of tandem MS with particular emphasis on its applicability for protein and peptide analysis. Key components of the instrument are the quadrupole, hexapole collision cell, and the reflectron-TOF analyzer. In normal mode, the quadrupole region and hexapole collision cell, are operated in a non-mass discriminative wide-band pass mode allowing all ions to pass unperturbated in the pusher of the TOF analyzer. Like all TOF analyzers, the m/z measurement is based on the amount of time required for an ion to travel the distance from the source of entry (pusher on a Q-TOF) to the multi-channel plate (MCP) detector. The signal detected by the MCP is integrated over an unspecified period of time and each integrated spectrum is written to disk.

The electronics of the detector must record the complete mass spectrum within the flight time of the ions (1–100 μs range) with peak widths in the ns range. This is possible since high scan rate (up to 20,000 scans/s) allows for the detection of narrow chromatographic peaks. There is virtually no limit on mass range and no ion loss. The use of time-dependent accelerating fields can improve the resolution of TOF instruments. The technique involves the introduction of an appropriate time-delay between the ion formation and ion acceleration. During this time, ions disperse with their individual kinetic energies. Since the accelerating potential varies linearly with the position of the ions

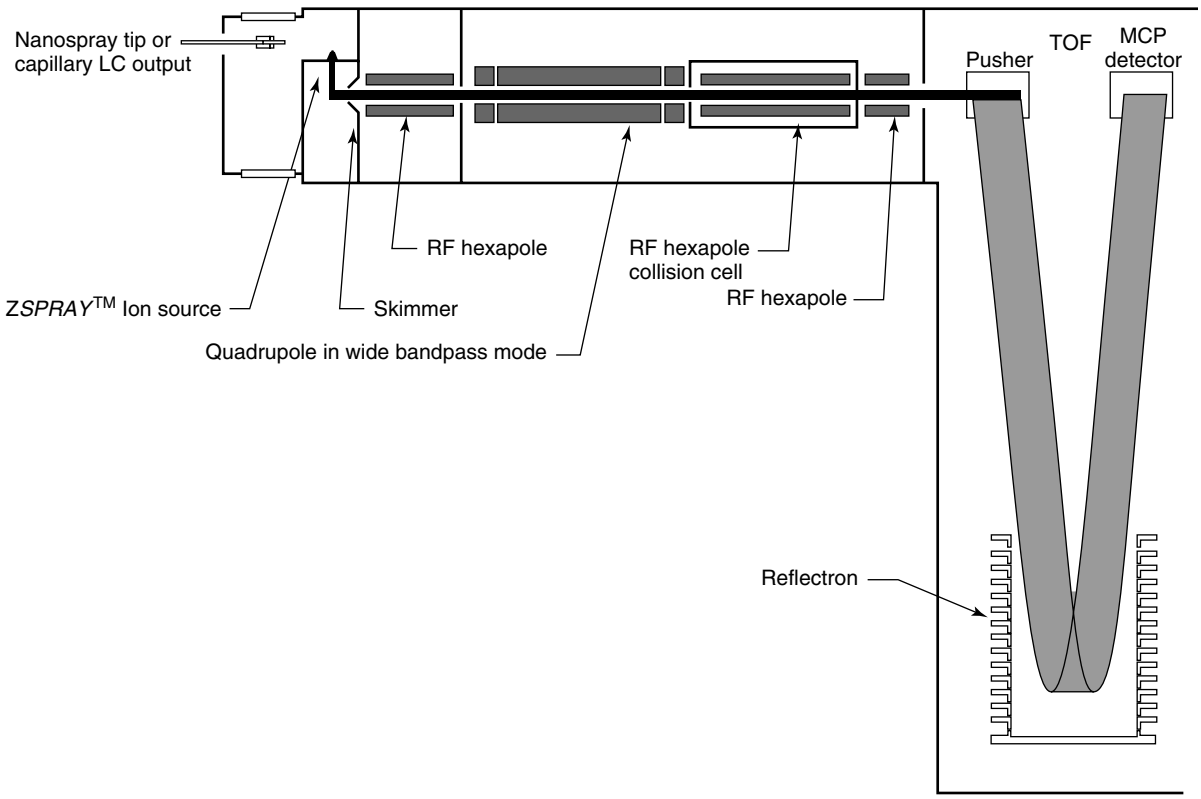

FIGURE 47.14 Schematic of a quadrupole time of flight (Q-TOF) mass spectrometer shown operating in MS mode. (Courtesy of Micromass.)

in the source region, ions with the same m/z ratio but different positions are accelerated through different acceleration voltages. In this way, correction for the initial ion velocity distribution is achieved.

TOF-MS has to a large extent replaced high resolution double-focusing magnetic sector instruments for LC-MS applications. With the fast acquisition capacity of the TOF instrument (>10 spectra/sec), the effluents from four HPLC columns are continuously electrosprayed.

C. ICP-MS

Inductively coupled plasma mass spectrometry is highly selective in ultra-trace-level metal detection technique. Interfacing HPLC to ICP-MS can be achieved with relative ease by means of a length of PEEK tubing connecting the HPLC column to the nebulizer of the ICP-MS. Performances are strongly dependent on the type of nebulizer utilized as the sample introduction device. HPLC-isotope dilution-ICPMS offers considerable potential for speciation studies.

D. NMR

On-line coupling of HPLC with nuclear magnetic resonance spectroscopy (NMR) has proved useful for a wide range of applications. The shortcoming of suppression of eluent signals can be circumvented by use of a capillary separation technique. Capillary concentration techniques are important to take advantage of the miniaturized rf coils. In this mode detection cells with internal volumes in the nanoliter scale and miniaturized probe heads have been developed by Albert and colleagues in Tübingen (24). The system can be used in either HPLC, CE, or CEC and consists of a capillary inserted into a 2.5 or 2.0 mm NMR microprobe equipped with a Helmholtz coil. In experiments a capillary tube of 315 μm can create a detection volume of 900 nL. The flow rate of the capillary HPLC-NMR can be adjusted to 3 μL/min with the help of a T piece inserted between the HPLC pump and the capillary device. The polyimide coating was removed over the length of the NMR coil directly after the outlet frit of the capillary packing. In another design the packed capillary LC column is placed directly below the cryomagnet. With the help of a transfer capillary (400*50 μm) the eluate is transferred to the detection capillary with an internal diameter of 180 μm. The NMR detection volume is thus 200 nL. For example, assignment of vitamin E structures is possible.

VI. PERFORMANCES

The HETP equation with packed columns has been devised by Knox (6) and is written in reduced variables:

$$h = A\,\nu^{1/3} + B/\nu + C\nu$$

where A stands for the anisotropy of flow rate, B is the molecular diffusion, and C is the mass transfer term. With good columns A = 1, B = 2, and C is around 0.01. h is the reduced plate height (h/d_p with packed columns, h/d_c in open tubular columns), and ν is the reduced velocity $\nu = ud_p/Dm$. Small particles yield HETP curves with negligible C term. In this mode, HETP does not vary too much when flow rates are increasing beyond the minimum but back pressures dramatically increase. It must be pointed out that the Van Deemter equation $H = A + B/u + Cu$ applies with monolithic columns.

The pressure used to pack a column can have a dramatic effect on the performance characteristics of the column.

Recorded peak width is the sum of column and extra-column contributions to band spreading. The instrument contribution comes from the injector, connecting tubings, column frits, detector, and data-handling. Since residence times of the solute in all these parts are independent, variances are additive and thus:

$$\sigma^2 = \sigma^2_{\text{injector}} + \sigma^2_{\text{column}} + \sigma^2_{\text{detector}} + \sigma^2_{\text{connecting tubes}} = \sigma^2_{\text{column}} + \sigma^2_{\text{extra column}}$$

There are two methods to obtain the extra column band broadening of the chromatographic system: a linear extrapolation method using σ^2_{peak} as a function of retention time; and a zero length column method where the column is removed from the system and replaced by a capillary.

In the linear extrapolation $N_{th} = (t_r/\sigma_{\text{column}})^2$; hence $\sigma^2_{\text{column}} = t_r^2/N_{th}$.

A plot of σ^2_{peak} versus t_r^2 will be linear with a slope determined by N_{th} and an intercept value on the vertical σ^2_{peak} axis representing $\sigma^2_{\text{extra column}}$.

Column performance is expressed as the number of theoretical plates per unit of time, N/t or per meter N/m or by separation impedance, $E = \Delta P t_o/N^2\eta$ where ΔP is the pressure drop, t_o the retention time of the inert solute, N the plate count, and η the mobile phase velocity. N is around 100,000 plates/m. A new monolith column can produce 38,000 plates/25 cm.

Recently, temperature has attracted attention from LC chromatographers since the eluent viscosity is reduced. The contribution of temperature to the retention is mainly given by the enthalpy term of the Van't Hoff equation

$$\text{Lnk} = -\Delta H/RT + \Delta S/R + \log\beta$$

where ΔH is the enthalpy change associated with the transfer of the solutes between phases, ΔS is the corresponding entropy change, R is the molar gas constant, T is the absolute temperature, and β is the phase ratio of the column. Plots of Lnk versus 1/T are usually called Van't Hoff plots and the slope of the curve yields ΔH. Most studies are related to reverse phase systems. When dealing with small solutes that experience hydrophobic interactions, lower selectivity is observed with elevated temperatures. Solutes with basic groups or ionizable compounds experience increased selectivity at high mobile phase pHs. In the Knox equation the A term is not affected by temperature, the C term is reduced, but the B term increases. The stability of silica-based C18 stationary phases is questionable over 80°C but PS-DVB are resistant up to 220°C. It must be pointed out that the dielectric constant of water is reduced at elevated temperatures giving it some characteristics of an organic solvent. A discussion on temperature effects can be found in (25).

Zhu et al. (26, 27) studied the combined effects of solvent gradients and temperature.

VII. OPTIMIZATION

When dealing with complex samples column switching is the method of choice to focus on solutes of interest. The method is rather simple; it uses two columns packed with different supports but the compatibility of eluent with the two phases is not straightforward.

The best chromatogram is the one which provides the complete resolution ($Rs \cong 1.25$) of all solutes in a minimum time. The large number of chromatographic parameters and the relationships between them rules out the possibility of empirical optimization by trial and error. Many methods have been developed to optimize parameters of interest. These methods were reviewed by Siouffi (28). The analyst either selects a response function (most often the resolution Rs) or tries to predict retention. There are roughly two types of approaches: the chemometrics approach and methods based on models. Because most useful variables in RPLC reside in the mobile phase, they are generally referred to as mobile phase optimization.

Full or fractional factorial designs are useful for screening the effects of a large number of parameters. One does not need to know the retention mechanism. Data from a Central Composite Design can be evaluated and plotted as a response surface which provides a graphical representation of the data over the range of the key parameters to study. It allows us to check the influence of a parameter but it is not predictive. Experimental retention data can be used to train an artificial neural network to enable it to predict the effects of changes in experimental variables.

Softwares and method development in LC separations are readily and widely available. Such products rely on the input of two or more pilot runs to calibrate a retention model. The Drylab computer simulation approach is widespread (29–31). The retention data of two initial gradient runs are used to adjust the steepness and the range of the gradient. In Chromsword from Galushko (32), a

molecule must be translated into volume fragments and bond dipoles

$$\text{Lnk} = a(\Sigma Vi)^{2/3} + b(\Sigma Ge \cdot sj_{H_2O})$$

where Vi are the increments of the partial molar volumes of fragments in water, $Ge \cdot sj_{H_2O}$ are the increments of energy of interaction of bond dipoles with water, and a, b, and c are the parameters of the RP system and the column (polarity, column ratio, etc.).

Baczek et al. (33) performed a comparison of the two softwares. The Prisma optimization model was developed by Nyiredy (34) for the purpose of TLC optimization and was extended to HPLC. It is a three-dimensional geometrical design which correlates the solvent strength with the selectivity of the mobile phase. A software package called Virtual Column enables simulation and optimization of ion chromatography separations (35).

The linear Solvation Energy Relationship advocated by Abraham (36) and extensively studied by Carr and Poole (37,38) relies on the following equation

$$\text{Lnk} = \text{Ln}K_0 + rR_2 + vV_x + s\pi^2_H + a\Sigma\alpha^2_H + b\Sigma\beta^2_H$$

where R_2 is an excess molar refraction of the analyte, V_x is its molar volume (in $cm^3 \cdot mol^{-1}/100$) according to the MacGowan algorithm, π^2_H is the solute dipolarity/polarizability descriptor, $\Sigma\alpha^2_H$ is the analytes ability to donate hydrogen bonds, $\Sigma\beta^2_H$ is the measure of hydrogen bond accepting capability. Lnk_0, r, s, a, and b are fitting coefficients which reflect the difference in specific bulk property between the mobile and stationary phases. The solvation parameter model is a useful tool for evidencing the contribution of defined intermolecular interactions to retention of neutral molecules (or polar but not ionized molecules) in chromatographic systems. The retention process is the sum of the *differential* interactions of a solute with the mobile phase and the stationary phase.

In general, the solute size and the basicity are the most important solute descriptors governing retention.

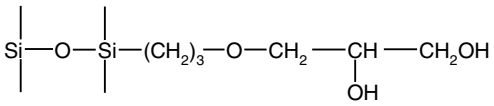
VIII. DIFFERENT MODES OF LC

A. Adsorption or NPLC (Normal Phase Liquid Chromatography)

In this mode the stationary phase is polar. Since only silicagel and alumina were utilized at the beginning of liquid chromatography and hydrophobic alkyl bonded phases were developed later, this mode is called normal phase.

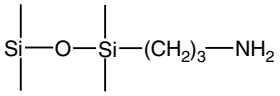
Stationary phases: Bare silicagel and alumina are declining but bare silica is still widely used in thin layer chromatography. Polar bonded phases are now widely used.

Synthesis of bonded silica is performed either by surface modification or bulk modification.



Diol phase Si—O—Si—$(CH_2)_3$—O—CH_2—CH(OH)— CH_2OH

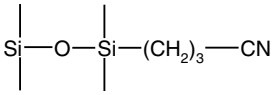
is very similar to bare silica but less retentive.



Si—O—Si—$(CH_2)_3NH_2$

– Amino phase

acts by the lone pair of electrons on the nitrogen atom.



– Cyano phase Si—O—Si—$(CH_2)_3CN$

is less polar and has been advocated in some optimization procedures as the unique phase since it may be used with any solvent.

Other polar phases are available but less often advocated.

Mobile phases: Theoretically any solvent is convenient.

Extensive work has been carried out on adsorption theory and retention mechanism since the pioneering work of Snyder (39). In this chromatographic mode physical adsorption of solute occurs. That means weak interactions with the stationary phase. Adsorption of the solutes occurs via donor acceptor mechanism (hydrogen bonding, charge transfer, etc.). According to Snyder's displacement model a solute S takes place of n molecules of previously adsorbed mobile phase solvent molecules M.

$$nM_S + S_m \overset{K}{\Leftrightarrow} S_s + nM_m$$

The subscripts s and m refer to stationary phase and mobile phase, respectively.

$$K = \frac{(S)_s}{(S)_m} \frac{(M_m)^n}{(M_s)^n}$$

From this starting equilibrium the Snyder-Soczewinski equation (40) yields the retention equation

$$\text{Ln } k = \text{Ln} \frac{V_a W}{Vm} + \alpha(\varepsilon^0 - S^0 A_s) + \Sigma \text{ secondary effects}$$

$V_a W$ is the volume of solvent forming a monolayer coverage on the absorbent surface.

When a solute is strongly adsorbed, eluent must exhibit a strong affinity towards the stationary phase to displace the solute. ε^0 represents the dimensionless energy of solvent adsorption. Ranking ε^0 gives a scale of adsorption strength. It is obvious that n alkanes exhibit weak affinity towards polar stationary phases. Conversely, silicagel and alumina are hygroscopic and exhibit strong affinity towards water. Ranking ε^0 constitutes the eluotropic strength scale (Table 47.2).

Fine retention tuning is somewhat difficult with a single solvent. Mixtures of solvents most often constitute the eluent. Binary mixtures are a blend of apolar diluent (A) and polar modifier (B). Direct calculation of the eluting strength is possible through a formula derived by Snyder (39). The plot of ε^0 versus % of B is displayed in Figure 47.15. These plots are readily available in most manufacturers' softwares. Three (or more) solvent mixtures as eluent are difficult to handle and reproduce. With a binary mixture retention is given by

$$\text{Ln } k = Ct - n \text{ Ln } (X_B)$$

where X_B is the molar fraction of modifier B and Ct is a constant.

Continuous increase of X_B is gradient elution (see below).

Normal phase chromatography is well adapted to separation of polar or moderately polar compounds. NPLC is well suited for the separation of structural isomers.

B. Reversed Phase LC (RPLC)

In this mode the stationary phase is hydrophobic (apolar) and to maximize the difference between the nature of both stationary and mobile phases, the former is hydrophobic, the latter is highly polar. Retention in RPLC is described in terms of free energy change

$$\Delta G^\circ = RT \text{ Log } K + \text{Log } \varphi$$

$$\text{Log } K = -\Delta H^\circ/RT + \Delta S^\circ/R + \log \varphi$$

where T is the absolute temperature, R is the gas constant, φ is the phase ratio, and ΔH° and $\Delta S^\circ$are enthalpy and entropy, respectively, associated with the transfer of a solute from an aqueous mobile phase to a non-polar stationary phase.

TABLE 47.2
Eluotropic Series for Different Adsorbents

	Solvent Strength Parameter					
Solvent	**Alumina**	**Silica**	**Carbon**	**Aminopropyl**	**Cyanopropyl**	**Diol**
Pentane	0.00	0.00				
Hexane	0.01	0.01	0.13–0.17			
Carbon tetrachloride	0.17	0.11		0.069		
1-Chlorobutane	0.26	0.20	0.09–0.14			
Benzene	0.32	0.25	0.20–0.22			
Methyl-tert. butyl ether	0.48		0.11–0.124	0.049–0.085	0.071	
Chloroform	0.36	0.26	0.12–0.20	0.13–0.14	0.106	0.097
Dichloromethane	0.40	0.30	0.14–0.17	0.13	0.120	0.096
Acetone	0.58	0.53			0.14	
Tetrahydrofurane	0.51	0.53	0.09–0.14	0.11		
Dioxane	0.61	0.51	0.14–0.17			
Ethyl acetate	0.60	0.48	0.04–0.09	0.113		
Acetonitrile	0.55	0.52	0.01–0.04			
Pyridine	0.70					
Methanol	0.95	0.70		0.00	0.24	

Buffering Ranges

Buffer	**pK_a**	**Range**
Phosphate	201	1.1–3.1
	7.2	6.2–8.2
Acetate	4.8	3.8–5.8
Citrate	3.1	2.1–4.1
	4.7	3.7–5.7
	5.4	4.4–6.4

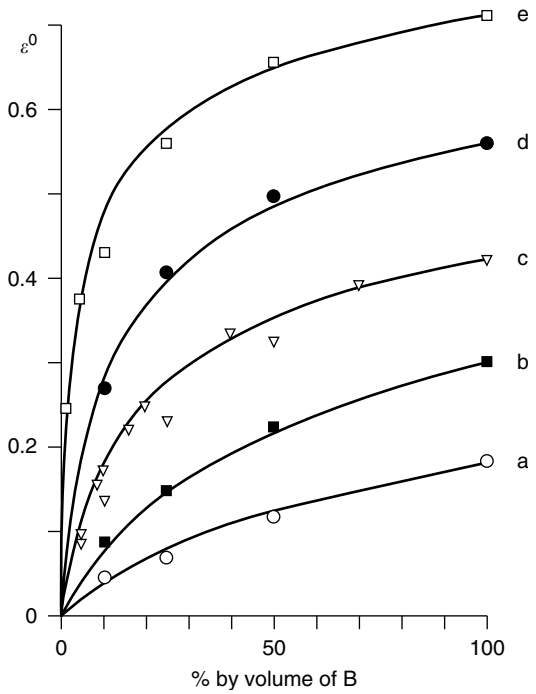


FIGURE 47.15 l Plot of eluent strength versus the % of modifier in a binary mixture (A: diluent; B: polar modifier) in NPLC. (a) carbon tetrachloride, (b) propyl chloride, (c) methylene chloride, (d) acetone, (e) pyridine. (reproduced with permission from Edinburgh University Press, (Scotland.)).

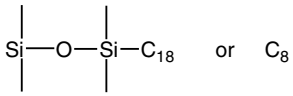
Stationary phases: More than 600 reversed phase columns are commercially available and every year new phases are released (see the annual review in LC-GC magazine). Most are silica bonded of the C_8 or C_{18} type.



In spite of many shortcomings silica backbone is still the material of choice and is considered as unsurpassed by other inorganic oxides such as zirconia or polymers, e.g., polystyrene/divinyl benzene. Hydrophilic solutes are more retained on porous graphite packings than on C_{18} bonded silica. Small, monodisperse, spherical particles are available in a variety of particle diameters (1.5–10.0 μm) and pore sizes (60–4000 Å). Differences exist between type of silica, type of ligand, end capping, bonding density, residual silanols, etc. Selection of the proper packing among the available types from manufacturers is not simple. The overall retention behavior of packed columns depends on the physico-chemical properties of the silica (specific surface area, packing density), the chemical surface properties (type and concentration of surface silanols, surface concentration of metal oxides), the bonding procedure (whether mono, di, or tri alkoxy or chlorosilanes have been used), the surface concentration of bonded groups achieved, and end capping or not. In many cases the manu-facturer's description is insufficient to characterize the stationary phases. ^{29}Si and ^{13}C NMR provide information on ligand attachment to substrate surface.

From the carbon content, %C and the specific surface area Sp the surface concentration (Sco) of the bonded phase is

$$\text{Sco} = \%\text{C}/(100\text{nC}*12\text{Sp})(1-\%\text{C}/100*\text{Ml-}1/\text{nC}*12)$$

Where nC is the number of carbon atoms (typically 8 or 18), Ml is the molecular mass of the ligand. Bonding density is expressed as μmoles/m^2. Silicagel has a maximum silanol density of 8.0 μmoles/m^2 but only part of them can react. With stationary phases with alkyl group surface concentrations below 3.8 μmoles/m^2, silanophilic interactions contribute to retention producing asymmetric peak shapes of basic solutes. At surface coverages of 4.24 μmoles/m^2, ca 85% of the silanol groups are blocked. To ensure that the minimum silanols are remaining manufacturers perform a further reaction with a small size silane (e.g., Trimethyl chloro silane). This is called end capping. Another procedure is to shield silanols with t-butyl groups, for example.

RP phases should be tested for

Efficiency expressed by N/m (plates per meter)
Hydrophobic properties
Steric selectivity
Silanophilic properties
Metal content

The majority of column characterization procedures can be divided into empirical methods, thermodynamically based methods, and model-based methods. A good chromatographic method for the characterization of a RP packing should attempt to measure several parameters. Many tests have been descibed in the literature. In Engelhardt's test (41), toluene, ethylbenzene, phenol, benzoic acid, aniline, NN-dimethylaniline, and p-ethylaniline are injected in methanol/water (49/51) eluent; the retention of toluene and ethylbenzene are measures of the hydrophobicity of a packing while the retention and the tailing factor of the bases are measures of the silanophilic interaction. Hydrophobic properties depend on the level of the surface coverage.

Hydrophobicity, which is usually considered as the ratio of the retention factors of successive homologues (e.g., pentylbenzene/butylbenzene), is a good guide to the carbon content of the column. The measured hydrophobicity is dependent on the mobile phase composition and temperature of the column (42).

All tests give good agreement on the hydrophobic retention, which is proportional to the carbon content per unit column volume, whereas hydrophobic selectivity, i.e.,

separation potential of two analytes differing for one methylene group, hardly shows differences between the various column types. Manufacturers who provide carbon content should also provide the specific surface area. In Tanaka's test (43) the analyst is able to measure the hydrophobic retentivity of the packing, the steric selectivity, the hydrogen bonding, and the ion exchange properties of the packing. Shape selectivity of RPLC phases refers to the ability of a packing to discriminate between conformational differences between molecules; however, it must be kept in mind that the majority of the evaluation methods for HPLC columns have been developed specifically for narrow pore phases using small molecular probes. Silanol activity is checked from the peak shape of benzylamine and phenol. Kele and Guiochon (44) extensively published on the reproducibility and performances of RP phases. Claessens (45) published a review of RP phases' characterization. McCalley (46) evaluated the performance of RP columns for the analysis of basic compounds.

Stationary phases especially developed for the analysis of basic compounds are phases in which the ionic interaction between basic analytes and silanols are minimized. In this mode various approaches of stationary phase manufacturing have been described: high purity silica, end capping procedures, polymer encapsulation, shielding of silanols, bidentate, or surface-modified silica. Polar-embedded phases provide good peak shapes of basic analytes and good compatibility towards highly aqueous mobile phases. To overcome the contamination by metal traces, silica is prepared by a sol-gel method which does not guarantee metal-free silica. It has been observed that basic analytes exhibit variable retention on RP packings; there may be partial or total exclusion effects giving rise to detrimental loss of resolution. At pH 7, which is often used to increase the retention of hydrophilic bases, poor peak shapes are obtained on many phases. The properties of RP columns also substantially depend on the actual eluent pH; addition of organic modifier to an aqueous buffer causes a shift which can be as high as one pH unit in the actual pH of the eluent. According to Neue (47), the pH needs to be controlled to better than 0.01 units, the mobile phase composition to better than 0.1% and the temperature to better than 0.1% if one wants to get reliable data on the batch to batch reproducibility of a packing. Classification and ranking of RP phases can be performed through principal component analysis (48).

Silica bonded phases are not stable over the whole pH range; low pH ($\leq$2) or high pH ($\geq$9) may damage the siloxane bond, and phosphate buffers lead to fast degradation. To overcome this drawback polymeric phases of the polystyrene divinylbenzene (PS-DVB) type have been developed. With a high degree of cross linking they are mechanically stable and can withstand high pressures. Porous glassy carbons (PGC) are pH stable as well but the number of published separations with this support is small compared to silica bonded supports.

On these hydrophobic supports, hydrophilic solutes are not retained and by consequence water is the weakest eluent. The eluotropic strength is thus exactly the reverse of the one observed in NPLC.

Mobile phases are typically water + organic modifier mixtures. Methanol, acetonitrile, and tetrahydrofuran (THF) are the usual organic modifiers.

The mechanism of retention has been a matter of dispute. The volume of "definitive" papers on the topic is impressive. Partition mechanism is generally accepted but some deviations from this mechanism may be observed. A low organic modifier content causes the collapse of the bonded chains that are brought together by the intermolecular C_{18} dispersive interactions while they tend to exclude water. A high organic modifier content induces the rupture of the C_{18} intermolecular interactions via chain solvation by the modifier and the formation of a brush-like structure.

Two features are important in RPLC. In an homologous series (n-alkanols, saturated fatty acids, etc.) linear plots of Ln k versus carbon number of the solutes are observed. Increasing the volume percentage of organic modifier in the mobile phases decreases retention according to

$$\text{Ln } k = a - b\phi - c\phi^2$$

where ϕ is the volume percentage of the modifier in a binary mixture water-organic modifier.

Curvature of the quadratic plot of Ln k versus ϕ is highly dependent on the nature of the solute (Figure 47.16). In a more or less limited range of the volume %, the above equation can be written as

$$\text{Ln } k = \text{Ln } k_w - S\phi$$

where Ln k_w is the retention with pure water as mobile phase. Values of k_w are obtained by extrapolation to $\phi = 0$.

S is the slope of the regression and is characteristic of the solute.

Discrepancy can occur when methanol, acetonitrile, or tetrahydrofurane (THF) is used as a modifier. k_w has often been considered the hydrophobicity of the solute. It comes from the correlation plot of Ln k_w versus Log P octanol-water. Like correlation plots, some discrepancies can occur, depending on the number of solutes in the plot and correlation coefficient values.

Slope (S) of the Ln k_w versus ϕ plot is typical of the solute considered. When considering, for example, two solutes, two situations can occur: either the two solutes have the same S, and in this case, selectivity remains constant whatever the ϕ value, or the two solutes exhibit S_1 and S_2 values which means that slope are different and consequently there exists a ϕ value where no separation occurs.

