HANDBOOK OF FOOD SCIENCE, TECHNOLOGY, AND ENGINEERING

Volume 1

FOOD SCIENCE AND TECHNOLOGY

A Series of Monographs, Textbooks, and Reference Books

Editorial Advisory Board

95. International Food Safety Handbook: Science, International Regulation, and Control, *edited by Kees van der Heijden, Maged Younes, Lawrence Fishbein, and Sanford Miller*
96. Fatty Acids in Foods and Their Health Implications: Second Edition, Revised and Expanded, *edited by Ching Kuang Chow*
97. Seafood Enzymes: Utilization and Influence on Postharvest Seafood Quality, *edited by Norman F. Haard and Benjamin K. Simpson*
98. Safe Handling of Foods, *edited by Jeffrey M. Farber and Ewen C. D. Todd*
99. Handbook of Cereal Science and Technology: Second Edition, Revised and Expanded, *edited by Karel Kulp and Joseph G. Ponte, Jr.*
100. Food Analysis by HPLC: Second Edition, Revised and Expanded, *edited by Leo M. L. Nollet*
101. Surimi and Surimi Seafood, *edited by Jae W. Park*
102. Drug Residues in Foods: Pharmacology, Food Safety, and Analysis, *Nickos A. Botsoglou and Dimitrios J. Fletouris*
103. Seafood and Freshwater Toxins: Pharmacology, Physiology, and Detection, *edited by Luis M. Botana*
104. Handbook of Nutrition and Diet, *Babasaheb B. Desai*
105. Nondestructive Food Evaluation: Techniques to Analyze Properties and Quality, *edited by Sundaram Gunasekaran*
106. Green Tea: Health Benefits and Applications, *Yukihiko Hara*
107. Food Processing Operations Modeling: Design and Analysis, *edited by Joseph Irudayaraj*
108. Wine Microbiology: Science and Technology, *Claudio Delfini and Joseph V. Formica*
109. Handbook of Microwave Technology for Food Applications, *edited by Ashim K. Datta and Ramaswamy C. Anantheswaran*
110. Applied Dairy Microbiology: Second Edition, Revised and Expanded, *edited by Elmer H. Marth and James L. Steele*
111. Transport Properties of Foods, *George D. Saravacos and Zacharias B. Maroulis*
112. Alternative Sweeteners: Third Edition, Revised and Expanded, *edited by Lyn O'Brien Nabors*
113. Handbook of Dietary Fiber, *edited by Susan Sungsoo Cho and Mark L. Dreher*
114. Control of Foodborne Microorganisms, *edited by Vijay K. Juneja and John N. Sofos*
115. Flavor, Fragrance, and Odor Analysis, *edited by Ray Marsili*
116. Food Additives: Second Edition, Revised and Expanded, *edited by A. Larry Branen, P. Michael Davidson, Seppo Salminen, and John H. Thorngate, III*
117. Food Lipids: Chemistry, Nutrition, and Biotechnology: Second Edition, Revised and Expanded, *edited by Casimir C. Akoh and David B. Min*
118. Food Protein Analysis: Quantitative Effects on Processing, *R. K. Owusu-Apenten*
119. Handbook of Food Toxicology, *S. S. Deshpande*
120. Food Plant Sanitation, *edited by Y. H. Hui, Bernard L. Bruinsma, J. Richard Gorham, Wai-Kit Nip, Phillip S. Tong, and Phil Ventresca*
121. Physical Chemistry of Foods, *Pieter Walstra*
122. Handbook of Food Enzymology, *edited by John R. Whitaker, Alphons G. J. Voragen, and Dominic W. S. Wong*
123. Postharvest Physiology and Pathology of Vegetables: Second Edition, Revised and Expanded, *edited by Jerry A. Bartz and Jeffrey K. Brecht*
124. Characterization of Cereals and Flours: Properties, Analysis, and Applications, *edited by Gönül Kaletunç and Kenneth J. Breslauer*
125. International Handbook of Foodborne Pathogens, *edited by Marianne D. Miliotis and Jeffrey W. Bier*
126. Food Process Design, *Zacharias B. Maroulis and George D. Saravacos*
127. Handbook of Dough Fermentations, *edited by Karel Kulp and Klaus Lorenz*
128. Extraction Optimization in Food Engineering, *edited by Constantina Tzia and George Liadakis*
129. Physical Properties of Food Preservation: Second Edition, Revised and Expanded, *Marcus Karel and Daryl B. Lund*

130. Handbook of Vegetable Preservation and Processing, *edited by Y. H. Hui, Sue Ghazala, Dee M. Graham, K. D. Murrell, and Wai-Kit Nip*
131. Handbook of Flavor Characterization: Sensory Analysis, Chemistry, and Physiology, *edited by Kathryn Deibler and Jeannine Delwiche*
132. Food Emulsions: Fourth Edition, Revised and Expanded, *edited by Stig E. Friberg, Kare Larsson, and Johan Sjoblom*
133. Handbook of Frozen Foods, *edited by Y. H. Hui, Paul Cornillon, Isabel Guerrero Legarret, Miang H. Lim, K. D. Murrell, and Wai-Kit Nip*
134. Handbook of Food and Beverage Fermentation Technology, *edited by Y. H. Hui, Lisbeth Meunier-Goddik, Ase Solvejg Hansen, Jytte Josephsen, Wai-Kit Nip, Peggy S. Stanfield, and Fidel Toldrá*
135. Genetic Variation in Taste Sensitivity, *edited by John Prescott and Beverly J. Tepper*
136. Industrialization of Indigenous Fermented Foods: Second Edition, Revised and Expanded, *edited by Keith H. Steinkraus*
137. Vitamin E: Food Chemistry, Composition, and Analysis, *Ronald Eitenmiller and Junsoo Lee*
138. Handbook of Food Analysis: Second Edition, Revised and Expanded, Volumes 1, 2, and 3, *edited by Leo M. L. Nollet*
139. Lactic Acid Bacteria: Microbiological and Functional Aspects: Third Edition, Revised and Expanded, *edited by Seppo Salminen, Atte von Wright, and Arthur Ouwehand*
140. Fat Crystal Networks, *Alejandro G. Marangoni*
141. Novel Food Processing Technologies, *edited by Gustavo V. Barbosa-Cánovas, M. Soledad Tapia, and M. Pilar Cano*
142. Surimi and Surimi Seafood: Second Edition, *edited by Jae W. Park*
143. Food Plant Design, *Antonio Lopez-Gomez; Gustavo V. Barbosa-Cánovas*
144. Engineering Properties of Foods: Third Edition, *edited by M. A. Rao, Syed S.H. Rizvi, and Ashim K. Datta*
145. Antimicrobials in Food: Third Edition, *edited by P. Michael Davidson, John N. Sofos, and A. L. Branen*
146. Encapsulated and Powdered Foods, *edited by Charles Onwulata*
147. Dairy Science and Technology: Second Edition, *Pieter Walstra, Jan T. M. Wouters and Tom J. Geurts*
148. Food Biotechnology, Second Edition, *edited by Kalidas Shetty, Gopinadhan Paliyath, Anthony Pometto and Robert E. Levin*
149. Handbook of Food Science, Technology, and Engineering - 4 Volume Set, *edited by Y. H. Hui*
150. Thermal Food Processing: New Technologies and Quality Issues, *edited by Da-Wen Sun*
151. Aflatoxin and Food Safety, *edited by Hamed K. Abbas*
152. Food Packaging: Principles and Practice, Second Edition, *Gordon L. Robertson*

Preface for Volumes 1 and 2

In the last 30 years, progress in food science, food technology, and food engineering has advanced exponentially. As usual, information dissemination for this progress is expressed in many media, both printed and electronic. Books are available for almost every specialty area within these three disciplines, numbering in the hundreds.

Collective works on the disciplines are also available, though in smaller number. Examples are encyclopedias (food science, food engineering, food packaging) and handbooks (nutrition, food processing, food technology). Because handbooks on these topics are limited, this four-volume treatise is released by Taylor & Francis to fill this gap. The title of these four volumes is *Handbook of Food Science, Technology, and Engineering* with individual volume title as follows:

- Volume 1: Food Science: Properties and Products
- Volume 2: Food Science: Ingredients, Health, and Safety
- Volume 3: Food Engineering and Food Processing
- Volume 4: Food Technology and Food Processing

This preface introduces Volumes 1 and 2. Each volume contains about 1,000 printed pages of scientific and technical information. Volume 1 contains 55 chapters and Volume 2 contains 46 chapters. Volume 1 presents the following categories of topics, with the number of chapters indicated:

- Food components and their properties, 14
- Food categories, 26
- Food analysis, 9
- Food microbiology, 6

Volume 2 presents the following categories of topics, with the number of chapters indicated:

- Food attributes, 7
- Food fermentation, 8
- Food and workers safety, food security, 12
- Functional food ingredients, 15
- Nutrition and health, 4

A brief discussion of the coverage for each volume is described below.

In Volume 1, the first group of topics covers the components and properties of food such as carbohydrate, protein, fat, vitamins, water, and pigments. The second group of topics covers the different categories of food products including, but not limited to, beverages, bakery, cereals, legumes, vegetables, fruits, milk, meat, poultry, fats, oils, seafood, and wine. The third group of topics describes the analysis of food such as basic principles and various techniques (chemical method, spectroscopy, chromatography, mass spectrometry, and other analytical methodology). The last group of topics covers food microbiology such as basic considerations, spoilage, land and marine animals, and analytical methodology.

In Volume 2, the first group of topics covers the attributes of food such as sensory science, data base concepts, flavor, texture, and color. The second group of topics covers food fermentation including basic principles, quality, flavor, meat, milk, cultured products, cheese, yeasts, and pickles. The third group of topics covers food from the perspective of safety, workers health, and security, especially in the United States, such as food standards, food protection methods, filth, pathogens, migratory chemicals, food plant sanitation, retail food sanitation, establishment safety, animal feeds and drugs, and bio-terrorism. The fourth group of topics covers major functional food ingredients including, but not limited to, antioxidants, colors, aroma, flavor, spice, enzyme, emulsifiers, phytates, sorbates, artificial sweeteners, eggs, gums. The last group of topics covers special topics in nutrition and health such as food allergy, Chinese edible botanicals, dietary supplements, and health related advertisement in the United States.

When studying the information in this two-volume text, please note two important considerations:

1. Although major topics in the discipline are included, there is no claim that the coverage is comprehensive.
2. Although the scientific information is applicable worldwide, a small number of topics with legal implications are especially pertinent in the United States.

These two volumes are the result of the combined effort of more than 150 professionals from industry, government, and academia. They are from more than 15 countries with diverse expertise and background in the discipline of food science. These experts were led by an international editorial team of 13 members from 8 countries. All these individuals, authors and editors, are responsible for assembling 2,000 printed pages of scientific topics of immense complexity. In sum, the end product is unique, both in depth and breadth, and will serve as an essential reference on food science for professionals in government, industry, and academia.

The editorial team thanks all the contributors for sharing their experience in their fields of expertise. They are the people who make this book possible. We hope you enjoy and benefit from the fruits of their labor.

We know how hard it is to develop the content of a book. However, we believe that the production of a professional book of this nature is even more difficult. We thank the editorial and production teams at Taylor & Francis for their time, effort, advice, and expertise. You are the best judge of the quality of this book.

The Editor

Dr. Y. H. Hui holds a Ph.D. in food and nutritional biochemistry from the University of California at Berkeley. He is semi-retired and has been a consultant to the food industry since 2000. He is currently a senior scientist with the consultant firm Science Technology System in West Sacramento, CA. He has authored, coauthored, edited, and coedited more than 35 books in food science, food technology, food engineering, food law, nutrition, health, and medicine, including the *Encyclopedia of Food Science and Technology*, *Bailey's Industrial Oils and Fat Products, Foodborne Disease Handbook*, *Food Plant Sanitation,* and *Food Processing: Principles and Applications*.

ASSOCIATE EDITORS

Dr. Jeff Culbertson is a professor of food science at the University of Idaho. He earned his B.S. and M.S. degrees at Oregon State University and his Ph.D. at Washington State University—all in Food Science. He previously taught at the University of Wisconsin–River Falls and Central Michigan University. For a number of years he was the manager of Corporate Quality at the Kellogg Corporation. He maintains an active consulting business with many Fortune 500 clients from the food and beverage industry.

Dr. Susan E. Duncan is a professor in the Department of Food Science and Technology, Virginia Polytechnic Institute and State University, Blacksburg, VA. She earned her Ph.D. in food technology and science, The University of Tennessee, Knoxville. She is the director of the Macromolecular Interfaces with Life Sciences Program, a multidisciplinary graduate program integrating polymer chemistry and life sciences. Dr. Duncan is a sensory specialist with a focus on quality issues of dairy, lipids, nutraceutical, and water/beverage products, emphasizing interactions with packaging materials. She has authored 50 peer-reviewed research publications and 7 book chapters. She is a member of the Institute of Food Technologists and American Dairy Science Association.

Dr. Eunice C. Y. Li-Chan is a professor of food science at the University of British Columbia, Faculty of Agricultural Sciences, Food Nutrition & Health Program. Her significant research contributions include pioneering studies that launched the use of Raman spectroscopy and fluorescent hydrophobic probes as tools to study food protein systems, research that established the potential and protocols for using egg yolk antibodies in lieu of mammalian polyclonal antibodies in immunochemistry and immunoaffinity techniques, and the isolation and characterization of value-added proteins and peptides as functional food ingredients. Her publication record includes authorship or coauthorship in over 75 original articles in peer-reviewed scientific journals, more than 25 chapters in books, and a book entitled *Hydrophobic Interactions in Food Systems* (1988, CRC Press).

Dr. Isabel Guerrero Legarreta is a profesor of food science, Department of Biotechnology, Universidad Autónoma Metropolitana, Iztapalapa, México. She received a B.Eng. degree (1972) in chemical engineering from the Universidad Nacional Autónoma de Mexico, Mexico City, an M.Sc. degree (1975) in food science from the University of Reading, England, and a Ph.D. (1983) in food science from the University of Guelph, Canada. Her research and teaching work has been focused on meat and fish preservation and utilization in subtropical areas. She has also studied the obtainment of products from marine resources, stressing the utilization of marine underutilized material and its by-products. Her professional contributions include over 100 papers, book chapters, and a patent on industrial carotenoid pigment separation from shrimp wastes.

Dr. C. Y. Ma obtained his Ph.D. in food chemistry from the University of British Columbia, Canada. After working as a research scientist in Agriculture and Agri-Food Canada for 16 years, he is now a professor of food science at the University of Hong Kong. His current research activities include the study of structure-function relationships of food proteins and bioactive peptides. The molecular structure and conformation of selected proteins with potential uses as food ingredients and peptides possessing biological/pharmaceutical activities are studied by various physical and chemical techniques. Professor Ma also studies the potential uses of under-utilized protein sources from cereal and legume seeds, and the improvements of functional properties of these proteins by various chemical and physical methods.

Dr. Charles Manley received his Ph.D. from the University of Massachusetts–Amherst for research in the area of food and flavor chemistry. He received a B.S. degree in chemistry at University of Massachusetts–Dartmouth. He has worked as a research chemist for the Givaudan Company, and in various research and management positions within a number of Unilever Companies, including manager of Beverage Development and Technology for Thomas J. Lipton, director of Flavor Operations for the National Starch and Chemical Company, and as vice president, International Business Development for Quest International. Currently he serves as vice president of science and technology for Takasago International Corporation (U.S.A.). Takasago is one of the leading Global Flavor and Fragrance Companies with sales volumes in the top five. His major corporate responsibilities have been in managing commercialization of scientific research efforts and departments at both Unilever and Takasago. He has made major professional contributions, including over 150 publications, patents, and presentations in the field of flavor ingredient safety, food processing and science, and natural product chemistry. He has served as the president of the Institute of Food Technologists (IFT) and the Flavor and Extract Manufacturers' Association (FEMA).

Professor Tom McMeekin holds a personal Chair of Microbiology at the University of Tasmania and is co-director of the Australian Food Safety Centre of Excellence. He is a Fellow of the Australian Academy of Technological Sciences and Engineering, Scientific Fellow of Food Standards Australia New Zealand, and Chair of the Food Safety Information Council. Professor McMeekin has contributed to more than 200 publications, including the monograph "Predictive Microbiology: Theory and Application," and has made greater than 30 invited international conference and workshop presentations. He is an executive board member of the International Committee of Food Microbiology and Hygiene and an editor of the *International Journal of Food Microbiology*. Awards include the JR Vickery Medal (International Institute of Refrigeration, 1987), the Annual Award of Merit (Australian Institute of Food Science and Technology, 1998), and International Leadership Award (International Association of Food Professionals, 2002).

Dr. Wai-Kit Nip is a food technologist emeritus from the Department of Molecular Biosciences and Bioengineering, University of Hawaii at Manoa, Honolulu. Dr. Nip received his B.S. degree (Food Technology, 1962) from National Chung-Hsing University, Taiwan, and an M.S. degree (Food Technology, 1965) and Ph.D. (1969) from Texas A&M University, College Station, Texas, U.S.A. He has taught classes in food processing, food safety, and experimental foods. Research activities include handling and processing of tropical fruits and vegetables, and aquatic foods. He has published numerous refereed articles, proceeding papers, and book chapters, and coedited several books in the food science and techology area. He is also the senior contributor of a patent. He has served at various capacities in local and national scientific organizations.

Dr. Leo M. L. Nollet is a professor of biotechnology at Hogeschool Ghent, Ghent, Belgium. The author and coauthor of numerous articles, abstracts, and presentations, Dr. Nollet is the editor of the *Handbook of Water Analysis*, *Food Analysis by HPLC*, and *Handbook of Food Analysis (3 volumes)* (all titles Marcel Dekker). His research interests include food analysis techniques, HPLC, and environmental analysis techniques. He received an M.S. degree (1973) and a Ph.D. (1978) in biology from the Katholieke Universiteit, Leuven, Blegium.

Dr. Mohammad Shafiur Rahman is an associate professor at the Sultan Qaboos University, Sultanate of Oman. He is the author or coauthor of over 150 technical articles and the author of the internationally acclaimed and award-winning *Food Properties Handbook* published by CRC Press, Boca Raton, FL. He is editor of the *Handbook of Food Preservation* published by Marcel Dekker, New York, which was translated into Spanish by Acribia, Spain in 2003. He is one of the editors for the *Handbook of Food and Bioprocess Modeling Techniques*, which will be published by Taylor & Francis. Dr. Rahman has initiated the *International Journal of Food Properties* (Marcel Dekker) and has been serving as the founding editor for more than 6 years. He is one of the section editors for the Sultan Qaboos University *Journal of Agricultural Sciences* (1999). In 1998 he was invited to serve as a food science adviser for the International Foundation for Science (IFS) in Sweden. He received B.Sc.Eng. (chemical) (1983) and M.Sc.Eng. (chemical) (1984) degrees from Bangladesh University of Engineering and Technology, Dhaka, an M.Sc. degree (1985) from Leeds University, England, and a Ph.D. (1992) in food engineering from the University of New South Wales, Sydney, Australia. Dr. Rahman has received numerous awards and fellowships in recognition of research/teaching achievements, including the HortResearch Chairman's Award, the Bilateral Research Activities Program (BRAP) Award, CAMS Outstanding Researcher Award 2003, and the British Council Fellowship.

Dr. Fidel Toldrá holds a B.Sc. degree in chemistry (1980), M.Sc. degree in food technology (1981), and a Ph.D. in chemistry (1984). Currently, he is research professor and head of the Laboratory of Meat Science, Department of Food Science,

at the Instituto de Agroquímica y Tecnología de Alimentos (CSIC) in Burjassot, Valencia (Spain). He is also an associate professor of food technology at the Polytechnical University of Valencia. Professor Toldrá has received several awards such as the 2002 International Prize for Meat Science and Technology, given by the International Meat Secretariat during the 14th World Meat Congress held in Berlin. Professor Toldrá has filed 7 patents, authored 1 book and 45 chapters of books, coedited 9 books, and published more than 121 manuscripts in worldwide recognized scientific journals. His research interests are based on food chemistry and biochemistry with special focus on muscle foods. He has served in several committees for international societies and, since May 2003, is also a member of the Scientific Commission on Food Additives, Flavorings, Processing Aids and Materials in contact with foods of the European Food Safety Authority (EFSA).

Dr. Youling L. Xiong is professor of food chemistry at the Department of Animal and Food Sciences, University of Kentucky. He obtained a Ph.D. from Washington State University (1989) and received postdoctoral training at Cornell University. Professor Xiong also holds joint appointments with the Graduate Center for Nutritional Sciences and the Center for Membrane Sciences at the university. Dr. Xiong's research focuses primarily on food protein chemistry and biochemistry, functionality, and applications, with an emphasis on muscle food processing. His fundamental work in food protein oxidation and the study of enzymic modification of soy, whey, wheat, and potato proteins to obtain physicochemically and biologically functional peptides has earned him several prestigious national awards. Dr. Xiong has published more than 130 research papers, contributed to 18 book chapters, and coedited two food science books. He also teaches undergraduate and graduate food chemistry, food protein, and meat science courses.

CONTENTS

I. INTRODUCTION TO CARBOHYDRATES

Carbohydrates, which in their basic form exhibit the general chemical formula $C_n(H_2O)_n$, are a class of organic compounds that were historically designated "hydrates of carbon" due to their observed elemental composition. As the most abundant class of organic compounds on Earth, carbohydrates are the primary constituents of plants and exoskeletons of crustaceans and insects. Therefore, carbohydrates are virtually an unavoidable element of daily life, as they are encountered in food (glucose, sucrose, starch, etc.), wood, paper, and cotton (cellulose). Carbohydrates

themselves can be sub-grouped according to the number of sugar building blocks comprising their respective structures from monomers (monosaccharides) right through to polymers (polysaccharides). In addition, the diversity of carbohydrates occurring within nature arises from the number of carbon atoms comprising sugar monomer units (monosaccharides of 3 to 9 carbon atoms), the varied chemical structure of monosaccharides (including substituent groups), and the nature of linkages joining monosaccharide units.

II. MONOSACCHARIDES

Monosaccharides, which represent the most basic carbohydrate elements, are polyhydroxy aldehydes and ketones commonly referred to as aldoses and ketoses, respectively. In addition, the number of carbon atoms present in the molecule also aids classification of monosaccharides. For sugars comprised of 3, 4, 5, 6, and 7 carbon atoms, the analogous aldose sugars are referred to as *trioses*, *tetroses*, *pentoses*, *hexoses*, and *heptoses*, respectively, while the same ketoses are correspondingly and officially named *triuloses*, *tertruloses*, *pentuloses*, *hexuloses*, and *heptuloses*, respectively. They may also be unofficially grouped with names such as ketopentose and ketohexose. The simplest aldose and ketose monosaccharides are the two entantiomers of glyceraldehyde (D and L) (Figure 1.1) and 1,3-dihydroxyacetone (Figure 1.2), respectively. Aldoses exhibit one additional chiral center compared to ketoses for the same number of carbon atoms. With the addition of an extra carbon atom to a growing monosaccharide chain, the number of possible stereoisomers increases. For the total number of chiral or asymmetric centers (n) possessed by a

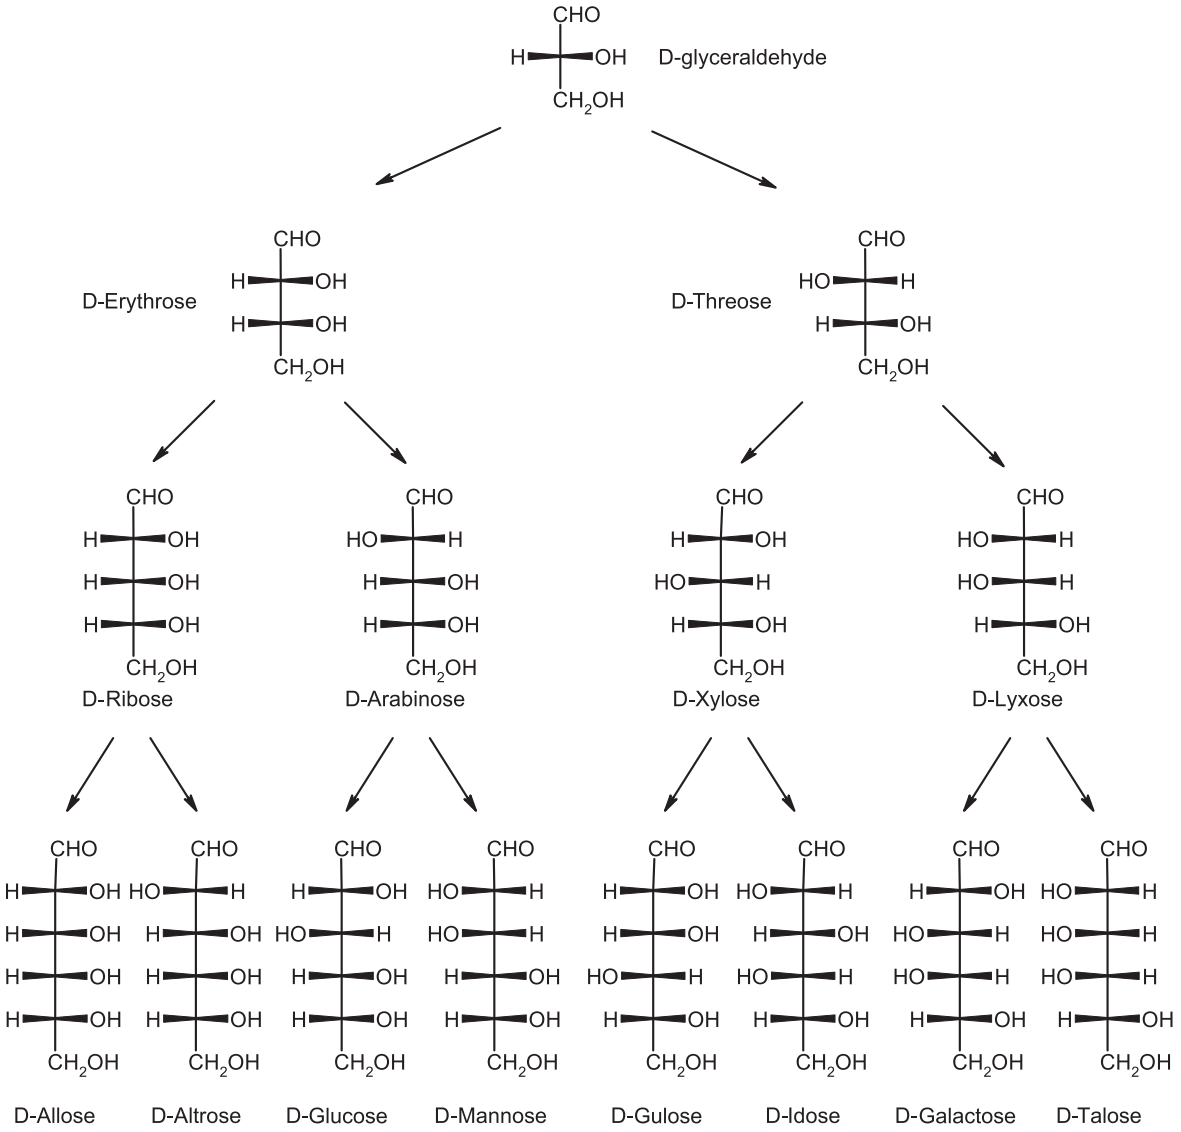

FIGURE 1.1 Acyclic form of the D-aldose series.