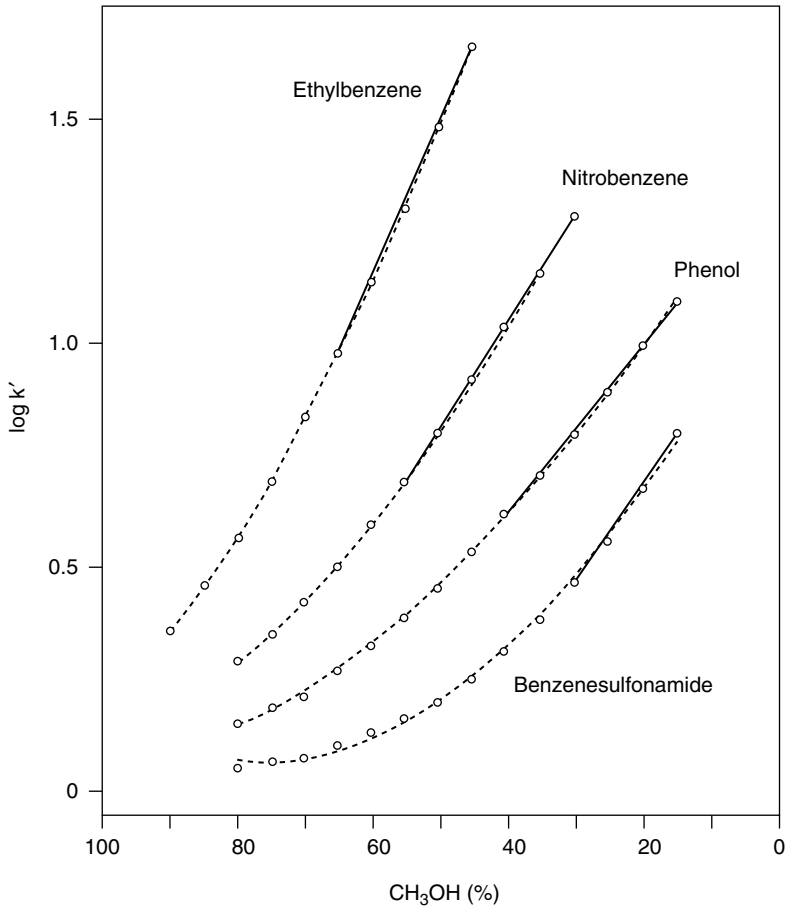


FIGURE 47.16 Plots of solute retention on C_{18} stationary phase (as logk) versus the volume fraction of modifier in RP. The solid line shows the linear region, the dotted line shows the quadratic region. (Reproduced from Chromatographia with permission from Vieweg.)

Beyond this value the order of retention is reversed. Peak crossover occurs when scanning the ϕ values range.

Selection of organic modifier is often achieved through trial and error. Experienced chromatographers are well aware of solute-solvent interactions. Snyder (49) has provided a useful selectivity triangle of solvent where dipole-dipole, proton donor, and proton acceptor interactions are the three apices (Figure 47.17). Solvents are gathered in eight groups. Solvents in a single group exhibit similar interactions. When considering the triangle, it is obvious that acetonitrile and methanol, for example, will interact differently. When solutes are eluted according to the sole hydrophobicity (for example, an homologous n alkanol series) use of either methanol or acetonitrile does not change the order of retention. Conversely, when very different chemical species are separated use of methanol or acetonitrile will yield different retention and selectivities and reversal of retention order is possible. In the same way chloroform and dichloromethane (two modifiers very often advocated in NPLC) may yield different retentions. A discussion on solvent classification has been published by Siouffi (50).

Gradient elution is performed when solutes are strongly retained. To decrease the t_r of these late eluting peaks modifier (stronger eluent) is incrased. From the above linear equation a linear increase in ϕ will result in a linear decrease in Ln k. This is called LSS (linear solvent strength).

The general approach is based on the solution of the basic differential equation $dV = k \cdot dVo$ where dV is the differential increase in the volume of mobile phase that has passed through the column, dVo is a differential fraction of the column hold up Vo, and k is the retention factor that is assumed constant during the migration of the solute band by an infinitely small distance corresponding to dVo. In binary gradients a "weaker" eluent (or diluent) A is associated with a "strong" eluent B. In linear gradient $\varphi = a + bt$ where a is the initial concentration φ of the solvent B in the mobile phase at the start of the gradient, and b is the steepness (slope) of the gradient per time or per volume unit of the eluate. Snyder (51) and Jandera (52) extensively published on gradient and derived equations which can be used for optimization of separation.

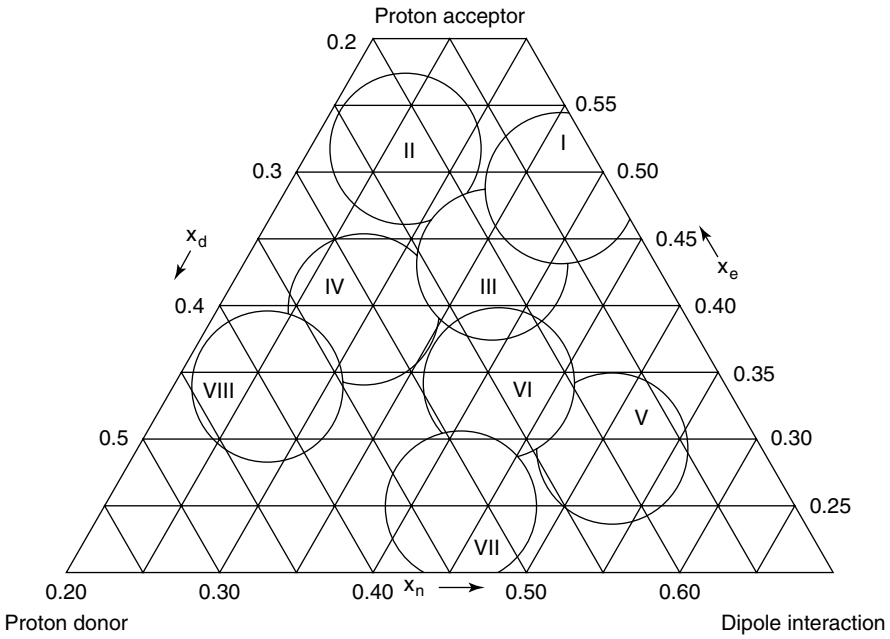

FIGURE 47.17 Selectivity triangle for solvents (Ref. 49). (Reproduced with permission from Preston Publications.)

Classificaiton of solvent selectivity according to snyder

Group Designation	Solvents
I	Aliphatic ethers, *mehtyl t-butyl ether*, tetramethylguanidine, hexamethyl phosphoric acid amide (trialkylamines)
II	Aliphatic alcohols, *methanol*
III	Pyridine derivatives, *tetrahydrofuran*, amides (except formamide), glycol ethers, sulfoxides
IV	Glycols, benzyl alcohol, *acetic acid*, *formamide*
V	Ethylene chloride
VI	a) Tricresyl phosphate, aliphatic ketones and esters, *dioxane*, polyesters b) Sulfones, nitriles, acetonitrile, propylene carbonate
VII	Aromatic hydrocarbons, *toluene*, halosubstituted aromatic hydrocarbons, nitro compounds, *methylene chloride*, aromatic ethers
VIII	Fluoroalcohols, m-cresol, water, (*chloroform*)

Gradient runs can be used to predict either isocratic or gradient separations. First, software was developed for RP separations. The model has been extended to other types. The selection of initial instrument parameters and separation mode are left to the user. Binary systems were first proposed. Extension to ternary mobile phase in RPLC permits a fine selectivity tuning.

RP phases allow a wide range of separation. They are well suited for polar organic solutes soluble in water. A rule of thumb is that retention order is similar to solubility in water or water modifier mixture. Apolar solutes such as polycyclic aromatic hydrocarbons are well separated on C_{18} phases according to their hydrophobicity.

In micellar liquid chromatography the mobile phase consists of surfactants at concentrations above their critical micelle concentration (CMC) in an aqueous solvent with an alkyl bonded phase. Micelles act as a mobile phase modifier. Retention behavior is controlled by solute partitioning from the bulk solvent into micelles and into the stationary phase as well as on direct transfer from the micelles in the mobile phase into the stationary phase. Reference (53) gives a broad overview of the method.

C. Ionizable Solutes

Separation of ionic or ionogenic solutes can be performed with three fundamental methods: ion pair formation, ion exchange, and ion exclusion.

a). Assume a weak acid AH. The dissociation equilibrium is

$$AH \Leftrightarrow A^- + H^+ \quad \text{with the dissociation constant } k_A$$

At low pH in a buffered solution only AH exists. Separation with a RP system is thus possible provided that the acid is not too strong. Alkyl sulfonic acids, for example, may exhibit very low pK_A. Separation of acids in RP occurs according to the degree of hydrophobicity. Knowledge of the analyte pKa can greatly assist in achieving a desired mobile phase pH. A requirement is that the buffer should be soluble in the amount of the organic modifier. This is particularly relevant in the case of gradient methods especially with methanol and phosphate buffer. For UV detection, the

buffer must be sufficiently transparent at the wavelength selected. LC-MS confers its own set of considerations regarding buffer concentration, buffer volatility, and ionization suppression. Ammonium acetate is better suited for LC-MS. Table 47.3 displays some characteristics of common buffers. Conversely, if pH solution is raised, A^- and H^+ are the only existing species. A^- can be chromatographed on an anion exchanger. Another method is ion pairing or ion interaction.

b). Ion pairing

In this technique a reversed phase column (most often RP8) is utilized with a mobile phase consisting of an aqueous organic mixture to which an ion pairing agent is added.

An ion pairing agent may form with analyte an ion pair with increased lipophilicity and consequently is retained on the RP stationary phase. Since the ion pairing agent is continuously fed onto the column it is most often advocated that the ion pairing agent induces a dynamic modification of the surface of the RP stationary phase. The lipophilic part of the ion pairing agent coats the surface, leaving the ionic part to interact with counter ions.

Retention can occur via

i. Retention of the ion pair formed between the cations (or the anions) of the analyte and the anion (or the cation) of the ion pairing agent. The ion pair itself is adsorbed onto the stationary phase.
ii. The analyte is retained through an ion pair complex formed with an amphiphilic ion previously absorbed onto the surface of the hydrophobic material.
iii. The analyte is retained through ion exchange reactions with the adsorbed pair reagent.

Retention increases as concentration of the ion pairing agent increases but decreases beyond a certain concentration; pH is a key parameter.

Ion pair reagents are most often either nitrogen (+) or sulfonate (−) species, e.g., cetyl trimethyl ammonium bromide, diamino dodecane, tributyl ammonium chloride, cetyl pyridinium chloride; sodium dodecyl sulfate, Chap:3-[(3 cholamidoproyl) dimethyl ammonio]-1propane sulfonate, Tris: tris-(hydroxymethyl) aminomethane.

TABLE 47.3
Buffering Ranges

Buffer	pKa	Range
Phosphate	2.1	1.1–3.1
	7.2	6.2–8.2
Acetate	4.8	3.8–5.8
Citrate	3.1	2.1–4.1
	4.7	3.7–5.7
	5.4	4.4–6.4

c). Ion chromatography (IC)

IC is the modern version of the well-known ion exchange chromatography. IC is able to separate any ion when the appropriate column is utilized: bromide, chloride, fluoride, nitrite, phosphate, sulphate, etc. It is able to speciate oxidation states of several metals such as Fe(II) and Fe(III). The challenge to IC comes from capillary electrophoresis.

Instrumentation required for IC simply comprises a metal-free HPLC system and conductivity detection. Since conductivity is a common property of ions this method is universal and quite sensitive.

In IC both mobile and stationary phases are ionic.

a. Ion exchange

Principle of operation: ion exchangers are insoluble solid materials which contain exchangeable cations or anions. These ions can be exchanged for a stoechiometrically equivalent amount of other ions present in an electrolyte solution.

Exchange reactions are written as (for example, in cation exchange)

$$R\text{—}H^+ + Na^+ \Leftrightarrow R\text{—}Na^+ + H^+$$

R— is the matrix of ion exchanger.

The thermodynamic equilibrium constant is

$$K_{H+}^{Na+} = \frac{(R\text{–}Na^+)\cdot(H^+)}{(Na^+)\cdot(R-H^+)}$$

Assume E^+ is a monovalent element cation, and M^{n+} is a sample metal ion

$$R\text{–}nE^+ + M^{n+} \Leftrightarrow R\text{–}M^{n+} + nE^+$$

$$K_{E/M} = \frac{(M^{n+}Rn)\cdot(E^+)^n}{(E^+\text{-}R)^n\cdot(M^{n+})}$$

At low loading of sample ions, the term (E^+-R) is equal to the exchanger capacity Q.

$$K_D = \frac{(M^{n+}Rn)}{(M^{n+})}$$

is proportional to k, the retention factor

and

$$k = K_{E/M}\cdot\frac{(Q)^n}{(E^+)^n}$$

More generally,

$$\text{Ln } k_A = \frac{1}{y}\cdot \text{Ln } K_{A/E} + \frac{x}{y}\cdot \text{Ln}\frac{Q}{y} + \text{Ln}\frac{W}{V_M}\frac{x}{y}\text{Ln}(E_m{}^y)$$

$$\text{Ln } k = \text{Constant} - \frac{x}{y}\text{Log } (E_m{}^y)$$

k_A is the retention factor for a solute A^x
$K_{A/E}$ is the ion exchange coefficient for solute A and eluent E

Q is the ion exchange capacity of the stationary phase
W is the weight of the stationary phase used in the column
V_M is the volume of mobile phase
x is the charge of the solute anion
E_m^y is the concentration of the element ion in the mobile phase.

In IC low capacity ion exchange columns are utilized. Eluents are in the range 1–10 mmol.

Stationary Phases. In ion exchange we can distinguish

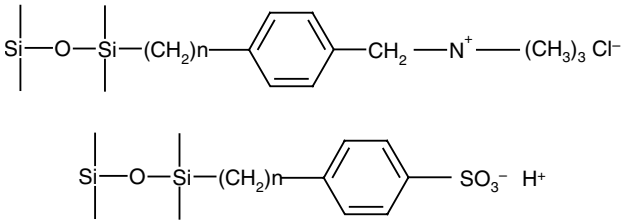
SCX: strong cation exchangers (functional group SO_3^-); in the H^+ form they represent "solid" acids.
WCX: weak cation exchangers (functional group COO^-)
SAX: strong anion exchangers or strong base (functional group alkanol quaternary amine)
WAX: weak anion exchanger (functional group amino)

Amphoteric ion exchangers contain anionic and cationic exchange sites.

Chelating ion exchange groups are: iminodiacetate, 8-hydroxyquinolinol, β diketone, triphenyl methane dyes, carbamates, EDTA, PAR [(4–2 pyridyl-azo)resorcinol]. New packings are compiled in the annual review which appears in LC/GC magazine.

Base materials

i. The majority of stationary phases are agglomerated or pellicular materials consisting of a monolayer of charged latex particles which are electrostatically attached to a functionalized internal core particle. Polystyrene Divinylbenzene (PS-DVB) with different degrees of cross linking is the substrate. Particle diameters are typically in the range of 5–25 μm while adsorbed latex particles are 0.1 μm. This material exhibits very good pH stability and excellent mass transfer properties. For example, analysis of oligosaccharides from honey is performed at pH 11–12.
ii. Microporous methacrylate-based materials are mainly used for anion exchange because of their resistance to high pH eluents.
iii. Silica-based materials are produced by grafting organic moieties according to the procedure utilized in producing reversed phase silica: aminopropyl bonded silica or functionalized silicas such as sulphonate are available. An advantage of silica-based materials is the low probability of secondary interactions between the solute ions and the silica substrate. Use of Silica-based materials is rapidly declining due to their poor hydrolytic stability.



iv. Electrostatic agglomerated films on ultra-wide-pore substrates (1000–3000 A) have been widely used. Wide pores accomodate a coating of ion exchange colloid on the interior or exterior surfaces. Another means of producing base material is the polymer coating of silica material. A layer of polybutadiene-maleic acid (PBDMA) is deposited on silica and then cross linked by peroxide-initiated radical chain reaction.

Mobile phases

Any ion in solution can be used that can compete with the analyte for the fixed ions on the stationary phase. In anion analysis hydroxyde eluents have distinct advantages over the carbonate eluents. These advantages include a wider linear working range for analyte conductivity, increased sensitivity, and the capacity to effectively elute highly retained ionic analytes using gradient capabilities. Conversely, carbonate is a divalent anion that possesses strong pushing properties in comparison to hydroxide eluents. In the EG 40™ eluent generator from Dionex, deionized water is pumped through the KOH generation chamber and a DC current is applied between the anode and the cathode of the cartridge (Figure 47.18). Under the applied field, the electrolysis of water occurs while hydronium ions generated at the anode displace K+ ions in the electrolyte reservoir. The displaced K+ ions migrate across the ion exchange connector into the KOH generation chamber and combine with OH− ions generated at the cathode to produce a KOH solution.

Factors influencing retention and selectivity are: hydration enthalpy, hydration entropy, polarizability, charge, and size and structure of both eluent and solute ions. Concentration of eluent ion (or ionic strength) and pH also play important roles.

A secondary equilibrium occurs according to the nature of the sorbent matrix. Hydrophobic interaction markedly influences retention (a typical example is the well-known aminoacid sequence on cation exchanger which does not follow the pKa sequence). With inorganic ions the perchlorate (ClO_4^-) effect is also well established. Non-ionic eluent modifiers are often used to change the ion exchange affinity of hydrophobic ions.

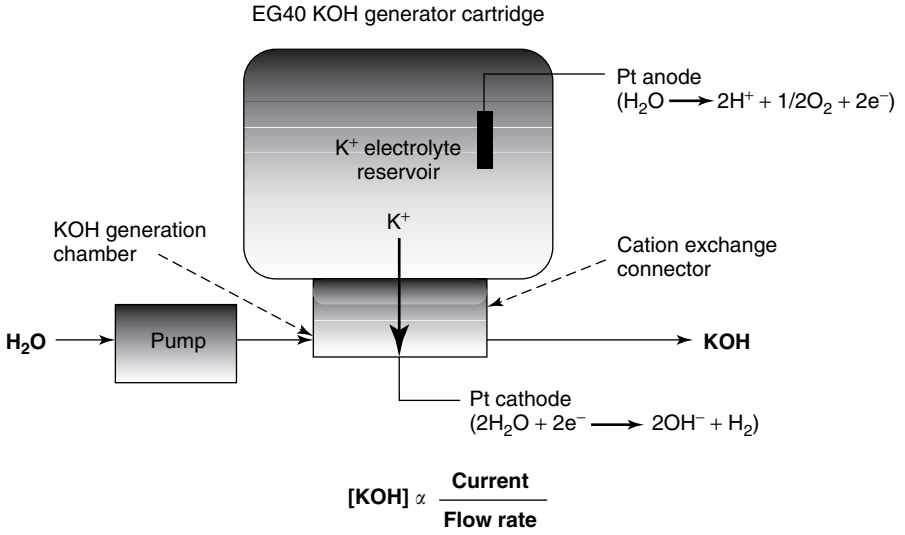


FIGURE 47.18 The EG 40 generator cartridge. (Courtesy of Dionex.)

Gradient elution starts with an eluent of low ionic strength for the resolution of the most weakly retained species. The dependence of the analyte retention on the eluent concentration is a straight line with slope given by the ratio of charges of analyte and eluent. Column switching permits the separation of both inorganic and organic anions in one run. Simultaneous analysis of ions is possible; column switching is configured for anion analysis in column A and cation analysis in column B.

Separation selectivity depends on the degree of electrostatic forces. With a SCX phase the binding force decreases with decreasing diameter.

$$H^+ < Li^+ < Na^+ < NH^{4+} < K^+ < Ag^+ < Be^{2+} < Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$$

With SAX material a selectivity series with respect to binding force also exists:

$$F^- < OH^- < CH_3COO^- < Cl^- NO_2^- < CN^- < NO_3^- < SO_4^{2-}$$

b. Ion exclusion

Ion exclusion relies upon Donnan equilibrium. The main parameter in this mode is the electrostatic interaction of the solute with the charged functional groups on the surface of the stationary phase.

The stationary phase can be considered as a charged membrane separating the flowing mobile phase from the static, occluded mobile phase trapped in the pores of the exchanger. Ionic solutes are rejected because of their inability to penetrate inside the pores and so are eluted at the void volume of the column. Conversely, non-ionic substances may partition between the occluded liquid phase and the flowing mobile phase. The degree of partition determines the extent of the retention. Sample anions are excluded from the resin phase by the fixed charges of the sulfonate groups of the cation exchange resin.

Separations by ion exclusion are usually performed on a cation exchange column with a PS-DVB resin. The solute retention volume is

$$V_R = V_o + K_D \cdot V_i$$

where

- V_o is the interstitial volume of eluent (eluent outside the resin beads)
- Vi is the occluded volume within the resin beads
- K_D is the distribution constant of the solute

When a very large solute or ion cannot enter the stationary phase K_D is 0; when the solute is free to enter $K_D = 1$.

The range of retention volumes is rather small and consequently, ion exclusion columns are rather long.

Acids are found to elute in decreasing order of their acid dissociation constants; the stronger acids elute first.

D. Chiral Stationary Phases

The food and beverage industry is becoming increasingly concerned with the analysis of enantiomers which can affect flavor, fragrance, age, and even the adulteration of products. Most efforts have been directed towards resolution of amino acids either native or derivatized.

In chiral chromatography, an enantioselective molecule (selector) is either immobilized on a surface support as a stationary phase or present as an additive to the mobile phase.

When a chiral selector is used as the stationary phase, the primary retention mechanism is complexation with the surface immobilized chiral selector. For 1:1 solute-selector

complexation, the equilibrium constant (Kcomp) is related to the retention factor k by

$$\text{Kcomp} = \frac{[\text{solute-selector}]}{[\text{solute}]\,[\text{selector}]} = \frac{\text{k}}{\varphi[\text{selector}]}$$

where [solute-selector], [solute], and [selector] represent the equilibrium concentrations of solute selector, free solute, free selector and respectively, and φ is the phase ratio.

Enantioselective ligand exchange chromatography was suggested by Davankov et al. (54) in the late 1960s for the resolution of racemic compounds into stereoisomers of amino acids, amino alcohols, and diamines. Such molecules exhibit a pair of heteroatoms which can form labile chelate type coordination complexes with Cu(II), Zn (II), or Ni(II). A chiral bidentate ligand such as hydroxyproline was attached to a support. Copper (II) was added to the mobile phase and coordinated with both the chiral selector on the stationary phase and the free amino acids in solution, to form a transient diastereomeric complex. This approach is limited to specific chiral molecules which can coordinate with the copper (II).

A discussion of the mixed-ligand ternary complexes between the chiral selector and the enantiomers to be separated can be found in Ref. 55.

The only commercially successful chiral stationary phase for thin layer chromatography is based on the ligand exchange approach (56).

The use of cyclodextrins as chiral selectors has grown rapidly in recent years. Cyclodextrins are cyclic oligosaccharides composed of D-glucose units connected through the 1 and 4 positions by α linkages (Figure 47.19). Those containing 6, 7, and 8 glucose units (i.e., α cyclodextrin, β cyclodextrin, γ cyclodextrin) are most common and available commercially. Cyclodextrins are usually described and depicted as toroidal molecules (conical cylindrical); they exhibit a relatively hydrophobic cavity in the middle and a relatively hydrophilic surface on the outside. They can form host-guest complexes with a variety of molecules. Since the internal cavity of the cyclodextrin tends to be more hydrophobic than either its exterior most non-polar or weakly polar molecules can penetrate and reside in the cavity. Cyclodextrins can be used as a mobile phase additive but the selectivity of covalently bonded cyclodextrins on a support is larger. There are many commercially available "cyclodextrin" stationary phases. Various moieties are utilized to functionalize the cyclodextrins and a huge amount of literature is available on the topic. Commercially available cyclodextrin derivatives are: acetylated, hydroxypropylether, naphtylethyl carbamate, or 3,5 diphenyl carbamate. The various moieties used to functionalize cyclodextrins can alter the enantioselectivity. It is possible to suppress the inclusion complexation by using a non-hydrogen bonding, polar organic solvent such as acetonitrile as the main component of the mobile phase. The acetonitrile occupies the cyclodextrin cavity and enhances hydrogen bonding between the hydroxyl groups on the cyclodextrin and any hydrogen bonding groups on the chiral analyte.

Macrocyclic glycopeptide antibiotics are multimodal as they can be used in the reverse phase mode, normal phase mode, or polar organic mode. The most successful are avoparcin, teicoplanin, ristocetin A, or vancomycin. They exhibit an aglycon "basket" made of fused macrocyclic rings and pendant carbohyhydrate moieties (Figure 47.20). Vancomycin and teicoplanin are the the most interesting. Teicoplanin, for example, (Mw1877) exhibits 2″ stereogenic centers; it has a hydrophobic acyl side chain attached to a 2-amino-2-deoxy-β-D-glycopyranosyl moiety. Teicoplanin has been used successfully in a number of applications (57); it can be used with no buffer in the mobile phase which greatly facilitates the LC/MS.

Protein LC columns have the least capacity of any chiral stationary phases. α1-acid glycoprotein, (AGP), ovomucoid, human serum albumin (HSA), or bovine serum albumin (BSA) are used in the reversed phase mode with aqueous buffers or hydro-organic solvents. HSA-based columns usually present the problem of a significant variation of the chromatographic performances, depending not only on the immobilization procedure but also on the origin of the anchored protein. Recombinant HSA can overcome the problem. AGP is one of the most used protein phases to separate enantiomeric amines. Reversal of elution order is not unusual in RPLC when working with protein-based enantioselective columns.

Historically, cellulose or starch components were the first to be used as chromatographic chiral selectors.

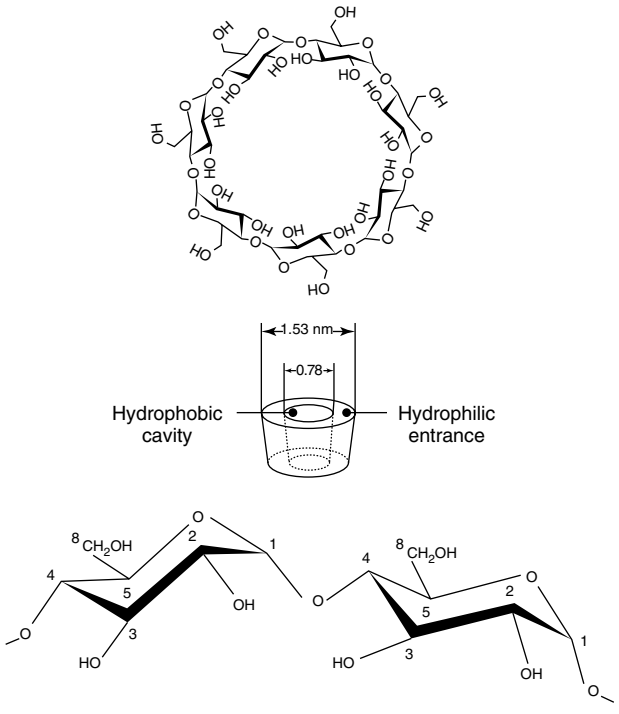

FIGURE 47.19 Schematic of the various cyclodextrins.