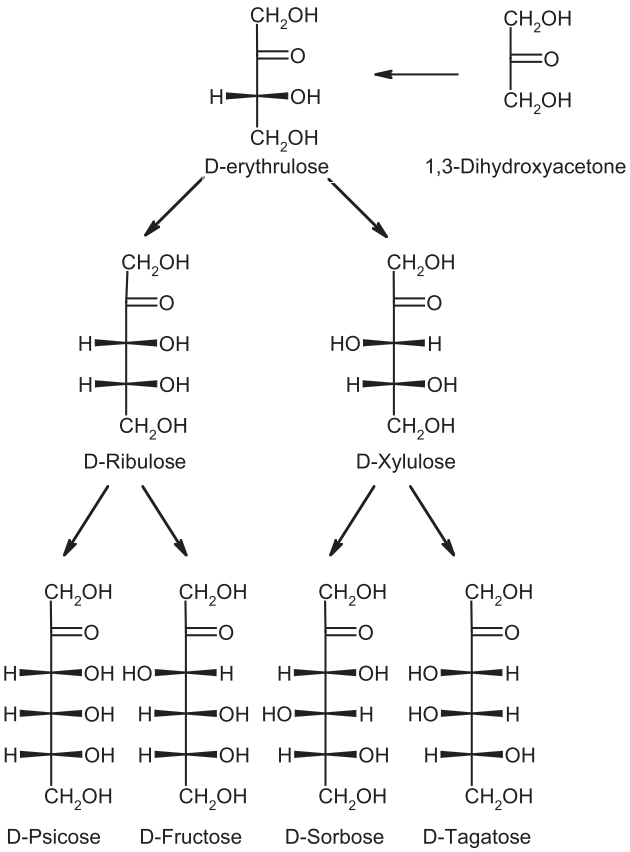

FIGURE 1.2 Acyclic form of the D-ketose series.

monosaccharide, there are 2^n possible arrangements. The reference monosaccharide is considered to be D-glyceraldehyde, which provides a template for generation of acyclic carbon skeletons (from 3 to 6 carbon atoms) as outlined in Figure 1.1 (Fischer projection format). For D-sugars, the hydroxyl group of the highest numbered asymmetric carbon atom (the one furthest from the carbonyl group) is situated on the right-hand side of the Fischer projection, while for L-sugars, the same hydroxyl group is positioned on the left. Thus, the analogous L-aldose series (for brevity not shown) is represented by the exact mirror image structures presented for the D-aldose series. Most sugars found in nature are of the D-configuration, though some common exceptions include L-arabinose, L-rhamnose, L-fucose, L-guluronic acid and L-iduronic acid. Monosaccharide units that differ only in the configuration about a single chiral carbon atom are referred to as epimers (diastereomers). For example, D-glucose and D-galactose are C-4 epimers. Similar to the pattern previously presented for the aldoses, the ketose acyclic series begins with 1,3-dihydroxyacetone; however, the chiral template series starts at D-erythrulose (Figure 1.2) [1,2].

The carbonyl group of aldoses and ketoses is reactive and readily forms an intramolecular cyclic hemiacetal. Therefore, most monosaccharides (except glyceraldehydes, 1,3-dihydroxyacetone and tetrulose) form energetically stable 5- (furan) and 6- (pyran) membered ring structures. Through cyclization, an additional chiral center is formed (compared to the acyclic form) at C-1 (aldoses) or C-2 (ketoses), which is designated the anomeric carbon atom. At the new chiral center, there are two possible anomeric configurations, α and β, which denote the hydroxyl group below and above the ring plane, respectively (true for D-sugars, while the opposite designation is true for L-sugars). The cyclic hemiacetal formation for both pyranose and furanose ring structures (Haworth projections) is illustrated in Figure 1.3 for D-glucose. The actual conformation of the glucopyranosyl structure exists predominantly in the form of a chair-shaped ring (not all ring atoms within the same plane) with the bulky hydroxyl groups in an equatorial arrangement to minimize steric (1,3-*syn*-diaxial) interactions and lessen bond angle strain. For example, β-D-glucopyranose is shown in the $^4C_1$ conformation (Figure 1.3). The superscript and subscript numbers of the conformational notation denote the numbers of the carbon atoms above and below the plane of the ring, respectively [1,2].

Aldoses and ketoses (both hemiacetals) can readily react with alcohols to produce acetals called glycosides. The

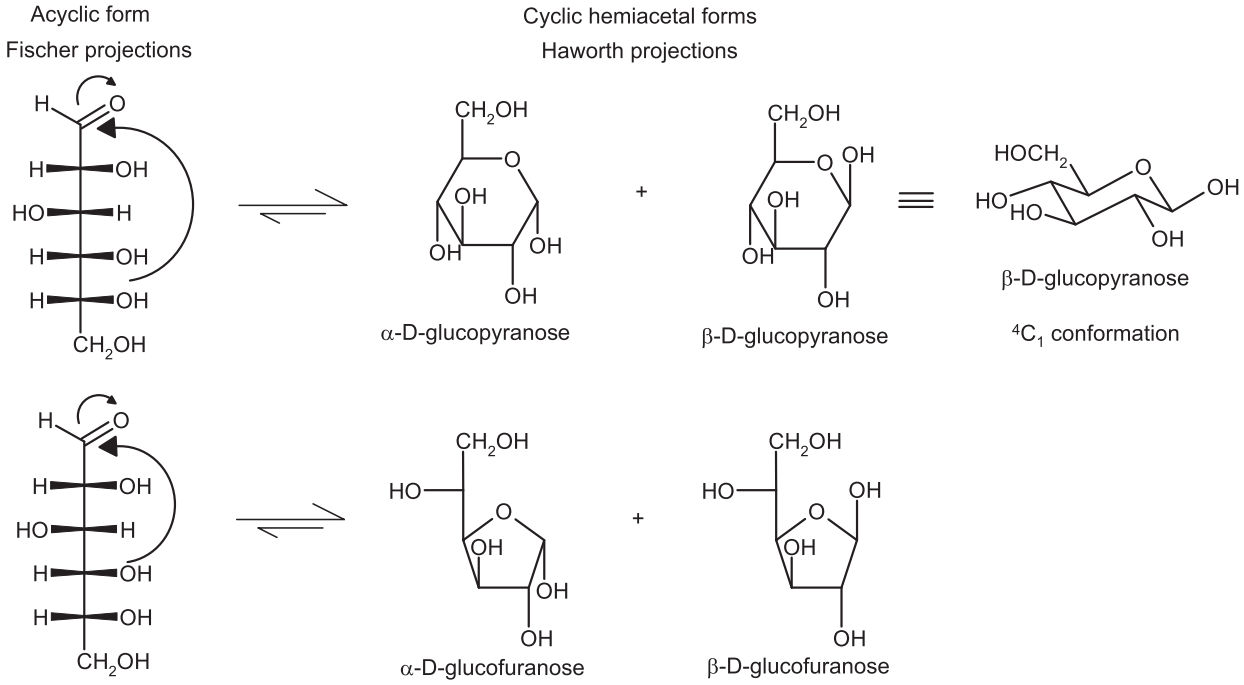

FIGURE 1.3 Cyclic hemiacetal formation of D-glucose and ring conformation.

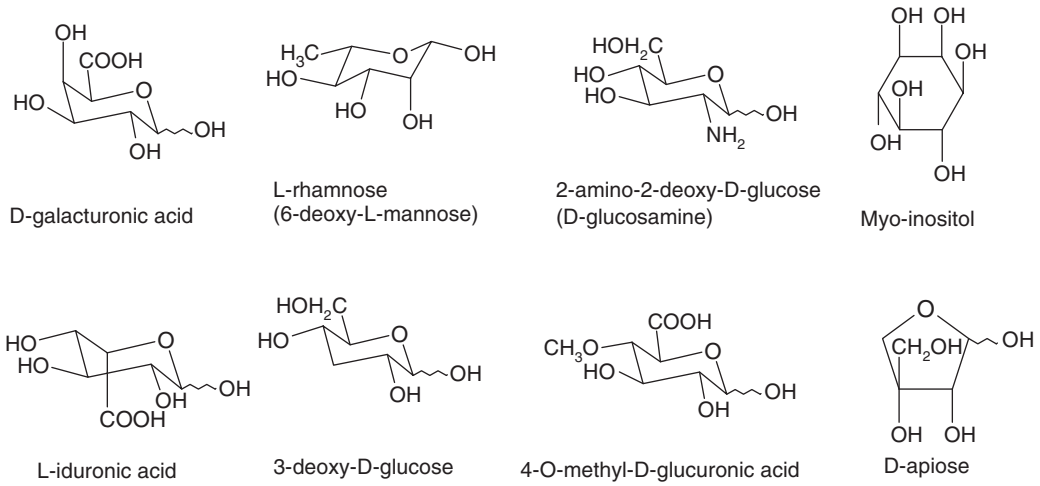

FIGURE 1.4 Structures of other common monosaccharides and inositol.

suffix *-ide* indicates an acetal linkage. For example, D-xylose reacting with methanol produces a mixure of methyl α-D-xylopyranoside and methyl β-D-xylopyranoside [1]. The alcohol (methanol in the above example) portion of the glycoside is called the *aglycon*. In nature, the aglycon (alcohol) is most often another monosaccharide unit, and the covalent bond joining two monosaccharide units is termed a glycosidic bond. This concept can be used to describe two (disaccharide) or more monosaccharide units attached through glycosidic linkages, including extensive polymeric chains (e.g., polysaccharides) comprised of many monosaccharide units.

In addition to the stereoisomeric configurations of sugars, the chemical diversity of monosaccharides can include chemical functionalities such as: carboxyl groups at the primary hydroxyl group position (uronic acids), amino groups in place of hydroxyl groups (amino sugars), hydroxyl groups replaced with hydrogen atoms (deoxy sugars), double bonds (unsaturated derivatives), branch chain sugars, ether substituents, and ester substituents. Examples of these diverse structures are shown in Figure 1.4. A uronic acid is an aldose in which the primary alcohol group (e.g., C-6) has been converted to a carboxylic acid (e.g., α-D-galacturonic acid). A deoxy monosaccharide involves the replacement of

a hydroxyl group with a substituent such as a hydrogen atom (e.g., 6-deoxy-L-mannopyranose, commonly known as L-rhamnose; 2-deoxy-D-*erythro*-pentose, also known as 2-deoxy-D-ribose; 3-deoxyl-D-*ribo*-hexose, also known as 3-deoxy-D-glucose). An amino sugar is a monosaccharide, in which a hydroxyl group is replaced by an amino group (e.g., 2-amino-2-deoxy-β-D-glucopyranose). A branch chain sugar is C-substituted at a non-terminal carbon (e.g., 3-C-hydroxymethyl-D-*erythro*-tetrose, also known as D-apiose). Ether and ester carbohydrate derivatives will be discussed later.

Polyhydroxycyclohexanes, also known as cyclitols or inositols, are discussed here due to their similarities to pyranoses. Nine stereoisomers are possible, and the most widespread in nature is *myo*-inositol (Figure 1.4). Methyl ether derivatives of inositols are also common.

III. REACTIONS OF CARBOHYDRATES

A. HYDROLYSIS

Glycosides, including disaccharides and polymeric chains (oligosaccharides and polysaccharides), undergo hydrolysis in aqueous acids to yield free sugars. The process somewhat randomly cleaves glycosidic bonds to reduce large carbohydrate chains into smaller fragments, which can in turn be further depolymerized to monosaccharide units. Hydrolysis is initiated in glycosides by protonation of the *exocyclic* oxygen atom followed by breakdown of the conjugate acid (cleavage of the bond between the anomeric carbon atom and the *glycosidic* oxygen atom) resulting in the formation of a cyclic carbocation, which is attacked by water to yield the hemiacetal product (Figure 1.5). Glycosidic bonds can also be cleaved by enzymes, which are very specific to the type of sugar residue (e.g., D-galactosyl vs. D-glucosyl), anomeric configuration (α or β), and the glycosidic linkage site (e.g., 1→3). Both acid- and enzyme-catalyzed hydrolysis are commonly employed in the manufacture of maltodextrins and corn syrups, as well as in the commercial production schemes of polysaccharides.

B. OXIDATION/REDUCTION

Aldoses can be readily oxidized to aldonic acids. Because during the oxidation there is a concurrent reduction of the oxidizing agent, aldoses are called reducing sugars (Figure 1.6). Aldonic acids can readily cyclize to form a stable lactone under neutral or acidic conditions. This oxidation reaction has been successfully exploited either chemically (Fehling solution, $Cu(OH)_2$; bromine solution; Tollens reagent) or enzymatically (glucose oxidase) to quantitatively determine sugars [1,2]. In contrast, ketoses must first be isomerized to an aldose (under alkaline conditions), which can then undergo oxidation.

Reduction of an aldose or ketose results in the formation of an alditol or sugar alcohol (denoted by the *-itol* suffix). Commercial-scale operations typically use high-pressure hydrogenation in conjunction with nickel catalyst for such reductions. Sorbitol (D-glucitol) is a commonly occurring alditol in fruits, and is 50% as sweet as sucrose. Sugar alcohols, such as D-glucitol, D-mannitol, and D-xylitol, are frequently used as alternative sweeteners (noncariogenic) in chewing gum and confectionary applications.

C. THERMAL REACTIONS

Heating of reducing sugars results in a complex series of reactions called caramelization. The process is a cascade of

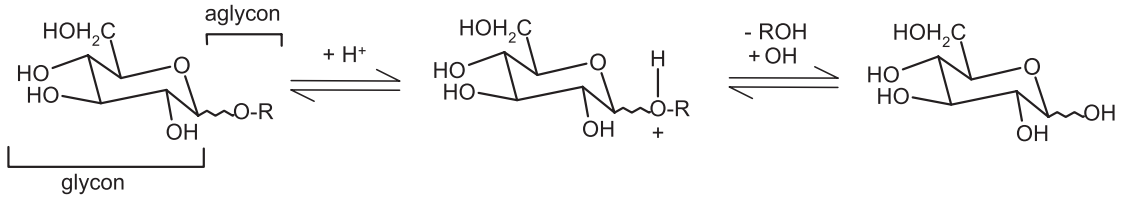

FIGURE 1.5 Abbreviated mechanism of acid-catalyzed hydrolysis of a glycoside.

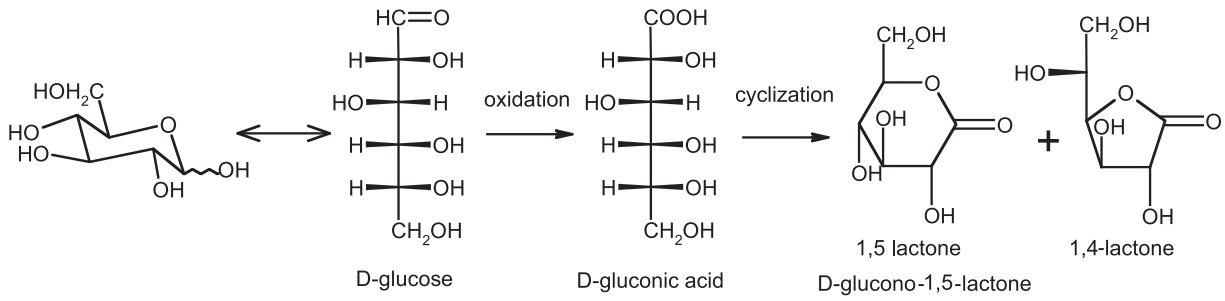

FIGURE 1.6 Oxidation of an aldose to an aldonic acid with subsequent formation of D-gluconolactone.

dehydration reactions that form semi-volatile anhydrides (e.g., 1,6-anhydro-β-D-glucopyranose (levo-glucosan)) and unsaturated compounds (e.g., 5-hydroxy-methyl-furaldehyde (HMF) and furaldehyde) as shown in Figure 1.7 [1]. Catalysts such as salts and acids are added to promote the reaction.

Reducing sugars in the presence of amines (such as proteins and amino acids) undergo a thermal reaction called the Amadori rearrangement. In the case of D-glucose, reaction with an amine ($R\text{-}NH_2$) will form a derivative of 1-amino-1-deoxy-D-fructose and D-glucosylamine (Figure 1.8a). If the reaction continues under acidic conditions, it will undergo dehydration reactions to form HMF. Above pH 5, reactive Amadori intermediates yield complex polymerized dark-colored products via the poorly understood non-enzymatic browning or Maillard reaction, which contributes both color and flavor components to a wide range of food systems (e.g., bread crust, chocolate, caramels, etc.) Recently, acrylamide has been detected in a myriad of high-temperature processed foods (French fries, bread, breakfast cereal, popcorn, etc.), and seems to be primarily derived by the reaction between D-glucose and asparagine. The reaction likely proceeds via the glucosyl-asparagine derivative, and then undergoes decarboxylative deamination to form acrylamide (Figure 1.8b) [4]. To date, it is not known whether the low levels (ppb) detected in food pose any significant health risk to humans.

D. Ester/Ether Formation

Hydroxyl groups of sugars can form esters with organic and inorganic acids. Reaction of hydroxyl groups with acyl chlorides or acid anhydrides in the presence of a catalyst (base) produces esters. Industrially, starches are esterified (acetates, phosphates, succinates, adipates, etc.) to improve their food-use properties. Acetates, sulfates, and phosphates are commonly found as native constituents of carbohydrates. For example, acetyl groups are present in certain polysaccharides such as the plant hemicelluloses (xylan and glucomannan), certain pectins, and xanthan, while sugar phosphates are common intermediates in the biosynthesis of monosaccharides and polysaccharides. The polysaccharide carrageenan contains sulfate half-ester substituents. In addition to esters from sugar hydroxyl groups, esterified uronic acid units are found in polysaccharides. The best example is pectin, in which some of its D-galacturonic acid units exist in the methyl ester form.

The hydroxyl groups of carbohydrates can also form ethers. In nature, ether groups are not common, though some D-glucuronic acid units, particularly in hemicelluloses, such as glucurononxylan, are methylated at the O-4 position (4-O-methyl-D-glucuronic acid). Industrially, starches and celluloses are methylated (cellulose), hydroxypropylated (starch, cellulose), and carboxymethylated (cellulose) to improve the properties of these polysaccharides for a variety of food applications.

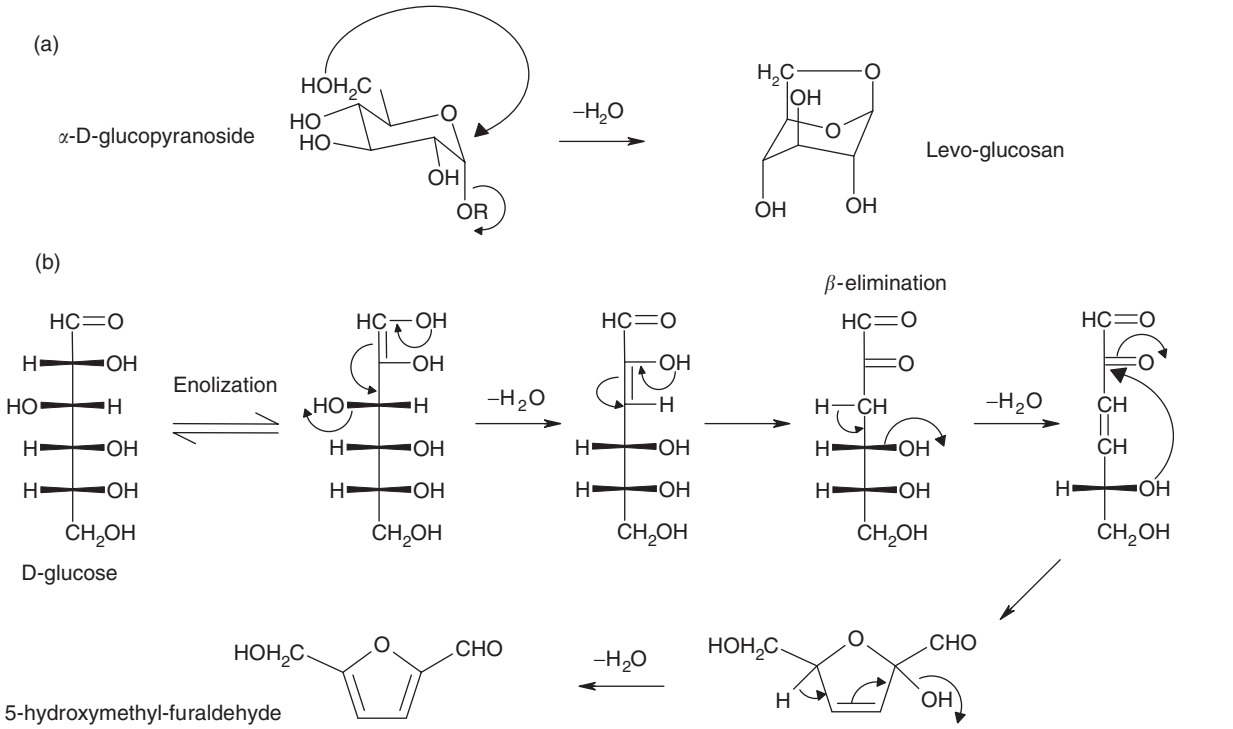

FIGURE 1.7 Reaction mechanism for the formation of (a) levo-glucosan and (b) HMF.

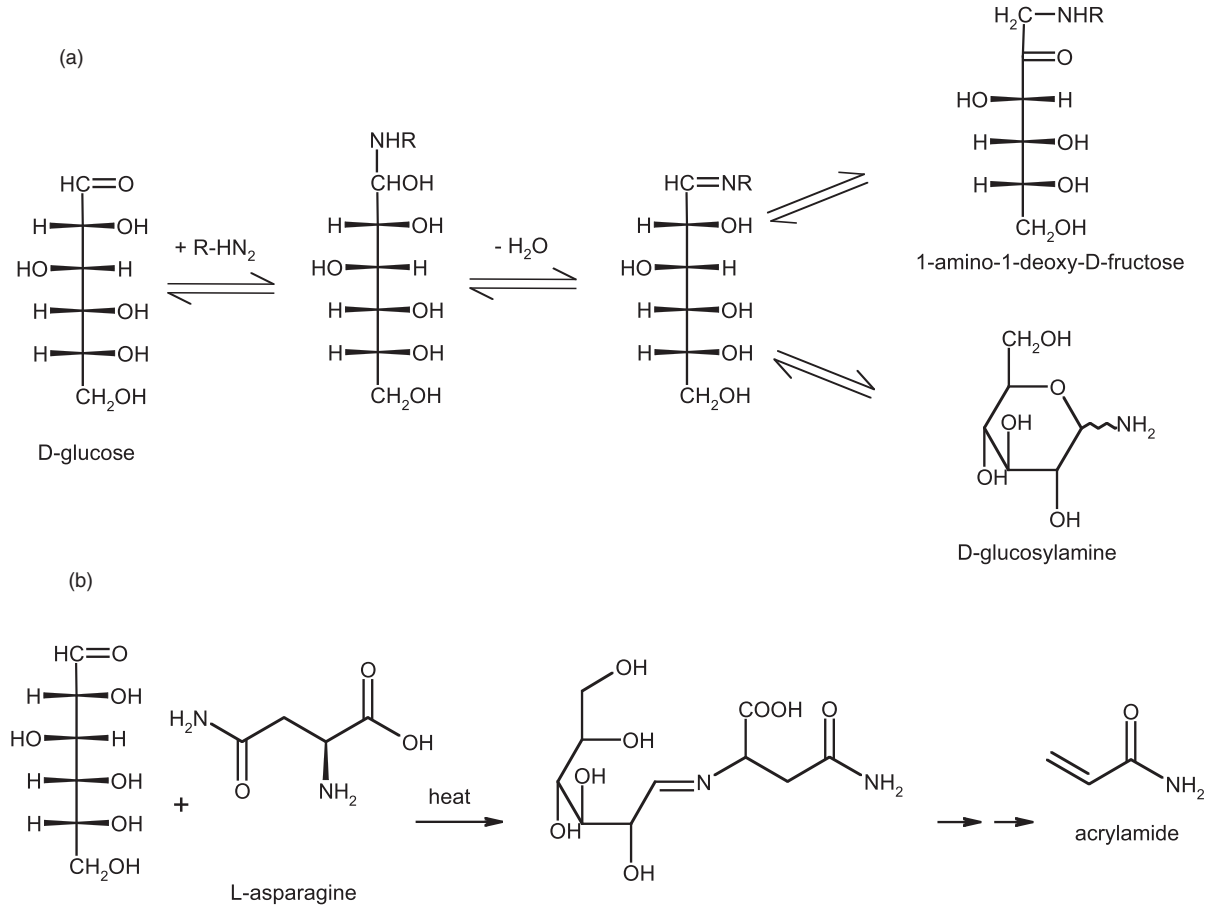

FIGURE 1.8 (a) Amadori reaction scheme and (b) formation of acrylamide.

IV. OLIGOSACCHARIDES

Oligosaccharides are comprised of 2 to 20 glycosidically-linked monosaccharide units [3]. In nature, enzymes called glycosyltransferases catalyze the biosynthesis of both oligosaccharides and larger polymeric carbohydrates (e.g., polysaccharides). These very specific enzymes link specific monosaccharide units together according to a defined anomeric configuration and linkage position (e.g., C-3) on the aglycon sugar. Commercially, oligosaccharides also can be generated through enzyme- or acid-catalyzed hydrolysis of polysaccharides. The following section will briefly discuss common disaccharides, trisaccharides, and fructo-oligosaccharides.

A. Disaccharides

Disaccharides are composed of two monosaccharide units joined by a glycosidic bond. Disaccharides can either be reducing (e.g., maltose and lactose, Figure 1.9) or non-reducing (e.g., sucrose, Figure 1.10), depending on whether one or both anomeric carbon atoms are involved in the disaccharide glycosidic bond. Maltose (Figure 1.9), a disaccharide formed by enzymatic hydrolysis of starch, is produced commercially from the malting of barley, and is the primary fermentable sugar used in the production of beer [3]. The structure of maltose (α-D-glucopyranosyl(1→4)-D-glucopyranose) can be written in shorthand notation as α-Glc*p*(1→4)Glc*p*. The shorthand abbreviation for a monosaccharide unit is based on its first three letters, except for glucose, which is designated as Glc. The position of the linkage is designated as (1→4) from carbon atom 1 of the glycosyl unit to carbon atom 4 of the agylcon unit. The sugar ring size is denoted as *p* for pyranose or *f* for furanose, while the anomeric configuration is designated as either α or β. In the case of D or L configuration, it is only necessary to stipulate L-sugars (D-sugars are assumed unless noted otherwise). This shorthand notation can be used to define both oligosaccharide and more complex polymeric (polysaccharide) carbohydrate structures.

Lactose (β-Gal*p*(1→4)Glc*p*; Figure 1.9) is found in milk at concentrations between 4 and 9%, and is the primary carbohydrate source for developing mammals. For energy utilization, it is necessary that lactose be hydrolyzed by the enzyme lactase (β-galactosidase) to D-galactose and D-glucose in the small intestine to facilitate absorption into the bloodstream. In some individuals, lactose is not (or is only partially) hydrolyzed (lactase deficiency), which

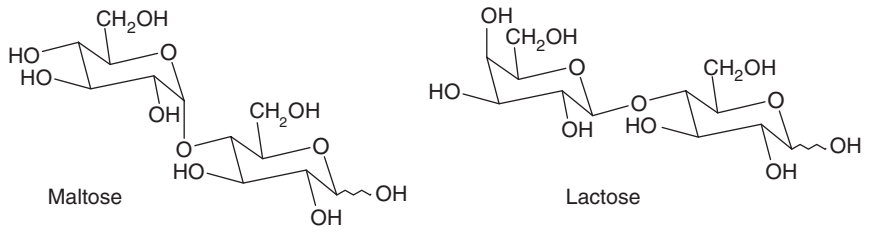

FIGURE 1.9 Structures of maltose and lactose.

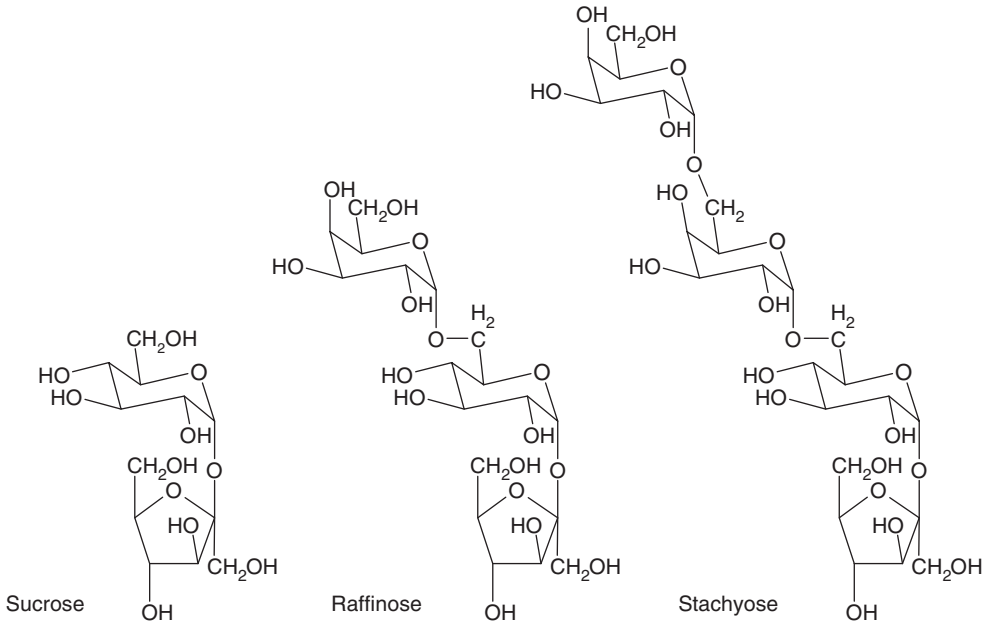

FIGURE 1.10 Structures of sucrose, raffinose, and stachyose.

condition is clinically termed lactose intolerance, and results in the bacterial, anaerobic fermentation of lactose in the large intestine to lactic acid and gaseous products [3].

Sucrose (αGlc*p*(1↔2)βFru*f*; Figure 1.10) is composed of an α-D-glucopyranosyl unit linked (reducing end to reducing end) to a β-D-fructofuranosyl unit, and therefore is non-reducing, because it has no free carbonyl (aldehyde) group. Sucrose (table sugar) is one of the most common low-molecular-weight carbohydrates in the human diet. It is found in plants (e.g., sugar beets, sugarcane, and fruit), where it represents an easily transportable energy and carbon source and an intermediate in starch and cellulose biosynthesis. Another attribute of sucrose is its solubility in water to form highly concentrated solutions, which result in the lowering of the freezing point of water (anti-freeze) and resistance against dehydration in plants and fruits [3]. As a food ingredient, sucrose is utilized due to its water-solubility, desirable sweet taste, effects on colligative properties (e.g., boiling and freezing point regulation), preservative function (osmotic effect), and texturizing effects.

In certain plants, some sucrose molecules are α-galactosylated to form the non-reducing trisaccharide, raffinose (αGal*p*(1→6)αGlc*p*(1↔2)βFru*f*), the tetrasaccharide, stachyose (αGal*p*(1→6)αGal*p*(1→6)αGlc*p*(1↔2)βFru*f*) as shown in Figure 1.10, and the pentasaccharide, verbascose. These oligosaccharides are found especially in beans, onions, and sugarcane. They are non-digestible and are responsible for causing the flatulence (due to microbial fermentation in the colon) associated with the eating of beans and onions [3].

B. Fructooligosaccharides

Fructans, which are polymers (polysaccharides) consisting of β-D-fructofuranosyl units, are found in higher plants, and are composed of two types, inulins and levans (Figure 1.11). Inulins consist of (2→1)-linked β-D-fructofuranosyl units and are found in Jerusalem artichoke, chicory, and dahlia tubers, while levans, consisting of (2→6)-linked β-D-fructofuranosyl units, are found in grasses. Both types of fructans are terminated at the reducing end with a sucrose unit [2]. Fructo-oligosaccharides, which are smaller versions of fructans are used in prebiotic food applications, and are believed to serve as a

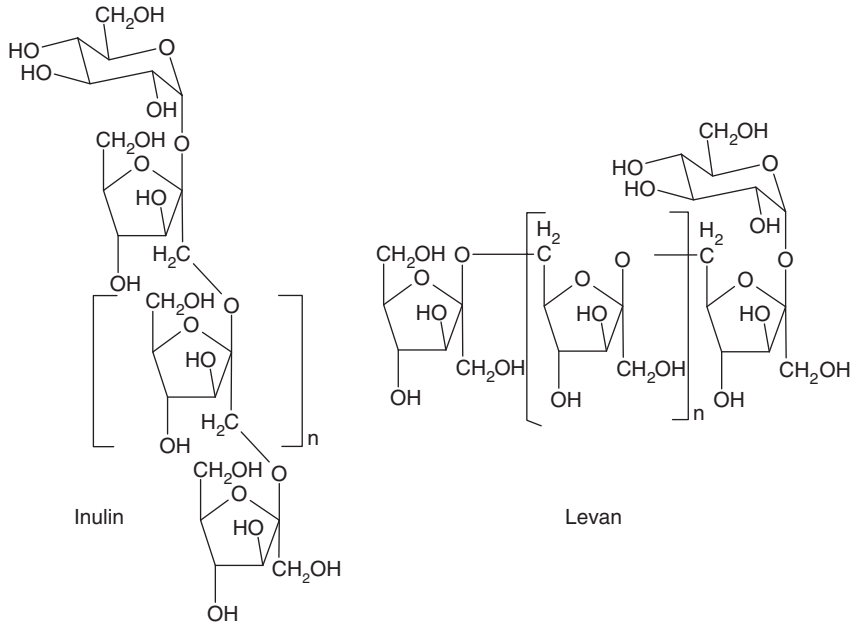

FIGURE 1.11 Structures of inulin and levan oligosaccharides.

TABLE 1.1
Categorization of Select Polysaccharides according to Origin[1]

Origin/Source	Polysaccharide Examples
Higher plants	
Cell wall associated	Cellulose, hemicellulose, pectin
Energy stores (seeds, roots, tubers)	Starch, guar gum, locust bean gum
Exudates	Gum arabic, gum karaya
Marine plants (seaweed extracts)	Carrageenan, alginate, agar
Microorganisms (bacterial fermentation)	Xanthan, gellan
Chemical derviatives (of varied native origin)	Hydroxypropylstarch, starch acetate, starch phosphate, carboxymethylcellulose, hydroxypropylmethylcellulose, methylcellulose
Synthetic	Polydextrose

[1]Adapted from Ref. [3].

preferred substrate to promote colonization of beneficial gut microflora (e.g., bifidobacteria).

V. POLYSACCHARIDES

By definition, polysaccharides (glycans) are long-chain, carbohydrate polymers comprised of, at minimum, 20 glycosidically linked monosaccharide (monomer) units [3]. The number of individual monosaccharide units that comprise a particular polysaccharide is referred to as the *degree of polymerization* (*DP*). Most indigenous polysaccharides possess DPs far in excess of the stated minimum (200–3000 DP is typical), though extremes are observed in nature at both ends of the DP spectrum [3]. While polysaccharides are present in a wide range of plant and animal biological systems, most glycans of commercial significance occur in higher plants (though a few are produced by bacteria). Collectively, polysaccharides from varied origins offer a multitude of structural and functional diversity consistent with their respective intended roles (e.g., structure, energy storage, hydration, etc.) within biological systems. Of the various carbohydrate classes, polysaccharides are by far the most abundant in nature [3], and, as a class of compounds, represent the greatest single component of biomass on the planet. Their relative abundance combined with their diverse structural and functional characteristics make them a superb source of biopolymers for utilization in a wide range of food applications.

A. Classification of Polysaccharides

Though commonly classified by source (Table 1.1), polysaccharides may also be categorized according to the number of different monosaccharide types contained

TABLE 1.2
Categorization of Select Polysaccharides according to Multiple Classification Schemes Related to Structure and Behavior[1]

Origin/Source	Polysaccharide Examples
By Shape	
Linear	Cellulose, starch (amylose[2]), pectin,[3] alginate, agar, carrageenan, gellan, cellulose derivatives (carboxymethylcellulose, hydroxypropylmethylcellulose, methylcellulose)
Branched	Guar gum, locust bean gum, xanthan
Branch-on-branch	Starch (amylopectin), gum arabic
By Number of Types of Monomeric Units	
Homoglycan	Cellulose, starch (amylose, amylopectin)
(Di)Heteroglycan	Guar gum, locust bean gum, alginate, agar, carrageenan, pectin[3]
(Tri)Heteroglycan	Xanthan, gellan
(Tetra)Heteroglycan	Gum arabic
By Charge	
Neutral	Cellulose, starch (amylose, amylopectin[4]), agar,[5] guar gum, locust bean gum, methylcellulose, hydroxypropylmethylcellulose, hydroxypropylstarch, starch acetate
Anionic	Xanthan, gellan, alginate, carageenan, pectin, gum arabic, gum karaya, carboxymethylcellulose, starch phosphate
By Rheological Properties	
Gelling	Starch and starch derivatives, alginate, agar, carrageenan (κ- and ι-types), pectin, gellan, hydroxypropylmethylcellulose, methylcellulose
Non-gelling	Celulose, xanthan,[6] locust bean gum,[7] guar gum, carrageenan (λ-type), gum arabic,[8] carboxymethylcellulose, polydextrose

[1] Adapted from Ref. [3].

[2] Depending on botanical source, amylose can contain some minor short branches toward the molecular reducing end [3].

[3] Categorization does not account for native pectin hairy regions (regions of extensive branching composed of multiple monosaccharide units), most of which are lost during processing to commercial grade pectin [26].

[4] Some starch amylopectin molecules (i.e., potato) may possess small amounts of native starch monophosphate [3].

[5] Agar does possess small amounts of sulfate [30], but is considered to be largely neutral.

[6] Though xanthan solutions do not gel, xanthan does form synergistic gels with locust bean gum, agar, and κ-carrageenan [3].

[7] Though primarily a thickener, locust bean gum exhibits synergistic gelling behavior with xanthan, agar, and κ-carrageenan [3].

[8] Forms gels at very high concentrations [3].

within their molecular structure (e.g., homoglycan: one type vs. heteroglycan: more than one type), molecular shape (e.g., branched vs. linear), electrostatic charge (e.g., neutral vs. anionic) and properties (e.g., gelling vs. non-gelling) (Table 1.2).

In addition, polysaccharides differ from proteins and nucleic acids in that they are both *polydisperse* and *polymolecular* [3]. With regard to polydispersity, a particular polysaccharide type (e.g., pectin) is not defined by a specific number of monomeric units or a defined molecular weight, but rather possesses a range of DPs and molecular weights. Further, the majority of polysaccharides are not chemically homogeneous (cellulose and bacterial polysaccharides are exceptions); they are polymolecular in the sense that individual molecules within a polysaccharide type (e.g., pectin) may differ from one another with respect to fine structure (monosaccharide sequence, proportion of monosaccharide constituents, linkage type, branching frequency). Thus, it is important to keep in mind that the described structure of a polysaccharide type often is not absolute; rather it is an idealized, statistical representation for a population of macromolecules. For every polysaccharide, the reported molecular weight is also an average value.

B. Structural Regimes of Polysaccharides

Nevertheless, structural aspects of polysaccharides may be defined on several different organizational levels (analogous to protein primary, secondary, tertiary, and quaternary structural regimes) [5]. Polysaccharide *primary structure* refers to the sequence of monosaccharide units and the configuration of accompanying glycosidic

linkages. However, it is the glycan primary structure that ultimately dictates the nature and extent of intramolecular and intermolecular associations within a polysaccharide system that lead to development of three-dimensional molecular order (secondary, tertiary, and quaternary structures). Of the two defining elements of primary structure, linkage type generally exerts a greater influence on molecular conformation than monosaccharide type [6]. While there is free rotation about glycosidic bonds, the extent of rotation is limited to a narrow range of thermodynamically favored conformations that coincide with potential energy minima (as a function of hydrogen bonding, van der Waals, polar, and torsional interactions) [5]. These preferred conformations define the proximity of adjacent glycosyl units one to another, and dictate the polysaccharide long-range, three-dimensional shape. This principle is illustrated by the classic comparison of cellulose, amylose, and dextran polysaccharides, which are all linear chains of polyglucose, differing only in the nature of their glycosidic linkages (Figures 1.12a–c) [3].

The equatorial-equatorial β(1→4) glycosidic linkage of cellulose, which facilitates a strong hydrogen bonding interaction between the ring oxygen atom and the C-3 hydroxyl group of adjacent glycosyl units, gives rise to a flat, ribbon-like molecular conformation. On the contrary, the axial-equatorial α(1→4) linkage of amylose leads to a more open, coiled, helical structure, based on favorable hydrogen bonding between the C-2 and C-3 hydroxyl groups of neighboring glucosyl units. Finally, the α(1→6) glycosidic linkage inherent to dextran introduces an additional bond (C-5–C-6), about which free rotation can occur. This additional bond also increases the distance between adjacent glycosyl units such that hydrogen bonding cannot occur. The resulting consequence is that dextran molecules do not generally possess an ordered three-dimensional conformation, but instead adopt the structure of a random coil (possess no defined shape).

The ability to form ordered secondary structure is favored by a high degree of chain uniformity (regularity of monosaccharide sequence and glycosidic linkage) [3], while a random coil results from the lack thereof. In summary, the *ribbon*, *helix*, and *random coil* conformations described for cellulose, amylose, and dextran, respectively, effectively demonstrate the range of *secondary structure* typical of polysaccharide systems.

An example of polysaccharide *tertiary structure* is observed with starch amylose molecules, which can associate to form sections of ordered, double-helical arrangements [5]. Triple-helical tertiary structures have also been reported to exist for various polysaccharides [7,8]. Most polysaccharide tertiary structures are typically stabilized through intermolecular hydrogen bonds.

Temperature and physical state also influence the tendency for a polysaccharide to adopt an ordered secondary

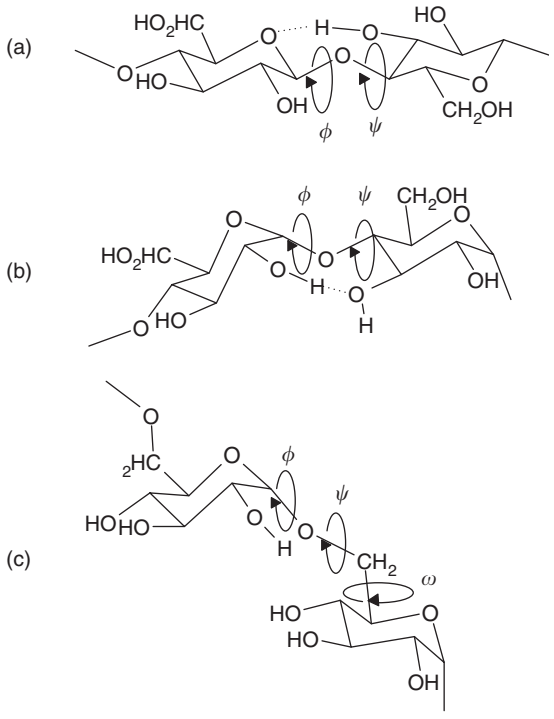

FIGURE 1.12 Rotation about glycosidic bonds (ϕ and ψ) exhibited by polyglucose chains of (a) cellulose, (b) amylose, and (c) dextran (also exhibits free rotation about C5–C6 bond, ω) that provide the basis for long-range, three-dimensional conformational structure (ribbon, helix, and random coil, respectively). Dotted lines between adjacent glucosyl units depict stabilizing hydrogen bonds.

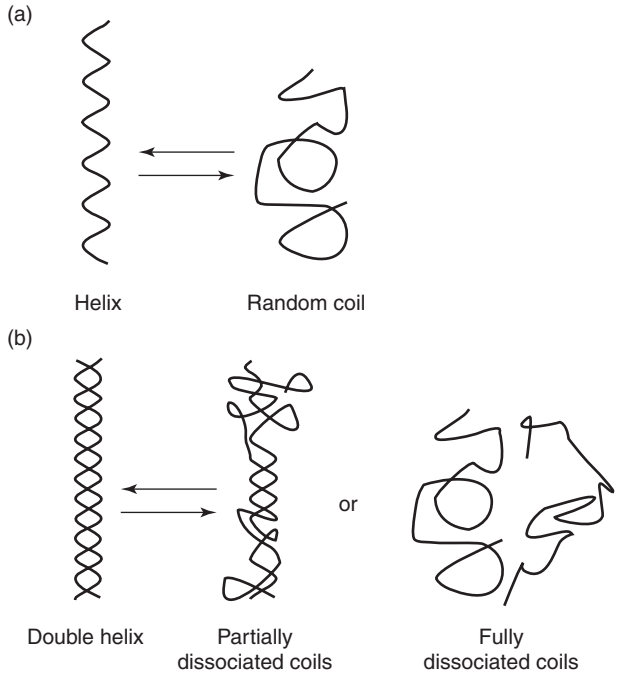

FIGURE 1.13 Depiction of the conformational changes associated with the thermoreversible order to disorder transition for (a) single- and (b) double-helical structures.

or tertiary structure. A polysaccharide in an ordered conformation typically undergoes a reversible order (helix) to disorder (random coil) transition with an increase in temperature sufficient to disrupt hydrogen bonds that stabilize the ordered conformation (Figure 1.13a) [9]. Under these circumstances, double-stranded tertiary structures generally unfold (Figure 1.13b). Upon cooling below the transition temperature, polysaccharide molecules are again able to regain their respective ordered secondary and/or tertiary arrangements. For polysaccharides capable of forming ordered secondary structures, the crystalline state generally favors the existence of the ordered conformation, while the solution state (in water) often results in adoption of a random coil [5]. In the solution state, competing hydrogen bonds between solute (polysaccharide) and solvent (water) molecules tend to minimize the stabilizing effects of intramolecular (solute-solute) hydrogen bonds that would otherwise stabilize an ordered polysaccharide secondary structure. Nevertheless, the solution state does not necessarily impede the formation of double-helical tertiary structures, though solvent conditions necessary for development of such structures may vary with polysaccharide type.

The ability to form some degree of ordered secondary or tertiary structure is generally a prerequisite (but not a guarantee) for polysaccharides to participate in advanced quaternary supramolecular structures. *Quaternary structure* develops through alignment and aggregation of secondary- and/or tertiary-ordered polysaccharide molecules [5], and is typically stabilized by non-covalent interactions (electrostatic, non-polar, hydrogen bond associations) under requisite solvent conditions. Such quaternary order is responsible for the intermolecular associations that lead to development of both gel (junction zone) and other crystalline structures, which are important to processed foods and native plant cell wall systems. However, in discussing any level of polysaccharide three-dimensional structure, it is important to note that polysaccharide molecules in solution are in a constant state of dynamic flux, and likely exist in a wide range of physical forms (helix, double helix, random coil, etc.) at any point in time (even though a statistically favored conformation may be dominant) [3,5]. Nevertheless, the three-dimensional structures discussed here provide a basis for many of the observed properties of polysaccharide systems. A more detailed description of molecular features impacting polysaccharide conformation and physical properties is presented next.

C. Impact of Polysaccharide Molecular Features on Physical Properties

While polysaccharides possess ring oxygen and hydroxyl groups capable of interacting with water through hydrogen bonds [3], physical properties such as solubility, viscosity, and gelling capability are additionally influenced by other molecular features inherent to a polysaccharide. Water solubility of a polysaccharide is generally enhanced by molecular features that prevent formation of

TABLE 1.3
General Description[1] of Polysaccharide Molecular Features and Conditions That Promote Water-Solubility, Viscosity Development, Gelling Behavior

Polysaccharide Feature	Water-Solubility	Viscosity Development	Gelling Behavior/Stability
Backbone linkage and/or monosaccharide repeat	Irregular	Regular (rigid structures)	Mixed (both regular and irregular segments)
Backbone shape	Branch-on-branch structure	Linear, extended structures	Linear, extended structures
Degree of branching and/or substitution	Regular, even distribution of sidechains or substituents along polymer chains	Regular, even distribution of short sidechains or substituents along polymer chains	Sporadic or irregular distribution of side chains or substituents along polymer chains
Molecular charge (if charged)	Even distribution of charge (repulsive) along polymer chains	Even distribution of charge (repulsive) along polymer chains	Uneven distribution of charge (repulsive) along polymer chains
Degree of solvation	Maximum	High	Balanced (segments of both polymer-polymer and polymer-water interactions)
Molecular size	Low	Intermediate to high	Low to intermediate

[1] It is important to note that polysaccharides do not necessarily need to possess all suggested molecular features or conditions to exhibit a particular property, though the greater number of molecular features present will increase the likelihood for a particular property to be exhibited. Exceptions do also exist.

an ordered three-dimensional structure (e.g., irregular backbone structure) or that present physical barriers to intermolecular interactions (e.g., uniform sidechains, backbone repulsive charge) (Table 1.3). An irregular polysaccharide glycosidic linkage or monosaccharide repeat tends to promote polymer flexibility, which can reduce opportunity for intermolecular association and aid solubility. The presence of regular sidechains or derivatized polysaccharide hydroxyl groups can introduce steric hindrance and molecular repulsion (if substituents are charged), which minimize polysaccharide intermolecular associations, leading to increased solubility [3].

The basis for the increased viscosity of polysaccharide solutions (relative to pure water) varies according to polysaccharide concentration. The viscosity of a polysaccharide system within the dilute regime arises from the restructuring of water at the polysaccharide-water interface, and represents the collective (additive) effect of individual polysaccharide molecules in solution [10]. At more intermediate concentrations, typical of industrial applications, intermolecular effects become more predominant. As a result of being in constant dynamic motion, a polysaccharide molecule in solution sweeps out or occupies a theoretical volume or domain of spherical shape [10]. With increasing polysaccharide concentration, the probability for individual polysaccharide molecular domains to collide or overlap becomes increasingly likely, leading to entanglements, internal friction, and increased viscosity [3,11]. The polysaccharide concentration at which interpenetration of polymer domains occurs is referred to as the overlap concentration, and coincides with a concurrent rise in the slope of the viscosity increase in response to an increasing polysaccharide concentration [11].

Aside from concentration effects, molecular characteristics of polysaccharides greatly influence solution viscosity. The greater the theoretical volume swept out by a polysaccharide molecule in motion, the greater the resulting viscosity (assuming a constant concentration). Thus, in principle, the volume swept out by a polysaccharide in solution is a function of both molecular size (DP) and shape (three-dimensional structure) [3]. While a polysaccharide of high molecular weight or DP might generally be expected to sweep out a greater volume compared to a glycan of relatively smaller size, the factor of molecular shape must also be considered. A random coil (highly flexible) structure will occupy a smaller spherical solution domain than that of a stiff, rod-like extended structure of equal molecular size (Figures 1.14a and 1.14b) [3]. Likewise, with the continued assumption of equal molecular weight, a highly branched polysaccharide is anticipated to exhibit a more compact shape and smaller volume in solution compared to that of a highly linear, extended glycan (Figures 1.14b and 1.14c) [3]. Thus, linear, high-molecular-weight polysaccharides capable of forming ordered secondary (helical) and/or tertiary (double-helical) rod-like, extended structures generally produce highly viscous solutions (at relatively low concentrations). As previously described, formation of ordered secondary or tertiary structures is generally favored by extended regions of chain uniformity (regularity of monosaccharide sequence and glycosidic linkage). Nevertheless, some degree of chain disruption (presence of sidechain, charged, or derivatized moieties

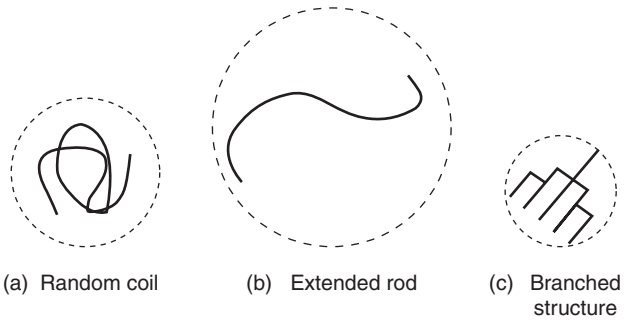

FIGURE 1.14 Comparison of theoretical solution volumes occupied or swept out by (a) a random coil, (b) a somewhat rigid rod, and (c) a branched macromolecule with the assumption of identical molecular weight.

along backbone, etc.) is often necessary to retain polysaccharide solubility (Table 1.2) [3,5]. In particular, charged groups along the polysaccharide backbone tend to keep polysaccharides in extended form by way of intramolecular repulsion, and enhance solubility and increase viscosity.

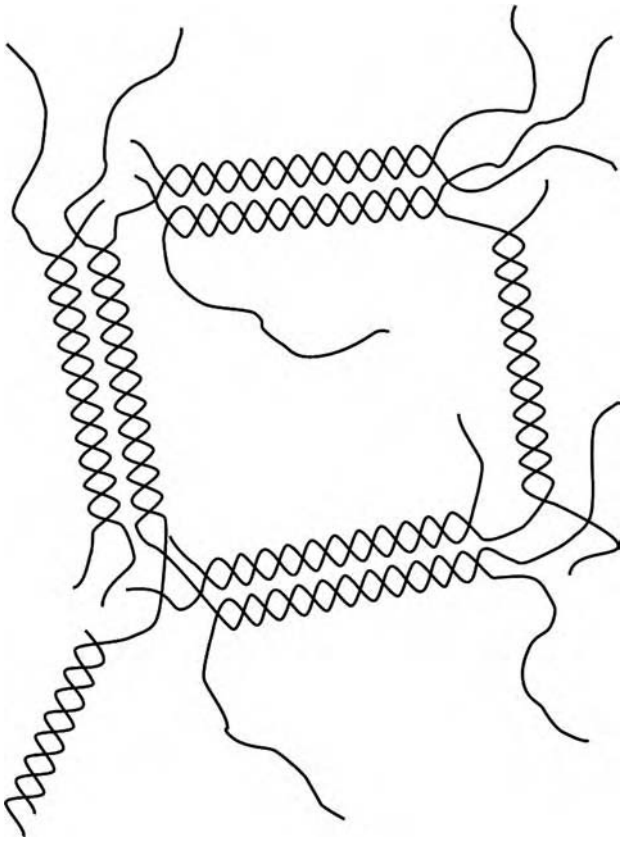

FIGURE 1.15 Schematic representation of a generalized polysaccharide gel structure consisting of segments of aggregated, ordered polysaccharide molecules (double helices) that comprise junction zones (intermolecular cross-links) stabilizing a porous, continuous three-dimensional network or suprastructure. Void spaces are occupied by entrapped solvent (water) and unordered (fully solvated) portions of polysaccharide molecules to yield a viscoelastic material.

The ability to form viscoelastic (combination of both liquid-like (viscous) and solid-like (elastic) behavior) gels represents another significant physical property inherent to many polysaccharide systems. A polysaccharide gel typically consists of some form of an open, continuous, three-dimensional network of aggregated solute macromolecules (polysaccharides) capable of entrapping significant volumes of solvent molecules (water) (Figure 1.15) [3]. The polysaccharide network is generally reinforced through limited aggregation of secondary- and/or tertiary-ordered polysaccharide molecules that form regions of supramolecular quaternary structure termed *junction zones* (intermolecular cross-links) [3,5]. Junction zones may be anchored by a range of stabilizing forces (hydrogen bonds, hydrophobic interactions, electrostatic forces, van der Waals attractions, molecular entanglement, etc.) defined by the polysaccharide structure and solvent conditions. Regions of polysaccharide molecules not involved in junction zone structure maintain strong interaction with water molecules to achieve a delicate balance between the solute-solute (junction zone structure) and solute-solvent (soluble polysaccharide) interactions that constitute a gel.

In general, the polysaccharide structural features that promote gel formation (junction zone development) are similar to those previously described to favor development of secondary- and/or tertiary-ordered structures (characteristics that encourage chain regularity). Nevertheless, to achieve gel stability, most gelling polysaccharides also possess some degree of structural perturbation or disruption that breaks up or limits the formation of the ordered arrangement at sites along the length of polysaccharide chains (Table 1.3) [5]. Such disruptions prevent excessive growth or development of junction zones that would otherwise lead to syneresis (loss of water-holding capacity) and gradual precipitation of polysaccharide molecules [3]. Specific structural features that serve this purpose include: occasional irregularity within the chain primary structure (e.g., carrageenan); occurrence of mixed blocks of monsaccharides within the primary chain (e.g., alginate); and presence of short, sporadic sidechains (e.g., locust bean gum in mixed gel systems with xanthan or carrageenan), substituent groups (e.g., hydroxypropylated starch), or charged moieties (e.g., high-methoxyl pectin). Formation of a stable gel structure also requires manipulation of solvent conditions to meet gelling requirements imposed by the specific structural features of a polysaccharide. Addition of low-molecular-weight solutes (acids, salts, sugar, etc.) or adjustment of temperature may also be used to encourage polysaccharide interaction (reduction of solvation), and regulate the balance of attractive and repulsive forces that coincide with the formation of a stable gel system.

D. Polysaccharide Stability and Reactivity

Polysaccharides are subject to a range of environments and conditions in food systems that have the potential to alter not only their conformations, but also their chemical structures and behaviors. A primary means by which molecular structure is significantly altered occurs through the cleavage of glycosidic bonds (depolymerization), which transpires by two primary means, *hydrolysis* and β-*elimination* reactions. The mechanism of chain cleavage by hydrolysis, which may be initiated by acids or enzymes, was described in an earlier section (Section II, Figure 1.5). While the rate of acid-catalyzed hydrolysis is influenced by pH (lower = faster rate), temperature, and time of exposure, it also varies with the nature of the glycosidic linkage [3]. For example, the rate of acid-catalyzed hydrolysis for uronic acid-based polysaccharides (e.g., alginate) is significantly slower than for corresponding neutral polysaccharides. For enzyme-catalyzed hydrolysis, polysaccharides such as starch can be readily hydrolyzed into maltose and branched oligosaccharides by treatment with β-amylase (*exo*-glucanase), which cleaves terminal maltosyl residues from starch polysaccharides. In contrast, α-amylase (*endo*-glucanase) cleaves α(1→4)-linked bonds at random points along the polysaccharide chain affording oligosaccharide products. Thus, for various polysaccharides, the pattern of enzymatic hydrolysis may differ according to the specific enzymes employed. Lastly, polysaccharide depolymerization by means of beta-elimination is favored under alkaline conditions, and requires oxidation at O-2, O-3, or O-6 for the reaction to proceed as depicted below (Figure 1.16). Aside from conditions encountered within food systems, it is important to note that depolymerization reactions are often intentionally employed in the production schemes of many commercial polysaccharides [3].