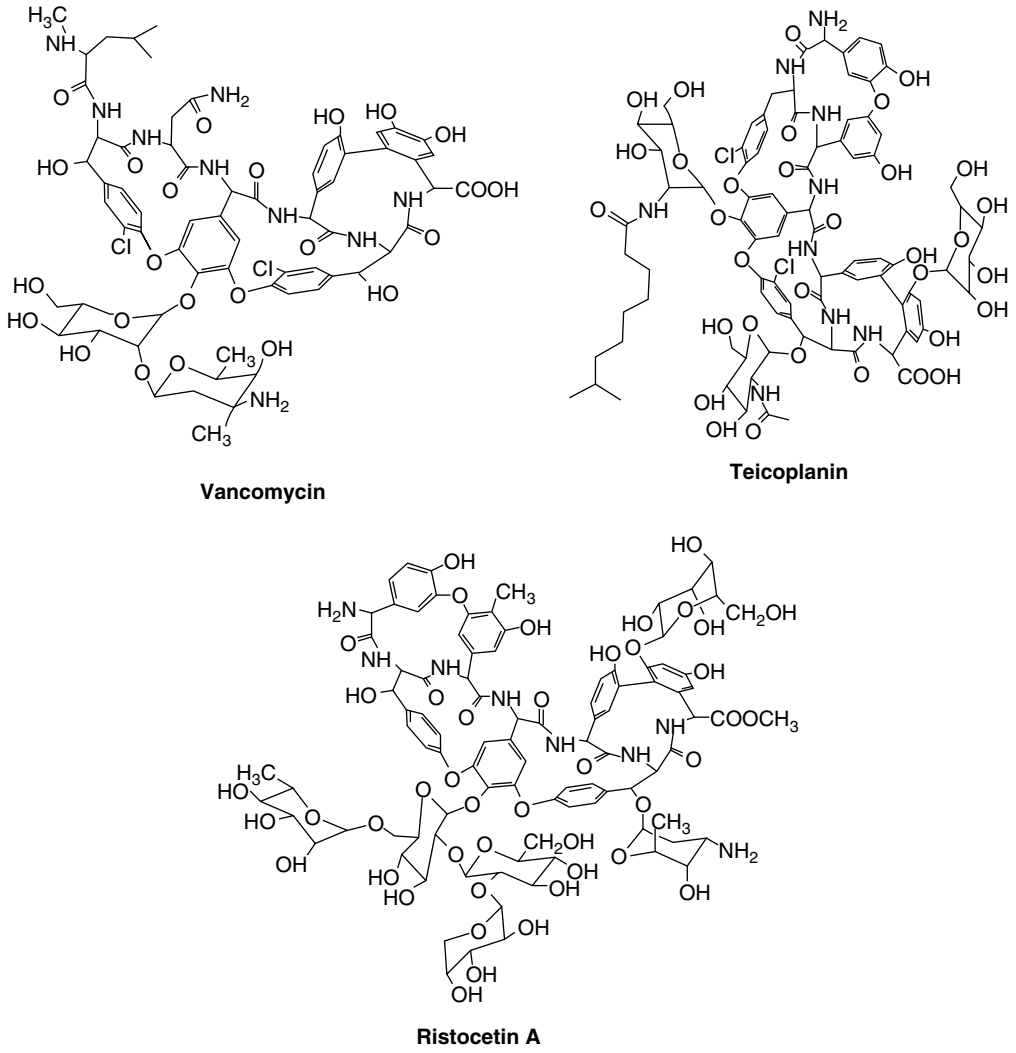

FIGURE 47.20 Structures of Vancomycin, Teicoplanin, and Ristocetin A.

Cellulose and amylose are the most accessible naturally occurring optically active polymers. These polysaccharides themselves show chiral recognition, but do not afford practical chiral stationary phases. Their derivatization brings about practically useful CSPs. Cellulose esters or phenylcarbamates, amylose phenylcarbamates are not covalently attached to the support, but rather are coated on wide pore silica that has first been silanized. Polysaccharide-derived CSPs supported on silica are classically prepared by reaction of the polysaccharide with a benzoyl chloride or a phenyl isocyanate in homogeneous conditions; these derivatives are coated from a solution onto a macroporous γ-aminopropylsilica matrix by evaporation of the solvent. They have good capacity in the normal phase mode. Among the various kinds of cellulose esters, cellulose tribenzoate and its derivatives show high chiral recognition abilities when adsorbed onto macroporous silica. The optical resolving ability of the benzoate or carbamate derivatives are dependent on the substituents on the phenyl group (58). Francotte (59) has demonstrated that many polymeric chains are involved in the chiral recognition mechanism. The supramolecular effect depends on the dissolution solvent which predetermines the geometry of chiral centers. A compilation of enantiomer separation by such phases can be found in Reference 60.

Pirkle and coworkers (61) first employed the concept of reciprocity of chiral recognition in designing effective chiral selectors. The reciprocity of chiral recognition states that if a chiral stationary phase (CSP) derived from an optically pure compound A can discriminate each isomer of compound B, then a CSP derived from an optically pure B may discriminate each enantiomer of compound A. Many CSP were synthesized. Some contain either a π acid or π base moiety (or even both). However, simultaneous interactions must be present, too (hydrogen bonding, dipolar interactions).

Molecular imprinted polymers (MIPs) can selectively recognize the template molecule used in the imprinting

process. In molecular imprinting, monomers, such as methacrylic acid and styrene, are first assembled around the template molecule. This arrangement of monomers is fixed on polymerization. After polymerization, the polymer is dried, ground, and sieved, the linker bond is chemically cleaved, and the templates are freed from the polymer matrix, leaving cavities that are complementary to the template in shape and spatial configuration. For a review, see Reference 62.

Chirbase provides comprehensive structural, experimental, and bibliographic information on successful or unsuccessful chiral separations which have been obtained on CSPs. Data mining and pattern recognition with a decision tree leads to a more rational choice of the CSP or of the mobile phase to a given CSP (63).

E. Size Exclusion

In this mode, the stationary phase is a porous solid support, the mobile phase is the most eluting one e.g. porous silica and water. All molecules are eluted in the void volume. Large molecules cannot enter the pores and travel in the external volume only, they are excluded; small molecules can penetrate into the pores and they travel through both external and internal volumes; by consequence their velocity is lower than the one of large molecules. The relevant retention parameter is the radius of gyration of the molecule which can be obtained by light scattering detection at several angles. Since there is no partition, the entropy is of paramount importance and the column temperature should be thoroughly controlled. The column set is calibrated using a series of polymer standards to determine a relationship between logM and the retention time of the standards. Calibration is typically performed using well-characterized standards (polystyrene, dextrans).

For any polymer, $Hv = M[\eta]$ where Hv is the hydrodynamic volume, M is the molecular weight (Mw), and $[\eta]$ is intrinsic viscosity. The intrinsic viscosity is the value of the reduced specific viscosity at infinite dilution $[\eta] = \lim c \to 0\ \eta_{sp}/c$. The Mark Houwink equation relates intrinsic viscosity and molecular weight for a given polymer/solvent combination.

$[\eta] = K\ M^{\alpha}$ where K and α are the Mark Houwink constants.

A triple detection (differential refractometry, viscosimetry, and light scattering detector) is often used which yields an accurate response and allows the determination of branching distribution of polyolefins, for example.

The number-average M_n, the weight-average M_w, molecular mass values, and polydispersity are defined by

$$M_n = \Sigma n_i M_i / n_i$$

$$M_w = \Sigma n_i M^2 / n_i M_i$$

Polydispersity $= M_w/M_n$ where n_i represents the number of oligomer molecules having a mass of M_i, M_n is the number-average molecular mass, and M_w is the weight-average molecular mass.

IX. SAMPLE PREPARATION

A sample preparation step is often necessary to isolate the components of interest from a sample matrix. Sample preparation is often the major source of error in analytical procedures as practitioners are often required by law to use traditional methods.

Ideal sample preparation technique should be simple, solvent free, efficient, and inexpensive. EPA method 3600C gives general guidance on the selection of clean-up methods that are appropriate for various target analytes.

A sample pretreatment will:

i. Improve accuracy
ii. Improve detectability
iii. Improve selectivity by removal of interfering matrix

A result is reproducible if the sample to be analyzed is fully representative of the material to be tested. That means that the samples taken can be equated with the entire batch.

We can distinguish off-line and on-line procedures.

A. Lyophilization

Relatively large samples containing water-soluble analytes are frozen in a dry ice-acetone bath or in liquid nitrogen. Subsequently, the frozen samples are placed in the freeze dryer where water is removed by vacuum sublimation. After freeze drying, the residues can be dissolved in a suitable organic solvent.

B. Ultrafiltration

Ultrafiltration involves the use of specialized membranes that allow rapid and gentle concentration or removal of molecules based on their molecular weight. Ultrafiltration membranes consist of a very thin and dense layer on top of a macroporous support that has progressively larger open spaces on the downstream side of the membrane. Substances that pass through the membrane will also pass easily through the macroporous support. Concentration can be accomplished because molecules smaller than the molecular weight cut-off of the membrane flow through. Molecules larger than the membrane cut-off will be retained on the sample side of the membrane. Performances are affected by pressure. As the pressure increases so does the flow rate but there is a resistance from the concentrated layer on the surface of the membrane. This phenomenon is called concentration polarization.

Membranes are usually made out of cellulose or polysulfone.

Porosity of membrane determines the size of molecules concentrated. In the supported liquid membrane device analytes are extracted in a flow system from an aqueous sample through a hydrophobic membrane liquid into a second aqueous solution. The impregnated membrane is clamped between two circular PTFE blocks. Two types of transport mechanisms across the membrane are in use: pH gradient or ion pairing formation.

C. Dialysis

Dialysis is a method used to separate molecules through a semi-permeable membrane separating two chambers. The concentration gradient of the components across the membrane drives the separation. Dialysis is used for removal of excess low-molecular-weight solutes. Analytes small enough to diffuse through the pores of the membrane are collected.

Microdialysis probes are implanted into the area of interest and slowly perfused with a solution usually matching the fluid outside. The probe is equipped with a membrane through which substances pass due to the concentration gradient. It can be coupled on line to liquid chromatography (HPLC), capillary electrophoresis (CE), or mass spectrometry.

The flux through a dialysis membrane is described by Fick's law:

$$I = -D \cdot A/\tau * dc/dx$$

where

- I is the flux (mol/s)
- D is the solute diffusion coefficient (m^2/s)
- A is the membrane area (m^2) τ: is the tortuosity of the membrane
- dc/dx is the concentration gradient across the membrane mol/m^4
- D is obtained from the Stocke Einstein equation,

$$D = k \cdot T / 6\pi \eta r$$

- k is the Boltzmann's constant
- T is the absolute temperature (^oK)
- η is the viscosity of the medium
- r is the radius of the molecule

The smaller the molecule, the larger the diffusion coefficient and the higher the flux. The relative recovery or the dialysis factor is the ratio of the dialysate (analyte in the outgoing liquid) to the concentration outside the membrane.

There are three modes of conducting a microdialysis experiment:

Perfusion and stirring are continuous over the monitoring period

Perfusion is carried out only during sampling but the stirring is maintained

Perfusion and stirring are carried out during sampling only

D. Liquid/Liquid Extraction (LLE)

This sample pretreatment is mainly devoted to organic compounds which can be removed from an aqueous solution by extracting them into a water-immiscible solvent. Chelation or ion pairing between large and poorly hydrated ions and chelating agent may form neutral compounds which can be extracted by organic solvents.

When two immiscible solvents are placed in contact, any substance soluble in both of them will distribute or partition between the two phases in a definite proportion. According to the Nernst partition isotherm, the following relationship for a solute partitioning between two phases a and b is

$$\frac{(A)_a}{(A)_b} = K_d \quad K_d \text{ is the partition coefficient}$$

$$(A)_a \Leftrightarrow (A)_b \text{ very often } (A)_{aq} \Leftrightarrow (A)_{org}$$

It assumes that no significant solute-solute interactions or strong specific solute-solvent interaction occurs. The K_d value is constant when the distributing substance does not chemically react in either phase and temperature is kept constant.

The fraction extracted R is related to K_d by

$$\frac{C_o V_o}{C_o V_o + C_w V_w} = K_d V/1 + K_d V$$

C_o and C_w represent the solute concentration in organic (o) and water (w) phases, respectively. V_o and V_w are volumes of organic and aqueous phases $V = V_o / V_w$.

It is possible to increase the extent of extraction with a given K_d by increasing the phase volume ratio. When performing micro LLE the analyst works with an extreme ratio of extracting solvent/extracted liquid (for example, 1/800). Another way is to carry out a second and a third extraction. After n extractions the final concentration of the compound in the aqueous phase is

$$Cw_n = C_w \left[\frac{Vw^n}{V_W + K_d V_0} \right]$$

An extraction process is more efficient if it is performed with several small portions of solvents.

Solubility increases as the values of solubility parameter δ of the solute and the solvent are close.

$$\text{Ln } K_d = \frac{\overline{V}_s}{RT} [(\delta_s - \delta_i)^2 - (\delta_j - \delta_s)^2]$$

$\overline{V}_s$ is the molar volume of the distributing solute, δ_s is its solubility parameter, and δ_i and δ_j are the solubility parameters of the pair of immiscible solvents.

It must be kept in mind that some species may exist under different forms in aqueous media. An acid, for example, must be written in this form:

$$HA \Leftrightarrow A^- + H^+$$

$$K_d = \frac{(HA)_0}{(HA)_w} = \frac{(HA)_0}{(HA)_{aq} + (A^-)_{aq}}$$

P_{ow} is the partition coefficient of a solute between octanol and water. It is a common measure of hydrophobicity. The usual measurement for Log P_{ow} is the shake flask method where a compound is shaken in an octanol-water mixture. After equilibrium the concentration is measured in one or both phases. Reversed phase HPLC has also been extensively used. Correlation plots of Log P_{ow} against retention time or capacity factors are drawn.

High values of Log P_{ow} give guidelines for extraction.

The single drop extraction is a micro LLE method in which a single drop of organic solvent is contained at the end of a PTFE rod. The procedure is as follows: 2 microliters of organic solvent are drawn into a microsyringe; the needle of the microsyringe is passed through the sample via valve and immersed in the aqueous sample; the syringe plunger is depressed to expose the solvent to the sample; the drop is drawn back into the syringe; and the needle is removed from the sample vial. Usually the needle is inserted into the hot injector of a GC instrument (64).

Microporous membrane liquid-liquid extraction (MMLLE) is a continuous liquid-liquid extraction proceeding via a hydrophobic membrane. The microporous membrane is sandwiched between two immiscible liquid phases: one aqueous and the other an organic solvent. The membrane is wetted with a suitable organic solvent that fills the pores of the membrane. The mass transfer process takes place between the two phases via the pores of the membrane (65).

E. Solid-Phase Extraction (SPE)

This is the most widely used method. Analytes (mainly organics) are trapped by a suitable sorbent by passing through a plastic cartridge containing an appropriate support. A selective organic solvent is used to wash out the target analytes. SPE is rapid and relies upon chromatographic retention and Log Pow. It can be easily automated. Off-line procedures are inexpensive. On-line devices are readily available from many companies.

1. Off-Line Methods

A typical SPE cartridge is displayed in Figure 47.21.

Sorbents are very similar to the liquid chromatography stationary phase. The analyst can take advantage of:

i. Non-polar interactions (hydrophobic): typically octadecyl modified silica, polystyrene, -divinyl benzene copolymers, or carbon-based sorbent.
ii. Polar interactions through hydrogen bond, for example. In this mode sorbents are: bare silica, polar-bonded silica, or polyamide.
iii. Ion exchange: benzene sulphonic acid (cation exchange) quaternary amine (anion exchange).
iv. Immuno sorbents: the lack of selective sorbents to trap organic analytes in water is certainly the most significant weakness of the SPE technique.

The most popular format is the cartridge filled with 40–60 μm d_p packing materials. The most second popular format is the disk which allows higher flow rates without channeling effects. One format devoted to high throughput

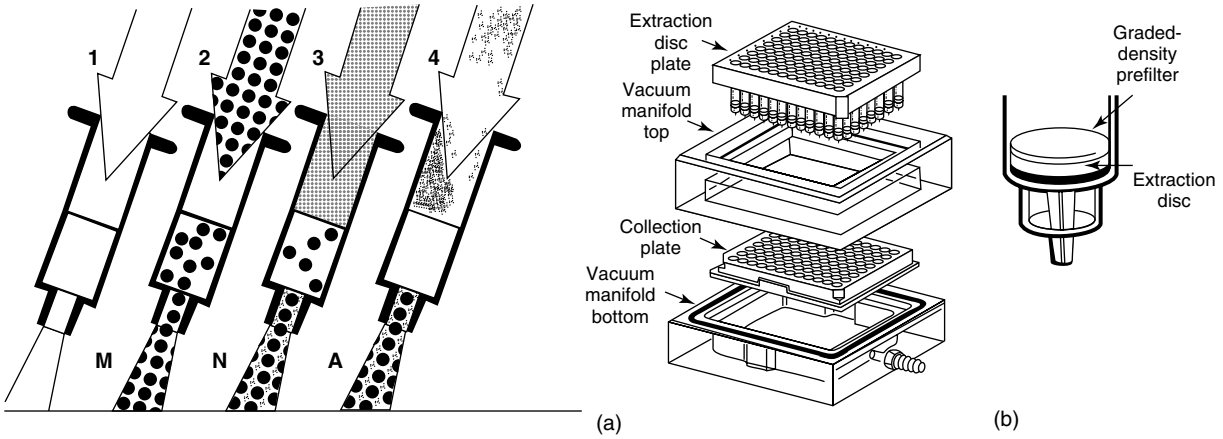

FIGURE 47.21 A SPE cartridge (far left), a 96 well plate format (a), and an extraction disk (b).

applications is the 96 well plate format (Figure 47.21) designed to fit automated plate handling systems.

The SPE technique procedure is as follows: conditioning, sample application, washing, and elution.

The adsorbent must be wetted. With bare silica no problem generally occurs but problems may occur with hydrophobic sorbents. In this case adsorbent must be treated with a suitable solvent. Methanol is preferred for most applications; however, other solvents which are miscible with water such as isopropanol, tetrahydrofuran, or acetonitrile are convenient as well. Conditioning is achieved with about 2–3 column volumes of solvent. Then 1–2 column volumes of the sample solvent are poured through the column. After this step the phase must not run dry. After adsorption of the sample molecules the phase may run dry through either a water jet pump or flushing with inert gas.

Elution is then performed with a strong solvent to elute with the lowest possible volume.

Capacity is the quantity of sample molecules retained per unit quantity of adsorbent. Capacity depends on solute size. It lies in the range of 4 to 60 mg/g of packing.

Breakthrough of solutes occurs when they are no longer retained by the sorbent. Overloading beyond the sorbent capacity may also lead to breakthrough of analytes. The breakthrough volume can be measured from the breakthrough curve obtained by monitoring the signal of the effluent from the extraction column (Figure 47.22).

V_b is usually defined at 1% of the initial absorbance and corresponds to the sample volume that can be handled without breakthrough.

V_r is the retention volume of the analyte.

V_m is defined at 99% of the initial absorbance.

The method is time consuming. Another method is proposed: a small volume spiked with a trace concentration (μg/L) level of all the analytes is percolated through the cartridge and peak areas are recorded. The first volume is selected so that breakthrough does not occur for any solute. The sample volume is then increased and the concentration decreased in order to have a constant amount of analytes in the percolated samples. In this mode peak areas remain constant. The breakthrough volume of an analyte is calculated when the peak area begins to decrease and the corresponding recovery can be also calculated by dividing the peak area obtained for the sample volume by the constant peak area obtained for sample volumes before breakthrough.

Prediction of breakthrough volume is important for selecting a convenient sorbent and consequently the amount of sorbent (66).

i. Hydrophobic sorbents: n alkyl silicas are by far the most utilized. A large number of applications on such sorbents has been published. The drawbacks (as with every bonded silica) are the poor stability in very acidic or basic media, the relatively low capacity for polar solutes, and the low recovery of basic analytes.

   From liquid chromatography we know that in reversed phase mode

$$\text{Ln } k = \text{Ln } k_w - S\,\phi$$
$$\text{or Ln } k = \text{Ln } k_w - b\phi - a\phi^2$$

   where ϕ is the organic modifier volume percent in the binary mobile phase (water/modifier).

   Ln k_w can be estimated by a graphical extrapolation to zero modifier content. Ln k_w represents the hypothetical capacity factor of the solute with pure water as eluent. Since Ln k_w is very often correlated with Log P octanol/water, it is often taken as a hydrophobicity constant. Values of Ln k_w may be as high as 3–4 which means that large sample volumes with trace amount of solutes can be handled.

   Styrene Divinyl Benzene copolymers (PS-DVB), either porous or rigid, are stable over the whole pH range. Calculated Ln k_w values on these sorbents are higher than those on C_{18}. Consequently, moderately polar compounds which are not retained by C_{18} silica are more

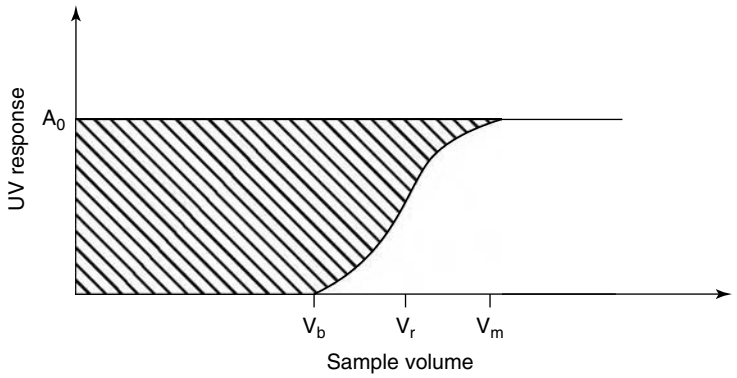

FIGURE 47.22 Breakthrough curve.

readily concentrated on these sorbents. Carbon-based sorbents are gaining acceptance since the availability of porous graphitic carbon. Data obtained with this support demonstrate that it exhibits high retention for apolar compounds but some differences with PS-DVB and C_{18} bonded silica are observed. Hydrophilic-lipophilic polymers do not require equilibration prior to extraction of the analytes.

Selection of eluting solvent is performed through knowledge of eluting strength ε^0 of the solvent in the chromatographic mode.

ii. Use of polar adsorbents is less advocated. Behavior of solutes is well understood since a lot of chromatographic data can be retrieved from TLC (thin layer chromatography) experiments. Flash chromatography is often a new version of silica-based cartridges. Flash chromatography is utilized for laboratory-scale separation. The apparatus is a sintered funnel partially filled with the sorbent (mostly bare silica or reverse phase silica). The mixture of compounds to be purified is adsorbed on the top of the sorbent and the funnel is connected to a flask under vacuum. The vacuum is maintained while the solvent is added to the surface of the column. The solvent is sucked through and collected in the flask.

iii. By pH adjusting many solutes can be ionized (e.g., carboxylic acids) and trapped on ion exchangers. Owing to pH stability resins are widely used. The drawback comes from high amounts of inorganic ions which easily overload the capacity of the sorbent. SPE products of the mixed mode type are gaining acceptance. Most of them are a mixture of hydrophobic and ion exchange materials.

iv. Classical SPE sorbents suffer from a lack of selectivity. Many compounds present in the sample and belonging to the same range of polarity as the target analytes are co-extracted, thus making difficult the determination of analytes of interest. A biological approach consists of developing antibodies against a target molecule. These antibodies are immobilized onto a solid phase to produce an immunosorbent. The most common approach involves covalent bonding of the antibodies onto activated silica or sepharose. Another method is the sol-gel one, which consists of encapsulating antibodies in the pores of a hydrophilic glass matrix. As usual, there are two procedures: off-line and on-line. Main requirements are cross reactivity (affinity towards compounds with a structure similar to the antigen), capacity (defined as the total number of immobilized active antibodies), and extraction recovery. It is now possible to produce antibodies against some target compounds including some small molecules such as pesticides. For example an immunosorbent made with polyclonal anti-isoproturon antibodies covalently bound to a silica sorbent is able to concentrate several phenylureas. Due to the high selectivity, phenylureas can be detected at 0.1 μg/L level in waste waters (67).

2. On-Line Methods

On-line coupling SPE to either LC or GC is easily performed. In the simplest way a precolumn is placed in the sample loop position of a six port switching valve. After conditioning, sample application, and cleaning via a low-cost pump the precolumn is coupled to an analytical column by switching the valve into the inject position. The solutes of interest are directly eluted from the precolumn to the analytical column by an appropriate mobile phase.

The sequence can be fully automated, for example, in the Prospekt system (69).

F. Solid-Phase Micro Extraction (SPME)

This process uses a 1 cm length of focused silica fiber, coated on the outer surface with a stationary phase and bonded to a stainless steel plunger holder that looks like a modified microliter syringe (68). The fused silica fiber can be drawn into a hollow needle by using the plunger. In the first process, the coated fiber is exposed to the sample and the target analytes are extracted from the sample matrix into the coating. The fiber is then transferred to an instrument for desorption (Figure 47.23). Miniaturized SPE devices were recently designed by Millipore. These Zip Tips™ are used with Maldi –TOF.

G. Clean-Up

Extracts obtained from either LLE or SPE contain analytes and other compounds which may interfere in the chromatographic separation. A clean-up is required. The most widely used is fractionation by LC. Extract is loaded onto a chromatographic column packed with an appropriate sorbent (silica, alumina, florisil, bonded silica), and step elution with solvents is carried out. Each fraction is collected and submitted to chromatography. Derivatization prior to fractionation is sometimes performed.

Coupling two sorbents in SPE procedure, for example, hydrophobic sorbent and ion exchange in series, is efficient.

A chart on sample preparation is available upon request from LC-GC International.

X. VALIDATION

Evaluation and validation of analytical methods and laboratory procedures are of paramount importance since the quality of produced chemical information must be

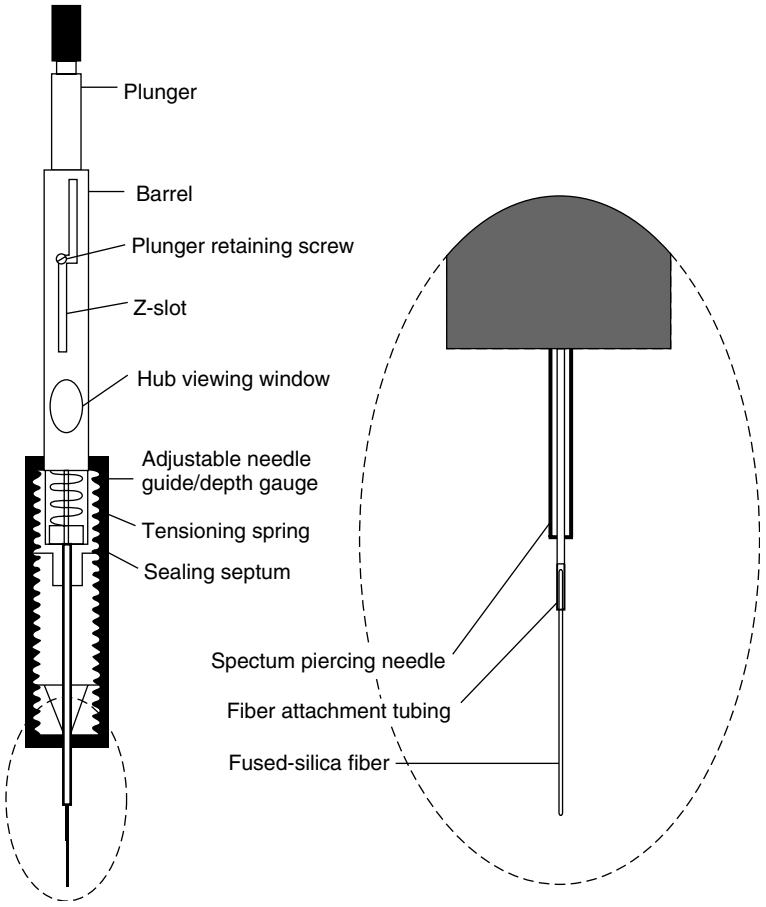

FIGURE 47.23 SPME system.

acknowledged by the customer as the end user of this information. A recognition of quality demands is achieved through accreditation or certification based on international quality standards as issued for example by ISO or OECD. The ideal validated method for food control was defined by the FAO, Food and Nutrition Paper 68, Validation of Analytical Methods for Food Control, Report of FAO/IAEA Expert Consultation FAO/UN Rome, 1998. The ideal validated method is one that has progressed fully through a collaborative study in accordance with internationally harmonized protocols for the design, conduct, and interpretation of method performance studies. This usually requires a study design involving a miniumum of five test materials, the participation of eight laboratories reporting valid data, and most often includes blind replicates or split levels to assess within laboratory repeatability parameters.

Validation begins at the vendor's site, in the structural validation stage. During this stage, the analytical instrument and software are developed, designed, and produced according to Good Laboratory Practice (GLP) and/or the International Organization for Standardization (ISO) guidelines. The FDA has published draft guideline 21 CFR Part 11, which focuses on software validation of computer systems (Draft Guidance for Industry: 21 CFR Part 11 Electronic Records; Electronic Signatures, Validation, U.S. Food and Drug administration, August 2001.