The reactivity of polysaccharides is also frequently manipulated to improve and extend their physical properties. The reactions described earlier in relation to monosaccharides (Section II) are also pertinent to polysaccharides, and generally involve derivatization of polysaccharide hydroxyl groups. The extent of chemical modification is most commonly described by the *degree of substitution* (*DS*). Most individual monosaccharide units within a polysaccharide structure possess an average of three hydroxyl groups available for reaction. The DS, which may exhibit a maximum value of three, depicts the average number of modified hydroxyl groups per glycosyl unit [3]. For reactions in which it is possible for a substituent group resulting from reaction with a polysaccharide hydroxyl group to further react with another reagent molecule, the degree of reaction is described in terms of *molar substitution* (*MS*), which is defined as the average number of moles of reactant per glycosyl unit [3].

VI. POLYSACCHARIDE STRUCTURES AND FUNCTIONS

Polysaccharides of commercial significance will be discussed in terms of their structural constituents that are ultimately responsible for their observed properties. The discussion of specific polysaccharides is anticipated to highlight the diversity of structures and functions common to food systems, but is not intended to represent a comprehensive list of polysaccharides present in foods either naturally or as added ingredients.

A. Starch and Its Derivatives

As the primary storage medium in higher plants, *starch* in its simplest form consists of two diverse homopolymers, *amylose* (linear structure) and *amylopectin* (branch-on-branch structure), both of which are comprised exclusively of D-glucosyl units (Figure 1.17a and 1.17b). The linear fraction, amylose, consists of (1→4)-linked α-D-glucopyranosyl units, and has a molecular weight in the range of 30,000 to greater than 10^6, depending on source [3]. While the amylopectin backbone exhibits a primary structure identical to that of amylose, it also possesses sidechains of (1→4)-linked α-D-glucosyl units (average chain length

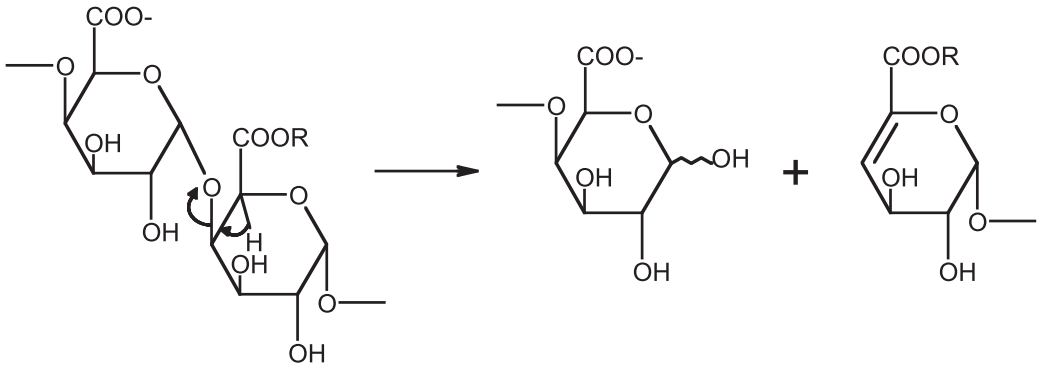

FIGURE 1.16 A possible mechanism for depolymerization of pectin, which possesses native carboxylate and carboxy methyl ester groups, via β-elimination.

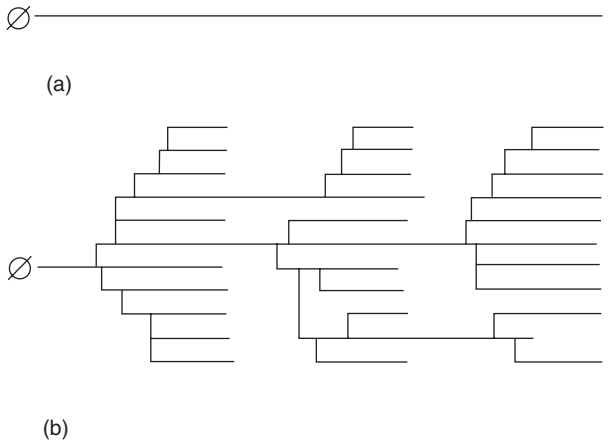

FIGURE 1.17 Idealized diagrams depicting the linear and branch-on-branch structures of starch molecules, (a) amylose and (b) amylopectin, respectively (∅ depicts the molecular reducing end).

of 20–30 units) attached to the main chain through α(1→6) linkages. The sidechains themselves give rise to further branches to yield large, yet compact, branch-on-branch structures of significant molecular weight (approaching 10^9) (Figure 1.17b) [3,12]. Starch is unique in the sense that amylose and amylopectin molecules are biosynthesized and assembled in the form of semi-crystalline aggregates, called *granules*, which vary in size (1–100 μm) and shape (spherical, elliptical, angular, lenticular, etc.) according to the botanical source. Starch granules, which are stabilized by regions of complex molecular order (double-helical association of polymer chains), are insoluble in room temperature water. Slurries of starch granules in water require heating sufficient to disrupt the native granular structure to achieve solubility and realize the functionality of starch [3].

Heating of starch granules in water brings about *gelatinization* or the irreversible loss of granular order, which is accompanied by increased granule hydration, swelling, and leaching of soluble components (primarily amylose) [3,12–14]. In the presence of shear, the fragile, swollen granules are reduced to a paste composed of granule remnants dispersed within a continuous phase of solubilized starch. As the paste is cooled, the linear amylose molecules *retrograde* (crystallize), adopting regions of double-helical structure, which through aggregation, form junction zones that comprise a continuous three-dimensional gel network (Figure 1.18) [15]. The dispersed phase of a starch gel network consists of amylopectin-rich regions and granule remnants. The branched nature of amylopectin limits its intermolecular association, and favors initial water solubility, though amylopectin chains do slowly interact (crystallize) in time [3,12]. Thus, waxy starches, which contain only amylopectin, lack the ability to form strong gel networks, but are nevertheless capable of generating highly viscous solutions over time at starch levels above the overlap concentration via the development of weak intermolecular associations.

Due to their properties and abundance, starches of varied biological origin are frequently exploited as thickeners, gelling agents, binding agents, texture modifiers, and substrates in diverse food applications. However, most food starch (≈75%) added as an ingredient is first chemically and/or physically modified [16], while yet in the granular form, to enhance the physical properties of starch polymers in accordance with the intended end-use. Several categories of starch derivatives will be discussed briefly, though in reality most commercial starch derivatives undergo multiple modifications.

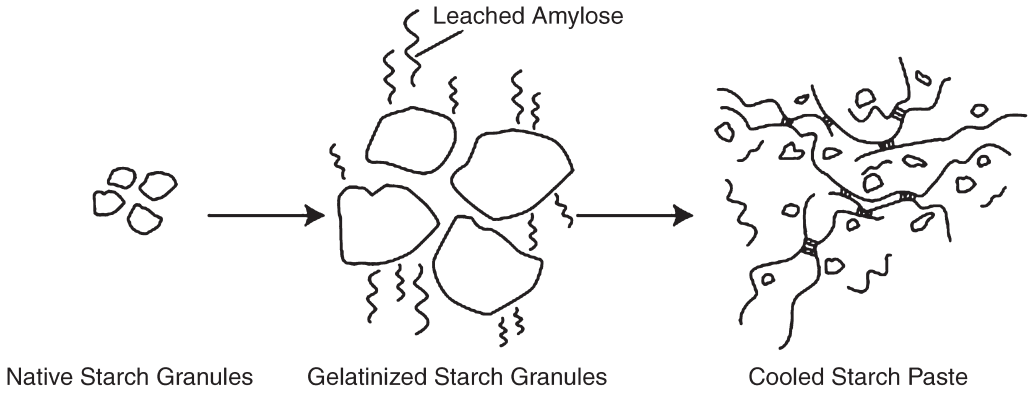

FIGURE 1.18 Schematic representation of the structural changes associated with the gelatinization and pasting of native starch granules. Gelatinization (loss of granular molecular order) is accompanied by granule swelling and leaching of soluble starch components (amylose) during aqueous heating. With the application of shear, swollen granules undergo further disintegration to yield a paste, which is composed of a continuous phase of solubilized starch and a dispersed phase of granule remnants. Upon cooling, amylose retrogradation (depicted by the cross-hatching between molecules within the paste) results in the formation of a gel network.

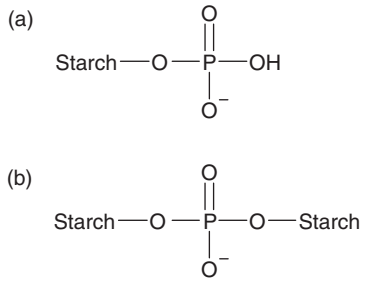

FIGURE 1.19 Chemical structures of a (a) stabilized (starch monophosphate) and (b) cross-linked (distarch phosphate) starch derivatives.

Starch *stabilization* generally involves conversion of starch hydroxyl groups to phosphate monoesters (DS $\leq$ 0.002), acetate esters (DS $\leq$ 0.09), or hydroxypropyl ethers (MS $\leq$ 0.1) [3]. Modification is employed to overcome the tendency for syneresis of native starch pastes, which occurs due to excessive junction zone growth. The periodic incorporation of bulky (hydroxypropyl) and/or charged (phosphate monoester) substituent groups onto starch molecules (particularly amylose) introduces a physical and/or electrostatic impediment to intermolecular association and formation of ordered structures (Figure 1.19a) [3,17]. By regulating junction zone growth, stabilized starches exhibit improved paste clarity and syneresis/freeze-thaw stability in comparison to their native counterparts [3,17].

Cross-linked food starches are most frequently generated through reaction with phosphorus oxychloride or sodium trimetaphosphate, and exhibit of low levels of distarch phosphate ester cross-links (one per 1000–2000 glycosyl units) between adjacent starch molecules and/or chains (Figure 1.19b) [17]. While the presence of cross-links generally reduces the swelling of granules during gelatinization, it also contributes stability and rigidity to the swollen granule structure (less breakdown with shear), leading to a higher ultimate paste viscosity (compared to the unmodified starch) [17]. Due to the reinforced granule structure, cross-linked starches display good stability to shear, acidic conditions, and extended heating, and are utilized in a broad array of food systems (retorted, extruded, frozen, baked, and dehydrated applications) [3].

Acid-modified starch results from treatment of granular starch with dilute acid to effect partial hydrolysis of starch molecules within granule amorphous (disordered) regions [17]. While retaining their granular shape, acid-modified starch granules display minimal swelling and almost complete disintegration upon heating in water. Most importantly, hot pastes of acid-modified starches exhibit very low viscosities (breakdown of swollen granules), and are easily pumped while hot, but form stiff, opaque gels upon cooling [17]. Acid treatment of starch increases the proportion of linear starch molecules (due to hydrolysis of branched starch chains), which facilitate development of tertiary- and quaternary-ordered structures that comprise a gel network. Primary applications of acid-thinned starches involve production of gelled candy products [3].

Generation of *pregelatinized* or *cold-water swelling* starches requires the partial or complete disruption of the native granule structure (molecular order) by pre-processing (heating) a starch slurry under prescribed conditions [3]. The resulting starch products exhibit either ambient temperature solubility (pregelatinized) or granule swelling (cold-water swelling) to achieve viscosity development in aqueous environments without the requirement of additional heating. Pregelatinized and cold-water swelling starches are incorporated as both thickening and gelling agents in dehydrated and/or instant food products that do not require heat preparation.

Lastly, starch is the substrate for an assortment of carbohydrate ingredients classified as starch *hydrolyzate products*, which include maltodextrins, dextrose (commercial name for glucose), corn syrups, and high fructose syrups (HFS) [18]. Generation of these products involves variable degrees of acid and/or enzyme conversion of starch to lower-molecular-weight polysaccharides, oligosaccharides, and glucose. With the exception of some maltodextrins (bulking agent), all other noted starch hydrolyzate products (sweeteners) are reduced in molecular size to the point they are no longer classified as polysaccharides.

B. Cellulosics

As the most abundant component of biomass on the planet, *cellulose* is the key structural constituent of plant primary cell walls. It consists of long, linear chains composed solely of (1→4)-linked β-D-glucopyranosyl units (Figure 1.12a) [3]. As previously described, the nature of the cellulose glycosidic linkage, its regular monosaccharide sequence, and its linear backbone causes cellulose molecules to adopt flat, rigid, ribbon-like secondary structures that readily aggregate to form crystalline, water-insoluble superstructures [3]. Thus, in the native state, while cellulose represents a good source of dietary fiber in indigenous whole foods or in isolated form (referred to as *powdered cellulose*), it generally requires further processing or derivatization to enhance functionality for broader food use. Several such cellulose derivatives will be highlighted below.

Microcrystalline cellulose (*MCC*), which is generated by acid-catalyzed hydrolysis of native crystalline cellulose fibers, can be categorized into two primary types, powdered and colloidal, based on processing scheme and function. Both are insoluble in water. For powdered MCC, hydrolysis is conducted to generate small crystalline

fragments, which are spray-dried and agglomerated to yield open, porous, aggregates of crystals of desired size (20–100 μm typical) [3]. Powdered MCC is used as a bulking agent and flow aid in food systems. On the other hand, colloidal MCC is produced by applying mechanical shear to crystalline fragments (obtained by acid hydrolysis) sufficient to further reduce crystallite size to the colloidal range (0.2 μm) [3]. A second polysaccharide (generally one with a backbone negative charge) is added to stabilize the dispersed phase (cellulose crystals) by providing a physical and or electrostatic barrier to aggregation [3,19]. Functioning as a protective colloid, the second polysaccharide interacts with cellulose crystals along uncharged segments of its backbone, while its charged regions provide electrostatic repulsion to prevent excessive association of cellulose particles. The dried dispersion, known as colloidal MCC, functions in food as an emulsion stabilizer, thickener, or fat replacer depending upon the properties of the protective colloid.

Production of *carboxymethylcellulose* (*CMC*) involves reaction of cellulose with chloroacetic acid, and converts native hydroxyl groups to carboxymethyl ethers (Figure 1.20a). For food applications, typical DS levels range from 0.4–0.95 [20]. The introduction of charged substituents along the cellulose backbone greatly enhances solubility (relative to that of native cellulose) by way of intermolecular repulsion [3]. At pH values above the carboxyl pK_a, CMC molecules occur as extended linear structures and sweep out large molecular domains to form high viscosity solutions. Commercially, CMC is available in a range of molecular weights (viscosity grades) as are most food gums. It is utilized primarily as a thickener in a wide range of food applications [20].

Methylcellulose (MC) and *hydroxypropylmethylcellulose* (*HPMC*) are additional ether derivatives that offer unique properties to food systems. Methylcellulose is achieved through reaction of cellulose with methyl chloride (MS levels 1.6–1.9) (Figure 1.20b), while production of HPMC involves additional derivatization with propylene oxide (DS levels 0.07–0.34) (Figure 1.20c) [3]. Relative to CMC, significantly higher derivatization levels are required to achieve water-solubility of methylcellulose, which is only marginally enabled by the presence of bulky (but nonpolar) substituent groups distributed along the length of cellulose chains. The marginal solubility of MC becomes further reduced at increased temperatures (due to loss of water molecules of solvation, which facilitates intermolecular association of polymer chains, through hydrophobic interactions). The result is thermoreversible gelation over the temperature range of 50–90°C [3,20]. Due to the ability to form thermal gels, MC may provide a physical barrier against moisture loss and fat uptake during high-temperature frying operations. While HPMC also exhibits thermal gelation behavior, gels are typically weaker (relative to those of MC), and increase in softness with an increasing degree of hydroxypropylation (decreases hydrophobic nature and provides a physical barrier to intermolecular associations) [20]. In addition, HPMC exhibits good surface activity as a foam stabilizer [3].

C. Galactomannans: Locust Bean and Guar Gums

Galactomannans of significance include *guar* and *locust bean* (carob) gums, which commercially are the ground crude flours of their respective seed endosperm [3]. The primary polysaccharide component of both guar and locust bean gums possesses a backbone structure comprising of (1→4)-linked β-D-mannopyranosyl units with the occurrence of solitary α-D-galactopyranosyl units attached glycosidically at C-6 of main-chain mannosyl units (Figure 1.21) [3,21].

While guar and locust bean gums have only low to moderate molecular weights (200,000 and 80,000, respectively) [21], the mannan backbone (extended ribbon-like structure) contributes molecular rigidity that facilitates a large hydrodynamic volume and development of high viscosity solutions [3]. The presence of sidechains (impede aggregation) enhances the solubility of both guar and locust bean gums relative to unsubstituted mannan, which forms insoluble, crystalline, intermolecular aggregates (akin to native cellulose) [21]. Though the two gums have similar structures, substitution with D-galactosyl units is more frequent in guar gum (about 1 of 2 backbone units substituted) and more evenly distributed over the length of the polysaccharide chains as compared to locust bean gum

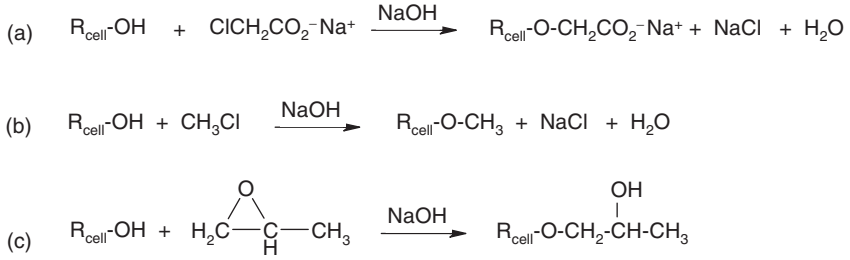

FIGURE 1.20 Reactions used for generation of (a) carboxymethyl-, (b) methyl-, and (c) hydroxypropylcellulose derivatives.

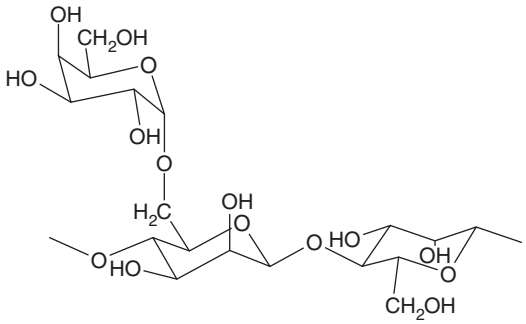

FIGURE 1.21 Generalized structural repeat of galactomannans.

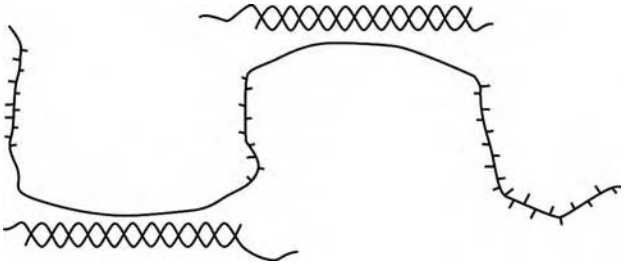

FIGURE 1.22 Schematic representation of the junction zone gel structure between locust bean gum "naked regions" and xanthan or carrageenan double-helical segments.

(about 1 of 4 backbone units substituted with irregular sidechain distribution) [3,21]. The regular substitution pattern of guar gum minimizes intermolecular associations, and explains the excellent water solubility and nongelling behavior of this polysaccharide. The "naked regions" (large polymer sections devoid of sidechains) of locust bean gum afford open segments of the main chain capable of intermolecular interaction, and account for the gel-forming capabilty with xanthan gum and κ-carrageenan (Figure 1.22) [3,21]. Thus, it is the differing patterns of sidechain substitution that primarily account for the basic differences in the properties of locust bean and guar gum.

D. Alginate

Extracted from brown seaweeds, *alginates* are complex, linear, block copolymers composed of (1→4)-linked β-D-mannopyranosyluronic acid and α-L-gulopyranosyluronic acid (occurs in $^1C_4$ chair conformation) units [3,5,22]. Three major types of primary structure generally describe the polymer backbone of alginate: 1) uninterrupted sections of D-mannuronate units (M blocks), 2) uninterrupted regions of L-guluronate units (G blocks), and 3) intermingled sequences of D-mannuronate and L-guluronate units (mixed or MG blocks) (Figure 1.23a) [23]. The occurrence of multiple, primary structural regimes within a single molecule has significant consequences on alginate three-dimensional structure and properties. Due to backbone charge, alginate molecules adopt an extended solution structure consisting of sections of M blocks (ribbon-like structure), G blocks (buckled shape), and MG blocks (irregular coil). In the presence of divalent cations, alginate forms gel structures that are described by the *egg-box* model (Figure 1.23b) [24]. In this model, junction zones are stabilized by divalent cations, which provide electrostatic cross-bridges between oriented G block regions of adjacent molecules. While the M and MG blocks do not participate in junction zone formation, they do serve to balance intermolecular associations by breaking up G block regions and limiting excessive junction zone growth. At excessively low pH values (below the pK_a of the carboxylate group), intermolecular electrostatic repulsion is lost, and precipitation can occur [3].

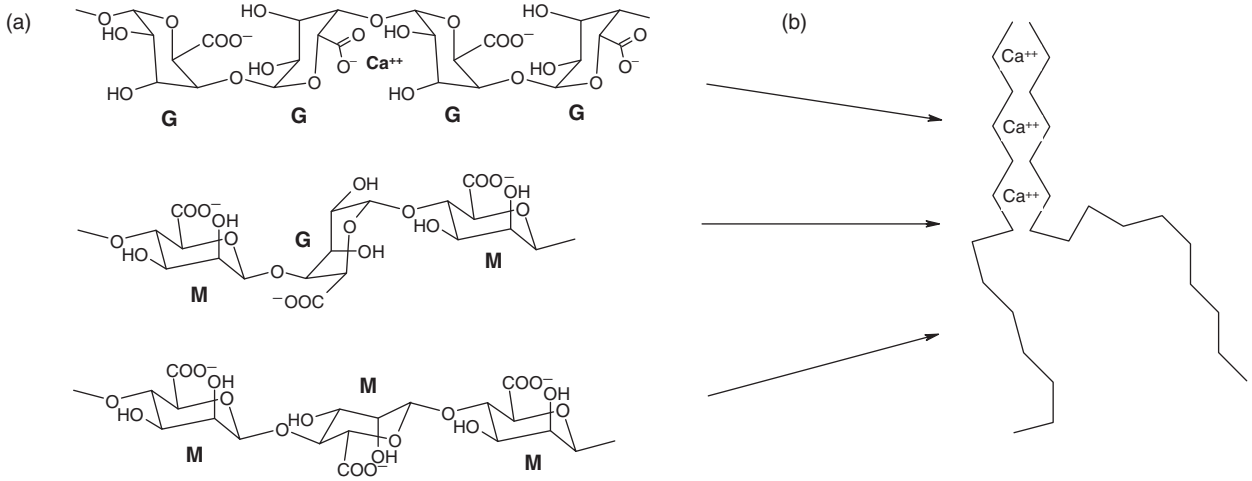

FIGURE 1.23 Depiction of alginate (a) G block, M block, and MG (mixed) block conformational structures and (b) the contribution of each respective conformation to junction zone gel structure characterized by the egg-box model.

E. Pectin

Pectin, a cell-wall associated polysaccharide of higher plants, is a predominantly linear glycan consisting of α-D-galactopyranosyluronic acid units, some of which are present in a methyl ester form [3,25,26]. The polygalacturonate chain may also be disrupted by the occasional insertion of an α-L-rhamnopyranosyl unit [3,25,26] and the presence of sporadic, highly branched segments (hairy regions) [25,26], both of which introduce backbone irregularity (though hairy regions are mostly removed during preparation of commercial pectin). Commercially, pectins are categorized according to their degree of esterification as either low-methoxyl (LM; <50% esterified) or high-methoxyl (HM; > 50% esterified), which designation also defines the optimum conditions in which they gel [3]. LM pectins form gels in the presence of divalent cations, and align to form an "egg box" junction zone structure similar to that previously depicted for alginate (LM pectin and alginate G blocks possess almost mirror image secondary structures).

For HM pectin, solvent conditions must be adjusted to reduce both polysaccharide solvation and intermolecular repulsion (due to ionized carboxylate groups) to facilitate junction zone development. In food systems, the addition of competing solute (usually sugar; 55% minimum) and acid (to achieve a pH <3.5 and reduce the amount of negative charge) provide conditions that lead to gelation [3]. Junction zones, which are stabilized by a combination of both hydrogen bonds and hydrophobic interactions (between methyl ester groups) on adjacent molecules [27], are also effectively limited in size by occasional backbone irregularity (insertion of rhamnose, presence of hairy regions) to benefit gel stability [3,25].

F. Carrageenans

Carrageenans represent a family of linear polysaccharides isolated from red seaweed species, and are generally categorized into three primary classes (κ-, ι-, and λ-types) according to chemical structure and physical properties [3]. All three classes exhibit a common, idealized, disaccharide repeat consisting of 3-O-substituted β-D-galactopyranosyl and 4-O-substituted α-D-galactopyranosyl units, but differ primarily with respect to their degree of sulfation (at C-6 and C-2), which generally follows the trend $\kappa < \iota < \lambda$ (Figure 1.24a–c) [3,28]. Both κ- and ι-types also possess significant proportions of 3,6-anhydro ring structures.

Due to the charged backbone arising from the presence of sulfate substituents, all classes of carrageenan (only sodium salt forms for κ- and ι-types) are highly soluble in water and adopt rigid, extended coil solution structures [3]. Below a particular transition temperature (40–70°C), both κ- and ι-types form regions of double-helical secondary order at sites along the polymer chain [3,5]. In the presence of K^+ and Ca^{2+} cations (κ- and ι-types, respectively), the shielding of negative charge by counterions facilitates aggregation of double-helical regions of polymer chains to form junction zones and a characteristic gel structure (Figure 1.25) [3,5]. Periodic irregularity (kinks) in the backbone structure limits the length of double-helical segments, which in turn regulate junction zone growth and promote gel stability [3,5].

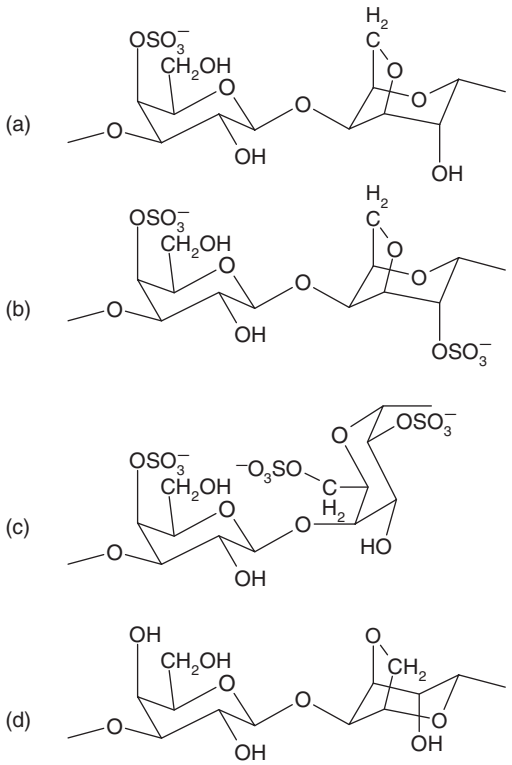

FIGURE 1.24 Idealized structural repeats for (a) κ-carrageenan, (b) ι-carrageenan, (c) λ-carrageenan, and (d) agar that provide insight into the physical properties of each respective polysaccharide.

In contrast, the high degree of negative charge and the different shape of the disaccharide repeat inherent to λ-type carrageenan molecules preclude significant intermolecular association and gel formation under any conditions common to food systems [3]. For carageenans, gel strength decreases in the order $\kappa > \iota > \lambda$ (non-gelling), which is inversely related to the degree of polysaccharide molecular charge.

G. Agar

Agar, which is also derived from specific species of red seaweed, exhibits a chemical structure similar to that of κ-carrageenan, except that the second unit of the characteristic disaccharide repeat is a 3,6-anhydro-α-L-galactopyranosyl unit (in carrageenans, D-entantiomer is present instead) (Figure 1.24d) [29]. Similar to the carrageenans, the backbone structure is interrupted by an occasional kink (presence of sulfate hemiester at C-6 of the α-L-galactosyl unit),

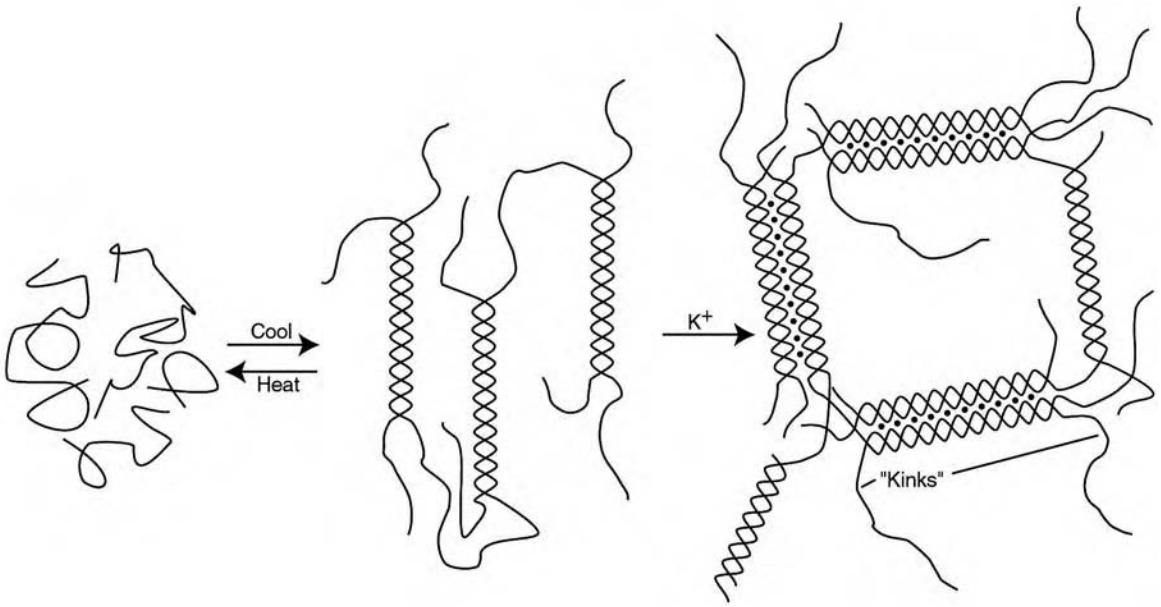

FIGURE 1.25 Representation of the gelation mechanism and junction zone structure for κ-carrageenan gels, in which potassium ions (•) shield backbone negative charges to allow intermolecular interaction of double-helical polysaccharide segments. The presence of "kinks" (occasional backbone structural irregularity) lends stability to the gel by limiting junction zone size and growth. Agar gels are believe to possess a similar gel mechanism and structure, except that potassium ions are not required to bring about gelation.

though the sulfate content of agar is nominal (1.5–2.5%) compared to that of carrageenan (>20%) [30]. While heating (85°C) is required to bring about water solubility, the lack of consistent negative charge along the length of the agar backbone results in a fairly flexible, non-extended polymer chain of relatively low viscosity (in comparison to carrageenan) [29]. However, upon cooling (40°C), agar molecules undergo a transition to an ordered double-helical tertiary structure, which leads to intermolecular aggregation of sections of ordered polymer chains and development of a quaternary gel structure [23]. Agar junction zone and gel structure are thought to mimic that of gelling carrageenans, with the exception that counterions are not required to promote gel formation in agar (lack significant negative charge that would require shielding for intermolecular association to occur) (Figure 1.25). Similar to carrageenan, occasional kinks in backbone structure disrupt the double-helical arrangement, which in turn prevents excessive growth of junction zones and aids gel stability [29].

H. Xanthan

Xanthan is the common name for the heteroglycan isolated from the bacterium *Xanthomonas campestris*. While xanthan has a backbone primary structure identical to that of cellulose, it differs from cellulose in that it possesses a trisaccharide sidechain glycosidically attached to O-3 of alternating backbone units [3,31]. The sidechain consists of two mannosyl units separated by a glucuronic acid unit (Figure 1.26). Approximately half of the terminal mannose units of the sidechain contain pyruvic acid, linked at C-4 and C-6 via a cyclic acetal structure, while the nonterminal mannosyl units contain an acetyl substituent attached at C-6.

The presence of the trisaccharide sidechain, which reduces intermolecular associations (due to electrostatic repulsion and steric hindrance), is thought to account for the excellent water solubility of xanthan relative to that of native cellulose (water-insoluble) [32]. Xanthan forms highly viscous, pseudoplastic (shear-thinning) solutions at low concentrations, which solutions are stable to viscosity change over a wide range of pH (1–12), salt concentration (up to 0.7%), and temperature (0–95°C) [3]. The relatively high-viscosity solutions are attributable to a high molecular weight ($2–10 \times 10^6$) and molecular rigidity derived from its ordered conformation, which is thought to consist of an extended double-stranded helix [33]. At a temperature of 120°C, xanthan solutions lose up to 98% of their original viscosity due to loss of molecular order and rigidity [34]. At reduced temperature, xanthan solutions regain up to 80% of their original viscosity as molecules appear to reform the ordered conformation [34]. Due to its unique solution behavior, xanthan is used as a multipurpose thickener in a wide range of food applications.

I. Gum Arabic

Gum arabic, also known as acacia gum, is the exudate material of the acacia tree common to the Sahel zone of

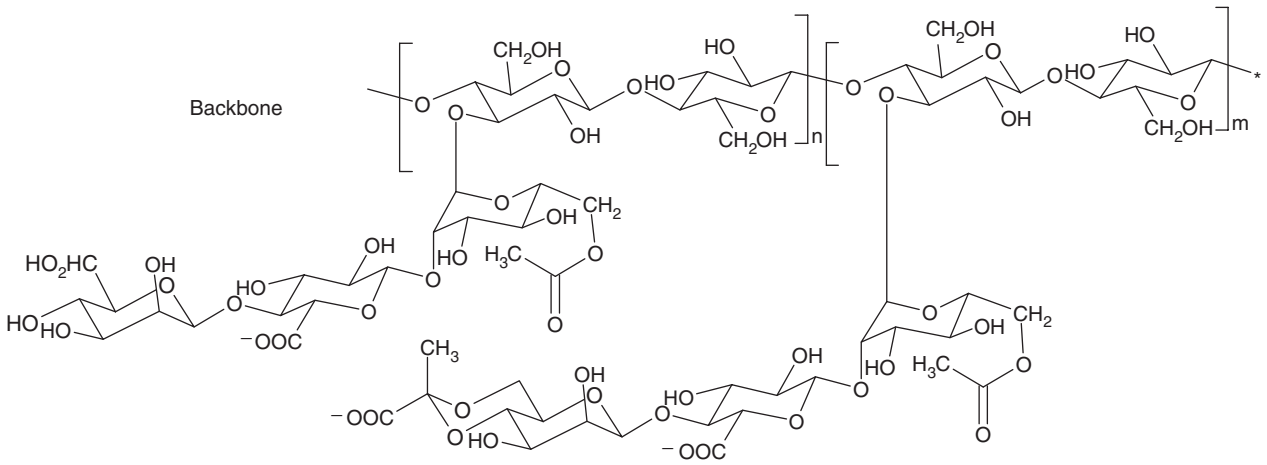

FIGURE 1.26 Chemical structural repeat of xanthan.

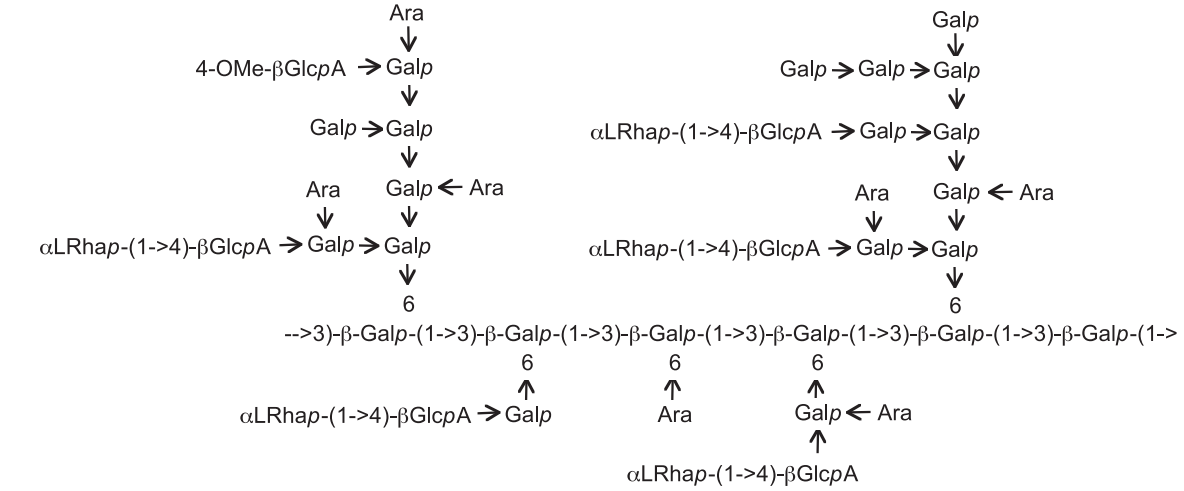

Galp = (1-> 3)- or (1->6)-linked β-D-Galp-residues

Ara = L-Araf , or (1->3)-linked LAraf oligosaccharide side chain, or αGal-(1->3)-LAraf

FIGURE 1.27 Representation of the branched chemical structure and composition of gum arabic.

Africa [35,36]. The gum contains 2–3% protein (gives rise to emulsification capability), which is covalently bound to the polysaccharide component [3]. Chemically, gum arabic has a (1→3)-linked backbone of β-D-galactopyranosyl units, which constitute approximately 40% of the total monosaccharide content of the gum (Figure 1.27) [3,36]. Further, the gum arabic backbone is highly substituted with sidechains (which themselves may give rise to further branching), producing a highly branched structure. It contains at least four additional types of monosaccharide units (L-arabinofuranosyl, L-rhamnopyranosyl, D-glucopyranosyluronic acid, and 4-*O*-methyl-D-glucopyranosyluronic acid units) attached to the branched backbone [3,35].

Due to its highly branched nature, gum arabic, though of substantial molecular weight (580,000), possesses a very compact three-dimensional structure, which provides the basis for its most unique physical properties, its astronomical solubility, and low viscosity (up to 50% gum solutions may be prepared) [3]. The compact nature of gum arabic molecules is best comprehended by the fact that gum solutions of up to 10% (w/v) display Newtonian flow behavior, and that it is not until 30% (w/v) solutions are achieved that steric overlap of individual molecular domains begins to occur accompanied by a more substantial rise in viscosity as a function of increasing gum concentration [36].

2 Carbohydrates: Physical Properties

Qi Wang and P.J. Wood
Food Research Program, Agriculture and Agri-Food Canada

CONTENTS

I. INTRODUCTION

Carbohydrates include monosaccharides, oligosaccharides, and polysaccharides as well as substances derived from them by various reactions such as reduction, oxidation, esterification, etc. Monosaccharides are the basic units from which all carbohydrates are built. Linking of monosaccharides via glycosidic bonds leads to the formation of oligosaccharides (2 to 20 monomers) and polysaccharides (more than 20 monomers). The term "sugars" is often used to refer to the monosaccharides and some disaccharides (e.g., sucrose). Polysaccharides are grouped into two major classes: (1) simple polysaccharides, which contain only monosaccharides and their derivatives (esters and ethers), and (2) conjugate polymers made up of a polysaccharide linked to another polymer, such as polypeptide. It is the purpose of this chapter to focus on the physical properties of simple carbohydrates and associated characterization techniques that are important to food sciences.

As one of the three major food components, carbohydrates have enormous functions and applications. They not only supply most of the energy in the diet of humans, but also have various functionalities which are used to confer desired texture in foods. In these latter applications, the physical properties of carbohydrates, such as solubility, water holding capacity, and solution rheology, play important roles. Although containing similar building blocks, mono-, oligo-, and poly-saccharides have different physical properties. An extreme example of this is the contrast between the highly soluble monomeric glucose and the completely insoluble cellulose, which is a polymer of glucose. It has long been known that the configuration and conformation of sugars are the determinants of their chemical and physical properties, and those of oligosaccharides and polysaccharides inevitably depend on the constituent monosaccharide as well as the intermonomeric linkages. Abundant evidence has shown that most of the physical properties of carbohydrates depend on the size, shape, charge, and polarity of the individual molecules. The study of structure-function relationships has been an important topic of carbohydrate research, and advances in physical techniques continue to improve our understanding and provide more insight into these relationships.

II. CONFORMATION OF CARBOHYDRATES

A. MONOSACCHARIDES

Most monosaccharides and their derivatives encountered in foods are polyhydric alcohols carrying a "reducing" keto or aldehydo unit, and they exist primarily in cyclic tetrahydropyran and tetrahydrofuran forms, with the latter occurring less frequently than the former. However, the common ketosugars are more likely than aldosugars to exist as furanoses. Seven-membered rings occur but are not common in foods. Free reducing sugars in solution may exist in different cyclic forms, which are in equilibrium via the acyclic aldehydo or keto form.

There are three potentially stable shapes for the six-membered saturated sugar rings, namely chair, boat, and skew (Figure 2.1). The chair conformation predominates in most cases because the widest separation of the electronegative oxygen atoms is usually achieved through equatorial orientations of most of the hydroxyl and CH_2OH groups. The anomeric hydroxyl unit differs in that it may adopt two orientations (α or β), which are strongly influenced by the ring oxygen. Similarly, there are two principal conformations for saturated furanoid rings, described as envelope (E) and twist (T) (Figure 2.1), each with four or three coplanar atoms, respectively. Because of the low energy barriers between the E and

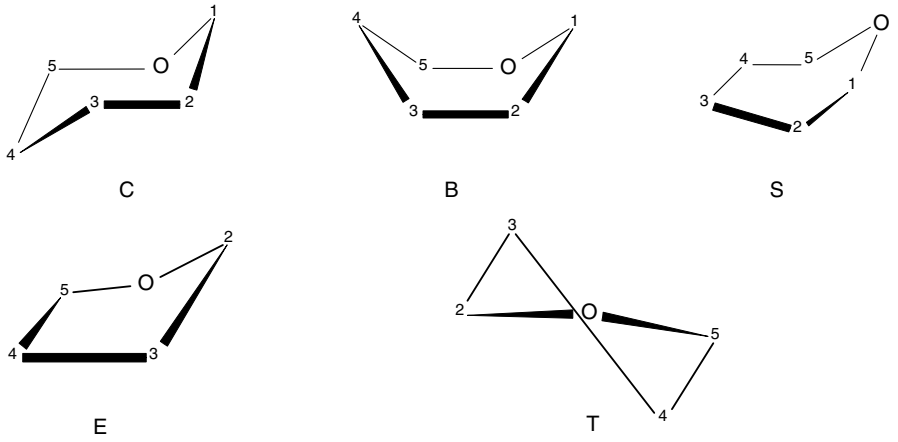

FIGURE 2.1 Examples of chair (C), boat (B), and skew (S) forms for pyranoid rings and envelope (E) and twist (T) forms for furanoid rings.

T conformers, interconversions of these occur more readily than between the pyranoid forms. The shapes of acyclic aldehydo and keto carbohydrates and their reduced forms are usually described as either a linear (zig-zag) or a sickle shape. The advent of diffraction and NMR techniques has allowed the determination of the configuration and conformation of almost all the important monosaccharides (1). In crystals, most molecules adopt a single conformation, whereas in solution there is generally more than one conformation undergoing fast interconversion.

For a more detailed treatment of monosaccharide chemistry and nomenclature, the readers are referred to standard textbooks (2).

B. Oligosaccharides

The conformation of oligosaccharides is less well documented than that of monosaccharides, although the naturally occurring common oligosaccharides are well characterized. Most data from x-ray diffraction and NMR analysis are limited to oligosaccharides having less than four monomeric units. There is considerable experimental difficulty encountered when applying these techniques to large oligosaccharides (3). However, although based on limited amount of data, some general features about the conformation of oligosaccharides can be drawn. Once incorporated into an oligosaccharide or polysaccharide chain, the monosaccharide ring is relatively rigid and the ring geometry becomes effectively fixed. Thus, the overall shape of oligosaccharides become more determined by the two torsion (dihedral) angles ϕ and ψ across the two single bonds of their connecting glycosidic linkage than by the unit geometries. Wells of minimum potential energy may be calculated, which limit the values adopted by ϕ and ψ but not rigidly so. Generally speaking, disaccharides should have a preference for staggered conformations about the two linkage bonds, unless there are geometric constraints imposed by, for example, a hydrogen bond between the two rings. The crystal structures of many oligosaccharides have been elucidated (3). Monosaccharides and certain oligosaccharides possess definite crystalline structures, and thus have well-defined melting points and solubilities.

C. Polysaccharides

Similar to polypeptides, polysaccharides also have different levels of structures, although higher level structures are less well defined. The primary structure describes the covalent sequence of monosaccharide units and the respective glycosidic linkages. The secondary structure describes the characteristic shapes of individual chains such as ribbons and helices, which arise from repetition of units adopting a particular average orientation in shape. Polysaccharide chains with well-defined secondary structure (or sufficient areas of such) may interact with each other, leading to further ordered organizations incorporating a group of molecules. This is known as the tertiary structure. Further association of these ordered entities results in large quaternary structures.

1. Ordered Structures in the Solid State

A repeated sequence of monomers or oligomers leads to an ordered and periodic conformation of polysaccharide molecules. The different linkage types, arising from the anomeric nature of glycosidic linkage and the orientation of OH units through which it is attached, impose certain general features on oligosaccharide and polysaccharide conformations because of the limitations placed on the dihedral angles. Fundamentally there are four different types of chain shapes: ribbons, hollow helices, loosely jointed, and crumpled types (4). For example, for β-(1→4) linked D-glucopyranosyl units, the two bonds from the ring to its two bridging oxygens define a zig-zag form, which promotes a tendency to adopt a flat, extended, ribbon-like conformation, in the polymer (Figure 2.2a). In contrast, when the links between the D-glucopyranosyl units are β-(1→3) or α-(1→4), they define a U-turn form (Figure 2.2b); this geometry extended over multiple units often produces a hollow helical conformation, which becomes stabilized in multiple helices. The linkage through the primary hydroxyl units, such as between (1→6) linked hexopyranose units, leads to a loosely jointed type of conformation and marked molecular flexibility in the resultant polysaccharides. This arises from the extra single bond and torsion angle (ω) between the two sugar rings that separates the rings, reducing inter-unit interactions and allowing a greater range of conformational

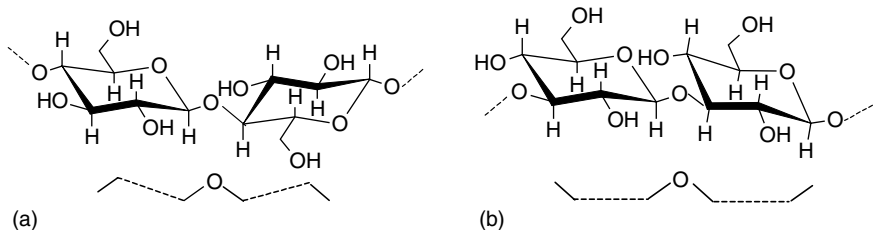

FIGURE 2.2 Examples of geometrical relationships across sugar rings. (a) Zig-zag relationship across 1,4-linked β-D-glucopyranose; (b) U-turn relationship across 1,3-linked β-D-glucopyranose.

possibilities. A further type of conformation known as "crumpled," such as in β-(1→2) linked glucopyranoxyl units, is less common in food carbohydrates.

The regular conformation of polysaccharides can always be described as a helix, which may be defined by just two parameters, the number of units per turn of the helix, and the translation of each repeating residue along the helical axis. The resultant single helix may associate to form multiple helices, which are then further packed in various ways to form higher ordered structures in the solid state. The majority of polysaccharides in their native form exist in an amorphous structure, examples being the antiparallel, extended twofold ribbon-like organized chain structure in the family of mannans and galactomannans (5). A relatively small number of polysaccharides are organized into a repeating crystalline or partly crystalline structure, examples being cellulose, starches, chitin, and some β-D-glucans. The crystalline element is usually capable of existing in different polymorphic forms. The ordered structures of polysaccharides have been extensively studied by x-ray and electron diffraction (6), and the x-ray structures of more than 50 well-defined polysaccharides are known (7).

2. Secondary and Tertiary Structures in Solutions and Gels

The extensively ordered conformation of a polysaccharide in the solid state may not be retained following hydration in solutions and gels. Polysaccharide chains tend to adopt a more or less coiled shape in solutions and fluctuate continuously between different local and overall conformations. A large group of non-gelling polysaccharides, or gelling polysaccharides in non-gelling conditions, exist in solutions with a conformation known as disordered random coils. Since polysaccharide molecules contain a large number of hydroxyl groups, they have a high tendency to associate into supramolecular aggregates through hydrogen bonding in aqueous solutions. For example, combining static and dynamic light scattering, a fringed micelle model was proposed for the aggregates formed in solutions by a number of neutral polysaccharides including tamarind xyloglucan (8) and cereal (1→3)(1→4)-β-glucans (9). The association of molecules in such a form markedly increases the stiffness of the single chains, leading to enhanced solution viscosity. More ordered structures may be developed, in solution through the so-called cooperative interactions, especially for polysaccharides in which identical repeat units result in a regularity of sequence. Conformational transitions in solution between random coils and helices have been well recognized and characterized for a number of polysaccharides such as curdlan, xanthan, and gellan (10). Under favorable conditions, these ordered structures may further associate, leading to the formation of three-dimensional gel networks.

D. Physical Techniques Used to Study Carbohydrate Conformation

A wide range of physical techniques has been used to study the structures of carbohydrates at different levels, i.e., molecular, macromolecular, and supramolecular structures (11). The use of such means as mass spectroscopy and molecular spectroscopy to elucidate the primary structure of carbohydrates will not be covered in this chapter. The purpose is to include only those physical techniques used for studying the conformation of carbohydrates in general, and for probing the higher level structures of polysaccharides. Generally there is a need to combine several physical techniques to provide complementary information about the structure of carbohydrates.

1. X-Ray Diffraction

a. Background

X-ray diffraction and other types of diffraction methods (electron and neutron) have contributed to our understanding of the molecular geometry of carbohydrates. Diffraction is essentially a scattering phenomenon. When a monochromatic x-ray beam travels through a test specimen, a small proportion of the radiation is scattered with mutual reinforcement of a large number of scattered rays, and the resultant x-ray intensity in specific directions depends on the arrangement of the scattering atoms within the sample. X-ray scattering techniques are divided into two categories: wide-angle x-ray scattering (WAXS) and small-angle x-ray scattering (SAXS). Typically, SAXS gives information on a scale of ~ a few nanometers and smaller, while WAXS gives information on a scale of 1–1000 nm. WAXS is used to measure crystal structure and related parameters, which is the topic of this section. SAXS will be discussed in the next section together with light and neutron scattering techniques.

The diffraction pattern, commonly recorded on photographic film, consists of an array of spots (reflections) of varying intensities, from which structural information for a chemical repeat may be deduced. If a large enough size of crystal can be prepared, it is usually possible to determine the crystal structure and hydrogen bonding to a high degree of accuracy. Information such as repeating unit cell dimensions, lattice type, space group symmetry and bond lengths, and valence angles can be derived from the analysis.

b. Monosaccharides and oligosaccharides

For almost all monosaccharides and many oligosaccharides with low degrees of polymerization, it is not a major problem to prepare single crystals for x-ray measurement. X-ray characterized structures are available for most of these molecules (3, 12–16). As an example, in the study of mannotriose (O-β-D-mannopyranosyl-(1→4)-O-β-D-mannopyranosyl-(1→4)-O-α-D-mannopyranose) (14), the unit cell was determined as monoclinic with dimensions of

a = 0.1183 nm, b = 0.1222 nm, and c = 0.9223 nm, and β = 112.34°; the space group was $P2_1$. The crystal structure includes three water molecules, two of which are involved in hydrogen bonding such that the mannotriose molecules occur effectively as sheets of long parallel chains, with each consecutive sheet having chains lying at approximately right angle to those in a neighboring sheet.

c. Polysaccharides

Large oligosaccharides rarely and polysaccharides never form single crystals that are good enough for classical x-ray crystallography. They tend to form fibers that are amorphous, or at best only partly crystalline, starch being a typical example of the latter. X-ray study of starches mostly measures the degree of crystallinity and identifies different polymorphic forms. To obtain useful x-ray diffraction data from other more amorphous non-starch polysaccharides, oriented fibers or films are used (6). These polycrystalline fibers or films are prepared in such a way that the polysaccharide helices are preferentially oriented with their long axes nearly parallel. The x-ray diffraction intensities then provide information about the helical structures such as repeat spacing of the helix and helix screw symmetry, and if the diffraction pattern is sufficiently "crystalline," the unit cell dimensions and lattice type. However, the x-ray data alone are inadequate to solve a fiber structure, and interpretation requires supplementation with molecular modeling analysis using existing stereochemical information derived from surveys of crystal structures of related mono- or oligosaccharides (7, 17).

X-ray fiber diffraction is of great value in the determination of the conformations of polysaccharides. Studies of the (1→3)-β-D-glucan family, curdlan, schizophyllan, and scleroglucan, are good examples. Curdlan is a linear (1→3)-β-D-glucan, whereas schizophyllan and scleroglucan also contain some β-(1→6)-glucosyl branches. These (1→3)-β-D-glucans usually form triple-stranded helices (18). The structure of curdlan (in both hydrated and anhydrous forms), determined from oriented fibers, assume a right-handed, parallel, six-fold triple-helical conformation. There are interstrand O2···O2 hydrogen bonds in the hexagonal unit cell, with parameters a = b = 1.441 nm and c = 0.587 nm. The space group is $P6_3$ and there is one helix per unit cell (19). The short-branch substitutions on the main chain primary hydroxyls in schizophyllan and scleroglucan do not seem to affect the fundamental triple-helical structure (20).

2. Light, X-Ray, and Neutron Scattering

a. Background

The principles on which light, x-ray, and neutron scattering depend are basically similar and can be treated by the same fundamental sets of equations. For all three modes of scattering, angular dependence of the normalized scattering intensity provides information on the size and shape of the macromolecules. The resolving power of scattering techniques is related to the wavelength of the scattered radiation (21). The wavelengths are 0.1–0.3 nm for SAXS, 0.2–1.0 nm for small angle neutron scattering (SANS), and ~500 nm for light scattering. Conventional light scattering typically reveals only the global dimensions of a macromolecule, which may be tens to hundreds of nanometers for a typical polysaccharide. SAXS and SANS can probe molecular structures at closer ranges of about 2–25 nm (22). SANS may additionally observe the Gaussian behavior of polymer chains in their own bulk (solid), which conventional light scattering cannot. Light scattering is effective in measuring the angular dependence of intensity typically in the range 30° to 135°. SAXS can be carried out at very small angles, typically less than 1°, and is thus superior for the determination of the size and shape of macromolecules, but it is less convenient for the determination of molecular weight and second virial coefficient.

b. Application to polysaccharides

Scattering measurements can be carried out in two modes, static and dynamic. The former measures the average scattering intensity within a selected time period, whereas the latter measures the fluctuation of the intensity over time. From static measurements, the weight average molecular weight (M_w), z-average radius of gyration (R_g), and the second virial coefficient can be extracted. From dynamic measurement, the translational diffusion coefficient is obtained from which the hydrodynamic radius (R_h) can be determined. The parameter, $\rho = R_g/R_h$, may provide information on the architecture of the macromolecules and their aggregates (23). From the combination of static and dynamic scattering data, other information may be derived including the linear mass density, Kuhn segment length, and polydispersity index. To obtain as much structural information as possible, experimental data from scattering are usually processed and presented through various plots, and need to be interpreted using molecular model such as the worm-like chain model (23).

Light scattering was applied to study the solution properties of amyloses and the retrogradation of amyloses as early as the 1960s (24–26). A typical flexible chain behavior was observed for high-molecular-weight amyloses in freshly prepared aqueous solutions. With decreasing molecular weight, the tendency to aggregate increased considerably so that a stable aqueous solution could not be prepared. The many studies on amylopectin and glycogen demonstrated how scattering techniques may be used for investigating the branching behavior of polysaccharides (27). The branching nature of amylopectin and glycogen can be detected clearly by light scattering from the Zimm plot, which shows an upturn (28, 29).

Scattering techniques can be used to probe the conformational transition of polysaccharides in solution. For

example, the thermal transition evident in low ionic strength xanthan solutions was followed by light scattering (30). It was observed that the apparent hydrodynamic radius significantly decreases with increasing temperature in the vicinity of the helix-coil transition temperature. As discussed above (Section II.C.2), light scattering is also useful in investigating aggregation properties of polysaccharides.