21 CFR Part11 has specific requirements that involve back-up and recovery of chromatographic data.

Calibration is a set of operations that establish, under specified conditions, the relationship between values of quantities indicated by a measuring instrument or measuring system, or values represented by a material measure or a reference material and corresponding values realized by standards. Calibration constitutes the link between materials and analyzed samples that is necessary for traceability of analytical results.

A. Detection

Dynamic range is that range of concentrations of the test substance over which a change in concentration produces a change in detector signal.

The lower limit of the dynamic range is defined as the concentration producing a detector output signal equal to a specified multiple of the detector short-term noise level.

The upper limit of the dynamic range is the concentration at the point where the slope of the curve obtained

by plotting detector response as a function of concentration becomes zero.

Linear range is that range of concentrations over which the sensitivity (S) is constant to within a defined tolerance (Figure 47.24).

Limit of detection (LOD) is defined as the lowest concentration of an analyte in a sample, below which the analytical method cannot reliably detect a response.

A widely used detection limit technique is the 3 σ approach which is mandated for EPA testing. The standard deviation in concentration units is calculated by computing the standard deviation of blank replicates (≥7) and dividing by the slope of the calibration curve. The number is multiplied by the appropriate value of the Student's t for the chosen α and for n−1 degrees of freedom. The method used to determine LOD should be documented and defined.

Limit of quantification (LOQ) is the smallest quantity of compound to be determined in given experimental conditions with defined reliability and accuracy. A signal to noise ratio of ten is adequate.

$$\text{Limit of detection} = (3Sx/y)/b$$

$$\text{Limit of quantification} = (10Sx/y)/b$$

where b = slope of best fit regression line and Sx/y = estimate of residual standard deviation.

Both LOD and LOQ are affected by chromatographic conditions. Peak height is proportional to the solute concentration in the sample and to the injected volume. If one wants to improve the plate count of the column he or she may lose sensitivity.

Detector's noise is short-term noise in the maximum amplitude of response for all random variations of the detector signal of a frequency greater than 1 cycle per minute. Long-term noise is similar to short-term noise except that the frequency range is between 6 and 60 cycles per hour. Drift is the measure of the amplitude of the deviation of detector response within 1 hour.

B. Repeatability (ISO 3534)

Qualitative means the closeness of agreement between the results obtained by the same method on identical test material under the same conditions (same operator), same laboratory, same apparatus, and short interval of time (same day).

Quantitative is the value below which the absolute difference between two single test results obtained under the above conditions may be accepted to lie with a specified probability (usually 95%).

It is generally assessed by a minimum of nine determinations over the prescribed range for the procedure, e.g., at three concentrations, three replicates each, or by a minimum of six determinations at 100% of the test concentration.

C. Reproducibility (ISO 3531)

Reproducibility expresses the precision between laboratories.

Qualitative means the closeness of agreement between individual results obtained with the same method on identical test material but under different conditions (different operators, different apparatus, different times, interday).

Quantitative is the value below which the absolute difference between two single test results on individual material obtained by operators in different laboratories using the standardized test method may be expected to lie within a specific probability (usually 95%).

D. Selectivity

Selectivity is a measure of the extent to which the method is able to determine a particular compound in the matrices

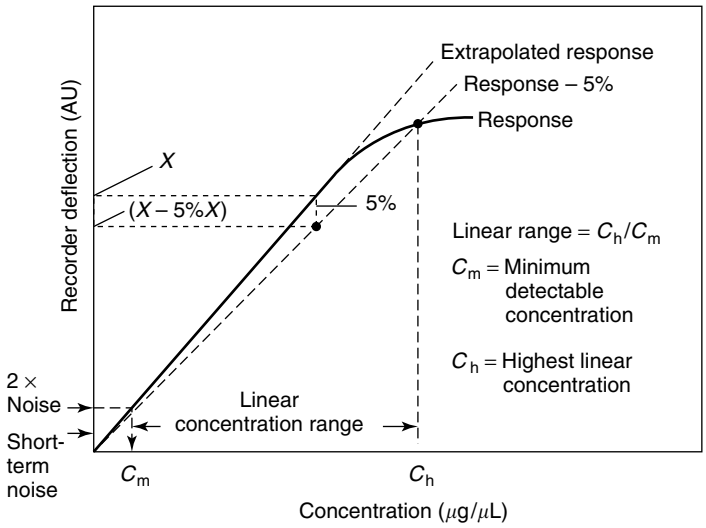

FIGURE 47.24 A calibration curve.

without interference from matrix components. Specificity is often used instead of selectivity.

E. Linearity

Linearity of analytical procedure it is the ability of the method to elicit test results that are directly proportional to analyte concentration (or mass) within a given range.

The analyst must determine:

- linear slope
- y intercept
- correlation coefficient
- relative standard deviation
- normalized intercept/slope.

F. Accuracy

Accuracy measures the difference between the true value and the mean value obtained from repeated analysis. Accuracy can be assessed by analyzing a sample of known concentration (reference material) and comparing the measured value to the true value. One can compare test results from the new method with results from an existing method. Another procedure is to spike the analyte in blank matrices or to perform standard additions. Analysis of variance (ANOVA) estimates the within run precision and the between run precision.

G. Precision

Precision is the measure of the degree of repeatability of an analytical method under normal operation and is normally expressed as the percent relative standard deviation (RSD) for a statistically significant number of samples.

H. Reliability

Reliability means the probability that the results lie in the interval defined by two selected limits. It gives a rigorous method for evaluating the correctness of a method of analysis in relation to two limits for error.

I. Ruggedness

Ruggedness is the capacity of an analytical method to produce accurate data in spite of small changes in experimental conditions (for example, small flow-rate variations in HPLC). The robustness of the method is evaluated by varying method parameters such as percent of organic modifier, pH of the buffer, column temperature, flow rate, etc.

J. Extraction Recovery

Percentage recovery of the extraction is determined by comparing the detector response of an extracted sample with that of a directly injected standard.

K. Internal Standard

Mostly used in chromatography and capillary electrophoresis, the internal standard monitors the behavior of sample solutes to be analyzed and quantitatively determined.

Internal standard must fulfill some requirements:

- It must exhibit retention behavior similar to the solutes.
- It must exhibit chemical functionalities and structure similar to the solute.
- If a derivatization step is involved in the method, the same reaction must be applied to the internal standard.
- If a sample pretreatment is required, it is better to submit the internal standard to the sample pretreatment and check recovery.

Analysis procedure

A standard solution contains the sample and the internal standard at concentrations C_T and C_E, respectively.

$$m_T = C_T{*}V_T = K_T \cdot A_T$$

$$m_E = C_E{*}V_E = K_E \cdot A_E$$

V_T, V_E are the injected volume of the sample and the internal standard. K_T is the response coefficient of the sample and A_T the peak area. K_E is the response coefficient and A_E the peak area of the internal standard. Usually $V_T = V_E$

The concentration ratio is kept constant whatever the injection volume. A sample solution contains the substance to quality at concentration C_X. Internal standard is added at the same C_E concentration as in the previous standard solution. We thus can write:

$$m_X = C_X \cdot V_{inj} = K_X \cdot A_X$$

$$m_E = C_E \cdot V_{inj} = K_E \cdot A'_E$$

$A'_E \neq A_E$ since two injections are performed. V_{inj} is constant.

$$\frac{C_X}{C_E} = \frac{K_X}{K_E} = \frac{A_X}{A'_E}$$

$$\frac{K_X}{K_E} = \frac{K_T}{K_E}$$

then

$$\frac{C_X}{C_E} = \frac{C_T \cdot A_E}{C_E \cdot A_T} = \frac{K_X}{K_E}$$

$$\frac{C_X}{C_E} = \frac{C_T}{C_E} \cdot \frac{A_X}{A_T} = \frac{K_X}{K_E}$$

$$C_X = C_T \cdot \frac{A_E}{A_T} \cdot \frac{A_X}{A'_E} \text{ if } C_E \text{ is kept constant}$$

It is necessary to check the detector response. Standard solutions are prepared.

$$C_{1T} + C_E \longrightarrow A_{1T} + A'_E$$

$$C_{2T} + C_E \longrightarrow A_{2T} + A''_E$$

$$C_{3T} + C_E \longrightarrow A_{3T} + A'''_E$$

Sample solution $$C_X + C_E \longrightarrow A_E + A_E$$

XI. CONCLUSIONS

The large volume of available literature on HPLC is highly indicative of the wide use of the technique. Columns are being constantly improved and are highly reproducible. Progress in instrumentation is based on the hyphenation with mass spectrometry which can be considered as *the* detector. Looking for a separation, one is 99% sure that it has been carried out previously. The drawback is that the published separation generally does not fit the analyst's purpose since it has been performed on standards or another matrix, but it is of great help. Analysts should not forget that selectivity is cheaper to achieve than efficiency.

The reader can find more information on chromatography in Refs. 70 to 73; on mass spectrometry in Refs. 74 to 77; and on sample preparation in Refs. 78 and 79.

ABBREVIATIONS AND ACRONYMS

%	Percent (parts per hundred)
A	Absorbance (A = log [1/T])
AAS	Atomic absorption spectrometry
ACN	Acetonitrile
amu	Atomic mass unit
APCI	Atmospheric pressure chemical ionization
API	Atmospheric pressure ionization
AU	Absorbance units
AUFS	Absorbance units full scale
CCD	Charge-coupled device
CE	Capillary electrophoresis
CEC	Capillary electrochromatography
CL	Chemiluminescence
CLND	Chemiluminescent nitrogen detection
CMC	Critical micelle concentration
CSP	Chiral stationary phase
DAD	Diode-array detection
ESI	Electrospray ionization
FTIR	Fourier transform infrared
GC	Gas chromatography
GLP	Good laboratory practice
HETP	Height equivalent to a theoretical plate
HPLC	High performance liquid chromatography
IC	Ion chromatography
ICP	Inductively coupled plasma
IEC	Ion-exchange chromatography
IR	Infrared
IS	Internal standard
ISO	International Organization for Standardization
LDR	Linear dynamic range
LIF	Laser-induced fluorescence
LIFD	Laser-induced fluorescence detection
LLE	Liquid liquid extraction
LSC	Liquid-solid chromatography
LSD	Light scattering detector
LSS	Linear solvent strength
MALDI	Matrix assisted laser desorption ionization
MCP	Multi channel plate
MIP	Molecular imprinted polymer
MMLLE	Micro membrane liquid liquid extraction
MS	Mass spectrometer or mass spectroscopy
MW	Molecular weight (also mol wt, M)
NMR	Nuclear magnetic resonance
NP	Normal phase
NPC	Normal phase chromatography
PDA-UV	Photodiode-array UV
PS-DVB	Polystyrene-divinylbenzene
Q-TOF	Quadrupole time of flight
RI	Refractive index
RP	Reversed phase
RP-HPLC	Reversed-phase high performance liquid chromatography
SAX	Strong anion exchanger
SCX	trong cation exchanger
SIM	Selected ion monitoring
SPE	Solid-phase extraction
SPME	Solid-phase microextraction
SSI	Sonic spray ionization
TLC	Thin layer chromatography
TOF	Time of flight
UV	Ultraviolet
UV-VIS	Ultraviolet-visible

48 The Use of Mass Spectrometry in Food Analysis

Sherri B. Turnipseed[*]
Animal Drug Research Center, U.S. Food and Drug Administration

CONTENTS

Mass spectrometry (MS) is a powerful modern analytical technique which provides detailed structural information for molecules. This capability, and the fact that it easily interfaces with commonly used chromatographic techniques, makes it a very useful tool for food analysis. MS can be used to characterize food composition or to monitor adulteration of foods by residues or other extraneous substances. A recent review by Careri et al. [1] is an excellent reference that demonstrates the wide scope of MS in the analysis of food, including the analysis of natural and xenobiotic substances as well as metals in food products. An earlier review by Careri et al. [2] described the use of LC/MS for residue analysis in food.

This chapter is not meant to be an exhaustive list of all references pertaining to the use of MS for food analysis, but rather is intended to further illustrate the many different applications in which MS has been used to characterize food. First, the types of modern instruments and experiments that may be used to perform MS on food samples are briefly described. An overview of how MS has been used to determine the natural components of food is followed by a description of the use of MS to determine residue level contaminants such as pesticides, animal drugs, mycotoxins, and packaging materials in foods. Further illustration of how MS has been used to study foods for a variety of purposes is given using examples of specific commodities (bovine milk and berries). Finally, some of the emerging trends in the analysis of food by MS are discussed.

I. MASS SPECTROMETRY (MS): INSTRUMENTS AND TECHNIQUES

The MS experiment consists of forming ions, separating those ions based on differences in their mass/charge (m/z) ratio, and detecting (counting) the number of ions at each m/z value. Although MS has changed dramatically in the past few decades, this basic process applies to modern techniques as well as those performed with more traditional MS instruments. A complete review of the fundamentals of MS theory is beyond the scope of this chapter, but many such resources are available [3, 4].

MS is an important modern analytical technique for the analysis of food because of the type of detailed information that is obtained. Traditionally, using an electron impact (EI) ion source, the analyte is introduced in the gas phase into an evacuated chamber and is bombarded with an electron beam of 70 eV. As a result of this interaction, the compound loses an electron and becomes a positively charged radical cation. In addition, the amount of energy used is generally enough to break bonds in the molecule and provide ionized fragments. The resulting fingerprint of ions at different m/z values with varying intensities can be used to determine a probable identity of the original analyte. This process of interpreting mass spectra to deduce molecular structure from EI experiments has been well studied and described [5].

In addition to collision with a high energy electron beam, there are many other methods of ionizing compounds so that they can be analyzed by MS. For example,

[*] The opinions expressed are those of the author and do not necessarily reflect the official views of the U.S. FDA.

positive ion chemical ionization (CI) transfers a proton from an ionized reagent gas, such as methane or isobutane, to an analyte with higher proton affinity to form a protonated (ionized) compound. Alternatively, a highly electronegative compound can capture thermalized (slower) electrons to form a negative ion when a reagent gas is present in the ion source. Desorption from high energy sources such as a lasers, fast atoms, high fields, etc. can also be used to form and eject ions from solids or liquids into the lower pressure region of an MS instrument. Matrix assisted laser desorption ionization (MALDI) has become a very popular method for introducing large biomolecules such as proteins into a mass spectrometer and has helped revolutionize the study of these compounds in many biological applications.

The introduction of two interfaces, electrospray ionization and atmospheric pressure chemical ionization, has allowed LC/MS to become widely used and commercially available. In electrospray ionization (ESI) the effluent from an LC is sprayed, usually pneumatically assisted with nitrogen gas, into a high electric field (3–5 kV) at atmospheric pressure. This process creates a stream of charged droplets that become smaller as they are accelerated into the field. Charged particles in the solution are ejected as the droplets evaporate or are released when the droplets explode as the surface forces become too high. The ionized molecules can then be sampled and accelerated through small orifices into a high vacuum region of the instrument where they can be separated and detected. One advantage of ESI is that multiply charged ions can be formed (e.g., on proteins with multiple sites available for protonation). This allows compounds with very high molecular weight to be analyzed with MS instruments utilizing traditional mass range (m/z 1000–2000) ion separators. With atmospheric pressure chemical ionization (APCI), the LC effluent is again sprayed into an atmospheric pressure chamber with nitrogen gas. However, in this case the LC mobile phase (water, methanol, etc.) is vaporized and ionized by a corona discharge. The ionized mobile phase can then act as a chemical ionization reagent gas and perform proton transfer reactions with the analyte to generate charged molecules. The bulk of the mobile phase must then be thermally vaporized before entering the lower pressure region of the MS instrument.

In contrast to electron ionization, the alternative ionization methods of CI, ESI, and APCI are relatively soft (low energy) ionization techniques. Therefore, not as many fragment ions are formed by the breaking of chemical bonds during these processes. As a result, the mass spectrum obtained may only consist of one peak, the protonated (or deprotonated) molecular ion. While these data give valuable information regarding the molecular weight of an analyte, structural ions are not available. For this reason, tandem MS or "MS/MS" is often used in conjunction with these ionization techniques to yield additional structural details. In the MS/MS experiment, one ion is isolated from all other ions, and a secondary energy source (such as bombardment with energized argon or helium gas) is introduced to break that ion into fragment ions. A second stage of ion separation is then performed to yield another mass spectrum consisting of only ions created from the collision induced dissociation of the initial parent ion. This secondary spectrum is referred to as a product ion spectrum and contains more information regarding fragments of the original molecule. For example, one common MS/MS instrument used is the triple quadrupole. After an ion is formed and introduced into the MS, it can be isolated from others using a quadrupole ion filter. A second quadrupole, which uses only RF frequency, acts as a collision cell, where the ion is impacted with argon. The third quadrupole can then be used to separate ions formed in the collision cell. This instrument can be used in other modes, but this is a common method to obtain structural information for a specific analyte. An ion trap separation device can also be used to obtain information-rich product ion spectra from molecular ions created from soft ionization techniques.

Mass spectrometers can be programmed to optimize for selectivity, specificity and sensitivity for any given compound. For example, when looking for a specific analyte in a complex mixture, an MS method can be programmed to scan for only one ion or set of ions (selected ion monitoring, or SIM). With an MS/MS instrument, specific ion transitions or parent-product ion pairs can be acquired (selective or multiple reaction monitoring, SRM or MRM). These techniques can greatly improve detection and confirmation limits for residues in food. Another valuable MS experiment that has been used in food analysis, for component characterization as well as residue analysis, is the measurement of the exact mass of molecules of interest using high resolution instruments. Time-of-flight analyzers have been used to obtain exact mass information for large biomolecules; these are often coupled to a MALDI MS source.

The commodities included for consideration under the category of food analysis represent a wide variety of complex matrices of plant and animal origin. In order to analyze a specific compound in a food product by MS, extensive sample preparation and analyte isolation is often required. Examples of some of the approaches used to accomplish this are liquid-liquid extraction, solid-phase extraction, and immunoaffinity techniques. The goal of these procedures is to remove as many matrix components as possible, while concentrating the analyte of interest. Often there is a trade-off between maximum recovery of the residue and the time and effort required to perform the analysis. This becomes more of an issue as requirements for high sample throughput increases.

Regardless of the sample preparation and extraction procedures used, a chromatographic separation step is

usually applied prior to MS analysis when analyzing components or residues in food. If the compounds of interest are sufficiently volatile and thermally stable, GC/MS is the preferred technique. Electron ionization is the most common MS technique used with GC because it gives structurally rich spectra. Chemical ionization with either positive or negative ion detection, is also possible with GC/MS. The most common LC/MS methods involve the use of a reverse-phase LC system interfaced to an electrospray or APCI MS source. Tandem MS can then be used to obtain additional structural ions. Often many compounds of interest in food analysis can be ionized using either ESI or APCI, and the best interface for each analyte may have to be determined empirically. Helpful resources detailing many more of the practical aspects for implementation of successful LC/MS analyses are also available [4].

II. MS ANALYSIS FOR DETERMINATION OF FOOD COMPOSITION

MS has been used to characterize the natural composition of food products. Specifically, this can be used to describe the profile of major components in a food product, to differentiate between similar products, or to measure small amounts of naturally occurring substances which are believed to be either beneficial or deleterious. The type of MS analysis used for the characterization of food components depends on the nature of the analytes. Many of the articles cited below are reviews and should serve as a guide to the reader looking for a specific type of analysis or food product.

Several reviews cover MS analysis of major components in foods including proteins and peptides [6, 7]. The analysis of peptides and proteins requires the use of technique that is designed for large non-volatile molecules such as electrospray ionization or MALDI. MS can be used in protein studies to characterize conformational changes or post-translational modifications such as glycosylation or phosphorylation. The information obtained by MS can then be used to help determine how these factors affect food qualities such as flavor, texture and nutritional value. The effect of processing (pasteurization, hydrolysis, etc.) on the structure and function of food proteins can also be examined using MS techniques. Analyses of the proteins associated with milk (casein, whey components lactalbumin and lactoglobulin), cereal (globulins, albumins, glutenins, prolamins), and eggs (ovalbumin, conalbumin, lyzosyme) have been performed using MS. One study characterized the different gluten proteins that are unique to various grains (wheat, rye, barley and oats) in cereal mixtures using MALDI time-of-flight (TOF) MS [8]. A few studies of meat proteins have been performed using MS. In one report, LC/MS using electrospray was used to study the polypeptides from whole and ground meat and how that profile changed during storage of the meat products [9].

The analysis of fatty foods (lipids, oils, fatty acids, etc.) can be accomplished using either GC/MS or LC/MS methods. In one study, GC/MS was used to determine the types and amounts of free fatty acids produced in the ripening of ewe milk cheese [10]. In this study, solid phase microextraction (SPME) was used to extract the fatty acids from the food matrix and the amount of butanoic, hexanoic, octanoic and decanoic acids were measured at part-per-million levels using GC/MS. Alternatively, a direct infusion electrospray MS method was developed to study different nut and vegetable oils and to determine if additional (adulterant) oils were added to olive oil [11]. Razzazi-Fazeli et al. [12] published a determination of cholesterol oxides in processed foods such as butter, lard, and egg powder using LC/MS with APCI and selected ion monitoring.

Characterizing the carbohydrate composition in food is also important. These compounds are difficult to analyze using traditional methods as they are nonvolatile, thermally unstable, and generally do not have a strong UV chromophore. In one food application, the saccharide profiles of caramel from different sources were evaluated using GC/MS after forming trimethylsilyl derivatives. Specific compounds were identified as possible indicators of the authenticity of the caramel product [13]. The carbohydrates found in human milk have been studied after derivatization with 2-aminoacridone using MALDI-TOF and electrospray MS, in addition to spectrofluorimetry [14]. The changes that occur to carbohydrates after processing can also by studied by MS methods. For instance, the starch components in treated potato starch were analyzed using anion exchange chromatography coupled to electrospray MS after enzymatic hydrolysis of the starch polymer [15]. In addition to studying carbohydrate profiles, MS is often used to characterize compounds such as peptides or flavonoids that may also include one or more sugar molecules.

Minor components of food products can also be characterized by MS analysis. Flavor and fragrance components tend to be inherently volatile and thermally stable organic compounds such as ketones, aldehydes, alcohols, and terpenes. GC/MS is the preferred MS analysis technique for these compounds. Isolation from the food product is often accomplished by head-space sampling techniques such as purge and trap or solid phase micro extraction methods [16, 17]. Examples of how these MS techniques are used in flavor analysis for specific food commodities, bovine milk and berries, are illustrated later in this chapter.

Recently there has been a great deal of interest in minor components of foods that may have high nutritional or nutraceutical value. Vitamins such as tocopherols and folates can be measured in food using MS techniques. For example, a method to determine alpha-tocopherol in infant foods (milk and cereal) was developed using

LC/MS (single quadrupole) with an APCI interface [18]. Deuterium- labeled tocopherol was used as an internal standard and detection limits of 2.5 ng/mL were achieved. A LC/fluorescence method for folic acid and 5-methyltetrahydrofolic acid in a variety of foods was validated using a complementary electrospray LC/MS method [19].

Flavanoids, including anthocyanins, may have beneficial antioxidant properties. The identification and quantification of these compounds in different foods is an important aspect of the research to determine the effects these chemicals may have on human health. There are many recent examples of how MS is being used in this emerging area of food analysis including the characterization of anthocyanins in food using LC/MS and capillary electrophoresis [20]. The oxidative phenolic compounds in artichokes have been characterized using electrospray LC/MS [21]. Flavonoid glycosides, such as kaempferol glucoside and others, were studied in almonds [22] using MALDI-TOF MS and in tomatoes using electrospray LC/MS/MS [23]. The distribution of anthocyanins, flavonols, and carbohydrates in different layers of red onion was also studied using electrospray LC/MS [24].

Some minor components in food products are thought to be deleterious and the characterization of these is also important. For example, the health effects of acrylamide residues that can be formed in various fried and baked foods have recently been questioned and can be monitored by LC/MS/MS [25]. Another area of interest is the presence of known cancer causing agents such as polycyclic aromatic hydrocarbons (PAHs) and heterocyclic aromatic amines that may occur in food treated in certain ways, such as frying or smoking. These compounds can also be monitored using MS analysis [26]. In one study, polyaromatic hydrocarbons in liquid smoke flavorings were analyzed by GC/MS, and a higher proportion of lower molecular weight PAHs were found; benzo(a)pyrene was present in a few samples, but at fairly low concentrations [27]. The determination of heterocyclic amines in lyophilized meat extracts was performed using LC/MS with an APCI source and ion trap MS/MS detection. Low part-per-billion levels could be detected [28]. Volatile nitrosamines in dry sausages were also monitored using an APCI LC/MS/MS method [29].

III. MS ANALYSIS IN THE DETECTION OF CONTAMINANTS AND RESIDUES IN FOOD

MS in also used to detect, measure, and identify foreign compounds such as pesticide or drug residues and environmental contaminants in food products. Several types of experiments can be performed when using MS to analyze food commodities for residues including screening, determinative or confirmatory analyses. Historically MS, often in conjunction with GC or LC, has been used for confirmatory analysis to positively identify a residue of concern. Mass spectrometry is the ideal tool to confirm the identity of a residue due to its inherent sensitivity and selectivity. There are established guidelines that define how closely the mass spectrum of an unknown or suspect residue must match that of a standard in order to be considered confirmed [30, 31]. MS methods can also be used to quantitate the amount of residue present. Traditionally, this has been more widespread with GC/MS, but is becoming more standard practice with LC/MS as well [32]. Care must be taken to use appropriate internal standards. If available, isotopically labeled analogues are the preferred internal standard because their response and fragmentation will most closely match that the analyte of interest. Because of its universal nature, MS can also be a powerful tool for screening for multiresidues or even multiclass residues in food analysis, and this application is becoming more common as MS is used more routinely.

Antibiotics are the most common type of drugs given to food animals. These are given both therapeutically and subtherapeutically to prevent disease and increase feed efficiency. The possibility of drug residues remaining in the edible product and the potential human health problems associated with exposure to these residues is a concern with widespread drug use in food animals. Mass spectrometry is commonly used to analyze antibiotic residues in foods [33, 34]. MS was traditionally used as a confirmatory analysis method to identify illegal residues in food. Many of the drugs of concern are polar nonvolatile compounds, so while it used to be more common to analyze derivatized residues by GC/MS, many recent reports utilize LC/MS methods. There are many examples of this including beta-lactam and sulfonamides residues in milk [35, 36], tetracycline residues in various foods [37], and fluoroquinolones and phenicols in aquacultured products [38], as well as many others. In addition to antibiotics, other animal drugs such as hormones can be monitored by MS. An example is a method that uses GC/MS not only to confirm, but also to quantitate anabolic steroids in bovine muscle tissue [39]. An upcoming trend is to use the universal response of the mass spectrometer, along with the capability of LC/MS/MS to provide diagnostic information, to screen for many types of residues with a generic extraction procedure [38, 40].

There is a long record of using MS for the determination and identification of pesticide residues in food products, especially in produce commodities. Historically pesticide residues could be monitored by GC/MS analysis only after extensive sample preparation using large sample sizes and liquid-liquid extraction procedures. Because many pesticides are volatile and thermally stable GC/MS is still the technique of choice for many of these compounds. The use of time-dependent selected ion monitoring GC/MS programs allows for the screening, determination and

confirmation of a large number of pesticides from a single analysis. This technique has been used to determine pesticides containing nitrogen, sulfur, or oxygen in a variety of foods [41]. Alternatively, the analysis of pesticides using GC/MS/MS with an ion trap detector to obtain product ion spectra can yield a very selective and sensitive method for a large number of compounds [42]. A new trend in the analysis of pesticides by GC/MS is the use of more rapid extraction methods. One report describes the use of automated solid phase extraction to isolate organochlorine and pyrethroid residues from a variety of fruits for analysis by GC with electron capture and confirmation by GC/MS [43]. In another example solid phase micro extraction (SPME) coupled directly to GC/MS has been used for the analysis of chlorpropham in potatoes and amitraz in honey at ppb levels [44]. Another innovation in this area is to use low-pressure fast GC coupled to MS for pesticide analysis [45]. In this approach a shorter, wider bore GC column with a thicker film was operated at fast flow rates and low pressure allowing for faster analysis, increased injection sample size and reduced thermal degradation.

Some classes of pesticides are not as amenable to GC/MS due to limitations of volatility or thermal stability, and LC/MS may be the technique of choice for these analytes [46]. For example, the determination of aldicarb and its metabolites in various food extracts has been reported using LC-APCI [47]. Carbamates are another class of pesticides that can be best analyzed by LC/MS. One report describes the isolation of thirteen carbamates from orange, grape, onion and tomatoes by matrix solid-phase dispersion with analysis by LC/MS [48]. These authors determined that both electrospray and APCI were suitable for the analysis of these compounds with similar sensitivity (ppb) and structural information obtained.

Dioxins are a class of compounds that create a particular analytical challenge. Formed as breakdown products from industrial chemicals, these compounds are extremely toxic and have a very long residence time in the environment. Because of this, the potential of very low, yet possibly still toxic, amounts of dioxins entering the food supply is a real concern. Analytical methods must therefore be able to detect part-per-trillion (and sub-ppt) amounts of these compounds in a wide variety of environmental and food matrices. Another challenge is that dioxins exist in many similar forms, or congeners. These compounds may have closely related molecular structure but different toxicological properties. Historically, extensive extraction methods (Soxlet, multi-stage column chromatography, etc.) using relatively large sample sizes were coupled with GC/MS detection [49]. The MS instruments used may need to have high enough resolution to distinguish between compounds with the same nominal molecular weight. Magnetic sector or high-resolution ion trap instruments typically have been employed for this purpose. Recently some of the newer MS techniques have been applied to dioxin analysis including the use of time-of-flight instruments and isotopic dilution quantitation [50].

The formation of mycotoxins is a prevalent problem in foods such as grains and peanuts. The use of MS, especially LC/MS, has allowed for much more efficient monitoring of these toxins. For example, the analysis of aflatoxin can be performed with great sensitivity and selectivity by LC/MS. One recent reference describes the use of MS to identify individual peanuts with high levels of aflatoxin in a processing stream by dipping the nuts into an extraction fluid and analyzing the fluid by MS/MS [51]. Other methods describe the optimized LC/MS APCI conditions for the determination of A-trichothecene mycotoxins in grains such as oats, maize, barley and wheat [52]. Mycotoxins can also occur in fruits and their juice products. LCMS and GC/MS have been used for the analysis of the mycotoxins alternariol and patulin in apples and other fruit [53, 54].

Several acute human illnesses can result from the consumption of shellfish containing marine toxins including diarrhetic shellfish poisoning, amnesic shellfish poisoning and azaspiracid poisoning. Diarrhetic shellfish poisoning is caused by compounds such as okadaic acid, dinophysistoxin, pectenotoxin, yessotoxin, dinophysistoxins, among others. MS has played an important role in the analysis of these compounds, as well as the initial characterization of newly discovered compounds [55, 56]. Domoic acid is a toxin which causes amnesic symptoms. Determination and confirmation of this compound can also be achieved using LC/MS methodology [57]. A series of related toxins, the azaspiracids, can also results in human illness after consumption of affected shellfish. These compounds have been characterized by electrospray LC/MS using an ion trap instrument and a method to quantitate the azaspiracids in mussel tissues has been developed [58, 59].

A recent concern involving packaged food products is that potentially harmful substances from the packaging material may migrate into the food and be consumed. MS can be used to characterize possible contaminants from processing or packaging materials or the degradation of those substances. For example the amount of styrene or styrene oxide or other volatile organic compounds from polystyrene containers and the factors affecting the rate of migration into the food commodity using GC/MS have been reported [60]. Plasticizers in food have also been determined by GC/MS with ion trap detection [61]. Bisphenols, which are breakdown products from canned food coating material, have been measured in a wide range of different canned foods including soup, fruit, infant formula, and meat products using GC/MS methods [62].

The potential threat for adulteration of food by deliberate tampering, either at the manufacturing facility, the retail outlet, or by individual consumers, has always been

a concern and has become more so in recent years. MS can be a very valuable tool for determining what foreign compound may have been added to a product, as well as the possible source of the contamination. Due to the sensitive nature of this work and possible legal and regulatory implication, there are not many references on this subject in the published literature. A few references include the determination of a rodenticide in consumer products [63] and the identification of cocaine in fruit (and syringes found at the same location) in a supermarket tampering case [64].

IV. SPECIFIC APPLICATIONS OF MS IN FOOD ANALYSIS

The use of MS to analyze two common food commodities, bovine milk and berries, is examined in more detail. The major components of bovine milk have been characterized by MS methods. The triacylglycerols in milk have been characterized by LC/MS using APCI as well as by GC/MS [65] after initial prefractionation using both TLC and gel permeation chromatography. LC/MS alone could not resolve the complicated mixture of triacylglycerols, and interpretation was difficult because many compounds shared common fragment ions. Fractions of the mixture were separated using either TLC or gel permeation and subsequent analysis of these portions was used to identify individual triacylglyceraols. GC/MS was also performed on the majority of the fractions and yielded complementary data to assist in the identification of individual components. Using these techniques, 120 triacylglycerols were identified. The whey proteins derived from milk have also been better described using LC/MS with an electrospray interface and time-of-flight MS detection [66]. This study found that the principle proteins in whey (lactalbumin and lactaglobulins) can be extensively modified by glycosylation and oxidation upon processing.

The more volatile compounds in foods or beverages often determine their flavor. The use of SPME coupled to GC/MS has become the method of choice to sample the volatile compounds present in milk [67, 68]. For a more rapid analysis, the GC column can be omitted and the compounds can be analyzed directly by electron impact MS. In this case, a short fused silica transfer line can take the place of an analytical GC column. The MS then acts as an "electronic nose" and pattern recognition techniques are required to distinguish significant differences in milk samples [69].

Phytoestrogens, which include isoflavones, lignans, and coumestans, are a class of compounds that are often a minor naturally occurring component of milk. These compounds can potentially act as endrocrine disruptors and are passed into bovine milk from injestion of compounds present in animal feed. A method was developed to analyze phytoestrogens in milk using LC/MS/MS [70]. An electrospray interface (using both positive and negative ionization) was used along with a triple quadrupole MS operated in the selected reaction monitoring mode. Identification limits for these compounds using this method was determined to be less than 1 μg/L. Analysis of milk samples confirmed the presence of the hydroxylated isolflavones genistein and daidzein and also higher amounts of the metabolite equol.

Potential residual compounds that could be present in milk include industrial compounds, mycotoxins, pesticides and animal drugs. Examples of industrial chemicals that have been analyzed in milk using MS include polycyclic aromatic hydrocarbons [71] and polychlorinated biphenyls [72]. Cyclopiazonic acid is a mycotoxin produced by *Aspergillus* and *Penicillium* genuses in milk. This compound has been analyzed using negative ion electrospray LC/MS with ion trap detection [73]. The authors were able to quantitate over three orders of magnitude with a detection limit of 5 ng/mL. Twenty milk samples were analyzed for cyclopiazonic acid by this method, and three of those samples were found to be contaminated at detectable levels.

Multiresidue methods for pesticide residues in milk have been developed. A method for detection, quantitation, and confirmation of over 100 pesticides using GC with ion trap MS/MS was developed and applied to several different types of foods including milk [42]. The advantage of using the ion trap as a detector, in this method or any other application, is the ability to achieve additional selectivity and sensitivity. This is demonstrated in this method by the ability to obtain very clean traces for individual compounds using specific individual acquisition parameters in very complex food matrices. Another method developed more specifically for milk uses GC/MS (single quadrupole detection) as well as GC with flame photometric detection to quantitate several classes of pesticides including organophosphorous compounds, organochlorine compounds, methylcarbamates, as well as others [74]. Residues were confirmed using high-resolution GC/MS and GC/MS-MS with a hybrid magnetic sector/quadrupole instrument.

Residues of animal drugs can be a potential problem in bovine milk because dairy cows may be treated for illness such as mastisis or respiratory disease. Some drugs are approved for treatment of affected dairy cattle, but they may result in violative residues if appropriate drugs, dosages, and withdrawal times are not used. Antibiotics are the most common drug residues found in milk, and MS has been used extensively to monitor for these residues. MS methods for residues in milk include sulfonamides [36, 75], tetracyclines [76], penicillins and related compounds [35, 77], aminoglycosides [78], and many others [33]. Other types of animal drugs that can be analyzed for in milk by MS methods include anthelmintics such as bendazoles [79].

Berries are another type of food product that have been extensively analyzed and characterized using MS

methods. One primary focus of analytical methods using berries as a matrix is understanding which chemical compounds give the fruit the best flavor and odor characteristics. A thorough study of the volatile components that define the aroma and flavor characteristics of strawberries has been reported [80]. This method employed SPME headspace analysis combined with thermal desorption GC/MS to identify and quantitate 23 different compounds. Statistical techniques were then utilized to classify and compare the different varieties of berries. GC/MS with headspace sampling was also used in a study [81] that compared the aroma components, primarily aliphatic esters, of strawberries grown in different conditions.

Another aspect of berry chemistry that has received a great deal of attention is the presence of anthocyanins, procyanidins, and flavanols in these fruits. These compounds are thought to have potential beneficial value due to their antioxidant properties. The flavonal components quercetin, myricetin and kaempferol were studied in 25 berries including cranberries, currants, whortleberries, blueberries and strawberries [82]. A LC/UV method was used to quantitate the amounts of those compounds in the various berries and electrospray LC/MS along with diode array data were used to identify the various compounds. In another study, an MS method using MALDI-TOF was compared to a traditional LC method to measure the amount of anthocyanin in blueberries [83]. While both techniques gave comparable profile results, the MS method was faster and also provided confirmatory information, although the LC method provided better information on isomeric compounds.

The chemical residues in berries that are of most concern are pesticide residues. One report describes the analysis of organochlorine and chlorobenzene pesticide residues in strawberries using GC/MS [84]. The residues were extracted from the fruit using the novel techniques accelerated solvent extraction, SPME, or stir bar sorptive extraction. Detection limits of 1–10 μg/kg were reported. This method was used to monitor contamination of strawberries in an industrial region. Another paper also reports on the use of SPME in conjunction with GC/MS (using selected ion monitoring) for a wide variety of pesticides and fungicides in strawberries [85]. In an alternative approach, capillary electrophoresis using an electrospray interface and selected ion monitoring was used to measure the fungicides procymidone and thiabendazole in strawberries as well as other fruits [86]. A survey of consumer samples using this method found that these residues are present in real samples more than 50% of the time.

V. EMERGING TRENDS IN THE MS ANALYSIS OF FOODS

MS should remain an important analytical tool in the characterization of food, and the application of new technologies will continue to expand. The flexibility of the new MS/MS instruments will allow multi-component methods to be developed with performance (in terms of sensitivity and selectivity) that was previously only possible for single compounds. Just as the advent of practical and commercially available LC/MS/MS instruments has had a great effect on food analysis, the introduction of time-of-flight and other high resolution instruments will also have a great impact. The use of exact mass measurements to identify and confirm food components or residues should increase.

Innovations from other areas of analytical chemistry and biology can be borrowed and adapted for food analysis. For example, the advances made in the area of drug discovery in terms of rapid throughput of compounds (multiplexing, robotics, etc.) should lead to the ability to screen a large number of food samples using some of the same technological advances. The use of MS, as well as other means of structural elucidation, to study a wide variety of proteins has exploded in recent years, giving rise to the whole field of proteomics. Researchers in this area are applying their knowledge to a wide variety of biological systems and disease mechanisms. The same analytical techniques should be able to be applied to food matrices as well, leading to better ways to distinguish species or varieties of commodities. Identification of bacterial food pathogens using MS is already an area of increasing development [87].

In the future, MS will likely become a valuable tool in determining not only what components are present in any given food, but also what role a particular compound may play in the food's esthetic quality, nutritional value, and perhaps even in its ability to mitigate or prevent disease.

49 Food Analysis: Other Methods

Manoj K. Rout and Ching-Yung Ma
Department of Botany, The University of Hong Kong

CONTENTS

I. INTRODUCTION

There is considerable demand in the food industry for analytical methods to quantitatively measure various components in raw materials and finished food products, and to monitor physicochemical changes during and after food processing. This chapter describes a number of classical and newly developed methods for food analysis not covered in other chapters. These techniques have wide application in the food industry due to their simplicity and potential applications to a wide variety of food materials.

II. POTENTIOMETRY

Potentiometry is one of the two main categories of electroanalytical techniques, being classified as voltammetry at zero current. The basic principle of potentiometry involves the use of an electrolytic cell composed of two electrodes dipped into a test solution. A voltage (electromotive force, EMF) develops, which is related to the ionic concentration of the solution. This EMF is measured under conditions such that an infinitesimal current (10^{-12} amperes or less) is drawn during measurement. Hence, the classification voltammetry at zero current is used in potentiometry. When an appreciable current is drawn, changes in solution concentration surrounding the electrodes will be produced, and the measured potential corresponds to a system different from the original. In addition, irreversible changes may occur in either of the two electrodes.

A. Electrode Potential

When an electrode is placed in a solution, it tends to send ions into the solution (electrolytic solution pressure), reacting with the electrode (activity). These two factors, the electrode pressure and the activity of the solution ions, combine to produce an electrode potential. At a given external pressure and temperature, the potential is a constant characteristic of the metal in solution.

The pH meter is a good example of a potentiometer. pH is defined as the logarithm of the reciprocal of hydrogen ion concentration. It may also be defined as the negative logarithm of the molar concentration of hydrogen ions. The four major parts of the pH meter system are: (1) reference electrode, (2) indicator electrode (pH sensitive), (3) voltmeter or amplifier that is capable of measuring small EMF differences in a circuit of very high resistance, and (4) the sample being analyzed.

Hydrogen ion concentration (activity) is determined by the voltage developed between the two electrodes. The Nernst equation relates the electrode response to the activity:

$$E = E^\circ + 2.3\frac{RT}{NF}\log A$$

Where E = actual electrode potential; E° = a constant, the sum of several potentials in the system; R = universal gas constant, 8.313 joules/degree/g mole; F = Faraday constant, 96,490 coulombs per g equivalent; T = absolute temperature (Kelvin); N = charge of the ion; and A = activity of the ion being measured.

At 25°C, the relationship of 2.3RT/F can be calculated as:

$$\frac{23 \times 8\,316 \times 298}{96{,}490} = 0.0591 \text{ volts}$$

Thus, the voltage produced by the electrode system follows a linear function of the pH, with the electrode potential being +60 millivolts for each change of one pH unit. At neutrality (pH 7), the electrode potential is zero millivolt. The above relationship of millivolt versus pH exists only at 25°C.

B. Reference Electrodes

1. Standard Hydrogen Electrode

The universally adopted primary standard reference electrode is the standard hydrogen electrode (SHE). It consists of a platinum wire or foil coated with platinum black, immersed in a hypothetical solution of unit hydrogen ion activity and in equilibrium with hydrogen gas at unit partial pressure. The potential of this standard electrode by convention is defined as zero millivolt at all temperatures. The standard hydrogen electrode is the international standard, but is seldom used for routine work because more convenient electrodes and reliable calibration buffers are available.

2. Saturated Calomel Electrode

The saturated calomel electrode is the most common reference electrode. It is based on the following reversible reaction:

$$Hg_2Cl_2 + 2e^- \leftrightharpoons 2Hg + 2Cl^-$$

Thus, the potential is dependent upon the chloride ion concentration, which is easily regulated by the use of saturated KCl solution in the electrode. A calomel reference electrode has three principal parts: (1) a platinum wire covered with a solution of calomel (Hg_2Cl_2), (2) a filling solution (saturated KCl), and (3) a permeable junction through which the filling solution slowly migrates into the sample being measured. Junctions are made of ceramic material or fibrous material. A sleeve junction may also be used. Because these junctions tend to clog up, causing a slow, unstable response and inaccurate results, one electrode manufacturer has introduced a free-flowing junction wherein electrolyte flowing from a cartridge is introduced at each measurement. The calomel electrode is unstable above 80°C or in strongly basic samples (pH >9), and should be replaced by a silver-silver chloride electrode.

3. Silver-Silver Chloride Electrode

The silver-silver chloride electrode is very reproducible and is based on the reversible reaction:

$$AgCl\ (s) + e^- \leftrightharpoons Ag(s) + Cl^-$$

The internal element is a silver-coated platinum wire with the surface silver being converted to silver chloride by hydrolysis in hydrochloric acid. The filling solution is a mixture of 4 M KCl saturated with AgCl used to prevent the AgCl surface of the internal element from dissolving. The permeable junction is usually of the porous ceramic type. Due to the relative insolubility of AgCl, this electrode tends to clog more readily than the calomel reference electrode. However, it is possible to obtain a double-junction electrode in which a separate inner body holds the Ag/AgCl internal element, electrolyte, and ceramic junction. An outer body containing a second electrolyte and junction isolates the inner body from the sample.

C. Indicator Electrodes

The indicator electrode most commonly used in measuring pH is referred to as the glass electrode. Prior to its development, the hydrogen electrode and the quinhydrone electrode were used. The history of the glass electrode goes back to 1875, when it was suggested by Lord Kelvin that glass was an electrical conductor. The glass electrode potential was discovered 30 years later when it was observed that a thin glass membrane placed between two aqueous solutions exhibited a potential sensitive to changes in acidity. Subsequently, the reaction was shown to be dependent upon hydrogen ion concentration. These observations were of great importance in the development of the pH meter.

The glass electrode has three principal parts: (1) a silver-silver chloride electrode with a mercury connection needed as a lead to the potentiometer, (2) a buffer solution consisting of 0.01N HCl, 0.09N KCl, and acetate buffer used to maintain a constant pH, and (3) a small pH–sensitive glass membrane whose potential varies with the pH of the test solution. Conventional glass electrodes are suitable for measuring pH in the range of 1–9. These electrodes are sensitive to higher pH, especially in the presence of sodium ions. Thus, modern glass electrodes developed are usable over the entire pH range of 0–14, and feature a very low sodium ion error, typically <0.01 pH unit at 25°C.

D. Ion-Selective Electrodes

The glass electrode is generally considered useful only in measuring pH, but if the composition of the glass membrane is changed, this type of electrode can be quite sensitive for detecting other cations. In recent years, much attention has been given to this potential. Many electrodes have been developed for the direct measurement of various cations and anions, such as bromide, calcium, chloride, fluoride, potassium, sodium, and sulfide. There are even electrodes available for measuring dissolved gases, such as ammonia and carbon dioxide. While some of these methods are limited in their application due to interference from other ions, the problem can be overcome by pH adjustment, reduction of the interfering ions, and removal of these ions by complexing or precipitation.

Varying the composition of the glass in a glass electrode is one means of changing the sensitivity of the glass membrane to different ions. For example, an electrode membrane containing 71% SiO_2, 11% Na_2O, and 18% Al_2O_3 is sensitive to potassium.

1. Precipitate Impregnated Membrane Electrodes

According to Rechnitz (1), the success of glass membranes as cation-selective electrodes rests largely on the fact that the hydrated glass lattice contains anionic ‘sites’ that are attractive to cations of appropriate charge-to-size ratio. It is quite easy to construct ion-exchange membranes that permit exchange of either cations or anions; the difficulty is that these membranes show insufficient selectivity among anions and cations of a given charge to be satisfactorily used as practical electrodes. The problem is to find an anion-exchange material that displays appreciable selectivity among anions of the same charge, and also possesses suitable properties to permit its processing into a membrane electrode. In this case silicone rubber has been found to be the most effective material.

An inert, semi-flexible matrix (silicone rubber) is used to hold an active precipitate phase (AgI for an iodide electrode) in place. Such membranes are called heterogeneous or precipitate impregnated membranes. Fisher and Babcock (2) used radioactive tracer materials to show that the electrode potential is determined by the electrical charge on the surface of the inorganic precipitate particles, and that the current is carried by the transport of the counter ions through the membrane. The main advantage of membrane type electrodes over the older metal-metal halide electrodes is their insensitivity to redox interferences and surface poisoning. Electrodes sensitive to chloride, bromide, iodide, sulfide, sulfate, phosphate, and hydroxide ions have been developed.

2. Solid-State Electrodes

The active membrane portion of a solid-state electrode consists of a single inorganic crystal doped with a rare earth. For example, the Orion fluoride electrode is crystalline lanthanum fluoride that has been doped with europium to lower its electrical resistance and to facilitate ionic charge transport. This electrode has approximately tenfold higher selectivity for fluoride than hydroxide, and at least 1000-fold higher selectivity for fluoride over chloride, bromide, iodide, hydrogen carbonate, nitrate, sulfate, and monohydrogen phosphate. The fluoride electrode does not require pre-conditioning or soaking prior to use. Solid-state electrodes are available for detecting the anions Cl^-, Br^-, I^-, and S^{2-}, and the cations Cd^{2+}, Co^{2+}, Pb^{2+}, and As^{3+}.

3. Liquid-Liquid Membrane Electrodes

The range of selective ion-exchange materials could be greatly extended if such materials could be used in electrodes in their liquid state. Liquid ion-exchange materials that possess high selectivity for specific ions may be tailored by appropriate chemical adjustment of the exchanger on the molecular level. The main problems hindering the development of successful liquid-liquid electrodes are mechanical. It is necessary, for example, that the liquid ion-exchanger be in electrolytic contact with the sample solution, yet actual mixing of the liquid phases must be minimal. Electrodes of this type are available for Ca^{2+}, Mg^{2+}, Cu^{2+}, Cl^-, ClO_3^-, and NO_3^-.

E. Enzyme Electrodes

Enzyme electrodes are used to determine certain uncharged molecules. This type of electrode contains an enzyme that can convert the molecule to be measured into an ion that can be detected with a conventional electrode. For example, urea can be determined by coating the end of an ammonium ion electrode with uricase imbedded in a gel. As urea in a sample penetrates the gel, it reacts with the enzyme, which converts part of the urea to ammonia. The ammonia, in the presence of water, becomes ammonium ion which is then detected by an ammonium ion electrode.

An enzyme electrode can be prepared by placing a piece of nylon stocking over the end of an electrode. A thin film of polyacrylamide gel containing the specific enzyme is polymerized onto this network. The gel is then covered with a film of clear plastic such as Saran wrap. Both the stocking and plastic membrane can be held in place with a rubber band placed around the neck of the electrode.

F. Applications

The measurement of pH has many uses in the food industry. The safety of many foods is pH-dependent, and the desired flavor of a food is often determined by the $[H^+]$ concentration. Thus, pH measurements are routinely conducted in both the laboratory and the processing plant.

The chloride and fluoride contents in several types of cheese have been determined by potentiometric titration with silver using ion-selective electrodes (3). The chloride and calcium contents of milk fats were measured by potentiometric titration to detect adulteration (4). A portable meter was developed by Dracheva (5) to determine nitrate in fruits and vegetables.

D-Fructose dehydrogenase was immobilized on an electrode and used for the selective determination of fructose (6). Glucose oxidase was immobilized on an electrode surface and found to be sufficiently fast and reliable to determine sucrose in flow injection systems (7). Sugar beet pulp precipitated with acetone was examined and found to be a suitable biocatalytic layer for a tyrosine tissue-based membrane electrode (8).

III. RADIOACTIVITY AND COUNTING TECHNIQUES

A. Radioactivity and High-Energy Particles

Radioactivity is a general term applied to the emission of high energy particles (e.g., alpha and beta particles) and electromagnetic radiation emanating from the unstable and excited nuclei of atoms. The main advantage of radioanalytical methods is their high sensitivity, allowing determinations to the nanogram (10^{-9}g), pictogram (10^{-12}), and sometimes fantogram (10^{-15}) range. These methods have high specificity and can be used to determine most inorganic elements including trace elements, and organic compounds such as amino acids, fatty acids, vitamins, and hormones.

Alpha particles are helium nuclei moving at high speeds (on the average, 1×10^7 cm/min) emitted from unstable nuclei having large atomic numbers. All alpha particles from a given isotope have the same energy, nearly identical penetration ranges which are very short,

and produce about 25,000 ion pairs/cm while they last. Beta particles are distinguishable from simple electrons only by the fact that they originate in the nucleus and are usually moving at high speed. A beta spectrum is continuous, having energies varying from a few thousand electron-volts to several million electron-volts. An average beta particle produces about 60 ion pairs/cm.

Following nuclear transformation, the formed nucleus is often found in an excited state. When the excited nucleus falls back to its ground state, electromagnetic radiations called gamma rays are emitted. Many equations have been developed to describe the various parts of the radioactive process, but the most widely used is the half-life equation:

$$t_{1/2} = 0.693/\lambda$$

where λ is the radioactive decay constant (sec^{-1}). If A is the count rate and A_0 is the number of counts at zero time then the above equation becomes:

$$A = A_0 \exp(-0.693\ t/t_{½})$$

B. Counting Devices

Although the radiations mentioned previously have high energies in bulk, individually the energies are not sufficient, by a factor of about one million, to permit direct observation and measurement. Detection and measurements are therefore done indirectly by utilizing the effects of interactions produced by these radiations as they traverse matters.

1. Geiger–Muller Counter

The Geiger–Muller (GM) counter or tube is very sensitive to alpha and beta particles (98% efficient) compared to gamma rays (2% efficient). The GM counter is relatively inexpensive and simple to operate, but it does not discriminate between the types of radiation and it has a finite lifetime. It is being steadily replaced by proportional and scintillation counters.

When a ray of radiation comes through the mica window of a GM tube and strikes an argon atom, the argon atom is ionized to produce a positive argon ion and an electron. The positive ion moves toward the cathode at a speed about 1000 times slower than the movement of the electron toward the anode. The electron, attracted by the high potential of the anode, is rapidly accelerated. It has sufficient energy that when it collides with an argon atom another ion and electron can be produced. The two electrons accelerating toward the anode produce 4, then 8, and 16, etc. electrons. The net result is called the Townsend avalanche. Thousands of electrons can reach the anode and a small current is produced and the pulse signal is measured.

In addition, some of the electrons striking the anode may have high enough energy to knock electrons from the anode. These electrons will immediately be re-attracted to the anode and they in turn can knock other electrons loose. This is known as photon spread. The total time it takes for this signal to build up is known as the rise time (t_r) and is usually 2–5 μsec in duration.

While electrons are moving toward the anode, the positive ions move slowly toward the cathode as a positive space charge. If they strike the cathode with their full energy, more photoelectrons will be generated, more than the tube can handle. The net result is that the counter will burn out. Something is needed to dissipate this energy and from photon spread. Molecules, with their many energy levels, are used for this purpose, and ethanol and chlorine are the favorites. The ionized argon atoms will transfer their energy to these molecules which may form ions or free radicals or simply absorb the energy. The energy is so spread out that the cathode has little affinity for these particles, and no photoelectrons are thus produced. Since there is a limit to the amount of quenching gas that can be added to this type of counter, the counter will only work as long as quenching gas is present.

What happens if a second ray of radiation enters the counter before the first ray has completed its reaction? If the second ray ionizes an argon atom at a point between the cathode and the positive space charge, then the electron produced will not "see" the anode but will combine with the argon ion instead. The net result is that the ray of radiation was not counted.

2. Proportional Counters

Geiger–Muller tubes are limited to about 15,000 counts per minute (cpm) because of their long dead time. If the voltage applied to the anode of a GM tube is reduced to a value at which the anode can collect electrons but not produces photon spread, the output pulse is proportional to the energy of the initial ionization, since the number of secondary electrons now depends only on the number of primary ion pairs produced initially. A device operated in this manner is called proportional counter.

The dead times of proportional counters are very short, of the order of 1 μsec, and they can therefore count up to 200,000 cpm. The pulse signal is much weaker than that with a GM tube and better amplification system is needed. It is not possible to make a proportional counter out of a GM tube by simply lowering the anode voltage.

Proportional counters can operate at atmospheric pressure, so the quenching gas can be added continuously. Hence, a proportional counter can count indefinitely. Proportional counters are very good for detecting alpha and beta particles, and because of their ionization efficiency, these counters can easily distinguish the two types of particles.

3. Scintillation Counters

The basic principle behind the operation of the scintillation counter is that an energetic particle incident upon a luminescent material (a phosphor) excites the material, and the photons created in the process of de-excitation are collected at the photocathode of the photomultiplier tube causing the ejection of electrons. The electrons ejected are then led to impinge upon other electrodes, each approximately 100V higher in potential than the previous one. During acceleration from dynode to dynode, more electrons are ejected and a large amplification is obtained.