3. Chiroptical Methods

a. Background

Optical activity is one of the most readily and often measured physical properties of carbohydrates. Carbohydrates contain several similarly substituted asymmetric carbon atoms and are therefore all optically active. The optical activity can be determined by optical rotation (OR), optical rotatory dispersion (ORD), and circular dichroism (CD). OR is measured by a polarimeter at a single wavelength, usually the sodium D line (589 nm), and expressed as specific (or molecular) rotations $[\alpha]_D$. A number of approaches, all of them empirical in nature, have been devised to interpret the relationship between the measured optical rotations and structural features of carbohydrates (31). Specific rotations are used extensively to characterize new derivatives and to recognize known ones. Instead of using a single wavelength, optical rotatory dispersion measures the optical rotation angle (φ) over a wide range of wavelengths, and circular dichroism measures the differential absorption of right- and left-circularly polarized light as a function of wavelength. Both ORD and CD spectra can exhibit marked changes in slope in the vicinity of the absorption maximum of a chromophore attached to the chiral center, known as the Cotton effect.

b. Optical rotation

In a monosaccharide molecule, several chiral carbons contribute to the overall optical rotation, but the configuration of the carbon atoms attached to the ring oxygen atom have the greatest influence on the overall rotation value. For many monosaccharides and reducing oligosaccharides, the initial optical rotation in aqueous solutions changes with time until reaching a constant value. This phenomenon is known as mutarotation, most often the outcome of interconversion between α and β ring isomers, until reaching an equilibrium.

Similar to monosaccharides, oligo- and polysaccharides have optical activity. With advances in the understanding of carbohydrate stereochemistry, it has become generally recognized that the overall optical rotation is determined more by the relative orientation of adjacent monosaccharide residues (defined by dihedral angles) than by the additive contributions from each asymmetric center. The optical activity of these is therefore beyond those arising from the simple monosaccharides, but is rather associated with the conformation of larger molecules or macromolecules. Stevens and co-workers developed a chiroptical technique to investigate disaccharide conformation (32), based upon the estimates of variation in the optical activity of a particular disaccharide as a function of its glycosidic conformation. A number of disaccharides, including sucrose, maltose and cellobiose, have been characterized using this method (33).

The optical rotation of polysaccharides at long wavelengths is usually dominated by the optical activity of the polymer backbone. Measurement of optical rotation at long wavelengths remains a standard and practical technique for polysaccharide systems despite the advent of ORD and CD instruments. For example, OR is used frequently for monitoring the progress of cooperative conformational transitions of polysaccharides (34).

c. Circular dichroism and optical rotatary dispersion

Monosaccharides of most food carbohydrates exist in cyclic forms, thus do not possess the unsaturated chromophores necessary to display a Cotton effect at long wavelengths. In the absence of unsaturated chromophores, two very short wavelength transitions associated with conformational transitions of carbohydrate backbone may be used (35–37). These can be observed by modern vacuum UV polarimetry. One such transition is centered near 175 nm, attributed to the $n \rightarrow \sigma^*$ transitions of the acetal oxygen atoms. The second is usually found around 150 nm and is closely related to the optical rotation at long wavelengths. CD and ORD experiments show that the variation in intensity of these two bands in polysaccharides is correlated to their composition and conformation (38). Thus, CD and ORD offer powerful tools to study structural and conformational transitions.

Some polysaccharides contain chromophores that absorb at substantially longer wavelengths than the polymeric backbone and thus give significant CD and ORD bands at wavelengths above ~185 nm. Examples are acyl and pyruvate ketal constituents and the carboxyl groups. In these cases, the CD spectra are close to those of the isolated monosaccharides, with little direct influence from the chain geometry. Since CD is very sensitive to the local environment of chromophores, conformational changes caused by, for example, specific site binding of uronate segments are usually accompanied by dramatic changes in CD spectra (39). This provides an alternative approach to study the gelation mechanisms of polysaccharides containing carboxyl groups such as alginate, pectin, xanthan, and gellan (40, 41).

4. Microscopy Techniques

a. Background

Direct imaging of polysaccharides using microscopy provides an important additional method for physical

characterization of polysaccharides. Two types of microscopy are especially of interest. First, electron microscopy (EM) is the traditional type, like light microscopy, but instead uses an electron beam to probe smaller structures than possible with light. Atomic force microscopy (AFM) senses forces such as electrostatic, magnetic, capillary, or van der Waals forces, as the molecular surface is approached by a probe. EM has considerable power to study supramolecular assemblies such as starch granules and mixed structures such as composite gels, whereas AFM has wide potential applications in investigating the structures of single molecules, as well as supramolecular assemblies and gel networks.

b. Electron microscopy

In EM, an electron beam produced from an electron gun is employed as an illuminating source instead of visible light. In transmission electron microscopy (TEM), when a fine electron beam hits the specimen, the electrons are transmitted after a series of interactions with the specimen, and then magnified to produce the image on a fluorescent screen or a photographic film. In scanning electron microscopy (SEM), the secondary electrons originating from ionization of the specimen atoms by the incident primary electrons are collected by an electron detector. The incident beam is scanned over a small area corresponding to the area of the micrograph. EM gives a better resolution than light microscopy because the wavelength of an electron beam is shorter than that of visible light.

A critical part of electron microscopy is adequate preparation of the specimen to minimize structural changes and to avoid artifacts. In most cases, the samples are exposed to a series of treatments prior to observation such as dehydration (or solidification), sectioning, and coating with electrical conducting materials. Thus, the image shapes obtained from the specimens may differ from their true shapes in the hydrated state.

Information can be obtained from EM on how macromolecules associate into supramolecular assemblies, and under favorable conditions, form gel networks (42). EM was used to monitor the conformational changes of polysaccharides that often initiate gelation such as coil-helix transitions (42). Direct visualizing of the structure of gel networks using EM has helped the understanding of structure-function relationships of polysaccharide gelation. In addition to these qualitative assessments of structural features, it is also possible to quantify properties like contour length, persistence length, linear mass density, and thickness of strands, using advanced image analysis systems (42, 43). Polysaccharides like xanthan and various β-D-glucans, all with a persistence length in the order of 100 nm, are ideally suited for such EM investigations. Since EM only provides a two-dimensional projection of the specimen, it is important to compare the parameters derived from EM with those obtained from other physical techniques, or from specimens prepared by different techniques.

c. Atomic force microscopy

AFM is still a relatively new form of microscopy and has only been applied to the study of biopolymers since the late 1990s. It generates images by sensing the changes in force between a probe and the sample surface as the sample is scanned. Using a variety of probing methods (44), a three-dimensional image with sub-nanometer resolution of the surface topography of tested samples can be produced (45). Thus, AFM affords an opportunity to directly image individual molecules and the helical structures of polysaccharides with minimal sample preparation (44, 46, 47). The polysaccharides are simply deposited from aqueous solution onto the surface of freshly cleaved mica, air dried, and then imaged directly under appropriate liquid (45).

For highly flexible polysaccharides such as dextrans, the AFM images show globular structures representing time-averaged pictures of the random coil structure. For more extended polysaccharides, such as xanthan and β-D-glucans, the AFM images may be quantified to yield persistence length, contour length, and its distributions (48). The dimensions observed by AFM are often larger than those derived from conventional techniques (44). This is believed to be due to the polymer-surface interactions which occur when the molecules are absorbed onto the mica surface prior to observation. AFM can be used to investigate the nature of association in junction zones, and also the overall structure of gel networks (49–51).

The use of EM and AFM has led to an improved understanding of the functional properties of polysaccharides at a molecular level. Furthermore, the ability to provide direct information about heterogeneity makes microscopy not simply complementary to other physical techniques, but also indispensable for obtaining additional detailed structural information.

5. Nuclear Magnetic Resonance

a. Background

Nuclear magnetic resonance (NMR) spectroscopy provides detailed structural information of carbohydrates, such as identification of monosaccharide composition, elucidation of α or β configurations, and establishment of linkage patterns and sequence of the sugar units in oligosaccharides and polysaccharides. Recent advances in two-dimensional NMR techniques allow the elucidation of some polysaccharides without chemical analysis (52). NMR can also be used to determine the conformation and chain stiffness/mobility of oligosaccharides and some polysaccharides in solution and to monitor coil-helix transitions and gel formation (53).

The principle of NMR spectroscopy is based on the magnetic property of the nucleus in atoms associated with

spins. The most useful nuclei in carbohydrate research are ^{1}H and ^{13}C, which by absorbing radio frequency energy in a strong magnetic field, jump to higher energy levels. Spins at the higher energy levels tend to relax to lower energy levels, and the transitions are dependent on the magnetic field strength in the local environment of the nucleus. Therefore, every nuclear spin in a molecule is influenced by the small magnetic fields of the nuclei of its nearest neighbors. Hence, the signal released by the nucleus reveals structural information of the nucleus in specific environment. The analysis of these individual signals relative to a standard, expressed by chemical shift and spin-coupling between nuclei, can yield detailed information on the structure and shape of molecules.

One-dimensional NMR experiments are limited to the portrayal of response intensity as a function of the observation frequency under the applied field. Two-dimensional NMR techniques utilize a second frequency domain, which greatly expands the information contained in the spectrum. The introduction of this second domain allows correlations to be established and hence connectivity information can be obtained. These are very useful in determining molecular structures, particularly of complex oligosaccharides and polysaccharides. For example, COSY (COrrelation SpectroscopY) and TOCSY (TOtal Correlation SpectroscopY) are used to establish connectivities around monosaccharide rings. Long-range correlation experiments, such as Nuclear Overhauser Effect (NOE), a through-space phenomenon, can be used in the study of shape and conformation. Long-range heteronuclear correlation experiments can establish interresidue connectivity, and the sequences of complex oligosaccharides and polysaccharides can therefore be determined.

b. NMR in molecular dynamics and conformational analysis

NMR relaxation data (T_1 and T_2^*) provide information on the dynamics of oligosaccharides and polysaccharides involving several different types of internal motion (53). NOESY provides information on inter-glycosidic spatial constraints, which helps define linkage conformations. Since they are able to provide conformational analysis of oligosaccharides in solution, NMR techniques are important means to obtain information on the three-dimensional structures free of crystal lattice constraints. NMR measurements of vicinal long-range homonuclear couplings ($^{3}J_{H,H}$) and long-range heteronuclear couplings ($^{3}J_{C,H}$) provide information on both intra- and inter-residue conformation(s) by measuring the parameters controlled by the dihedral angles between constituent monosaccharides of oligosaccharides and polysaccharides. In a recent application of NMR spectroscopy, long-range heteronuclear coupling constants were measured across the glycosidic linkages of a series of eight α- or β-linked disaccharides in solution (54). The $^{3}J_{C,H}$ values were determined by multiple ^{13}C site-selective excitation experiments using ^{1}H decoupling under pulsed field gradient-enhanced spectroscopy. The experimentally determined long-range three-bond heteronuclear coupling constants were converted to calculate values of the glycosidic dihedral angles of each disaccharide using a Karplus-type equation. Wide applications of NMR in solution dynamics, conformational analysis, and prediction of helical structure of oligosaccharides and polysaccharides can be found in the literature (55–57).

In summary, NMR spectroscopy is a very powerful tool not only for analyzing the primary structures of carbohydrates to provide information such as anomeric configuration, linkage sites, and sequences of monosaccharides, but also to determine the dynamics and shape of carbohydrates in solutions. The information can be further enhanced by combining with molecular modeling techniques. In this way, a deeper understanding of the dynamic properties and three-dimensional conformation of oligosaccharides and polysaccharides, and hence, the structure-property relationships, are obtained.

III. MOLECULAR WEIGHT AND MOLECULAR WEIGHT DISTRIBUTION

A. Polydispersity and Molecular Weight Averages

Monosaccharides and oligosaccharides have well-defined chemical structures, and specific molecular weights. However, polysaccharides contain molecules with different numbers of monosaccharide units (thus different molecular weights) and are said to be polydisperse. The distribution of molecular weight (MWD) varies, depending on the synthetic pathway and environments, as well as the extraction conditions to isolate the polysaccharides. The distribution may be described as mono-, bi-, or polymodal. Before we discuss how to quantitatively describe this polydispersity in molecular weight, we have to introduce the concept of molecular weight averages.

There are four statistically described molecular weight averages in common use, number average molecular weight (M_n), weight average molecular weight (M_w), z-average molecular weight (M_z), and viscosity average molecular weight (M_v). The mathematical descriptions of

* T_1 relaxation, or spin-lattice relaxation, is characterized by the longitudinal return of the net magnetization to its ground state of maximum length in the direction of the main magnetic field through energy loss to the surrounding lattice. T_2 relaxation, or spin-spin relaxation, is characterized by the exchange of energy of spins at different energy levels, and does not lose the energy to the surrounding lattice.

these averages in terms of the numbers of molecules N_i having molecular weight M_i are:

$$M_n = \frac{\sum_{i=1}^{\infty} M_i N_i}{\sum_{i=1}^{\infty} N_i} \quad (2.1)$$

$$M_w = \frac{\sum_{i=1}^{\infty} M_i^2 N_i}{\sum_{i=1}^{\infty} M_i N_i} \quad (2.2)$$

$$M_z = \frac{\sum_{i=1}^{\infty} M_i^3 N_i}{\sum_{i=1}^{\infty} M_i^2 N_i} \quad (2.3)$$

$$M_v = \left[\frac{\sum_{i=1}^{\infty} M_i^{1+\alpha} N_i}{\sum_{i=1}^{\infty} M_i N_i} \right]^{1/\alpha} \quad (2.4)$$

In Equation 2.4, α is the Mark Houwink exponent (Section V.B.2). Most of the thermodynamic properties are dependent on M_n and bulk properties such as viscosity are particularly affected by M_w. M_w and M_z emphasize the heavier molecules to a greater extent than does M_n. M_v is usually between M_w and M_n and closer to M_w; when $\alpha = 1$, $M_w = M_v$. For very stiff polysaccharides with $\alpha > 1$, M_v exceeds M_w.

A convenient measure of the range of molecular weights present in a distribution is the ratio M_w/M_n, called the polydispersity index (PI). In a random MWD produced by condensation syntheses, as with polysaccharides, PI is typically around 1.5~2.

B. Physical Methods for Molecular Weight Determination

Absolute techniques for MW determination include membrane osmometry, static light scattering and equilibrium sedimentation. These techniques require no assumptions about molecular conformation and do not require calibration employing standards of known MW. Relative techniques include gel permeation chromatography (GPC), dynamic light scattering, velocity sedimentation and viscometry, and require either knowledge/assumptions concerning macromolecular conformation or calibration using standards of known MW. Combined techniques use information from two or more methods, such as velocity sedimentation combined with dynamic light scattering, velocity sedimentation combined with intrinsic viscosity measurements, and GPC combined with on-line (or off-line) static light scattering or equilibrium sedimentation.

1. Osmometry

Polymer solutions exert osmotic pressure across a porous boundary because the chemical potentials of a pure solvent and the solvent in a polymer solution are unequal. There is a thermodynamic drive toward dilution of the polymer-containing solution with a net flow of solvent through a separating membrane, toward the side containing the polymer. When sufficient pressure is built up on the solution side of the membrane, equilibrium is restored. The osmotic pressure π depends on M_n and polymer concentration c as follows (58):

$$\pi = RT\left(\frac{c}{M_n} + A_2c^2 + A_3c^3 + \cdots\right) \quad (2.5)$$

where R is the molar universal gas constant, T is the absolute temperature, and A_2 and A_3 are the second and the third virial coefficients, respectively. In very dilute solutions, it is usually sufficient to consider only the first two terms in the equation, which can then be rearranged as:

$$\frac{\pi}{c} = \frac{RT}{M_n} + RTA_2c \quad (2.6)$$

where π/c is called the reduced osmotic pressure. According to the above equation, M_n may be determined by a plot of π/c versus c extrapolated to zero concentration. The intercept gives RT/M_n, and the slope of the plot yields A_2.

For neutral polysaccharides, osmotic pressure measurements can be made in water. However, for charged polysaccharides, salt solutions should be used to suppress the charge effects on apparent molecular weights. Usually 0.1–1 M NaCl or LiI is of sufficient ionic strength. Since osmotic pressure is dependent on the number of molecules present in solution, it is less sensitive to high MW polysaccharides. In practice, this method is only useful for polysaccharides having MW less than 500,000 g/mol (59).

2. Static Light Scattering

Static light scattering is widely used for determining the MW of macromolecules and measures M_w. For a highly dilute solution, the normalized intensity of scattered light R(q) as a function of scattering wave vector (q) and concentration (c) is given as (60):

$$\frac{Kc}{R(q)} = \frac{1}{M_wP(q)} + 2A_2c \quad (2.7)$$

where K is a contrast constant and P(q) is the particle scattering factor. For a random coil, P(q) is expressed by:

$$P(q) = 1 - \frac{q^2R_g^2}{3} + \ldots \quad (2.8)$$

$$\text{and } q = \frac{4\pi}{\lambda}\sin\left(\frac{\theta}{2}\right) \quad (2.9)$$

where λ is the wavelength, θ is the scattering angle, and R_g is the radius of gyration. Equations 2.7–2.9 form the

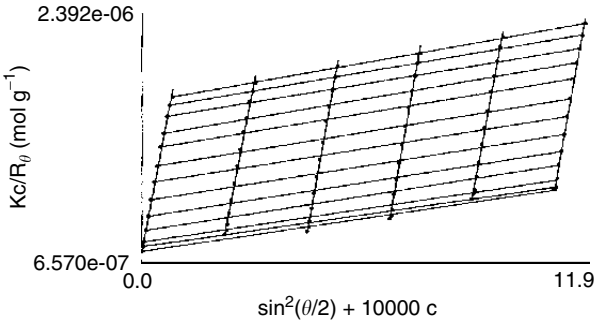

FIGURE 2.3 Zimm plot of tricarbanilate of β-D-(1→3) (1→4)-glucan measured in dioxan.

basic theory for MW determination using static light scattering. In practice, this is done by measuring the angular dependence of scattered light from a series of dilute solutions. The scattering data are then processed in the form of a Zimm plot or other associated plots (Berry and Gunniur plots). In a typical Zimm plot, Kc/R(q, c) is plotted against q^2 + kc, where k is an arbitrary constant to separate the angle-dependent curves from different concentrations. The double extrapolation to c = 0 and q = 0 (i.e., θ=0) results in two limiting curves intersecting the ordinate at the same point. This point gives $1/M_w$. The initial slope of the curve at θ = 0 is $2A_2$, and from the initial slope of the curve at c = 0, R_g is obtained. Figure 2.3 is a Zimm plot of (1→3) (1→4)-β-D-glucan tricarbanilate measured in dioxan by static light scattering.

The measurement of the MW of polysaccharides by light scattering has not been an easy task when compared to many other macromolecules. The major difficulty is the preparation of optically clear solutions that are free of dust and molecular aggregates. A detailed procedure for the preparation and clarification of polymer solutions is given by Tabor (61) and Harding *et al*. (59). The measurement of MW is especially complicated by the existence of aggregates. Extreme caution has to be taken in interpreting the data. Poor reproducibility is often an indication of the presence of aggregates. Extensive efforts have been made to eliminate aggregates by the selection of appropriate solvents (9, 62, 63) or by chemically transforming the polysaccharides to reduce H-bonding, using derivatives such as carbanilates (64).

3. Sedimentation

Sedimentation methods are of two types, sedimentation equilibrium and sedimentation velocity. The equilibrium technique employs a centrifugal field to create concentration gradients in a polymer solution contained in a special centrifuge cell. For a solute under appropriate conditions (sedimentation equilibrium), sedimentation and diffusion become comparable so that there is no net transport of the solute. Analysis of the distribution of the solute concentration along the centrifugal field at such an equilibrium provides a means to study the MWD and the average MW. For polysaccharides, such an equilibrium distribution is generally achieved in 24–48 hours depending on the nature of the solute and experimental conditions (59).

The basic equation describing the distribution of solute concentration J(r) at sedimentation equilibrium is given for an ideal system as (65):

$$\frac{d\ln J(r)}{d(r^2)} = \frac{M_w(r)(1 - \upsilon\rho)\omega^2}{2RT} \tag{2.10}$$

where r is the distance of a given point in the cell from the center of the rotor, ω is the rotor speed (rad/s), υ is the partial specific volume (ml/g), and ρ is the solution density. The solute concentration profile is recorded, usually by a Rayleigh interference optical system, and transformed into plots of log J(r) versus r^2, from which the (point) weight average molecular weight can be obtained. The whole-cell M_w can then be calculated as

$$M_w = \frac{J(b) - J(a)}{J_0(b^2 - a^2)} \frac{2RT}{\omega^2(1 - \upsilon\rho)} \tag{2.11}$$

where a and b are the distance from the center of the rotor to the cell meniscus and cell bottom, respectively, and J_0 is the initial loading concentration.

Sedimentation equilibrium can cover a very wide range of molecular weights compared to light scattering and osmotic pressure methods. However, since the procedure is inherently time consuming and the thermodynamic non-ideality of polysaccharides can complicate interpretation of the measurements, the technique is not frequently applied in polysaccharide research.

As with equilibrium sedimentation, velocity sedimentation is based on the principle that the sedimentation rate of a polymer under a centrifugal field is directly proportional to its MW and shape. Velocity sedimentation monitors the boundary movement during ultracentrifugation by an optical method, from which the sedimentation coefficient, and hence MW, can be estimated provided the conformation of the molecule is known. By the use of high angular velocities, initial sedimentation may occur before diffusion effects become important. Compared to equilibrium sedimentation, velocity sedimentation is less time consuming, but can only provide qualitative information on average MW and MWD.

4. Viscometry

Because of the simple experimental setup and ease of operation, viscometry is extensively used to determine the MW of polysaccharides. The method simply requires the measurement of the relative viscosity η_r and polymer concentration of dilute solutions. Experimentally, η_r can be measured either by a capillary viscometer, a rotational viscometer, or

a differential viscometer (66). The MW of the polysaccharides is then calculated via the Mark-Houwink relationship (Equation 2.18). The Mark-Houwink constants K and α are usually determined experimentally using a series of ideally monodisperse substances with known molecular weights. More discussion of this method will follow (Section V.B).

Caution is needed when applying this relative method to polysaccharides with chemical heterogeneity. Any factors that may change chain extension lead to changes in K and α values; examples are degree of branching (as with amylopectin and dextrans) and the distribution and/or substitution of certain monosaccharide units (as with alginates and galactomannans). The chemical composition and structure of the material under test should resemble those of the calibration substances.

5. Gel Permeation Chromatography

Gel permeation chromatography (GPC) or size exclusion chromatography (SEC) is widely used for the determination of MW and MWD of polysaccharides. In GPC, the polymer chains are separated according to differences in hydrodynamic volume by the column packing material. Separation is achieved by partitioning the polymer chains between the mobile phase flowing through the column and the static liquid phase that is present in the interior of the packing material, which is constructed to allow access of smaller molecules and exclude larger ones. Thus, larger molecules are eluted before smaller ones.

Conversion of the retention (or elution) volume of a polymer solute on a given column to MW can be accomplished in a number of ways. Narrow MWD standards with known MW, such as pullulan and dextran, may be used to calibrate the column. As with viscometry, the difference in structure between the calibration standards and the tested sample may lead to over- or underestimating the MW. To overcome this, a universal calibration approach may be applied in which the product of intrinsic viscosity [η] and MW, being proportional to hydrodynamic volume, is used (67). For different polysaccharides, a plot of log [η] MW versus elution volume emerges to a common line, the so-called "universal calibration curve." The calibration is usually obtained using narrow MWD standards from which the MW of a test sample can be read, provided the intrinsic viscosity is known.

In the last two decades or so, methods for the determination of MWD have been facilitated by combining GPC with a laser light scattering detector (68, 69). These methods provide absolute measurement of average MW and information on MWD and molecular conformations.

6. Other Methods

There are a number of other less frequently used methods for MW determination of carbohydrates, such as mass spectrometry, end group analysis, and NMR. The readers are referred to the review by Harding (59) for a detailed discussion of alternative methods on MW determination of carbohydrates. In addition, recent development in AFM has shown that it is a potential means for MW determination of polysaccharides. The power of this approach is that it permits MW measurements of single polysaccharide molecules rather than mixtures of single molecules and aggregates. All the other methods described above determine the apparent MW of samples that often include molecular aggregates. Round *et al.* (46) found that M_n and M_w obtained from AFM is 2–3 times smaller than that for similar samples measured by conventional techniques.

IV. HYDRATION AND SOLUBILITY OF CARBOHYDRATES

A. Low-Molecular-Weight Carbohydrates

Carbohydrates contain both polar -OH groups and non-polar -CH groups. In an aqueous system, the numerous hydroxyl groups of carbohydrates may hydrogen bond strongly with water molecules. Also, the ring oxygen atom and the glycosidic bridging oxygen atom can form hydrogen bonds with water. Franks and coworkers discussed the thermodynamic data of small carbohydrates in the context of NMR and dielectric relaxation data (70). They found no solute-solute interactions in aqueous solutions even at fairly high concentrations. Both the sites of hydration and their relative conformations are important factors in the resultant hydration properties. Molecular dynamics studies have revealed that hydroxyl groups make on average between two and three hydrogen bonds with solvent (71, 72). Because of the proximity of adjacent hydroxyl groups, many water molecules were found to simultaneously hydrogen bond to two hydroxyl groups (71). The geometric requirements of these solute-solvent hydrogen bonds favor one conformation over another, leading to some solutes experiencing less favorable interactions with water, and hence being less soluble (73, 74). Nevertheless, low-molecular-weight carbohydrates, with degrees of polymerization less than 15~20, are generally very soluble in water and other polar solvents (75). The solubility decreases with increasing degree of polymerization because of increased solute-solute interactions.

Addition of polar organic solvents to solutions of carbohydrates results in the precipitation of an amorphous or crystalline form of the carbohydrates. Increasing the concentration of alcohol decreases the solubility of mono- and oligosaccharides, and they are only slightly soluble when the alcohol concentration is higher than 80% (76).

B. Polysaccharides

Polysaccharides display a wide range of solubilities conventionally described as easily soluble, intermediately

soluble, and insoluble. There is no clear boundary between the three groups but the general consensus is: easily soluble polysaccharides are readily dissolved in cold water; intermediately soluble ones are only soluble in hot water; and insoluble ones cannot be dissolved even in boiling water. Structure and molecular weight are the two primary factors that determine solubility. Polysaccharides with a highly regular conformation that can form crystalline or partial crystalline structures (Section II.C.1) are usually insoluble in water. Linear polysaccharides with high regularity in structure, such as 1→4 or 1→3 linked β-D-glucans, and 1→4 linked β-D-mannans, are examples of this group. Although (1→4)-β-D-mannan can be dissolved in 5% alkaline solution, neutralization leads to reassociation and precipitation. Cellulose is insoluble, but swells in strong alkaline solutions such as 18% sodium hydroxide (77). Only cellodextrins with DP of about 15–80 can be dissolved or dispersed in such alkaline solutions; for DP less than 15, there is solubility in neutral aqueous solutions (75). Amylose, an α-(1→4)-homoglycan, is insoluble in cold water but can be dissolved in hot water.

A decrease in uniformity/regularity of molecular structure is always accompanied by an increase in solubility. The irregularity of the molecular chains prevents the formation of a closely packed structure, allowing many polysaccharides to readily hydrate and dissolve when water is available. The mixed linkage (1→3) (1→4)-β-D-glucans from cereals differ from cellulose only by the introduction of occasional single (1→3) linkages. The insertion of these linkages introduces "kink" points into the otherwise stiff cellulosic backbone, rendering the polymer soluble in water. Branching or substitution of the polysaccharide chain also reduces the possibility of intermolecular association and usually increases solubility. Examples are easily seen by comparing the solubility of galactomannans with that of (1→4)-β-D-mannan. By introducing single α-D-galactopyranosyl constituents (1→6) linked to the mannan backbone, the resulting galactomannans are fairly soluble in water. Any structures which contain especially flexible units such as (1→6) linkages will lead to higher solubility because of a larger favorable entropy of solution. Highly branched polysaccharides are almost always very soluble in water as in the case of amylopectin which has a much better solubility compared to its linear counterpart, amylose.

C. Dissolution Kinetics

The ability of a substance to be solvated is governed by the fundamental thermodynamic equation:

$$\Delta G = \Delta H - T\Delta S \tag{2.12}$$

where ΔG, ΔH, and ΔS are the changes of Gibbs free energy, enthalpy, and entropy of mixing, respectively. T is the absolute temperature of the system. A homogeneous solution is obtained when the Gibbs free energy is negative. For an ideal system, ΔH is usually small, so dissolution is an entropically driven process.

For low-molecular-weight carbohydrates, dissolution of the molecules is promoted by a large increase in entropy on mixing. The dissolution rate is mainly controlled by the diffusion or convective transport of solute from the interfacial boundaries to the bulk solution, which in turn is determined by the difference between the solute concentration and the saturated concentration at a given temperature. The dissolution process is generally fast as long as the solution is not close to the saturation point. Increase in the hydrodynamic field, such as stirring, promotes dissolution.