It would be expected that the greater the energy of the incident particle, the greater the number of electrons is produced. Thus the scintillation counter could be used to measure the energy of the particle. In a scintillation counter, advantage is not taken of the proportional properties of the scintillation process. However, a scintillation spectrometer uses these proportional characteristics to good advantage.

The liquid scintillation counter is particularly convenient for the counting of beta emitters with very low energy, such as tritium, carbon-14, and sulfur-35. The pulses of light emitted by the scintillating solution (caused by the particles in the radioactive decay process) are observed with a photomultiplier tube and counted. It is common practice to cool the photomultipliers to lower their noise, caused in part by thermal emission from the photocathode.

4. Semiconductor Detectors

Germanium, a semi-conducting material, can be made sensitive to gamma radiation by placing small amounts of an impurity, such as lithium, into the germanium crystal structure. When a gamma ray interacts in the crystal, an electrical charge is produced. The charge is collected and amplified to produce a voltage pulse whose height is proportional to the amount of energy deposited in the crystal by the gamma ray.

A single crystal of semiconductor material, such as silicon or germanium, will not make a suitable counter because of the direct current in the crystal. Random variations of this current may produce pulses similar to the radiation-induced pulses. To reduce this current, a p-n (positive-negative) junction in reverse bias is used.

C. Applications

Radioactivity techniques are widely applied in the food industry due to their high sensitivity. A wide variety of food components can be detected and quantified. Positron lifetime spectroscopy has been used to study the structural changes of water in the presence of dissolved sugar molecules such as sucrose, D-glucose, and D-fructose (9). Proton-induced X-ray and radioisotope-induced X-ray fluorescence methods were used to determine trace elements in beef, mutton, and chicken (10). Radioactivity tracing of anthocyanins has been carried out in food and beverages (e.g., red wine) where products are difficult to isolate and analyze (11). Variations in cell wall polysaccharides of ready-to-use grated carrots after treatment with ionizing gamma radiation and $CaCl_2$ were demonstrated (12). Calcium did not modify the polysaccharide composition or the effects of the ionizing radiation. The gamma radiolysis of phenylalanine in aqueous solution has been studied as a model for the formation of o-tyrosine in irradiated food containing phenylalanine (13). Several methods have been developed to detect irradiated foods, including the thermoluminescence technique which appears to originate from mineral contamination in food materials which have a natural thermoluminescence (14).

IV. ENZYMATIC METHODS

Enzymes are protein molecules that catalyze various metabolic reactions in living organisms (15). Enzymes are capable of very high specificity and reactivity under physiological conditions. Enzymatic analysis is the measurement of compounds with the aid of added enzymes or the measurement of endogenous enzyme activity to give an indication of the state of a biological system including foods. The fact that enzyme catalysis can take place under relatively mild conditions allows for the measurement of unstable compounds not amenable to some other techniques. In addition, the specificity of enzyme reactions can allow for measurement of components in complex mixtures without the need of complicated and expensive chromatographic separation.

A. Enzyme Kinetics

Enzymes are biological catalysts which increase the rate (velocity) of a thermodynamic reaction. An enzyme does not modify the equilibrium constant of the reaction and is not consumed in the reaction. To measure the rate of an enzyme-catalyzed reaction, the enzyme is mixed with the substrate under specified conditions (pH, temperature, ionic strength, etc.) and the reaction is monitored by measuring the disappearance of the substrate. An enzyme-catalyzed reaction is represented as:

$$S + E \leftrightharpoons ES \rightarrow P + E$$

where S = substrate, E = enzyme, ES = enzyme-substrate complex and P = product. The formation of the enzyme-substrate complex is very rapid (in millisecond scale) and is not normally seen in the laboratory. The time course of an enzyme-catalyzed reaction is illustrated in Figure 49.1 (15). The brief time in which the enzyme-substrate complex is formed is called the pre-steady state period. The slope of the linear portion of the curve following the pre-steady state period gives the initial velocity (V_0).

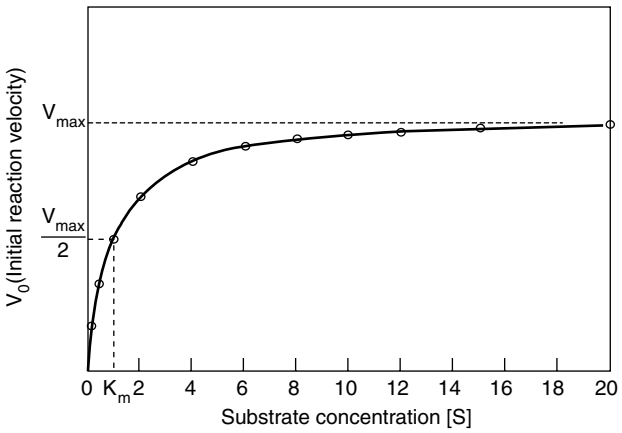

FIGURE 49.1 Effect of substrate concentration on the rate of an enzyme-catalyzed reaction plotted according to the Michaelis-Menten equation.

The rate of the enzyme-catalyzed reactions depends on the concentration of both the enzyme and the substrate. With a fixed enzyme concentration, increasing substrate concentration will result in increased velocity. As the substrate concentration increases further, increase in velocity slows, and at very high substrate concentration, the maximum velocity (V_{max}) of the reaction is reached and no further velocity increase is noted. The substrate concentration at which one-half V_{max} is observed is defined as the Michaelis constant or K_m which is an important characteristic of an enzyme. It is an indication of the relative binding affinity of the enzyme for a particular substrate. The lower the K_m, the greater is the affinity of the enzyme for the substrate.

The Michaelis-Menten equation is derived from a simplified enzyme-catalyzed reaction as:

$$E + S \underset{k_1}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

where k_1, k_{-1}, k_2 are reaction rate constants.

B. Measurement of Enzyme Activity

A wide variety of methods is available to follow enzyme reactions, including spectrophotometry, fluorimetry, manometric methods, titration, and isotope and viscosity measurements. The review by Whitaker (16) provides a comprehensive guide to enzyme methods applicable to foods.

C. Applications

There are several applications of enzyme analyses in food science and technology. In several instances, enzyme activity is a useful measure for adequate processing of a food product. For example, peroxidase activity is used as a measure of adequacy of blanching of vegetable products. Enzyme activity assays are also used by the food technologists to assess potency of enzyme preparations used as processing aids.

Enzymatic analysis is currently being used more often in the determinations of various substrates and enzymes in food products, such as beverages, milk (lactose), fats (cholesterol), and meats (pyrophosphates, creatine, creatinine, gluconate). A few examples of enzymatic analysis of food components are shown.

1. Sulfite

Sulfite is a food additive that can be measured by several techniques, including titration, gas chromatography, and colorimetric analysis. Sulfite can also be specifically oxidized to sulfate by the commercially available enzyme sulfite oxidase (SO). The H_2O_2 product can be measured by several methods, including the use of the enzyme NADH-peroxidase. The reactions are shown as follow:

$$SO_3^{=} + O_2 + H_2O \xrightarrow{SO} SO_4^{=} + H_2O_2$$

$$H_2O_2 + NADH + H^+ \xrightarrow{\text{NADH-peroxidease}} 2H_2O + NAD^+$$

The amount of sulfite in the system is equal to the NADH oxidized, which is determined by the decrease in absorbance at 340 nm. Ascorbic acid can interfere with the assay but can be removed by using ascorbic acid oxidase (17).

2. Glucose

Glucose in food can be measured by a colorimetric method using glucose oxidase and peroxidase (18). Glucose is preferentially oxidized by glucose oxidase to produce gluconolactone and hydrogen peroxide. In the presence of peroxidase, hydrogen peroxide and o-dianisidine react to produce a yellow colored dye that absorbs at 420 nm:

$$\beta\text{-D-glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \delta\text{-gluconolactone} + H_2O_2$$

$$H_2O_2 + \text{o-dianisidine} \xrightarrow{\text{peroxidase}} H_2O + \text{oxidized dye (colored)}$$

3. Starch/Dextrin

Starch and dextrin contents in food can be determined by enzymatic hydrolysis using amyloglucosidase, an enzyme that cleaves α-1,4 and α-1,6 bonds of starch, glycogen and dextrins, liberating glucose. The glucose formed can be subsequently determined enzymatically.

V. SEROLOGY, IMMUNOCHEMISTRY AND IMMUNOELECTROPHORESIS

Immunology is both a fundamental medical science and a technology. As a technology it has engendered the development of a whole ensemble of techniques based on the

antigen-antibody (*Ag-Ab*) reaction, categorized under the term *immunochemistry*. These techniques have been highly developed in other domains of biology to seek, identify, quantify, and even purify various molecules or associations of molecules (such as microorganisms) using antibodies.

A. Antigens and Antibodies

An antigen is any substance that, when introduced into a living organism, is susceptible to inducing the production of antibodies that are able to recognize it. Antigens can be molecules (proteins, polysaccharides, etc.) or associations of molecules (viruses, bacteria, etc.). All antigenic molecules are constituted of an assortment of determinants or antigenic sites called epitopes, each possessing a molecular component that is recognized by an antibody. A given antigen can have several identical or different epitopes, with the latter introducing a set of different antibodies. Thus, microorganisms that possess a variety of antigens contain a large number of epitopes.

Antibodies are substances produced by an animal in response to the introduction of a foreign substance (antigen). They react specifically with the antigens that induced their formation. These antibodies (or immunoglobulins) are produced by the B lymphocytes and are present in the blood. There are five classes of immunoglobulins, IgG, IgM, IgA, IgD, and IgE. Immunoglobulins are composed of a pair of long polypeptide heavy chains and a pair of short polypeptide light chains. Both inter- and intra-chain disulfide bonds are present. The heavy chains of different immunoglobulin classes differ chemically, while the light chains are of two types, kappa (*K*) and lambda (λ). All immunoglobulin classes contain either type of light chain. Each immunoglobulin molecule, therefore, consists of a pair of heavy chains specific for its class and a pair of either kappa or lambda light chains (Figure 49.2) (15).

All immunoglobulin molecules have a constant carboxyl-terminal end and a variable amino-terminal end. The amino-terminal end is the "antibody active site" or the "antigen combining site" with an amino acid sequence that varies to correspond with the configuration of challenging antigens. The specificity of antibodies formed in response to an antigen varies. Although antibodies generally react only with the antigen used, cross reactions due to structural similarities between antigens may occur. For example, antibodies to horse serum protein also react with donkey serum protein, and ovalbumin from duck eggs also reacts with antibodies to hen egg albumin. Serum albumins of different mammalian species are antigenically similar, though not identical. The more closely related any two species are, the greater the serological likeness of their corresponding proteins.

The structure of antibodies resembles a "Y" constituted of four polypeptide chains (Figure 49.2) (15). Each

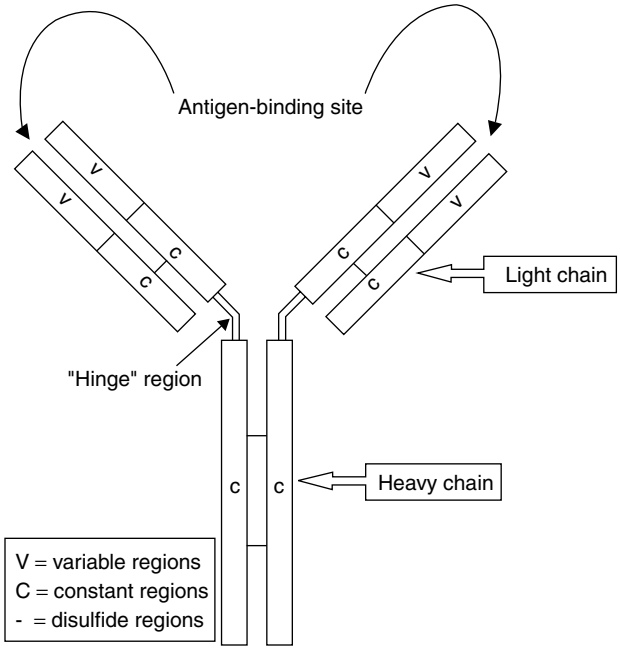

FIGURE 49.2 Diagram of the IgG tetrachain monomer.

branch of the "V" shaped section (or F_{ab} fragment) carries an active site that is complementary to an epitope. Thus, each antibody molecule can bind to two antigenic molecules with identical epitopes. The tail of the "Y" (or the F_c fragment) does not directly participate in binding with the antigen, but can fix to specific cells and activates the complement. Each lymphocyte descendant produces only one type of antibody that recognizes only one type of epitope.

1. Polyclonal Antibodies

After injecting an animal with antigen, antibodies appear fairly rapidly in its blood, and their concentration increases to a maximum and then decreases, constituting the primary response. When the same antigen is then re-injected (booster injection), antibody production is accelerated to higher levels and diminishes more slowly than the first time, constituting the secondary response. This production can be maintained at a relatively high level by re-injecting the antigen at regular intervals. Rabbit is often chosen, but other animals (mice, goats, sheep, etc.) can also be used. Immunization protocols are varied, and the injection can be intravenously (when working with bacteria), intramuscularly, or subcutaneously with the antigen preferably in suspensions (or emulsions) rather than in solution. The quantity of antigen injected (a few μg to a few mg) depends on the nature of the antigen, the animal, and its size.

2. Monoclonal Antibodies

Even if the antigen used to inoculate the animal is pure, the immunoserum collected is composed of a mixture of

antibodies directed against different epitopes. A more recent development involves obtaining a cellular clone that produces only one antibody with a well-defined specificity, known as monoclonal antibody. Kohler and Milstein in 1975 first developed the techniques for the production of monoclonal antibody.

B. Immunodiffusion

Several methods based on specific precipitation of antigen and antibody in agarose gels have been developed (19), and are called immunodiffusion. Single diffusion is a technique in which only one of the two reactants (generally the antigens) migrates in the agarose gel, and double diffusion techniques involve both components migrating simultaneously toward each other. The precipitate forms at a location where the concentrations of the two reactants reach equivalence, leaving a limited precipitation zone for each antigen.

1. Tube Precipitin Test

Qudin (20) devised a method by which complex antigen-antibody systems could be analyzed by allowing them to react in a capillary tube filled with agar. The antibody solution is mixed with warm agar, which is then allowed to harden in the tube. When an antigen solution is added, the antigen reacts with the antibody, forming a precipitation zone. The number of such zones is less than or equal to the number of independent precipitation systems (i.e., antigen-antibody reactions) present in the mixture.

2. Single Radial Diffusion

Mancini (21) developed this method, in which agarose containing the antibody is poured onto a transparent plate. The antigen solutions are deposited in circular wells cut in the gel. The antigens diffuse around the well and form a precipitation ring or halo, and the square root of the inner diameter is proportional to their concentrations. The quantity of antigen contained in the unknown sample is determined by comparing with a range of reference values. The sensitivity threshold is about 3 μg/ml.

3. Double-Diffusion

The double-diffusion method was developed by Ouchterlony (22). It permits both antigen and antibody to diffuse into an agar-filled glass dish that initially contains neither reagents. A few drops each of antigen and antibody solutions are placed separately in small wells in the agar. Antigen and antibody diffuse toward each other at a rate related to their concentrations and their diffusion coefficients. A precipitate line is formed where an antigen interacts with its antibody. Because of differences in diffusion rates, the lines are distinctly separated. The clean separation of lines on these Ouchterlony plates makes it possible to distinguish more reactions than with Qudin tubes. Consequently the plates are more useful in studying complex systems. The line of precipitation formed by an individual reaction can be identified if either the antigen or the antibody is available in relatively pure form.

C. Immunoenzymology

The technique of immunoenzymology was first applied to histochemistry and only assumed its present form as ELISA (Enzyme Linked Immunosorbent Assay) in 1971 simultaneously in France, Sweden, and Holland. The most commonly used enzyme markers are catalase, glucose oxidase, β-galactosidase, alkaline phosphatase, and peroxidase. The enzymatic reaction that allows detection is in the last step of the procedure. The technique involves the addition of a substrate which produces a colored product that can be read visually, or by a simple adapted colorimeter when micro-titration plates are used. The diverse substrates that can be used depend on the enzymes. The most common substrates for peroxidase are orthophenyldiamine (OPD) and 2,2′-di (ethyl 3-benzothiazoline-sulfonic-6) acid (BTSA) coupled to H_2O_2. With certain enzymes, substrates that produce fluorescent or luminescent products can also be used to increase sensitivity, but special measuring devices are required.

ELISA is a heterogeneous assay requiring washing between each step to remove unbound reagents. Widely used enzyme labels include alkaline phosphatase, glucose oxidase, and horseradish peroxidase. These enzymes catalyze reactions that cause substrates to degrade, forming colored products that can be read visually or spectrophotometrically. Depending on the format, either antibody or antigen is adsorbed onto a solid phase, which can be polystyrene tubes, polystyrene microtiter wells, or membranes (nitrocellulose and nylon) (23).

D. Immunoelectrophoresis

To improve the resolution and interpretation of the double-diffusion method, immunoelectrophoresis was developed by Grabar (24).

1. Classical Immunoelectrophoresis

Classical immunoelectrophoresis (25) is performed in two steps. First, there is a classical electrophoresis of the antigen mixture deposited in wells, in which the antigens are separated into small spots as a function of their charge. Customarily, two runs are done in parallel on the same gel, one with the sample mixture, and the other with a standard for comparison (Figure 49.3) (26). Then there is a double diffusion, in which antibodies placed in a central groove between the antigen spots migrate toward the antigens. This produces one or more precipitation lines

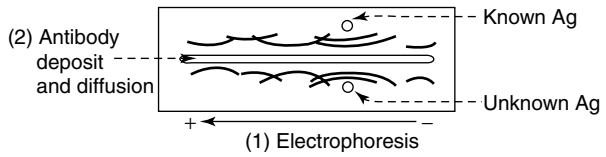

FIGURE 49.3 Classical immunoelectrophoresis (*Source*: From Ref. 26).

depending on whether each electrophoretically separated antigen spot is pure, or is constituted of several antigens that have the same charge. This method is sensitive, reproducible and qualitative in nature (26).

2. Rocket Immunoelectrophoresis

Rocket immunoelectrophoresis is a quantitative technique directly derived from radial immunodiffusion by applying an electric current to the gel (27). The antibodies are distributed evenly throughout the gel, and the sample (antigen) is placed in a small well at one end. As the antigen moves toward the positive electrode, it diffuses outward and reacts with the antibody, forming a precipitate. During migration, the antigen meets more antibodies, but since the antigen is now less concentrated, it will diffuse slower and the line of precipitate is less far away from the center of migration. Eventually, all antigens will have moved forward and reacted, and the resulting shape looks like a rocket (Figure 49.4) (26). The length or the area of the rocket is measured and correlated with standards for quantification.

3. Crossed Immunoelectrophoresis

Crossed immunoelectrophoresis is a two-dimensional separation technique (28, 29). The antigen mixture placed in the well is subjected to simple electrophoresis. The gel band is cut out and placed on a plate, and agarose gel containing antibodies is poured. A second electrophoresis is run perpendicularly to the first. The antigen migrates in the second gel, and produces one or several lines or peaks. This technique is more sensitive than simple immunoelectrophoresis.

E. Applications

The application of immunochemical methods in food analysis has been reviewed by Hitchcock (30). Sinnell and Mentz (31) described the use of electroimmunodiffusion methods for quantitative determination of non-meat proteins added to meat products. Kurth and Shaw (32) reviewed the identification of the species of origin of meat by immunochemical methods. Griffith et al. (33) recommended the use of a commercial ELISA system to measure levels of soya protein in meat. The presence of the major food allergen ovomucoid in human milk was studied

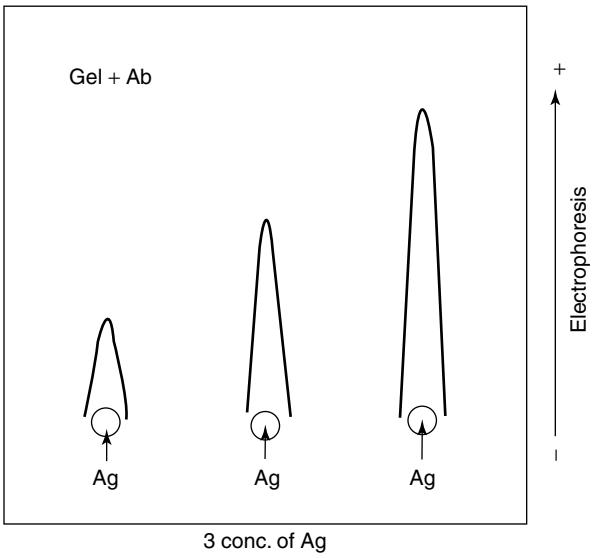

FIGURE 49.4 Rocket immunoelectrophoresis (*Source*: From Ref. 26).

using ELISA (34). ELISA-based methodologies were applied to detect and quantify allergenic proteins in peanut, soy, egg, milk, tree nuts, and crustacea (35).

VI. NUCLEIC ACID-BASED METHODS

Nucleic acids are high-molecular-weight macromolecules that form the genetic material of all living organisms. Two types of nucleic acids are generally encountered, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA serves as the repository for genetic information for both prokaryotes and eukaryotes. RNA serves a functional role in the conversion of genetic information into cellular proteins, and in the case of some viruses RNA serves as the genetic material as well.

Nucleic acids can be considered polymers of deoxyribo- or ribonucleotides. Each nucleotide unit is composed of a nitrogenous heterocyclic base, a sugar residue, and a phosphate group. The heterocyclic bases are either six-membered pyrimidine rings or nine-membered purine rings. Two types of purines and two types of pyrimidines are found in nucleic acids. Both DNA and RNA contain the purines adenine and guanine. DNA contains the pyrimidines cytosine and thymine, whereas RNA contains the pyrimidines cytosine and uracil. The heterocyclic bases are linked to the sugar via an N-glycosyl bond. The resulting compound is called a nucleoside. The nucleoside units in nucleic acids are joined through the 3′-hydroxyl group of one sugar and the 5′-hydroxyl group of the next sugar via a phosphodiester bond. This 3′-5′ internucleotide bond is found in both DNA and RNA. The double-helix model of DNA structure was first deduced in 1953 by James Watson and Francis Crick.

A. Basic Methodology

One of the landmark events in molecular biology was the development in 1975 by Edwin Southern of a DNA:DNA hybridization technique (36). This technique can detect rare DNA sequences in complex populations of DNA fragments generated by restriction enzymes. Nucleic acid strands having complementary base sequences can form double-stranded helices. The process of duplex formation is generally referred to as nucleic acid hybridization. Hybridization can occur between single strands of DNA and RNA or between complementary strands of DNA and RNA. Hybridization also includes the formation of complexes between single-stranded nucleic acids and complementary oligonucleotides. These reactions can be carried out in solution or with the nucleic acid immobilized on solid matrices such as nitrocellulose, nylon, or gels. Hybridization in solution is used to study the sequence complexity of cellular or viral DNA. Radioactively labeled nucleic acid probes (37) or probes capable of being tagged with fluorescent antibodies are used to search for and identify nucleic acid sequences (38). In this case the immobilized nucleic acid on nitrocellulose is bathed in a solution containing the probe.

1. Southern Analysis

Southern analysis is among the most powerful methods for DNA analysis. The first step in Southern analysis is the electrophoresis of DNA. DNA fragments digested with restriction enzymes are fractionated on agarose gels (0.7% to 1%) no more than 6 mm thick to allow for efficient transfer of the separated DNA to the filter membrane. The total amount of DNA loaded per lane of gel is dependent upon the relative abundance of the target sequence that is probed during hybridization.

Prior to transfer, the DNA is usually fragmented into smaller pieces and then denatured. This process can be divided into depurination, denaturation, and neutralization steps. The DNA is then transferred to the membrane using one of several methods: capillary, vacuum-assisted, pressure-assisted, or electrophoretic transfer. The DNA is then hrybridized with a probe.

2. Northern Analysis

Northern analysis involves a three-stage process: gel electrophoresis, gel blotting and hybridization to a labeled probe. Gel electrophoresis separates molecules of RNA on the basis of their size and conformation. Molecular size is the main determinant of migration speed, with smaller molecules moving through the matrix faster than larger molecules. Compact molecules also migrate faster than extended molecules of the same size. However, since RNA aggregation may occur, it is necessary to use denaturing gels to determine the actual size of RNA in the absence of conformational factors, aggregation, and nicks in the RNA. The choice of denaturing conditions depends on the nature of the gel and electrophoretic conditions. Formaldehyde is perhaps the most commonly used denaturant. A fact worthy of consideration during experimental design is that nonlinear RNA migrates more slowly than would be expected from its size since it cannot pass through the pores as easily as linear RNA.

The blotting of gels onto membranes can be achieved by capillary action or by electrophoresis. Nucleic acid transferred to a membrane is fixed into position by baking or UV crosslinking to the membrane. Subsequent hybridization of DNA probes to the bound RNA is carried out under stringent conditions to ensure that only complementary sequences hybridize.

B. Polymerase Chain Reaction

The polymerase chain reaction (PCR) was discovered in 1983 by Kary Mullis. PCR is an *in vitro* method for the enzymatic synthesis of specific DNA sequences, using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA. The standard PCR has three steps defined by temperature: denaturation, annealing and primer extension. The first step, denaturation, occurs when the reaction mixture is heated to 92–96°C. At this temperature the template DNA is single-stranded and the enzyme *Taq* (thermostable DNA polymerase isolated from *Thermus aquaticus*) has no measurable synthetic activity and is not denatured by the near-boiling temperature. Successful amplification is dependent upon complete denaturation of the template DNA during this step.

The middle step of the PCR cycle results in the annealing of the oligonucleotide primers to the template DNA. The temperature for this step varies from 45°C to 65°C depending upon the homology of the primers for the target sequence as well as the base composition of the oligonucleotide. The primers hybridize to their target sequences at an annealing rate several orders of magnitude faster than the target DNA duplex can reform. The ideal temperature for annealing oligonucleotides to the target template is 2–5°C below the melting temperature (T_m) for the primers. If the two primers used for a reaction have different T_m, this 2–5°C rule applies for the one with the lower T_m.

The final step is the primer-dependent DNA synthesis by the *Taq* polymerase. This portion of the cycle is carried out at 72°C. The thermal activation of *Taq* is complemented by the use of Tris buffers since *Taq* has a broad pH optimum, with maximum activity at pH 7.3. The pH of the Tris buffer drops from 8.3 at room temperature to 7.3 at 72°C. The increase in temperature leads to maximum enzyme activity. The published rate of DNA synthesis by this highly processive enzyme 72°C is 60 nucleotides per second (39).

A repetitive series of cycles involving template denaturation, primer annealing, and extension of the annealed primers by DNA polymerase results in the exponential accumulation of a specific fragment whose termini are defined by the 5′ ends of the primers. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies approximately doubles at every cycle. The simplest detection method of amplified product is the standard agarose ethidium bromide stained gel electrophoresis.

C. Applications

Due to recent advances in these nucleic acid-based techniques, numerous food applications have been developed. DNA probes offer an exciting new approach to the highly specific detection of cells in any given environment such as microorganisms in foods. The concept of hybridization and DNA probes, as well as potential applications, have been reviewed (40, 41). The rapid development of biotechnology enables the launching of products and ingredients derived from genetically modified organisms (GMOs) into the food market. Information availability and transparency are essential for the acceptance of these new products by the consumers. A key factor in this issue is the availability of methods to distinguish between GM foods and their traditional counterparts. PCR has been found to be the method of choice for the detection of GMOs in food. PCR methods for the detection of GMOs were developed that can be used for screening purposes and for specific detection of glyphosate–tolerant soybean and insect-resistant maize in foods (42).

CONTENTS

I. INTRODUCTION: MICROORGANISMS IN FOODS

Microbiology is the study of living organisms that are so small that they can only be observed with the aid of a powerful microscope. In food microbiology, the organisms of concern are usually classified as bacteria, fungi (yeasts and molds), viruses, and parasitic protozoa. Bacteria are single-celled microorganisms found in nearly all environments. Bacterial cells are often classified by their outward appearance, including their size, shape, and arrangement.

Some bacteria have the ability to form spores. Spores can typically withstand adverse environmental conditions better than the vegetative form of the bacteria. For example, spores can be highly resistant to boiling water or chemical sanitizers. Bacterial spores are not a means of reproduction. Fungi include organisms as small as a single cell or as large as a mushroom. True fungi produce large masses of filamentous hyphae that form a mycelium. Yeasts, along with bacteria, reproduce by fission. Other fungi typically reproduce by spores carried on fruiting structures. Viruses are extremely small parasites. They require living cells of plants, animals, or bacteria for growth. The virus is mainly a packet of genetic material which must be reproduced by the host cells. Protozoa are single-celled organisms that can cause disease in humans and animals. Their cell structure is more complex than that of bacteria.

The presence of microorganisms in foods may have adverse or beneficial effects. Some microorganisms may hasten the spoilage of foods, thereby reducing sensory quality and shelf-life. Other organisms may be pathogenic, or could cause human illness. Some species of bacteria, yeast, and molds can be used to ferment foods or to produce desirable changes in quality, especially in taste and texture. These organisms can be intentionally used to process a wide variety of plant or animal foods.

II. HISTORY OF FOOD MICROBIOLOGY

Microorganisms have always been closely related to food and food systems. Authorities believe that approximately 8,000 to 10,000 years ago, humans began to have problems associated with food poisoning and food spoilage. The importance of one's ability to produce and preserve food was recognized early. Both livestock and salt had monetary value and could be compared to today's currency. Wealth and social status in many cases was based upon the amount of success one had at producing in times of plenty and preserving what could not be consumed immediately for times of hardship. Many early religious laws prohibiting the consumption of "impure" or "unclean" foods were based on hygiene, and were similarly seen in countries not conforming to the same religious beliefs.

The first individual to describe microorganisms was Kircher in 1658 who reported "worms" that were undetectable to the naked eye on several decomposing items. Shortly thereafter the theory of spontaneous generation, later known as abiogenisis, became widely accepted. In 1683, Leeuwenhoek's superior knowledge of lens design allowed him to be the first to observe and record yeast cells using a primitive microscope. Spallanzani sought to disprove spontaneous generation in 1765 when his beef broth did not spoil after being boiled in a sealed container for an hour. Critics, however, disagreed, believing his process was void of oxygen, a vital ingredient to spontaneous generation. In 1785, the French government offered a prize to anyone who could develop a practical method to preserve food. In 1809, Nicholas Appert was successful by preserving meats that had been boiled in water in corked glass bottles. At the time, he was unaware of the microbiological logic behind this process. Louis Pasteur, however, was the first to understand the role of microorganisms in food. He was most noted for his heat pasteurization process to destroy deleterious organisms in beer and wine. Pasteur's process was later commercialized in 1867. He also proved that microorganisms caused souring milk. Some other examples of important dates in food microbiology history include:

1825 - U.S. patent issued for food preservation in tin cans.
1840 - Fresh fruit and fish were first canned.
1857 - Milk identified as a vector for typhoid fever.
1874 - Use of ice for transport of meat at sea was widespread.
1880 - Milk pasteurization began in Germany.
1888 - *Salmonella enteriditis* isolated from meat in a food poisoning outbreak.
1895 - First bacteriological study of canning.
1906 - U.S. Congress passed the Federal Food and Drug Act.
1928 - Controlled atmosphere was commercially used for storage of apples.
1929 - Frozen foods introduced into retail markets.
1967 - United States was the first to design a commercial irradiation facility.
1976 - In California infant botulism was identified.
1981 - First outbreak of foodborne listeriosis occurred in the U.S.
1986 - The first diagnosis of Bovine Spongiform Encephalopathy (BSE).

III. SOURCES OF CONTAMINATION: ANIMAL, PLANT, PROCESSING, FOOD HANDLERS

Foods or their ingredients may harbor a wide variety of microorganisms. Some of these microorganisms may be a part of the natural microbiota of raw foods of plant and animal origin, while others may be introduced during production, processing, and preparation for consumption. Microbial contamination refers to the presence or added presence of pathogenic or spoilage microorganisms that were not originally present in or on the food. Microbial cross-contamination refers to the situation where microorganisms are transferred from one surface or food to another food or food contact surface.

Raw and processed foods can be contaminated with many types of bacteria, yeast, or molds prior to consumption. Contamination may occur during all steps of food processing. These steps may include: harvest, slaughter, transportation, processing, packaging, storage, and preparation for consumption. Prior to crop harvest or food animal slaughter, raw agricultural commodities may become contaminated with pathogenic and spoilage organisms from soil, irrigation water, animal feces, insects, manure, and wild or domestic animals. During transport and processing, foods can be contaminated by harvesting and transport equipment. Furthermore, contamination by sorting, packing, cutting, packaging, or other further processing equipment may occur. Also, process water, air or dust, and worker contact may further contaminate food products. Processed or packaged foods can become contaminated by food handlers, including foodservice and retail employees and consumers. Cross-contamination of raw and ready-to-eat foods can occur due to improper sanitation of food contact surfaces or equipment or when

raw and ready-to-eat foods are poorly separated during preparation.

Prevention of contamination or cross-contamination by unwanted microorganisms is a critical element for ensuring the safety and quality of raw and processed foods. At the farm level, biosecurity programs can enhance prevention of microbial contamination. At the processing level food manufacturers can practice regular cleaning and sanitizing of equipment and facilities. Cleaning requires removing visible soil or food residue from equipment, utensils, floors, and walls. Subsequent sanitizing must reduce the number of microorganisms to a very low or safe level. Also, good employee hygiene practices such as handwashing, protective clothing, and prohibiting food and drink consumption in work areas can limit opportunities for microbial contamination of foods and ingredients. During food preparation, workers or consumers should frequently wash their hands and work surfaces. Hands or utensils should not touch raw food prior to ready-to-eat food without washing. Food contact surfaces and utensils must be regularly cleaned and sanitized.

IV. MICROBIAL GROWTH

Microorganisms can grow and reproduce at different rates over time. When bacteria are in a rapid growth phase they may be able to double their population in just 20–30 minutes. Prior to achieving a rapid or exponential growth rate, organisms may need time to adjust to their environment. During food processing, microbes may need time to adjust to changing conditions of acidity, temperature, oxygen level, nutrient levels, or available moisture. The population of bacteria may only marginally increase during the time that the organisms are adjusting to a new environment. After this lag phase of growth, the bacteria may enter into a rapid growth phase that greatly increases their numbers. Eventually the growth rate will slow as a key nutrient becomes exhausted or environmental conditions act to limit growth. When the population or the growth rate is plotted against time, a sigmoid or s-shaped curve often expresses how the growth changes over time. In these plots, a lag phase is followed by a (exponential) growth phase, a stationary phase, and a die-off phase (Figure 50.1).

Microorganism growth rates are influenced by many environmental factors. Similar to other living organisms, they need water and nutrients to grow. Temperature is also a very important factor affecting microbial growth. The time that microorganisms need to grow and reproduce can vary greatly depending on the environmental temperature. Other important factors affecting growth include pH, atmospheric gas concentrations, and available water for growth.

Water is necessary for growth, but microbes cannot grow in pure water. While all foods contain some water, some of this water is not available to the bacteria. Often the water in foods is bound with some of the molecules of the food such as the proteins, fats, and carbohydrates. The bound water may not be accessible to microorganisms to use for growth. Water activity, or a_w, is a measure of the water available to microorganisms in foods. Water activity is measured on a scale of zero to one (pure water). For growth, most bacteria require a a_w of at least 0.90. Yeasts and molds can tolerate a lower water activity, perhaps as low as 0.7. A water activity of less than 0.85 in food will suppress the growth of organisms of public health significance.

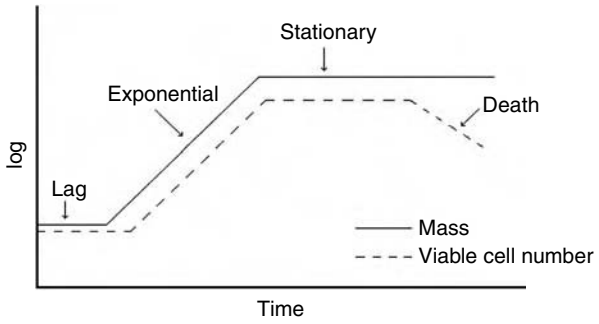

FIGURE 50.1 Bacterial growth curve.

Microorganisms can generally grow over a wide range of temperatures, but their growth rate at different temperatures can vary greatly. Organisms grow fastest at an optimal temperature. The optimum growth temperature for most organisms is near room temperature or body temperature (25–35°C). However, microorganisms may still be able to grow over a temperature range of 10–45°C. Foodborne microorganisms can survive temperatures of 0°C, but typically will not grow at this temperature.

Acidity can be measured with the pH scale where 0 is strongly acidic, 7 is neutral, and 14 is strongly basic. Many bacteria multiply more rapidly when the pH of their surroundings is near neutral, but may be able to grow when the pH ranges from 4 to 9. Yeasts and molds are more tolerant of low pH (high acidity) than bacteria. Many foods have a pH value between 4 and 7 which favors the growth of most pathogenic and spoilage microorganisms. As microorganisms reproduce, their metabolic by-products may alter the pH of their surroundings.

Just as microbial temperature and pH requirements can vary, microbial oxygen requirements can also differ greatly. Bacteria that require oxygen for growth are commonly called aerobes. Anaerobic bacteria do not grow in the presence of oxygen, but can grow in vacuum-packed foods. Some organisms can grow with or without oxygen and are referred to as facultative anaerobes. Finally, some organisms grow favorably under a low oxygen atmosphere. These microaerophiles grow optimally when the oxygen concentration in the atmosphere is 5–10% whereas the concentration in air is 18–20%.

V. MICROBIAL INACTIVATION, SURVIVAL, AND DEATH

Often a correlation exists between the rate and amount of treatment applied during the preserving process and the rate of microbial inactivation, survival, and death. In using heat processing to preserve foods, the temperature denatures proteins, which destroys enzyme activity and enzyme-controlled metabolism in microorganisms. The rate of microbial inactivation follows the first order reaction, by which when the product is heated to a temperature that is high enough to destroy contaminates, the same percentage die in a given time interval regardless of the numbers present initially. This is known as the logarithmic order of death and is described by a death rate curve (Figure 50.2). Microbial inactivation, survival, and death rate of the microorganism can be extrapolated from this curve.

The decimal reduction time, also known as the *D*-value, is defined as the time in minutes to achieve a $1-\log_{10}$ reduction in a specific microorganism at a specific temperature in a specific growth medium. *D*-values are variables for different microbial species and a higher *D*-value indicates greater heat resistance. Since microbial destruction occurs logarithmically, it is theoretically impossible to destroy all cells. The heating process therefore aims to reduce the number of surviving microorganisms by a pre-determined amount, depending on the type of microorganisms that is expected to contaminate the raw product. Usually, foods are processed to ensure at least a 12*D* reduction for *Clostridium botulinum* in low acid foods. This organism is targeted due to its importance in the food industry as well as its spore-forming abilities.

If the destruction of microorganisms is determined by temperature, cells die more rapidly at higher temperatures. The z-value characterizes the change in temperature required to achieve a $1-\log_{10}$ change in the *D*-value. This gives an indication of the temperature dependency of the heat resistance of an organism. Most heat-resistant spores have a z-value of 10°C.

The thermal death time (*F*-value) is used as a basis of comparing heat sterilization techniques. The *F*-value is defined as the equivalency in minutes at a given temperature, of all things considered, with respect to its capacity to destroy spores or vegetative cells of a particular organism. It can also be considered as the time needed to reduce the microbial numbers by a multiple of the *D*-value. When plotted, it is a bell-shaped curve, which is affected by product type, container size, container shape, and method of load of the unit for heat process. $F = D(\log n_1 - \log n_2)$, where n_1 = initial number of microorganisms and n_2 = final number of microorganisms.

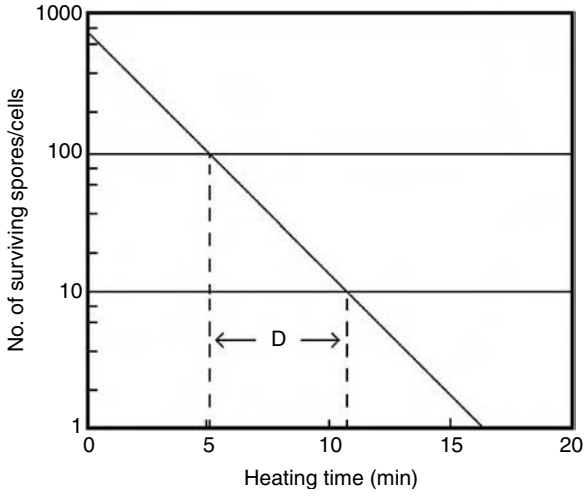

FIGURE 50.2 Death rate curve.

VI. DETECTION OF MICROORGANISMS

Food microbiologists examine foods for the presence, types, and numbers of microorganisms and/or their products. Sampling techniques as well as the enumeration of the affected food product or surface are crucial in obtaining an accurate analysis. In spite of its importance, the enumeration methods used commonly permit only the estimation of microorganisms in a food product or their surrounding environment. Although some analytical methods are more sensitive and more rapid than others, every method has certain inherent limitations associated with its use.

A. Sampling from Foods or the Environment

Many methods exist for sampling the environment of the food plant as well as the foods and air for the presence and relative numbers of microorganisms. Some commonly used methods are described below.

1. Gravimetric and volumetric sampling: Defined portions of food or water samples can be collected and analyzed by numerous microbiological methods. For liquids a volumetric sample of 10–100 mL is typically analyzed. For solids, a gravimetric or weighed sample of approximately 10–50 grams is analyzed. Solid foods may need to be diluted with one of several aqueous solutions during an analysis. In these cases, microbial concentrations can be reported as "per volume of diluent."
2. Swab sampling: Swabbing is the oldest and most prevalently used method for the microbiologic surface examination not only in the food and dairy industries but also in hospitals and restaurants. With this method, surface areas can be sampled corresponding to the size of the

surface with the use of a sterile template. A moistened swab is used to thoroughly rub the exposed surface. After exposure, the swab is returned to its holder containing a suitable diluent which can contain selective media and neutralizers for sanitation chemicals, if necessary. After proper dislodging from the swab, the organisms are then examined by enumeration or qualitative analysis. The swab method is best suited for flexible, uneven, and heavily contaminated surfaces. The ease of removal of the microorganism is dependent on the texture of the surface and the nature and type of flora.

3. Contact plate: The replicate organism direct agar contact (RODAC) method consists of a raised agar surface on the petri plate. When the plate is inverted, the agar surface makes direct contact with the surface. Once exposed, the plate is then covered, incubated, and enumerated for viable colonies. With this method, foods surfaces as well as environmental surfaces can be examined. In testing a surface that may have been cleaned with certain compounds, it may be necessary to add a neutralizer in the medium. This method, however, is not effective for enumerating heavily contaminated surfaces.
4. Air sampling: Numerous methods exist for the sampling of air in food plants for the presence and relative numbers of the microorganism. The most commonly used methods are impingement in liquids, impaction on solid surfaces, and sedimentation. Impingers are advantageous in that a specific quantity of air can be sampled. Filtration, centrifugation, electrostatic precipitation, and thermal precipitation may be used in air sampling. The simplest of air sampling techniques is to open pre-poured petri dishes for specific periods of time in the area to be assessed. The results obtained are influenced by size of particles and speed and direction of air flow.

B. Isolation and Identification

Isolation and identification of microorganisms can be as simple as performing isolation streaks for a colony and gram stains to much more sophisticated procedures using immunologic assays, chemical assays, and physical assays. Many microbiological analytical methods require that samples be immersed into an enrichment media to encourage growth of the target organism and to discourage growth of other naturally occurring organisms. Subsequent transfers to other microbiological media are used to purify food extract and isolate specific bacterial species. Additional confirmatory tests can be used to identify microbial species and biotypes. Selection and use of any microbiological methods should depend on resources available, analysis time, cost, sensitivity, specificity, technical expertise required, etc. In this chapter, it is not possible to go into detail about all of the procedures that may be used to identify microorganisms in foods. Some of these methods are briefly described below.

1. Nucleic acid (DNA) probes: DNA probes have been prepared for a number of foodborne microorganisms such as *salmonellae*, *listeriae*, staphylococcal enterotoxins, *Clostridium perfringens* enterotoxin, *Entamoeba histolytica*, and enterotoxigenic *E. coli*. A DNA probe, which is usually labeled with a radioisotope, consists of the DNA sequence of an organism of interest that can be used to detect homologous DNA or RNA sequences. The probe DNA must hybridize with that of the strain to be sought. Ideally, the DNA sequence that contains the genes that code for a specific contaminant is used.
2. PCR: An increasingly popular and highly reliable method for identification is DNA amplification – polymerase chain reaction (PCR) method. This method is a powerful, rapid system for detecting the presence of foodborne pathogens. This technique, performed in a very clean work environment, employs thermostable DNA polymerase and 5′ and 3′ specified oligonucleotide primers. It enables amplification of a single molecule of DNA to 10^7 molecules after a series of amplification cycles, typically from 20 to 50. The amplified DNA is then detected by use of either agarose gels or Southern hybridization employing a radiolabeled probe. Most PCR reagents now come in kit form.
3. Immunoassays: These methods are based on the interaction of antibodies, and consist of a wide range of rapid detection methods that are relatively simple to detect and identify contaminants associated with food products. Many are readily available in kits. Examples of immunoassays used in the food industry include the use of fluorescent antibodies, immunoaffinity columns, enrichment serology, enzyme-linked immunosorbent assay (ELISA), radioimmunoassay, and hemaggultination. The technique of radioimmunoassay (RIA) consists of adding a radioactive label to an antigen, allowing the antigen to react with its specific antibody, and measuring the amount of antigen that combined with the antibody by the use of a

counter to measure radioactivity. Using this method, detection and identification of bacterial cells can be achieved. RIA is used for identifying and enumerating staphylococcal enterotoxins, *V. cholerae* that produce cholera toxin, aflatoxins, and other mycotoxins. Multibacterial species can be detected in one operation when mixtures of homologous antibodies are used. The RIA method can also be used to identify biological hazards such as endotoxins and paralytic shellfish toxins in foods examined.

The ELISA method is similar to that of the RIA but rather than employing a radioactive isotope, it uses an enzyme coupled to antigen. A typical ELISA is performed with a solid phase (e.g., beads, test wells, or dipstick) coated with antigen and incubated with antiserum. Following incubation and washing, an enzyme-labeled preparation of anti-immunoglobulin is added. After gentle washing, the amount of enzyme remaining in the tube or microtiter well is measured colorimetrically. The color change reveals the presence or absence of the contaminant as well as estimation on enumeration. There are many variations of ELISA.

C. Enumeration

Many procedures exist for estimating a microbial population. Ideally, the method used should be accurate, rapid, inexpensive, and standardized. Methods should be selected based on the use of the information that is obtained. Examples of systems used in estimating the number of microorganisms in foods are listed in Table 50.1. The basic methods used in quantitative analysis include standard plate counts (SPC) for viable cells, the most probable number (MPN) method as a statistical determination of viable cells, dye-reduction techniques to estimate numbers of viable cells that possess reducing capacities, and direct microscopic count (DMC) for both viable and non-viable cells.

1. Plate Counts for Viable Cells

The most widely used and basic technique used for enumeration of microorganisms is the standard plate count (SPC). It is relatively simple and consists of plating appropriate dilutions by transferring an aliquot for either pour plating (pouring molten agar onto plate) or spread plating (evenly transferring the aliquot onto a hardened agar surface). The plates are incubated at an appropriate temperature/time and the colonies are enumerated. Use of spiral plates and use of selective media in the agar further enhance this procedure. SPC is considered one of the most precise methods for determining microorganisms such as bacteria and yeast that will grow in an agar medium.

TABLE 50.1
Systems Used in Enumeration of Microorganisms in Foods

Direct microscopic count (DMC)	Electrical
Breed clump count	Conductance
Electronic particle count	Impedance
Howard mold counts	Capacitance
	Voltage drop
Pour plate	Spectrophotometric (optical density)
Spread plate	Adenosine triphosphate (ATP)
Spiral plate	Reductase tests
Drop plate	Easicult-TTC
Plate loop	Immuno-affinity columns
Roll tube	Respiration rates
Oval tube	*Limulus* amoebocyte lysate (LAL)
Burri strip/slant	Chemical indicators
Restriction fragment length polymorphism (RFLP)	(decomposition products)
Little plate	pH
Tube dilution	Agar droplets
Most probable number	Millipore sampler
Membrane filter	Bactoscan
Hydrophobic grid (HGMF)	Microcalorimetry
Direct epifluorescent filter technique (DEFT)	Flow cytometry
	Gas chromatography
Microcolony-DEFT	Radioimmunoassay (RIA)
Agar droplets	Thermostable nuclease
Microtiter-Spot plate	Fluorescent antibody
Dry rehydratable film	Enzyme-linked immunosorbent
Petri film	assay (ELISA)

2. Total Cell Counts

Some methods do not differentiate between viable and non-viable cells, giving total cell counts. These methods are appropriate for use when evaluating the microbial content of a food and/or evaluating the number of body cells in milk such as the detection for mastitis in cows. The value of total cell counts is limited to samples with high cell loads. Total cell counts are useful in determining the quality of pasteurization and recontamination of foods, and are a rapid method to estimate the bacterial load. Examples of total cell counts are direct microscopic count (DMC), spectrophotometric assay, and electronic particle count. In DMC, a suspension of the sample is stained and observed using a counting chamber or spread over a prescribed area on a glass slide and the number of cells calculated per area. Using this method, cell morphology can be seen and it lends itself to fluorescent probes for improved efficiency. However, since it is a microscopic analysis, it is fatiguing to the analyst, and food particles are not always distinguishable from the bacteria.

A rapid method to estimate total cell count is the spectrophotometric analysis. A suspended sample is analyzed by a spectrophotometer, where a light of a specified wavelength is passed through the sample. The amount of

absorbance and percentage of transmittance of the light can then be correlated to an estimated cell count. However, using this method, no selectivity is made to the microorganism or debris in the sample such as food particles. Clumping of cells may also lead to a miscued estimation. Due to the various size of contaminates, adjustments may have to be made to the readings as well as the wavelength used.

Many more methods exist for the enumeration of viable organisms in foods. Most of the basic systems for enumeration of viable organisms are based on the plate count or the tube dilution method. Selective media or environmental conditions are often used if a specific contaminant is targeted. More advanced assays for rapid analysis are based on the metabolic activity of the contaminant on given substrates, measurements of growth response, or the immunologic responses to the microorganism.

Use of nitrocellulose or hydrophobic grid membranes to filter the sample solution through pores that retain bacteria or mycobacterium (usually 0.45 μm) but allow for the suspension to flow through is especially suited for assays when the microbial count of the sample is expected to be relatively low. Following the collection of the contaminant upon filtering a given volume, the membrane is placed on a hardened growth media and incubated at an appropriate temperature. To improve microbial yield and decrease background particles on the filter such as food and sediments, use of prefilters, surfactants and enzymes, and stains are incorporated into the assay. Analysis of the samples can be made after 2–4 hours with a microscope or 24–48 hours similarly to plate counts after incubation.

3. Most Probable Number (MPN) Methods

To estimate a low concentration of organisms in a sample, the most probable number (MPN) method can be used. Several tubes are prepared from consecutive ten-fold sample dilutions and recorded as either positive or negative for growth. In some instances, MPN is easier and simpler to perform than the plate count. It is particularly useful for samples with only a few organisms and can be used to detect organisms in samples larger than 1 g. The relationship between positive and negative tubes has been determined mathematically and tables have been developed for convenient estimations of cell concentrations.

The adenosine triphosphate (ATP) bioluminescence measurement system is relatively simple and rapid, with its results being reliable and acceptable for food and water analysis. The method for determining ATP is based on the reaction of luciferin and luciferase, which when reacted with ATP in the presence of magnesium ions causes a light emission. By using a photometer to measure the light emission when bacterial ATP reacts with the luciferin-luciferase system, quantitative analysis is made of the microbial load. Limitation to the analysis is that, since the luciferin-luciferase system accounts for all ATP in the sample, non-bacteria ATP must be removed prior to analysis.

D. Indicator Organisms

The first use of indicator organisms probably occurred in 1892, when Schardinger tested water for *E. coli* in search of *Salmonella typhi*. He theorized that, while it is difficult to detect *S. typhi* in a water supply, the presence of *E. coli* would indicate that there might have been contamination from sewage and that *Salmonella* or other coliforms might be present. Certain criteria are used to determine the value of an indicator organism in instances where specific pathogens such as fecal coliforms are targeted. Exclusive association with contamination and specificity with the pathogen should be seen. The usual source of the indicator and the significance of it should be known. The indicator should not be present as a natural contaminant of the material being analyzed. Moreover, detection, differentiation from background microorganisms, and enumeration of the indicator should be rapid and accurate. It is also beneficial if a standardized test for detection and enumeration exists. In using indicator organisms to determine product quality or shelf life, it is ideal that the indicator organism used possess qualities such as: presence and detection in all foods to assess quality growth and numbers have a direct correlation with product quality (in spoilage, the indicator organisms can be a natural contaminant of the material being analyzed) detection; and enumeration should be relatively easy, quick, and distinguishable from background microorganisms; growth of indicator microorganisms are not affected adversely by other components of the food flora.

VII. FOOD SAFETY

Ensuring safe food is an important public health priority for our nation. An estimated 76 million illnesses, 323,914 hospitalizations, and 5,194 deaths are attributable to foodborne illness in the United States each year. The estimated cost of foodborne illness is $10–$83 billion annually. For some consumers, foodborne illness results only in mild, temporary discomfort or lost time from work or other daily activity. For others, especially pre-school age children, older adults, and those with impaired immune systems, foodborne illness may have serious long-term consequences or may even be life threatening. The risk of foodborne illness is of increasing concern due to changes in the global market, aging of our population, increasing numbers of immunocompromised and immunosuppressed individuals, and changes in food production practices.

Numerous biological agents other than bacteria are known to cause foodborne illness. Many of these organisms or substances, such as the toxins produced by some

fungi, were identified and confirmed as a causative agent of foodborne illness several decades ago. Others, especially prions and some of the parasitic protozoa, have only been studied during the past 20 years. The etiology of foodborne disease outbreaks is changing and can be a subject of great debate. The majority of illnesses or deaths due to food consumption are grossly underreported worldwide. The ability to link particular food sources, and food production, processing and preparation practices to foodborne illness is a challenge for epidemiologists. In the U.S., fewer than 1 in 1,000 estimated cases of foodborne illness are confirmed. Bacteria are the causative agents in approximately half of the confirmed cases of foodborne illness in the U.S. The remainder are attributed primarily to viruses or to other chemical agents or parasites. In the future, we should expect the proportion of confirmed cases and outbreaks of foodborne illness to increase as improved diagnostic tools are developed and surveillance for foodborne diseases improves.

Over the past two decades, microbiological food safety has received greater attention from regulatory authorities, researchers, public health officials, and consumers. We are continually learning more about the sources of microbial foodborne safety problems and how to prevent them. For several reasons, we may discover new food safety problems that may shift our current priorities for control of microbial foodborne illnesses. For example, we may be able to more easily detect and quantify microbial disease agents due to advances in laboratory methodologies. Also, we may discover new or emerging pathogenic organisms. Many microbial species have been shown to become more or less virulent over time. And, increased global food trade and international travel can lead to rapid transmission of foodborne pathogens around the world.

VIII. SPOILAGE BY MICROORGANISMS

Many species of microorganisms are known to cause spoilage of some foods. Spoiled foods are generally considered unacceptable to eat because of a poor odor, flavor, texture or appearance. Microbiological food spoilage occurs when the growth of bacteria, yeast, or mold leads to the production of microbial metabolic byproducts which make the food product unacceptable to eat.

The shelf life of a food refers to its useful storage life. At the end of shelf life, foods may be perceived as significantly different or unacceptably different from fresh quality. In foods, the shelf life of a perishable item is greatly affected by the initial microbial load present. Generally, if a food contains a large population of spoilage organisms, it will have a shorter shelf life than the same food containing fewer numbers of the same spoilage organisms. Excessive growth of spoilage microorganisms in a food can lead to changes in its composition or structure which may ultimately render the food unacceptable to consumers. For example, many microorganisms produce enzymes that can cause fats or proteins to breakdown into aromatic compounds that can diminish sensory qualities and consumer acceptance. The breakdown of food components may also change the texture or water holding capacity of the food, especially near the surface. High temperature storage of these products can accelerate the rate that these enzymes promote changes in food quality.