For polysaccharides, the contribution of entropy changes during dissolution is limited because of conformational constraints of the polymer chains. Most linear polysaccharides only form colloidal dispersions in aqueous systems that are not in thermodynamic equilibrium. In the initial stage of dissolution, amorphous polymer starts to swell as a result of water diffusing into the particle with a simultaneous transition from a glassy state to a rubbery gel-like state. Consequently, a gel layer forms on the surface of the polymer particle. The dissolution rate may be determined by a number of factors, either individually or combined together, including the rate of water penetration into the polymer, the rate of disentanglement of the polymer from the gel layer, and the diffusion or convective transport of solute from the interfacial boundaries to the bulk solution. In the case of high MW polysaccharides, the disentanglement of molecules is often the limiting step of dissolution. Thus the dissolution rate is expected to decrease with increasing MW because disentanglement of large molecules from the gel layer takes a longer time. The dissolution rate of guar gum was shown to be inversely related to the MW of the galactomannan (78). Diffusion or transport of solutes may also be the controlling factor in combination with disentanglements, such as in the case of a low MW polymer in low hydrodynamic environment (low temperature, low agitation), or when the viscosity of the solvent phase has built up significantly (78). The initial solvent content may also affect the dissolution of certain polysaccharides, but in various ways. Theoretical work and experiments suggest that dissolution rate increases with the level of residual solvent in the solid polymer (79, 80). However, if the presence of low levels of solvent leads to an increase in structure ordering, the suggested enhanced dissolution may not occur. For example, it has been observed that purified (1→3) (1→4)-β-D-glucan is very difficult to dissolve in water when it is precipitated from an aqueous solution and air dried. Solvent exchange using isopropanol before drying greatly improves solubility and dissolution. This is presumably due to the presence of water in the polymer, resulting in increased ordering of

the polymer and poorer solubility. Other factors such as particle size and porosity of the polymer may also influence dissolution rate.

V. RHEOLOGICAL PROPERTIES OF POLYSACCHARIDES

A. Concentration Regime

Rheology is the study of flow and deformation of materials, and for any given polysaccharide, concentration is of course of primary importance. A dilute polymer solution is one in which each polymer coil and the solvent associated with it occupies a discrete hydrodynamic domain within the solution. The isolated macromolecules provide their individual contribution to the rheological properties of the system almost independently of the imposed shear rate. As the concentration of polymer increases, a stage is reached at which the individual molecular domains begin to touch one another frequently. The corresponding concentration is called the overlap concentration c*. At polymer concentration c>c*, the solution is called semi-dilute and when c>>c* the solution is concentrated.

B. Dilute Solutions

1. Steady Shear Viscosity

The ratio of applied shearing stress (τ) to rate of shear ($\dot{\gamma}$) for an ideal viscous fluid is called the coefficient of viscosity, or simply viscosity (η), which is a measure of the resistance to flow. The term "fluidity," which is the reciprocal of viscosity, is sometimes used in the food industry. The viscosity increase due to the contribution of dissolved or dispersed solutes over the solvent is described by the relative viscosity (η_r) and specific viscosity (η_{sp}):

$$\eta_r = \frac{\eta}{\eta_s} \tag{2.13}$$

$$\eta_{sp} = \frac{\eta - \eta_s}{\eta_s} = \eta_r - 1 \tag{2.14}$$

where η_s is the solvent viscosity and η the overall solution viscosity. For most polysaccharides, especially of the random coil type, dilute solutions under shear flow show essentially Newtonian behavior. That means the viscosity of the solution is a constant independent of share rate. However, non-Newtonian flow behavior is observed for dilute solutions of some rigid polysaccharides, such as xanthan and some other β-glucans (81). For these systems, the apparent viscosity falls as the shear rate increases — a phenomenon called shear thinning. The shear thinning behavior of such polysaccharide solutions is a result of progressive orientation of the stiff molecules in increasing field of shear.

2. Intrinsic Viscosity

In dilute solutions, viscosity usually increases with concentration according to the Huggins and the Kramer equations:

$$\eta_{sp} = [\eta]c + K'[\eta]^2c^2 \tag{2.15}$$

$$\ln(\eta_r) = [\eta]c + (K' - 0.5)[\eta]^2c^2 \tag{2.16}$$

where K′ is the Huggins coefficient. [η] is known as intrinsic viscosity and is the limit of reduced viscosity (η_{sp}/c) as c→0:

$$[\eta] = \lim_{c\to 0}(\eta_{sp}/c) \tag{2.17}$$

Experimentally, [η] is usually determined from the measurement of η_r or η_{sp} over a series of dilute solutions. By plotting η_{sp}/c or ln (η_r)/c versus c, [η] is obtained as the average of the two intercepts at the ordinate via graphic extrapolations of c→0.

Intrinsic viscosity is not actually a viscosity but is a characteristic property of an isolated polymeric molecule in a given solvent, and is a measure of its hydrodynamic volume. It has a unit of volume per unit weight. Mark (82) and Houwink (83) independently correlated the intrinsic viscosity with the viscosity average molecular weight M_v

$$[\eta] = KM_v^{\alpha} \tag{2.18}$$

where both K and α are constants for a given polysaccharide-solvent pair at a given temperature. The exponent α is a conformation-sensitive parameter and usually lies in the range of 0.5–0.8 for random coil polymers, and increases with increasing chain stiffness. It can be as high as 1.8 for polysaccharides with a stiff rod conformation. Low values of α (<0.5) tend to indicate significant branching or a compact structure. Values of K and α for some food polysaccharides have been documented by Harding (66).

C. Semi-Dilute and Concentrated Solutions

1. Steady Shear Viscosity

Polysaccharides of sufficiently high molecular weights and concentrations can form an entangled network in solution which impedes flow. Such a system usually shows strong shear thinning behavior. Unlike dilute solutions, the shear thinning behavior of a semi-dilute or concentrated solution is associated with the continuous interchange between entanglement and disentanglement. At high shear rates, the newly formed entanglements cannot compensate for those being disentangled, which leads to a decrease in viscosity. A typical viscosity-shear rate

flow curve consists of a low shear rate Newtonian plateau, followed by a shear thinning region where viscosity decreases as shear rate increases (Figure 2.4). In theory, there exists an upper Newtonian plateau at very high shear rates, but this is not accessible for most polysaccharide solutions using current instrumentation. As shown in Figure 2.4, the increase in viscosity with concentration is more pronounced at low shear rates. Therefore, for meaningful comparison of different systems, zero-shear rate viscosity (η_0) should be used. η_0 is obtained by measuring viscosity at a range of low shear rates and extrapolating to zero concentration, as illustrated in Figure 2.4 (84).

Shear thickening of polysaccharide solution, although rare, is observed occasionally. This phenomenon usually results from a shear-induced formation of ordered structures (10).

2. Concentration and Molecular Weight Effects

As with dilute solutions, the viscosity of semi-dilute or concentrated polysaccharide solutions also increases with increasing concentration. The relationship normally can be described by the power-law type correlation:

$$\eta_{sp} = ac^n \tag{2.19}$$

where η_{sp} is zero-shear specific viscosity. At a concentration above the overlap concentration c*, a more pronounced increase in both the zero-shear viscosity and the shear rate dependence of viscosity develops. For most random coil systems, the exponent n lies between 1~1.5 when c < c*, and 3.5~5 at c > c* (85).

Precisely, the viscosity generated by disordered polymer coils is dependent on the degree of space-occupancy by the polymer, which is determined by both concentration and molecular weight. In general, for linear polysaccharides in a given solvent, solution viscosity increases proportionally to their molecular weight and concentration. The space occupancy is characterized by the dimensionless product of concentration and intrinsic viscosity c[η], since [η] is a measure of volume occupancy of the isolated coil in the solvent. Morris *et al.* (86) found that the double-logarithmic plots of η_{sp} vs. c[η] for a number of different disordered polysaccharides and the same polysaccharides with different molecular weights are virtually identical.

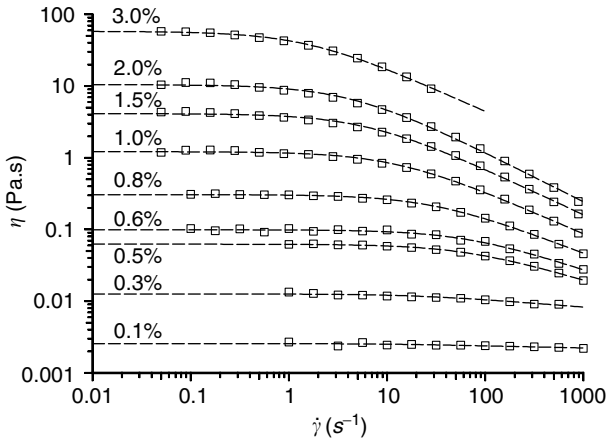

FIGURE 2.4 Shear rate ($\dot{\gamma}$) dependence of viscosity (η) for xyloglucan from *Detarium senegalense* Gmelin in aqueous solutions at different concentrations. From Wang *et al.*, 1997 (84).

3. Temperature and Ionic Strength Effects

Another important factor that may affect the viscosity values and the profile of flow curves is temperature. In the absence of temperature-induced conformational changes, increasing the temperature leads to a monotonical decrease of solution viscosity and an increase of the shear rate of onset of the non-Newtonian region. For polysaccharides with charged groups, the shear viscosity is also sensitive to ionic strength and pH. Due to an expanded chain conformation caused by like-charge repulsions, a higher viscosity is normally obtained at lower ionic strength. Electrostatic repulsions are suppressed at higher ionic strength, leading to a less extended chain conformation and hence lower viscosity.

4. Dynamic Properties

Polysaccharide solutions are viscoelastic substances, i.e., have both solid and liquid characteristics. An important experimental approach to the study of the viscoelasticity of a polymer solution is to use a dynamic oscillatory measurement. A sample is subjected to a small sinusoidal oscillating strain (γ); this generates two stress components in viscoelastic materials, an elastic component which is in phase with the applied strain and a viscous component which is 90° out of phase with the strain:

$$\sigma_0 = G'\gamma_0 \sin\omega t + G''\gamma_0 \cos\omega t \tag{2.20}$$

$$\tan\delta = \frac{G''}{G'} \tag{2.21}$$

where G′ is the elastic or storage modulus, G″ is the viscous or loss modulus, tanδ is the loss tangent, and ω is the frequency of oscillation. The loss tangent is the ratio of the energy dissipated to that stored per cycle of deformation. The frequency dependency of these viscoelastic quantities allows specific features of different classes of polysaccharides to be distinguished. Based on the relative magnitudes of G′ and G″ in a frequency sweep experiment within the linear viscoelastic strain range, three types of polysaccharide systems may be distinguished: solutions, weak gels, and gels (85). For dilute solutions of polysaccharides, G″ values are higher than G′, with $G'' \propto \omega$ and $G' \propto \omega^2$ at low frequency. When the frequency or concentration is increased, there is a crossover between G′ and G″, implying that the system passes from being a more and

more viscous liquid to being a viscoelastic solid. Also, both G′ and G″ become less frequency dependent as the frequency is increased; a "rubbery" plateau of G′ is seen at high frequencies. Gels have a very different spectrum, with G′ remaining almost constant and G″ only increasing slightly as frequency increases; and G′ values are higher than G″ at all frequencies, with tanδ around 10^{-1} for a weak gel and 10^{-2} for a true gel.

D. Polysaccharide Gels

1. Gelation Mechanism

Under certain conditions, the association of hydrated polysaccharides results in a three-dimensional polymeric network (a gel) that fills the liquid available rather than precipitation of the polysaccharide. In these resultant gels, polysaccharide molecules or portions of these are aggregated in the junction zones through interactions such as hydrogen bonding, hydrophobic association, and cation-mediated cross-linking. To induce gelation, polysaccharides usually have to be first dissolved or dispersed in a solution, in order to disrupt mostly the hydrogen bonds from the solid state. The subsequent transformation of sols to gels is achieved by treatments such as heating and cooling, addition of cations, and change of pH.

The adoption of an ordered secondary and tertiary structure such as a helix or flat ribbon is a primary mechanism for the gelation of polysaccharides. The familiar gelation of algal polysaccharides agarose and κ-carrageenan, and bacterial polysaccharide gellan, involves the formation of helices (87). These helices may further associate to form a quaternary structure (gel network) through intermolecular hydrogen bonding or incorporation of counterions in the case of some charged polymers. The gelation of some other polysaccharides is through the formation of pleated sheets, sometimes described as an egg-box structure. Familiar examples of this are gels of low-methoxyl pectin and alginate. In this structure, the polysaccharides associate into matched aggregates in a twofold ribbon-like conformation, with the metal ions cooperatively bound during the process, sitting inside the electronegative cavities like eggs in an egg box.

2. Physical Properties of Polysaccharide Gels

Polysaccharides are able to form a vast range of gel structures which can be controlled by the properties of polysaccharides themselves and by the gelling conditions. A list of gelling food polysaccharides and a comparison of their relative textural characteristics are given by Williams and Phillips (88). Some polysaccharides form thermo-reversible gels and examples exist where gelation occurs on either the cooling or heating cycle. Thermal hysteresis may exist in some of the thermo-reversible gels; the melting temperature of the gel is significantly higher than the setting temperature. Thus, gelation occurs when hot agarose solutions are cooled to below 40°C, but this gel does not melt until the temperature is raised to above ~90°C. Some polysaccharides form thermally irreversible gels, which are usually formed by cross-linking polysaccharide chains with divalent cations.

Gel formation occurs above a critical minimum concentration for each polysaccharide, and gel strength normally increases with increasing concentration. Molecular weight is also important. Intermolecular associations of polysaccharides are stable only above a minimum critical chain length necessary for the cooperative nature of the interaction, typically in the range of 15–20 residues (75). Gel strength normally increases significantly as MW increases up to a certain point, then becomes MW independent at higher values.

The gelation of anionic polysaccharides is also dependent on the type and concentration of associated cations because the association of the charged tertiary structures may be promoted by specific counterions whose radii and charges are suitable for incorporation into the structure of the junction zones.

Mixed gels from two or three polysaccharides may impart novel and improved rheological characteristics to food products. Synergy is observed for a number of binary systems including pectin-alginate, xanthan-galactomannan or glucomannan, and agarose or carrageenan–galactomannan or glucomannan. In these mixtures, synergism confers either enhanced gelling properties at a given polysaccharide concentration, or gelation under conditions in which the individual components will not gel. Although the gelation mechanisms for mixed polysaccharides are still controversial, there is evidence that some form of binding and structure compatibility has to be present between the two polysaccharides (87).

3 Carbohydrates: Starch

Lorraine L. Niba
Department of Human Nutrition, Foods and Exercise,
Virginia Polytechnic Institute and State University

CONTENTS

Starch is the major source of calories and dietary energy in most human food systems. As the primary human metabolic substrate, starch is preferentially digested, absorbed and metabolized. Most diets worldwide have a substantial starchy component as a main or side item. For instance, potatoes are a major item in most northern European diets, rice is popular in Asian diets, maize-based foods are common in Latin America, and starchy root and tuber crops constitute a significant part of the diet in most tropical areas.

Starch occurs naturally in plants and is the storage polysaccharide of plants. It is heterogeneous, consisting of two glucose polymers: amylose and amylopectin. It is a polymer of glucose and a complex carbohydrate, which finds multiple applications in various industries such as pharmaceuticals, textiles, paper, and the food industry.

Starch performs various functions in food systems. It is used as a carrier in various products, as a texture modifier, as a thickener, and as a raw material for the production

of other valuable food ingredients and products. Physiologically, it is a source of energy. In addition, starches that are resistant to amylase digestion have properties similar to soluble fiber.

I. STARCH COMPOSITION AND STRUCTURE

Starch is composed of two basic molecular components: amylose and amylopectin. These are identical in their constituent basic units (glucose), but differ in their structural organization (linkages). These variations in the linkages in turn affect their functionality in food applications. Amylose is a straight chain molecule, while amylopectin is a branched molecule. In addition, each is hydrolyzed, digested, and absorbed differently. Amylose is hydrolyzed mainly by amylases, while amylopectin requires debranching enzymes such as pullulanase for complete hydrolysis. As a result of their structure, the nature and products of hydrolysis of amylose and amylopectin differ. The proportions of amylose and amylopectin in foods therefore influence the extent of digestibility of the starch.

The ratios of amylose to amylopectin vary among starch sources and play a considerable role in determining reactions and physicochemical properties of starches in processing and food applications (1–6). Most tuber starches contain high levels of amylopectin, imparting a "waxy" texture.

Amylose and amylopectin are the polymers which constitute the starch granule (Table 3.1).

A. AMYLOSE

Amylose is composed of D-glucose molecules, which are linked in an α-1→4 conformation. The glucose monomers therefore form a linear straight chain polymer.

Amylose is less predominant (about 20%) and typically constitutes about 20–40% in proportion (7).

Amylose contains α-1→4 glycosidic bonds and is slightly soluble in water. Amylose molecules are arranged in a helical conformation. This facilitates formation of complexes with iodine, lipids, and other polar substances (2,8,9). The iodide ions are sequestered in the central tunnel of the helix. Amylose forms a blue complex with iodine, which can be read at about 650 nm.

The starch iodine test is often used to determine amylose content of various starches and starch types (4,10). Amylose is more suitable for the starch-iodine test. The affinity of pure amylose for iodine is 19–20% compared to only about 1% for amylopectin (1,2,6). Amylose would adsorb 19–20.5 g of iodine per 100 g compared to only about 1.2 g for amylopectin. The starch iodine test is often considered to be a measure of apparent amylose content of the starch.

Amylose is the key component involved in water absorption, swelling, and gelation of starch in food processing. High amylose starches are therefore most commonly applied in food products that require quick-setting gels such as candies and confectionery. Amylose is more susceptible to gelatinization and retrogradation, and hence is most commonly involved in resistant starch formation.

TABLE 3.1
Properties of Amylose and Amylopectin (1–6,9)

Property	Amylose	Amylopectin
Structure	Linear (branched chains isolated from some starches)	Branched chains (long segments of linear chains in some starches)
Molecular weight	Up to 1 000 000	Up to 5 000 000
Glycosidic linkage	α-1→4	α-1→4 and α-1→6
Iodine complex	Blue	Purple
Iodine affinity	19–20.5%	0–1.2%
Blue value	1.2–1.6	0–0.05
Polar agents	Complexes with polar agents	Does not complex with polar agents
X-ray diffraction pattern	Crystalline	Amorphous
Phosphorus	Phosphorus-free	0.06–0.9% phosphorus (mostly in root/tuber starches)
Association with lipids	High	Low
α-Amylase hydrolysis products	Glucose, maltose, maltotriose, mainly oligosaccharides	Small amounts of reducing sugars, mainly oligosaccharides
Hydrolysis to maltose	100%	55–60 (100% with limit dextrinase and β-amylase)
Pullulanase	No effect	Debranches α-1→6 linkages
Gel stability	Firm, translucent, quick-setting gels	Clear viscous gels
Susceptibility to retrogradation	Retrogrades readily	Mostly stable
Common sources	Typically higher in cereal starches (e.g., corn starch)	Typically high in tubers and root starches (e.g., tapioca starch)

B. Amylopectin

Amylopectin consists of D-glucose units which are linked in an α-1→4 conformation as is the case with amylose, as well as D-glucose units in an α-1→6 conformation. Amylopectin is therefore highly branched as the α-1→4 linear chains are punctuated with the α-1→6 linkages. The α-1→6 constitute about 5% of the structure of amylopectin and gives rise to the branching (11). The amylopectin molecule therefore is much larger than the amylose molecule. The larger molecular size of amylopectin from amylose facilitates separation of these two polymers by size exclusion chromatography (2,7). Negligible amounts of unbranched amylopectin (A chains) in some starches have also been reported. In addition, there are long unbranched portions of the glucose polymer in some amylopectin molecules. While the straight chain of amylose is readily hydrolyzed by β-amylases, de-branching enzymes have to be used to obtain full hydrolysis of amylopectin (2,3,8).

Amylopectin has short branched chains and branch linkages, and thus cannot form the helical complex with iodine. The branched dextrin of amylopectin, however, gives a purple color with the iodine complex, identifiable at about 550 nm (3,9).

The enzymes required for amylopectin hydrolysis vary from those required for hydrolysis of amylose. Pullulanase, an enzyme which is specific for the α-1→6 glycosidic linkage, and other debranching enzymes are needed to hydrolyze amylopectin.

The properties of amylopectin in food applications differ considerably from those of amylose. Amylopectin gels are more flexible and resistant. Amylopectin also is much more resistant to retrogradation than amylose. High amylopectin starches (waxy starches) are therefore commonly used in noodle processing and in some baked products to extend shelf-life. They also are used to improve freeze-thaw stability due to their resistance to retrogradation.

C. The Starch Granule

The basic components of starch, amylose and amylopectin, are located in granules. The size, shape, and characteristics of the granules are specific to the plant source. The growth and development of the granule originates at the center of the granule, which is known as the hilum. Under magnification and polarized light, native starch granules typically appear to have a cross-like structure, similar to a maltese cross, exhibiting birefringence. The size and shape of this cross-like shape varies among botanical starch sources. For instance, starch from pinto bean has elliptical shaped lobes, while some starches have more than four lobes (12).

The ordered arrangement of amylopectin molecules intertwines to form three-dimensional double helices between adjacent branches of the same amylopectin molecule or between adjacent clusters. The double helices are stabilized by weak van der Waals and hydrogen bonds. The various arrangements of the helices result in the presence of crystalline regions on the granule (11,13,14). The nature of these regions becomes clear by their X-ray diffraction patterns. The crystalline patterns vary under X-ray diffraction patterns. These polymorphic arrangements occur in two patterns, which are classified as A or B, and an intermediate form or mixture of A and B forms, known as C type (11,14,15). Most cereal starches have A type patterns. Root and tuber starches such as potato starch contain mostly B type patterns, while legume starches have a combination of both polymorphic A and B forms, and hence are classified as C forms (11,14,15). The crystalline nature and diffraction of starch is greatly altered by processing (16).

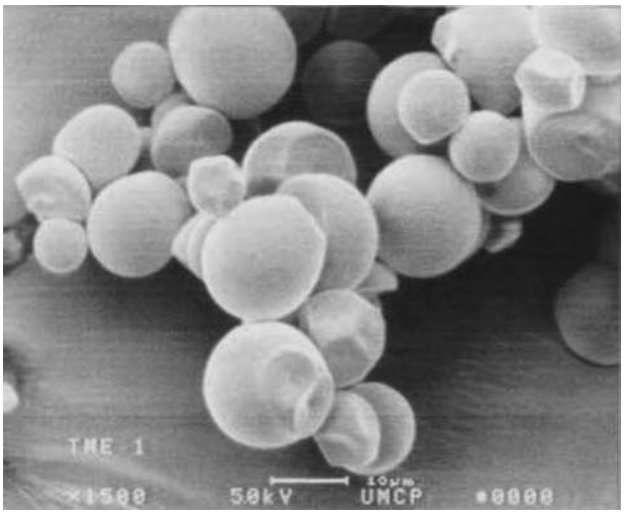

FIGURE 3.1 Tapioca starch granules.

Natural starch granules are insoluble in water, which is why starch is separated by sedimentation. This shape is disfigured and lost as starch loses its structure with modification such as heat and moisture.

Granules vary in shape and size and are characteristic of the starch sources. These shapes may be round, lenticular, or oval (11,17). Starch granule properties are used as diagnostic characteristics for identification and characterization of starches, based on structure and shape (Figure 3.1).

D. Non-Starch Components

Various non-starch components are covalently linked to amylose or amylopectin in starch. Structural and functional proteins are present which surround the starch granule. The protein friabilin, responsible for hardness of the endosperm in most cereals, is located on the granule. In addition, the enzyme responsible for starch synthesis, granule-bound starch synthase (GBSS), is located on the granule (18,19). Wheat starch characteristics are especially influenced by the presence of proteins. The proportion of protein in starches could be up to 0.5%.

Most starches contain glycolipids, complexed to amylose or amylopectin. Wheat starch, for instance, contains amylose-lipid complexes. The nature of lipids present in starches differs depending on the origin and nature of the starch. Lipids such as monoglycerides and lysophosphatidyl choline form complexes with amylose and amylopectin. Lipids may occur on the surface of the starch granule as well as in the interior of the granule. Lipids that occur within the starch granule are typically monoacyl lipids which could either be mostly free fatty acids or lysophospholipids (20). In addition, most of the lipids on the surface of the granules are monoacyl lipids. Some lipids are non-starch lipids and not associated with starch, but rather occur in the endosperm (21).

Phosphorus is a common constituent of many starches, occurring primarily as phosphate monoesters on amylose and amylopectin. Rice starch, corn starch, wheat starch, and potato starch contain various proportions of organic phosphorus or phosphate groups (22,23). Banana starches are reported to contain potassium and magnesium (24).

Non-starch components such as protein and lipids influence starch behavior in food applications. Functional properties such as water absorption, gelatinization, and starch hydrolysis are influenced by the presence of these components. The presence of lipids, for instance, affects water absorption and hence gelatinization properties. This in turn influences the formation of resistant starch and starch susceptibility to enzymatic digestion.

II. STARCH SOURCES

Starch is obtained from various plant sources. The most common sources of dietary and industrial starch are grains, such as maize and wheat, and roots such as potato and cassava (tapioca). Roots and tubers are significant sources of dietary starch (25).

A. Grain Starches

The grains primarily used as dietary and industrial starch sources include various cereal grains, mainly maize, wheat, and rice. Legumes and pulses also contribute considerably to dietary starch consumption. Corn starch, from maize (*Zea mays*), is the most commonly used source of industrial starch. Corn contains about 86% starch on a dry weight basis. As a high amylose starch, it forms heavy and easy setting gels, and therefore is commonly used for thickening. Corn starch is also used as a carrier, as an ingredient for various applications, and as raw material for other industrial products. For instance, it is hydrolyzed in various ways to obtain sweeteners and glucose. Starch from wheat (*Triticale aestivum*) and rice (*Oryza sativa*) is also a predominant ingredient in food industry applications. Other cereal grains such as sorghum (*Sorghum bicolor*) and barley (*Hordeum distichon*) are sources of starch, less commonly used than maize or wheat starch (Figure 3.2).

Grain starches tend to have high levels of amylose. Furthermore, these starches typically contain amylopectin in the crystalline regions. The amylose of these starches meanwhile may form complexes with glycolipids (26). Most cereal starch sources such as maize and wheat starches are A-type starches (15).

Various legumes contain up to 45% starch (12). Legumes commonly used as sources of starch include pinto bean, faba bean, moth bean, chickpea, and mung bean. As a result of their high amylopectin content, some legume starches such as mung bean starch have restricted swelling and increased overall stability during processing. They are therefore of high suitable quality for application in food products such as starch noodles (27).

Most legumes contain B-type starches that are generally more resistant to digestion (28,29). In addition, other legume starches such as pea starch meanwhile contain C-type starches. Legume starches have lower digestibility than other starches and hence result in a lower post-prandial glycemic and insulin response (30) (Figure 3.3).

B. Root and Tuber Starches

Among the root starches, potato (*Solanum tuberosum*) starch and tapioca (*Manihot esculenta*) or cassava starch are the most predominant industrial starch sources. Root starches have high amylopectin content and therefore have greater clarity, minimal flavor, and acceptable water absorption, and subsequently swelling capacity. Tapioca (cassava) starch is a major ingredient in dietary and industrial starch application. Also known as yucca or manioc, this root crop is the primary source of dietary energy in various tropical regions of the world. Tapioca starch has unique attributes that make it particularly desirable in food applications.

Potato is a dietary staple of most European and Scandinavian diets. Potato starch has high water-binding capacity and a bland taste, and is commonly used in the food industry in many applications for thickening and texture modification.

Other dietary and industrially important root and tuber starch sources include banana and plantain (*Musa* spp.), taro (*Colocasia esculenta*), cocoyams (*Xanthosoma* spp.), and various yams (*Dioscorea* spp.), sweet potato (*Ipomea batatas*) (31,32). Even though there are multiple sources of dietary starch in the tropics, including grains and legumes, roots and tubers constitute dietary staples in most areas as their cultivation is suited to the hot humid tropics. When freshly harvested, they are high in moisture, containing about 70–80% moisture and between 16–24% starch (32). Starchy foods are generally processed in some manner prior to utilization in food preparation. In addition, they are processed into raw material for secondary products. These therefore satisfy needs for calories, food preferences, and convenience foods (Figure 3.4).

Some of these find limited use in industrial applications such as is the case with yam starches (32). Root

starches contain amylopectin in the crystalline regions, while amylose is more common in the amorphous regions of the starch granule (26).