Microbiological food spoilage can occur when bacteria, yeast, or mold grows to a sufficient level leading to the production of metabolic by-products that ultimately make the food unacceptable for consumption. Generally, many foods are considered spoiled or at the end of their typical shelf life when their total bacterial concentration is approximately 10^7 per g or per mL. Also, foods may be at the end of their shelf life if the yeast concentration is 10^5 per g or per mL, or if visible mold is present. Since bacteria, yeast, and molds are typically present in some foods and proliferate under different environmental conditions, spoilage of particular foods is usually caused by specific species of bacteria, yeast, or mold.

Generally, spoilage of foods can be delayed by appropriate processing, packaging, and storage of these products. Food processors can also delay microbiological spoilage by using quality raw materials with low microbial loads. Also, strict adherence to industry current Good Manufacturing Practices or processing under sanitary conditions will also prevent the introduction or growth of spoilage microorganisms in processed foods. The processing and packaging techniques used to inactivate or inhibit pathogenic microorganisms may also inhibit spoilage-causing microorganisms.

Microorganisms that may cause spoilage can replicate to unacceptably high concentrations in foods that are stored at higher temperatures and for longer times than recommended. After processing, most foods have optimum or prescribed storage conditions including time, temperature, and humidity. Processors, retailers, and consumers should follow proper storage recommendations for raw and processed foods to ensure optimal product quality.

IX. FOOD PRESERVATION

From the first stage of processing, the quality of food can deteriorate over time. The shorter the amount of time it takes a product or ingredient to be transformed or transported to its final destination, the consumer, the more advantageous. For this reason many foods are kept “alive” and “healthy” as long as possible. Once a food is no longer “alive” the quality decreases at varying rates dependant on the product and its environment. Degradation begins on many physical and chemical levels. This may be caused by microbiological, enzymatic, chemical, or physical means. Environmental

conditions that may increase or decrease the quality of a product include temperature, humidity, handling, packaging, transport, and, of course, time. Product water activity (Table 50.2), pH, amino acid content, fatty acid content, vitamin content, and naturally occurring enzymes may also affect the quality of a product. Atmospheric modification, acidification, temperature reduction, thermal processing, reduction of water activity (Table 50.2), fermentation, and the addition of antimicrobials can combat naturally occurring microbiological processes.

The two major categories of food preservation are chemical methods and physical methods. Chemical methods are chemical preservatives, which include antimicrobials, antioxidants, and anti-browning agents. Physical methods of preservation include low temperature preservation, high temperature preservation, radiation, modified atmosphere packaging, and drying.

A. Antimicrobials and Preservatives

Many antimicrobials are bacteriostatic or fungistatic and can only be added to certain levels within strict accordance with established regulations. Therefore, preservation of the quality of the food will not last indefinitely. Oftentimes use is in conjunction with other methods of preservation in order to provide a "multiple hurdle" defense against microorganisms. Occasionally, preservatives are added to foods for one purpose, but they may also indirectly act as antimicrobials. For many antimicrobials the exact mechanism or component that the chemical affects on the microorganism's cellular level is unknown. In general, particular cellular components such as the cell wall, cell membrane, metabolic processes, and genetic material are targeted for disruption, causing cell death or inhibition. No antimicrobial is the "silver bullet" for all microorganisms. Some may affect several types of microorganism but with only a limited effect; therefore, several different antimicrobials may be applied to help control the multiple microbiological concerns of a single product. A list of several common antimicrobials is provided in Table 50.3.

TABLE 50.2
Water Activity of Microorganisms and Select Foods

Food	Minimal a_w
Fresh fruits, vegetables, meat, and fish	0.98
Cooked meat	0.98–0.95
Cured meat products, cheeses	0.95–0.91
Sausages, syrups	0.91–0.87
Most bacteria can grow	0.91
Most yeasts can grow	0.88
Flours, rice, beans, peas	0.87–0.80
Most molds can grow	0.80
Jams	0.80–0.75
Halophilic bacteria can grow	0.75
Xerotolerant molds can grow	0.71
Dried fruits	0.65–0.60
Spices, milk powder	0.60–0.20

B. Low Temperature Preservation

The ability of low temperatures to preserve foods is based on the principal that all biological systems are controlled by enzymatic reactions including those that control microorganisms and cause quality degradation. The rate of these reactions is directly related to temperature. With a rise or fall in temperature the enzymatic rate of reaction increases or decreases, respectively. In biological systems, for each rise in temperature of 10°C there is approximately a two-fold increase in the enzymatic rate of reaction. Keep in mind that the temperature range and increase must be within appropriate parameters for that particular enzymatic function. Most microorganisms are significantly slowed at temperatures ranging from 0–7°C and many will not replicate with the exception of psychrotrophic organisms that will cause spoilage at these temperatures. Below 0°C all microbiological activity ceases; however, some enzymatic activity may still occur.

TABLE 50.3
Chemical Food Preservatives

Preservatives	Maximum Tolerance	Organisms Affected	Foods
Propionic acids	0.32%	Molds	Bread, cakes, cheeses
Sorbic acid	0.2%	Molds	Hard cheeses, syrups, salad dressings
Benzoic acid	0.1%	Yeasts and molds	Margarine, pickle, relishes, soft drinks, salad dressings
Parabens	0.1%	Yeasts and molds	Bakery products, soft drinks, pickles
Sulfites	200–300 ppm	Insects, microorganisms	Molasses, dried fruits, wines
Ethylene/propylene oxides	700 ppm	Yeasts, molds	Fumigant for spices, nuts
Sodium diacetate	0.32%	Molds	Bread
Nisin	1%	Lactis, clostridia	Pasteurized cheese
Dehydroacetic acid	65 ppm	Insects	Pesticide on strawberries, squash
Sodium nitrite	120 ppm	Clostridia	Meat-curing preparations

C. High Temperature Preservation

Two common types of high temperature preservation are pasteurization and sterilization. These processes are successful due to the general destruction of microorganisms at elevated temperatures. Pasteurization employs a technique of heating a substance, usually a liquid, to temperatures high enough to destroy most bacteria, including pathogens, without major chemical alteration of the product. The organisms that survive fit into either thermoduric or thermophilic categories. Thermoduric organisms, including the genus *Lactobacillus*, can withstand relatively high temperatures but are non-spore forming. Thermophiles, including the genera *Bacillus* and *Clostridium*, are sporeformers that require high temperatures for regular metabolic activity. The complete elimination of all microorganisms is referred to as sterilization. No viable organisms can be detected after this process.

D. Radiation Preservation

Radiation can be defined as the emission of radiant energy in the form of particles or waves. The food industry uses four major forms of radiation, including ultraviolet light, gamma radiation, electron beam radiation, and microwave radiation. The first three types depend on disruption at a molecular level causing lethal mutations in the microorganism's genetic code to destroy microorganisms. Ultraviolet light is most destructive at a range between 240 nm and 280 nm. Gram-negative bacteria are most affected by this kind of radiation. Gamma radiation is radiation emitted from Cobalt or Cesium sources. Electron beam radiation has a lower penetration power and requires a higher dose. Electron beam and gamma radiation are referred to as cold sterilization, achieving no increase in heat to produce to the required bactericidal effect. These methods can, however, cause undesirable color changes in the product at higher dosages. Microwaves use the friction of oscillating molecules to produce heat and thereby destroy microorganisms. Depending upon the radiation source, dose, product, presence or absence of oxygen, condition of food, target organism, microbial load, packaging, and surface cleanliness the effect of radiation varies widely.

In using radiation to preserve foods, the reactive ions produced by irradiating foods injure or destroy microorganisms by altering the cell membrane structure and affecting metabolic enzyme activity. More importantly, the DNA and RNA molecules in cell nuclei, which are essential for growth and replication, are affected. Analogous to heat processing, the rate of destruction of individual cells depends on the rate at which ions are produced and interreact with DNA, whereas the reduction in cell numbers depends on the total dose of radiation received. The rate of reduction is expressed as the D-value, in which the units are expressed in kiloGrays (kGy). A Gray (Gy) is the absorbed dose where 1Gy is the absorption of 1 J of energy per kilogram of food. Like thermal processing, irradiation is a first-order reaction, in which theoretically, a logarithmic reduction in microbial numbers with increasing dose is expected.

E. Drying Preservation

Microorganisms and enzymes require water in order to be active. Low-moisture foods, including freeze-dried foods, and intermediate-moisture foods are the two categories of shelf stable dried food preservation. To be defined as a low-moisture food, the product cannot contain more than 25% moisture and has to achieve a_w less than 0.60. If the product contains between 15–50% moisture and a a_w of between 0.60 and 0.85 it is defined as an intermediate moisture food. During drying a wet hot heat causes more damage to microbial cells than dry heat. Freeze drying employs a vacuum sublimation of the ice content. The lowered a_w and moisture levels produced through these processes are capable of inhibiting any spoilage or pathogenic organisms.

F. Modified Atmosphere Packaging

Modified atmosphere packaging (MAP) is any package that contains a gas composition deviant from atmospheric air. Typically this is achieved by varying the amounts of oxygen, carbon dioxide, and nitrogen, in effect to increase the amount of CO_2. Carbon dioxide has been known to extend the shelf life of food products for over 100 years. The reduction or removal of atmospheric air does not provide an environment conducive for growth of typical spoilage organisms. Occasionally, as in the case with vacuum packaging, a product may begin with little atmospheric oxygen, which is consumed and converted to CO_2 by normal aerobic microflora. The concentration of CO_2 may reach as high as 30%. Most of the time a known concentration of CO_2 is added to a high barrier plastic film in order to achieve a preservation effect. Many different variations of this general principle are used to achieve the proper effect for different products. Another way to manipulate the atmosphere of a package is to employ the use of different types of plastics for packaging. Depending upon the molecular composition of the plastic and how it is formed the rate at which molecules of oxygen, carbon dioxide, and water vapor pass through it vary. These are referred to as the oxygen transmission rate (OTR), carbon dioxide transmission rate (CO_2TR), and the water vapor transmission rate (WVTR). The units for these measurements are cc/m^2/24 h at 70°F. Transmission rates are also proportional to the thickness of the film. Some plastics may possess a low OTR but a high WVTR; therefore, many manufacturers use several combinations of plastics added in layers to achieve the desired film. No

plastic has a zero transmission rate; therefore, a food package, no matter how well constructed, may start with one type of atmosphere which will change over time.

Unfortunately, there are some problems associated with MAP. Pathogenic organisms compete for nutrients with spoilage organisms. Usually, the consumer would reject a food before pathogenic organisms are in high enough concentrations to cause harm. In the MAP environment the normal spoilage organisms are not there to compete with pathogens. What develops is a food product that smells and looks edible but is in fact riddled with pathogenic organisms. Due to the fear of *Clostridium botulinum* the FDA has recently increased the minimum recommended OTR to 10,000 cc/m^2/24 h at 70°F. An increase in CO_2 also causes some physiological changes such as the exudative loss of water. The binding of CO_2 to moisture in the product forms carbonic acid ultimately changing the pH. This can lead to off-flavors and consumer rejection.

G. Other Processes for Food Preservation

Other methods of preservation are increasingly used by researchers and are commercially available to a limited extent. Destruction of microorganisms through the use of high-power ultrasound has been attempted but thus far has not been made economically feasible. High-intensity pulsed light using high-intensity xenon arc lamps on quick short bursts utilizing a UV affect is currently being studied. Finally, high hydrostatic pressure (300 to 1,000 MPa) is used with products that are liquid or mostly consisting of liquid. The underlying mechanism hinges on the destruction of non-covalent bonds, which in turn disrupt the target organism's cellular function causing deactivation.

X. FERMENTATION

Fermentation is probably the oldest form of food preservation and can be defined as the breakdown of carbohydrates under anaerobic conditions. Fermented foods do not always fall under this strict definition and many times are produced from the breakdown of carbohydrates and carbohydrate-like components under aerobic and anaerobic conditions. Most fermentations, however, seldom break down only carbohydrates. These foods are products of microbial and enzymatic actions affecting many food constituents including fats, carbohydrates, proteins, and many others, each of which contributes to the final product.

Most forms of spoilage are undesirable. Conversely, fermentative spoilage produces favorable benefits of increased shelf life and added flavor. This beneficial spoilage is encouraged by the promotional growth of selected microorganisms for their unique end products and metabolic processes. Most forms of food preservation try to reduce or inhibit growth of microorganisms. Essentially, fermentation is a controlled spoilage using many variables such as atmosphere, temperature, salt content, and starter cultures.

Fermented foods can also be microbiologically safe as well as more nutritious. Many organisms used for fermentation produce acid as a by-product of their metabolic processes. As these organisms increase in number, the amount of acid produced increases, ultimately accumulating in the food and lowering the total pH of the product. Many pathogenic bacteria such as *Clostridium botulinum* cannot proliferate in low acid environments; therefore, the product remains microbiologically safe for extended periods of time. These same organisms can synthesize growth factors and vitamins, release nutrients from indigestible materials, and enzymatically break down indigestible sugars such as hemicellulose into usable sugar derivatives.

A list of several common fermented products, their substrates, and the microorganisms involved can be found in Table 50.4. One classic fermented product is beer. In this fermentation carbohydrates are broken down by the yeast *Saccharomyces cerevisae*, producing alcohol and carbon dioxide as by-products. Dairy fermentations are also very common whereby cheeses, yogurt, buttermilk, and sour cream are produced. For most common cheeses such as blue, cheddar, cottage, and gouda as well as buttermilk and sour cream *Lactococcus lactis* subsp. *cremoris/lactis* are the primary acid producers with a wide variety of secondary microflora.

Vegetable fermentation is also a major industry for food production. Cabbage (sauerkraut), cucumbers (pickles), olives (green olives), and soybeans (soy sauce) are but a few examples of vegetable fermentation. The three major types of vegetable fermentation include lactic acid,

TABLE 50.4
Fermented Food Products

Fermentation Product	Substrate	Microorganism
Cocoa beans	Cacao fruit	*Candida krusei*, *Geotrichum* spp.
Coffee beans	Coffee cherries	*Erwinia dissolvens*, *Saccharomyces* spp.
Miso	Soybeans	*Aspergillus oryzae*
Olives	Green olives	*Leuconostoc mesenteroides*, *Lactobacillus plantarum*
Pickles	Cucumbers	*Lactobacillus plantarum*
Sauerkraut	Cabbage	*Leuconostoc mesenteroides*
Soy sauce	Soybeans	*Rhizopus oligosporus*
Beer and ale	Cereal wort	*Saccharomyces cerevisae*
Bourbon whiskey	Corn, rye	*Saccharomyces cerevisae*
Cider	Apples	*Saccharomyces* spp.
Sake	Rice	*Saccharomyces sake*
Vinegar	Cider, wines	*Acetobacter* spp.
Wines	Grapes	*Saccharomyces* spp.

acetic acid, and alcoholic fermentation. Lactic acid may be produced in fermented vegetables by species including *Leuconostoc mesenteroides*, *Lactobacillus plantarum*, *Lactobacillus bavaricus*, and *Lactobacillus casei*. Other bacterial species, including *Acetobacter hansenii* and *Gluconobacter oxydans*, may produce acetic acid or vinegar during fermentation. Fermentations that result in alcoholic products may be produced by microbial species including *Saccharomyces cerevisae*, *Kluveromyces marxianus*, and *Aspergillus oryzae*. Meat, fish, and poultry can also be fermented to produce desirable products. For example, meats can be fermented to produce products such as pepperoni and sausage. Although the origins of fermentation may be ancient, the processes are still used today to provide a rich variety of safe and shelf stable foods.

XI. OTHER USES OF MICROORGANISMS IN FOOD PRODUCTION AND PROCESSING

Many bacteria are beneficial and essential to human health. At any time numbers of bacteria on and in a human body outnumber human body cells. Areas that contain consistently large numbers of microflora are the nose, throat, and gastrointestinal tract. When certain amounts of these beneficial bacteria, typically in the live state, are consumed or applied certain health benefits may be experienced. Generally, these microbial cocktails may contain one or many different strains in addition to viable cells, dead cells, and/or certain cellular components, and are loosely defined as probiotics. Prebiotics are indigestible components that influence certain numbers of targeted bacteria in the colon stimulating their activity and/or growth to benefit the host. Synbiotics are prebiotic and probiotic components combined.

Some dairy products contain probiotic bacteria, most commonly from the genera *Bifidobacterium* and *Lactobacillus.* When these harmless types of bacteria establish themselves in the gastrointestinal tract they occupy available space, thereby aiding in the inhibition of colonization of pathogenic bacteria. This concept has been expanded to an on-farm strategy called competitive exclusion. Young animals are given cocktails of nonpathogenic bacteria at a young age to colonize the gut in an attempt to prevent the infection of certain pathogenic strains. It has been successfully achieved in poultry with a combination of 29 species of bacteria and proven effective in cattle with one *Proteus mirabilis* strain and 17 strains of *E. coli*. In addition to reduced numbers of pathogenically infected animals, these treatments allow for faster growth and weight gain. If further developed, probiotic use may ultimately reduce the need for extensive antibiotic treatments for farm animals and aid in the reduction of the appearance of antibiotic-resistant strains of bacteria.

All the benefits from probiotic treatments are not currently known; however, successful treatments do increase the immune response and disrupt metabolic pathways for detrimental flora in the gastrointestinal tract. It is difficult to draw conclusions because key aspects of the studies (i.e., type and amount of cultures used, initial participant health, age, and resident flora) all vary greatly. As we learn more about the intricate relationship between nonpathogenic, pathogenic bacteria, and host response, this new technology will provide a healthier food system.

51 Microbial Food Spoilage

Lone Gram
Danish Institute for Fisheries Research, Technical University of Denmark

CONTENTS

I. INTRODUCTION

Descriptions of the potentially negative influence of microorganisms on food quality often focus on describing potential disease-causing organisms. Typically, many reviews or books on food microbiology contain many sections or chapters describing different pathogenic agents, and often spoilage of all foods is dealt with in a briefer manner. Although microbial spoilage of foods may somehow not be as spectacular as the intriguing behaviour of pathogenic agents, the problem must not be underestimated. Thus, microbial growth and metabolism, which is the major cause of *post-harvest* spoilage of foods, causes an estimated loss of 10–50% of all raw agricultural commodities produced globally (1). In some cases (fruits, vegetables, nuts), spoilage processes may also be initiated *pre-harvest*.

In the context of the present chapter, spoilage will describe changes in a product which render it unaccceptable for the consumer from a sensory perspective. Spoilage is product specific; for instance, formation of ammonia is a sign of spoilage in fresh, chill-stored fish but may be a desired quality in Camembert cheese.

Reactions or events other than microbial growth may lead to spoilage (sensory rejection). This includes phenomena such as lipid oxidation or discolouration, which will not be dealt with in this chapter.

II. CONCEPTS IN MICROBIAL FOOD SPOILAGE

Foods constitute a range of different ecosystems. Some foods are "alive" (fruits, vegetables, grains, nuts) and contain

defense systems which microorganisms need to overcome when growing. Other "dead" foods (meat, fish) are typically preserved by manipulating the physical and chemical environment by cooling, acidifying, salting, etc. (2). Microbial spoilage is almost always a consequence of growth of the spoiling organism to high numbers. Hence, a primary assessment of the microorganisms potentially involved in spoilage of a particular product can be done by matching the growth characteristics of different microorganisms with the preserving characteristics of the product. Although this will not identify the exact cause of spoilage, it will narrow the spectrum of potential culprits.

Microbial spoilage is detectable in many forms: as gas formation causing bombage, as slime formation due to production of extracellular polymers or the degradation of food matrixes, as visible colonial growth, or as off-flavours and off-odours arising from the microbial metabolism of food components. Mostly, growth of microorganisms to high numbers ($>10^5$ yeast cfu/g or $>10^7$–10^8 bacteria cfu/g) is required for spoilage to be noticable. In a few products, enzymes produced by microorganisms may remain active after inactivation of the microorganisms and cause spoilage during storage.

The microbiota on raw foods is very varied but a few species typically become dominant during storage. These are the ones capable of tolerating the specific preservation conditions used. The microbiota on freshly processed foods is also heterogenous and is a function of the microorganisms found on raw materials, on ingredients, and in the processing environment. Logically, the food processing steps, such as heat treatment or acidification, also have a major influence.

The concepts in microbial food spoilage have been outlined (3): the microbiota present when the product is spoiled is called the spoilage association or the spoilage microbiota. To determine the importance of the different microorganisms in the spoilage process, pure cultures are isolated from spoiled foods and tested for their ability to produce the sensory (and chemical) changes associated with the naturally spoiling product. Microorganisms with these abilities are said to posess a spoilage potential. However, it is crucial for the understanding of the spoilage process that quantitative considerations are included. Hence, for each organism with a spoilage potential, it must be evaluated if it is capable of growing in the "spoiling" product and if it reaches cell numbers in the spoiling product that are sufficient for the sensory and chemical changes to take place. Organisms that both qualitatively and quantitatively are linked to the spoiling product are said to have a spoilage activity. Verifying that these organisms are indeed the causative agents of spoilage requires trials with food systems. Thus, the identification of specific spoilage organism(s) of a product will require a combination of sensory, chemical, and microbiological analyses (4). The term spoilage domain is used to describe the range of conditions under which a specific spoilage organism is capable of influencing the spoilage process.

Using such approaches the specific spoilage microorganisms of several food products have been determined (Table 51.1). Gram-negative psychrotrophic bacteria such as pseudomonads are important spoilage agents of most fresh foods. As preservation "pressure" increases, e.g., by adding salt and acid, lactic acid bacteria and other fermentative organisms take over. Filamentous fungi and yeast are the spoilage agents of many products with low water activity or products such as citrus fruits where the fungi tolerate the specific defense components of the food (5). Although the same organisms may be the spoiling agent of different food products, the reactions leading to spoilage can be very different. Thus, pseudomonads are the main spoilage agents of fresh, chilled, aerobically packed meat where they degrade amino acids producing spoilage off-odours (4). In vegetables, where *Pseudomonas* spp. are also identified as one of the main spoilage organisms, they typically degrade the polymer (pectin) by pectinolytic acitivity, leaving a soft rotting liquified product (6).

Different organisms may, as single species, be the cause of spoilage. Hence, both Enterobacteriaceae (mostly *Erwinia* species) and *Pseudomonas* spp. may cause soft rot of vegetables. In some products, it may be difficult identifying one organism as the specific agent of spoilage and here mixtures of organisms may be responsible for spoilage. Examples of such metabiotic relationships include the combination of Enterobacteriaceae and lactic acid bacteria, which in vacuum-packed meat or cold-smoked salmon only produce spoilage metabolites similar to the spoiling products when both groups are present (7–10).

III. EXAMPLES OF SPECIFIC SPOILAGE ORGANISMS

Although many different types of microorganisms grow in different food products, several groups or species often are involved in the spoilage process. The sections below provide examples of the involvement of different microorganisms in food spoilage.

A. Pseudomonads, *Shewanella*, *Photobacterium*, *Pseudoalteromonas*

The psychrotrophic, Gram-negative, non-fermentative bacteria belonging to *Pseudomonas* spp. or identified as *Shewanella* spp. are very often identified as specific spoilage organisms. *Pseudomonas* spp. are the spoilage agents of vegetables where they degrade pectin (6), of aerobically packed meat where they degrade amino acids to volatile compounds such as sulfides (4), and of aerobically stored iced freshwater fish (11) and iced crustaceans where they produce esters and sulphydryl compounds (12). Also, extracellular hydrolytic enzymes of

TABLE 51.1
Typical Spoilage Organisms of Food Products

Organism	Vegetables	Chilled Meat			Chilled Fish			Milk	Flavoured Yogurt	Egg	Fruit	Soft Drinks	Beer	Bakery Goods	Oil-Based
		Fresh	Packed	Cured	Fresh	Packed	Cured								
Pseudomonas	+	+			+			+		+

Bacillus								+							
Clostridium			+												
Acyclobacillus															
Anaerobes													+		
Halophiles															
Yeasts							+		+			+	+	+	+
Filamentous fungi	+										+	+		+	

pseudomonads may be the cause of milk spoilage where lipolytic and proteolytic activity contributes to off-flavour formation and clotting (13). *Pseudomonas* spp. are also the main cause of rotting in eggs (14) where they cause pink rot (*P. fluorescens*) or fluorescent green rot (*P. putida*) (15). *Pseudomonas* spp. are strict respiratory organisms and are most important in products where oxygen is available.

Psychrotolerant *Shewanella* species are often involved in spoilage of marine products. Their ability to reduce the odourless trimethyl amine oxide (TMAO) to trimethylamine (TMA), which has a fishy smell, and to produce hydrogen sulphide involves them in spoilage of iced marine fish and shellfish. Psychrotrophic *Shewanella* spp. are sensitive to low pH and are not normally associated with spoilage of meat. However, they have been identified as a cause of off-odour in high-pH meat (16) and in chicken (17). The H_2S formation by *Shewanella* spp. in high-pH meat may also cause greening of the meat. Although strictly respiratory, *Shewanella* spp. are capable of utilizing several compounds as electron acceptors in an anaerobic respiration and they are therefore also associated with spoilage of vacuum-packed foods. The type strain of *Shewanella putrefaciens* was originally isolated from tainted butter (18).

In CO_2-packed marine fish, respiratory bacteria are inhibited and a marine, psychrotolerant bacterium *Photobacterium phosphoreum* is selected (19). The organism belongs to the Vibrionaceae family and produces large amounts of TMA (19).

Recently, another marine bacterium, *Pseudoalteromonas,* was identified as part of the spoilage microbiota of iced squid (20). These bacteria are capable of degrading urea, which occurs in high concentrations in squid, and they may be contributing to spoilage through ammonia formation.

B. Enterobacteriaceae

In classical food microbiology, members of the Enterobacteriaceae family are enteric mesophilic organisms and their presence in food products is an indication of hygienic failure. However, the family also covers psychrotrophic environmental strains that may occur in the environment of food raw materials and that may grow on chill-stored products. *Erwinia* species are common spoilage organisms of vegetables where, due to pectinolytic and proteolytic activity, they cause extensive soft rot spoilage (21, 22). Organisms like *Serratia*, *Enterobacter*, *Rahnella*, and *Hafnia* are often isolated in high numbers from fresh proteinaceous products such as milk, meat, or fish. Enterobacteraiceae may spoil liquid milk products during prolonged storage (23, 24) due to formation of off-odours or proteases causing "sweet curdling." Their interactive behaviour with lactic acid bacteria has been suggested to play a role in the spoilage process of vacuum-packed meat (7–9) and cold-smoked salmon (10).

C. Lactic Acid Bacteria and *Brochothrix*

Lactic acid bacteria (LAB) covers a conglomerate of many bacteria. LAB grow well under vacuum-packing and have a relatively high tolerance towards salt and acid. Hence, they must be considered when evaluating spoilage of packed and/or preserved products. Yeasts, as will be discussed below, tolerate many of the same preservation parameters and are often selected in the same products where LAB dominate. Many of the LAB have no effect on food quality and, for instance, some *Carnobacterium* spp. may grow to numbers of 10^8–10^9 cfu/g with no adverse effects on quality (25). Some may even have a preserving effect on the product. However, some species are potent spoilage organisms producing sour off-odours (26, 27), gas (28, 29), or exopolysaccharides (30, 31). Some species (e.g., *L. saké* or *L. curvatus*) are able to produce hydrogen sulphide (32, 33), causing sulphorous off-odours. The green discolouration which may sometimes be seen on meats can be caused by LAB due to hydrogen peroxide oxidation of meat pigment (33). Greening may also be explained by the formation of sulfmyoglobin caused by Gram-negative H_2S-producing bacteria, typically *Shewanella* (34). LAB have also been identified as spoilage organisms of beer and soft drinks. Some species of LAB, such as *Lactobacillus curvatus* and *Lactobacillus saké*, are potent producers of hydrogen sulphide whereas other species produce acid and/or CO_2 in large amounts, causing souring or bombage of the product. Some homofermentative *Lactobacillus* may also form so-called ropy slime due to exopolymer production (9).

If allowed to grow to high numbers, *Leuconostoc* species are often associated with spoilage. They may produce off-odours and off-flavours as well as bombage. However, their most prominent characteristic is their ability to produce slime (exo-polysaccharides), which can be a spoilage sign of cured meat products (9, 35).