C. Other Sources of Starch

In addition to the major sources of dietary and industrial starch such as maize and tapioca starch, other starch-containing plants find considerable application as dietary and commercial sources of starch. These include lesser known sources of starch such as sago (*Metroxylon sagu*), arrow root (*Maranta arundinacea*), and edible canna (*Canna edulis*). Sago starch is obtained from the trunk of the plant *Metroxylon sagu*. The starch is used in various food products as it has high storage stability. Refined sago starch finds application in noodles, as well as raw material in industry for monosodium glutamate (MSG), glucose, and caramel (33). It is susceptible to enzymatic hydrolysis to glucose, which can then be fermented to produce fermentation products.

Arrowroot starch contains up to 23% amylose and is used in dietary applications as a thickener in various

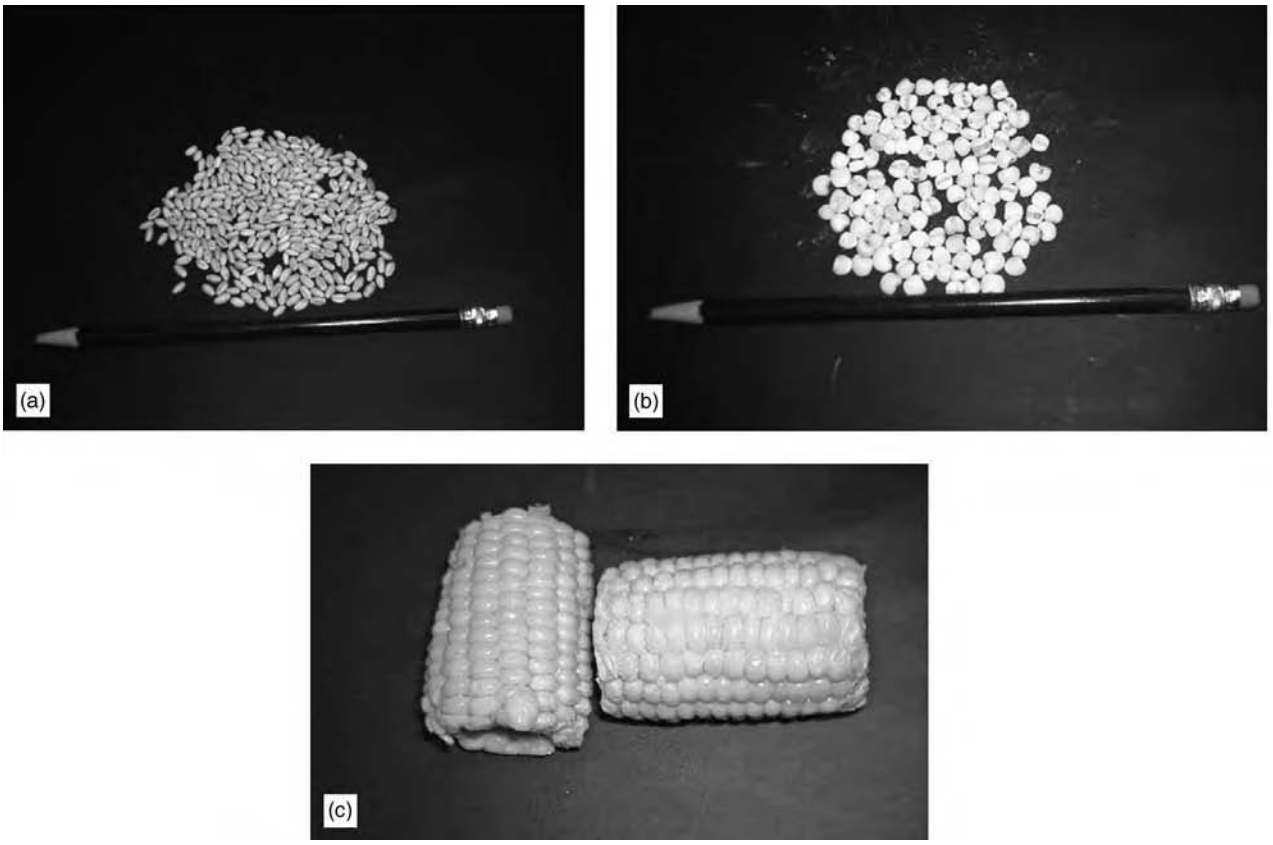

FIGURE 3.2 Some common cereal grain starch sources: (a) wheat, (b) barley, (c) maize.

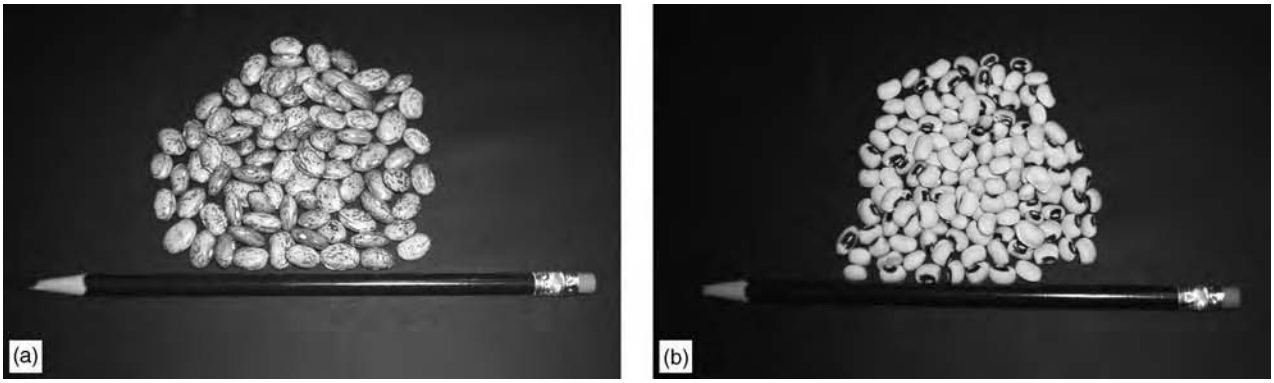

FIGURE 3.3 Some legume starch sources: (a) pinto bean, (b) black-eye pea.

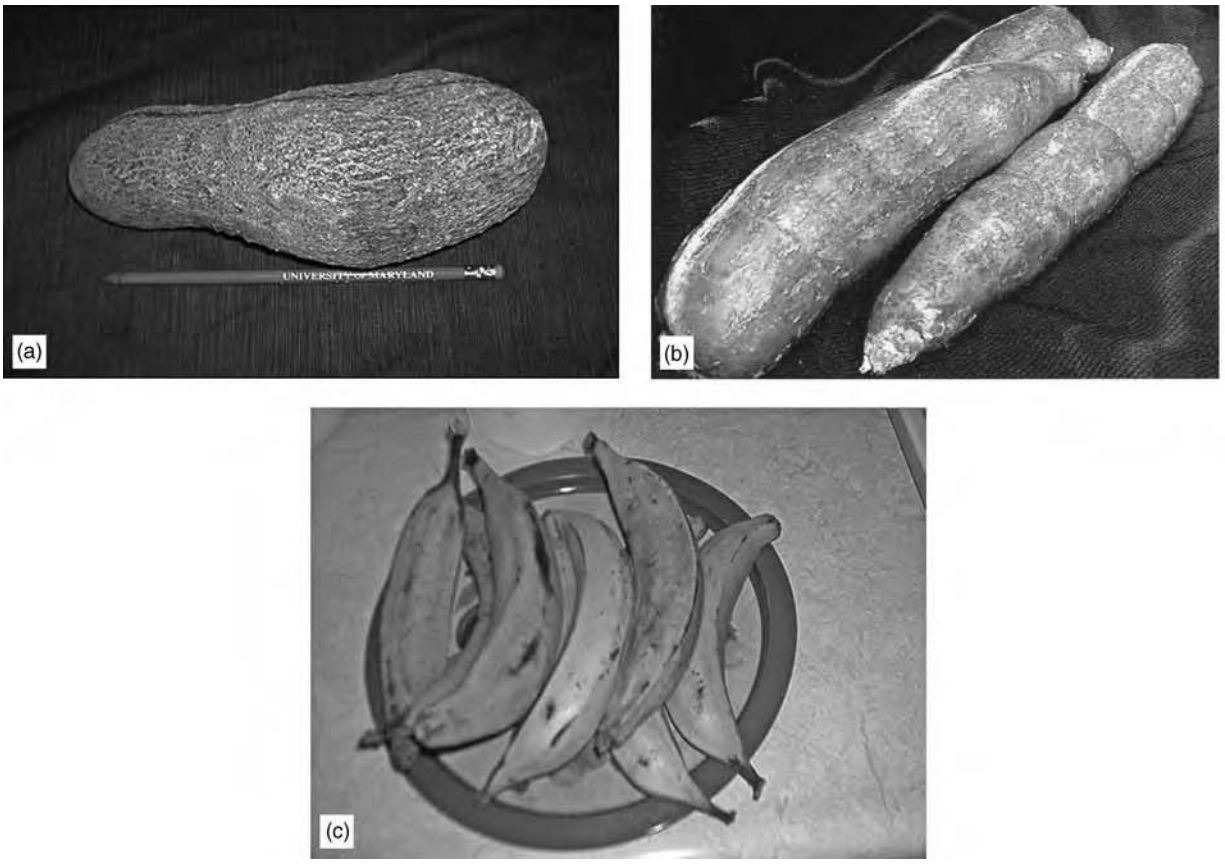

FIGURE 3.4 (a) Brazil yam, (b) cassava (tapioca) root, (c) plantain.

sauces. Another lesser known root crop commonly used in starch production for food application is edible canna, obtained from *Canna edulis* (34). The root contains up to 16% high amylose starch. The separated starch is used in production of noodles in various parts of Asia, particularly Vietnam. The properties of the canna starch are desirable for noodle production.

III. STARCH PHYSICOCHEMICAL PROPERTIES AND FUNCTIONALITY

The application of starch in food products is greatly influenced by its physicochemical properties and interactions with various components. The reaction of starch molecules in foods is essential for the multiple properties that they contribute to the quality of food products. For instance, water absorption and gel formation are extremely essential for the thickening properties of starch. In addition, hydrolysis and digestion of starch, for instance, are not feasible if starch is not gelatinized as the amylases and starch hydrolysis enzymes do not interact with intact, ungelatinized granules.

Characteristics such as gelatinization temperature, granule size, and shape are specific to the type of starch. They are diagnostic properties characteristic of native starches and can therefore be used for identification. The quality of products formulated with starch, such as carriers and thickeners, is largely affected by its functional and pasting properties (35,36).

Water-holding capacity, solubility, and paste viscosity are important parameters that influence the quality of products such as carbohydrate-based fat substitutes (37). These in turn influence gelling ability, water- and fat-binding ability, slicing ability, and hence textural quality of food products. Functionality and physicochemical properties vary among starches as they are influenced by the ratios of amylose to amylopectin. High amylopectin starches for instance are preferred for high viscosity products. In addition, the presence of phosphate esters in some starches such as potato starch may influence starch water-binding capacity by weakening the bonds between starch molecules due to ionic repulsion.

A. Starch Gelatinization

Gelatinization occurs when the ordered structure of the starch granule is disrupted and reorganized in the presence of heat and sufficient moisture. The granules are disrupted with absorption of water, losing their organized molecular structure, to facilitate swelling (29,38).

Starch gelatinization is critical in the utilization of starch in food applications. Native starch granules are insoluble in cold water and gelatinization is essential to facilitate water absorption and enhances the chemical and physical reactivity of inert starch granules in food processing (11). Granular characteristics of starches are characteristic of the plant source. The structure of the granule in turn influences the structure of the gels or pastes formed on heating.

Gelatinization results in starch swelling, and formation of a viscous paste that may be opaque or translucent depending on the nature of the starch (12). Gelatinization is followed by gelation, a process in which the swollen granules are disrupted and amylose is released into the starch-water medium. The leaching of amylose from gelatinized granules contributes to the thickening characteristics of starch and gel formation, a colloidal dispersion of starch in water. The leached amylose in the starch-water system associates to form a structural network to entrap the granules, resulting in the formation of a gel.

Viscosity of starches such as maize and tapioca starch are greatly influenced by ratios of amylose to amylopectin (10). Genetically modified high amylose starches form highly resistant and firmer gels (39). Increasing amylose content also increases early onset of gelation. Starches with low levels of amylose such as waxy maize — less than 1% amylose — do not form gels effectively. Instead, they form clear pastes that are generally resistant to syneresis (11).

The strength of the starch gel is influenced by the presence of ionic components which may interact with the negatively charged starch molecules. Water absorption and swelling of starch is limited by the presence of amylose-lipid complexes (20).

B. Starch Retrogradation

Cooling of gelatinized starch results in the re-association of the leached amylose from gelatinized granules. This is the process of retrogradation. Retrogradation is also referred to as setback, and occurs with re-crystallization of amylose. Amylose is much more susceptible to retrogradation and amylopectin is only minimally involved in starch retrogradation even though amylopectin has been shown to influence retrogradation and syneresis in corn starch gels (5). This re-association and re-crystallization of amylose causes release of the water absorbed and bound during gelatinization, leading to the phenomenon known as syneresis.

Retrogradation of starch in food products is a concern as it affects product quality. The stability of starch-containing products during cold storage in particular is greatly affected by the extent of retrogradation. Freeze-thaw cycles result in extensive retrogradation and syneresis.

Retrogradation of starch in some instances enhances quality as such starches are resistant to enzyme hydrolysis and hence more stable. Cooling retrograded starches at room temperature prior to freezing at −20°C results in the formation of resistant starch as the retrograded starch is no longer susceptible to enzyme hydrolysis (29). This procedure is used in the production of industrial resistant starch.

C. Starch Damage

Starch damage is the modification or destruction of starch granule structure to the extent that it affects physicochemical properties such as water absorption. This in turn influences functionality of damaged starch in food applications, and subsequently, the quality of the final product. Starch damage results from various processes such as milling of grains. Starch damage affects the susceptibility of starch to hydrolysis and reactions as enzymes do not properly interact with the restructured granules.

Starch damage by processing or mechanical action causes a cracked appearance to granules. Extensive starch damage causes disruptions in the molecular structure of the starch. Modification to the starch granule therefore results in increased swelling ability and is more susceptible to enzymatic hydrolysis (19). In addition, cold water solubility of starch is enhanced. This affects the applicability in baking and food applications.

D. Interactions with Acids, Sugar, and Salts

The presence of chemical components such as sugar and salts has a great effect on the characteristics of starch in food systems. The granule surface structure is affected and restructured in the presence of acid, as there is de-polymerization and hydrolysis of amylose and amylopectin (40). This results in lower viscosities of starch pastes. Solubility of starch is enhanced by acid. These effects are due to the disintegration of the component amylose and amylopectin at the low pHs typical of highly acidic solutions.

Starch competes with sugars such as glucose, fructose, and sucrose for water absorption. Gelling and swelling of a starch is therefore modified in the presence of sugars. This is because sugars contain hydrophilic hydroxyl groups identical to the glucose monomers of starch. As a result they decrease the water activity of the starch-water system. There is an overall increase in the free volume of water, reducing its effectiveness as a desirable plasticizer required to facilitate starch gelatinization (41,42). Slade and Levine (1988) report that sugar has an anti-plasticization effect on starch. The sugars bind the water, reducing its availability for starch gelatinization (43). Consequently, sugars elevate the temperature at which the gelatinization of various starches occurs.

The ionic nature of salts is responsible for their interaction with starch and the subsequent effects on starch physicochemical properties. Starch molecules possess a

weakly charged ionic structure. In the presence of cations, the granules are stabilized and protected, whereas in the presence of anions, the hydrogen bonds are ruptured. This destabilizes the granules, enhancing and facilitating gelatinization (44,45).

Various salts such as phosphates form complexes with the amylose and amylopectin, a property exploited for use in industrial in starch modification. Salts overall delay loss of birefringence and depress overall extent of gelatinization.

Sodium chloride has great influence on starch physicochemical properties. Sodium chloride increases the gelatinization temperature of various starches. At concentrations of 6–9%, sodium chloride solution inhibits starch gelatinization (46). Various procedures for starch pre-treatment are commonly used in food processing. A common procedure is alkalization, in which alkalizing agents are added to maize, wheat, or rice in the preparation of tortillas, Chinese wheat noodles or rice dumplings, respectively. Common alkalizing agents include sodium hydroxide, or sodium and potassium carbonate (47).

Addition of alkali contributes to improving starch swelling capacity. The presence of lime (calcium hydroxide) has been shown to decrease starch crystallinity in corn (48). Gelatinization temperature of corn starch is also increased by the presence of lime, attributed to cross linking of calcium with the starch, as well as due to ionic interactions with hydroxyl groups on the starches (47). It is expected that these would in turn lead to variations in gelatinized starch quality characteristics — color, gelation, and retrogradation tendency.

IV. STARCH HYDROLYSIS

Starch hydrolysis is the cleaving of the starch polymer to short chain fragments such as dextrins and maltose, or to the glucose monomers. Starch hydrolysis is essential in many aspects of the application of starch. For instance, starch is hydrolyzed by various means for the production of sweeteners. Hydrolysis products of starch are multifold and include products such as dextrins and simple sugars. Starch hydrolysis is carried out primarily by the use of enzymes or chemicals, or in combination.

A. Enzyme Hydrolysis

Enzymatic hydrolysis of starch is carried out for various purposes, but most notably for the industrial production of maltose syrup (49). The key enzymes used for starch hydrolysis are β-glucosidases, which hydrolyze the amylose and amylopectin in starch. These include α-amylase, amyloglucosidase, and pullulanase.

The extent of starch hydrolysis is quantified by various parameters. This could be the hydrolysis index (HI), or by the dextrose equivalent (DE). The hydrolysis index quantifies the proportion of starch hydrolyzed. Dextrose equivalent describes the potential for starch conversion to dextrose (glucose) and is defined as the sum of reducing sugars expressed as dextrose. This is because starch in its native form has few reducing sugar ends. The number of reducing ends is influenced by the proportion of amylopectin. Degree of polymerization is indicative of the number of glucose residues. Amylose from starches such as maize or wheat have DP of 200–1200, while amylose from potato or tapioca starch have DP of about 1000–6000.

Hydrolysis of starch to maltodextrins is achieved by use of α-amylase enzymes. These enzymes are categorized either as endoamylases, exoamylases, debranching enzymes, or transferases (26). The endoamylases, the most common being α-amylase (EC 3.2.1.1), are specific for the α-1→4 linkage in amylose and amylopectin. Their hydrolysis products from starch hydrolysis are mainly oligosaccharides and dextrins (26). Exoamylases, on the other hand, have the ability to hydrolyze both the α-1→4 and α-1→6 bonds of amylose and amylopectin. A common example is amyloglucosidase (EC 3.2.1.20). β-Amylase is an exoamylase that has the ability to hydrolyze the α-1→4 bond of amylose.

Debranching enzymes used in starch hydrolysis are targeted at hydrolyzing the α-1→6 bonds in amylopectin. These include pullulanases. Hydrolysis products of these are mainly maltose and maltotriose. The transferases have low activity with regard to starch hydrolysis but are involved in formation of new glycosidic linkages (26).

Enzymatic hydrolysis of starch is influenced by the presence of non-starch components such as lipids, particularly lipids bound to amylose. This is because the presence of these complexes renders the amylose less susceptible to hydrolysis enzymes (20). Additional enzymes such as lysophospholipase are therefore sometimes required for complete hydrolysis of starch in the production of glucose from starch.

Amylase enzymes produced by lactic acid bacteria — *Lactobacillus plantarum*, *Lactobacillus amylophilus*, and *Lactobacillus delbruecki*, in particular — are used for industrial hydrolysis of starch for conversation of starch to glucose. This is a process known as saccharification (50). Yeasts such as *Saccharomyces cerevisiae*, which produce α-amylase, are also used in bioreactors for enzymatic hydrolysis of starch and subsequent fermentation of the hydrolysis product (glucose) by the yeast strains (33). These micro-organisms produce heat-stable amylase which can survive the high bioreactor process temperatures required for gelatinization and hydrolysis of the starch. The lactobacilli produce enzymes that hydrolyze the starch to glucose, and then the bacteria ferment the starch of the industrial production of lactic acid.

Immobilized enzymes also are used in industrial hydrolysis of starch. The enzymes are extracted from an

industrial source, usually microorganisms such as *Aspergillus*, and then immobilized on inert particles such as silica (51). This ensures that the enzyme has optimum activity and access for starch hydrolysis. Co-enzymes and ionic particles such as calcium are required for starch hydrolysis.

While traditionally acids (mainly hydrochloric acid) have been used for hydrolysis of starch, there has been an increase in use of industrial enzymes for starch hydrolysis. Most of these convert starches for the production of maltodextrin, modified starches, glucose syrup, or fructose syrup. Hydrolysis of starch in foods is increased by processing. Enzymatic hydrolysis of starch in various legumes for instance is enhanced by soaking and sprouting. Gelatinization of starch is required prior to enzymatic hydrolysis.

B. Acid Hydrolysis

Acids are used to facilitate the hydrolysis of starch. The α-1$\rightarrow$4 linkages in amylose and amylopectin are susceptible to hydrolysis at the low pH typical of acids. Hydrochloric acid at low concentrations (0.36% w/v) hydrolyzes starch (52).

The use of acids in combination of alcohols has been suggested for starch hydrolysis. Formation of limit-dextrins with varying degrees of polymerization occurs in the presence of various alcohols such as methanol, ethanol, and propanol. These alcohols are possibly involved in disrupting the hydrophobic and hydrogen bonds of the starch helical structure in the granule. Increase in temperature further increases the susceptibility of starch to acid hydrolysis in alcohol (52).

C. Alkaline Hydrolysis

Alkaline hydrolysis of starch is enhanced and influenced in the presence of heat and inorganic salts. There is complete hydrolysis of starch with microwave heating in the presence of metal chlorides (53). The theoretical yield of glucose (111%) is obtained in the presence of chloride salts such as lithium chloride, barium chloride, and iron trichloride. On the other hand, acid hydrolysis of starch is greatly limited in the presence of sulfate salts. In the presence of sulfate salts — sodium sulfate, magnesium sulfate and or zinc sulfate — acid hydrolysis is actually greatly impeded (53).

D. Heat-Induced Hydrolysis

Extrusion of starch is used in combination with enzymes for effective starch hydrolysis. The starch is treated under conditions of high temperature, high pressure, shear, and moisture (54). Heat stable amylase is used for starch hydrolysis. Extrusion cooking facilitates disruption of the granule structure and the crystallinity. This renders the amylose and amylopectin susceptible to gelatinization (55). Application of extrusion in starch hydrolysis has the advantage in that the process conditions can be modified such that the extent of hydrolysis is controlled for desired end products and dextrins (55).

V. STARCH MODIFICATION

Native starches such as tapioca starch often require considerable modification to enhance quality and versatility in food applications, and for storage stability. The components of starch — amylose and amylopectin — are highly sensitive to shear, stress, acidity, and high temperatures, and are typically altered by heat-moisture conditions of processing (15). Most native starches such as tapioca starch have limited swelling power and solubility. Modification is essential to improve paste clarity, paste stability, resistance to degradation, and freeze-thaw stability. Modification of starch is important to improve the reactivity of glucose, as well as introduce reactive side chains (56). The integrity and structure of the granule is also enhanced by modification. Additional side chains interfere with potentially deleterious post-process starch properties such as retrogradation. Most starches used in food applications are modified starches.

Modification of starches is by physical and chemical procedures. Modification procedures include acetylation, hydroxypropylation, and a combination of hydroxypropylation and cross-linking (57). Hydroxypropylated starches are most commonly used in the food industry (57). Stabilization of starch is facilitated by use of acetates and hydroxypropyl esters (58). These modification procedures greatly increase freeze-thaw stabilization and increase resistance to process conditions such as heat and shear.

Cross-linking is commonly carried out with various chemical agents such as phosphorus oxychloride, sodium trimetaphosphate, and anhydrides (58). Cross-linked starches are more resistant to process conditions such as temperature and acidity as a result of the fact that the hydrogen bonds have been reinforced and act as bridges. These are useful in preventing re-crystallization of amylose and the subsequent retrogradation in processed starchy foods.

Some procedures that have been shown to be effective in modification of banana starch include cross-linking with sodium trimetaphosphate, formation of starch phosphate with sodium tripolyphosphate, and hydroxypropylation using a combination of sodium hydroxide and sodium sulphate (24). These procedures result in starches with enhanced water-binding capacity, and in most cases, increased solubility. Starch phosphates in particular have increased freeze-thaw stability.

Acid-thinned starches are obtained by reducing the concentration of concentrated starch slurry with a mineral

acid at 40–60°C, to obtain a desirable viscosity. The starch is recovered after the acid is neutralized (59). The granule structure of the starch is not destroyed in the process, but various changes to the properties of the starches occur. Starch solubility and gel strength for instance are increased, while starch viscosity is decreased (60). Rate of starch hydrolysis is increased with increasing concentration of acid (59).

Physical modification procedures that have been used include pre-gelatinization. Pre-gelatinization increases swelling power and paste clarity of banana starch (24). Extrusion cooking of starch is used to improve quality and characteristics of starch.

VI. STARCH IN FOOD APPLICATIONS

Starch is a functional ingredient in many food products. There are multiple functions of starch in food products. Most commonly, starch is used as a bulking agent, binder, carrier, in fat-replacers, as a texture-modifier, and as raw material for other starch-related products. It is a basic ingredient in products such as breads, puddings, marinades, and sauces, and also serves a considerable function in other products such as powdered spices and beverages. The applicability and utility of a starch in food products is enhanced by factors such as its composition and functionality. Starch is a substrate for lactic acid bacteria in fermentation to produce lactic acid (61).

Starch-based foods play a major role in the diet in various areas because of their bulking quality, and ability to contribute to satiety. Fermentation of cassava for instance imparts a sour taste that is sometimes highly desirable.

A. Functional Properties

Starch is used as to facilitate thickening and gel formation in various food products such as fruit preparations (62). The consistency of products such as tapioca pudding and many custards would not be attainable without the thickening and stabilizing properties of starch.

High amylose starches have high viscosity, and form thick gels. This enhances their properties as thickeners in food products. Starches with lower amylose content are better suited for use in certain types of noodles, such as Japanese noodles (23). High amylose starches are desirable for application in fried products as they have minimal fat absorption. High amylose starches are also applicable as thickeners and for use as gelling agents in foods such as jellies. High amylose starch gels set rapidly hence are desirable in production of confectionary and candies (56). Other desirable properties of high amylose starches include their flexibility, water resistance, and tensile strength (63).

Starches with high swelling ability and high viscosity are desirable for various types of Asian noodles (18). Starches high in amylopectin and low in amylose (waxy starches) such as waxy wheat are produced for use in such products. The higher levels of amylopectin further contribute to extending shelf-life, by reducing retrogradation and staling in baked products. High amylopectin starches are less susceptible to retrogradation, and hence very applicable in improving freeze-thaw stability (63).

Modified starches are highly effective as stabilizers in products such as yogurt (57). The presence of side groups such as acetyl and hydroxyl groups in modified starches, however, results in interactions with amylose and amylopectin, improving overall stabilizing ability.

Fermented, sun-dried cassava starch is commonly used in baked products in various parts of South America and Brazil. This is unique in that the fermentation facilitates expansion which is desirable in the baked products (64). Viscosity of sour starch pastes is lower than for non-fermented starch, attributable to the solubilization of amylopectin.

Starch is used to improve quality of extruded food products. Addition of cassava starch to cassava flour prior to extrusion increases water solubility, but decreases water absorption and bulk density properties (65).

Shear thinning of starch is an important characteristic with regards to stability of starch pastes during processing, particular in food products that require extensive stirring and agitation. Removal of lipids (defatting) in sorghum starch has been associated with increased shear-thinning characteristics (66). Starches that are resistant to shear thinning are generally highly desirable to ensure product stability and suitable consistency.

Products of starch hydrolysis find considerable application in food products. Maltodextrins, for instance, are commonly used in heat-stable gels (67).

B. Value-Added Food Applications

Starch is used as a basic ingredient in starch-based fat substitutes. These simulate the functional properties of fats, particularly texture modification, but with less caloric value. Various starch-based fat substitutes are commonly used in industry. Some examples of these include TrimChoice™ (Specialty Grain products, NE) made from hydrolyzed oat starch, Amalean™ (American Maize Products, IN) made from modified high-amylose corn starch, and SlenderLean™ (National Starch, NJ) made from tapioca starch (37).

Starch-based fat substitutes are especially applicable in baked products and value-added foods.

Resistant and minimally digestible starches are used in value-added food products. Most of these products are targeted at the management of diet-related diseases such as obesity and type II diabetes. An example of such a product is Extend™, a snack bar formulated with resistant starch (corn and rice starch), which has been formulated for the

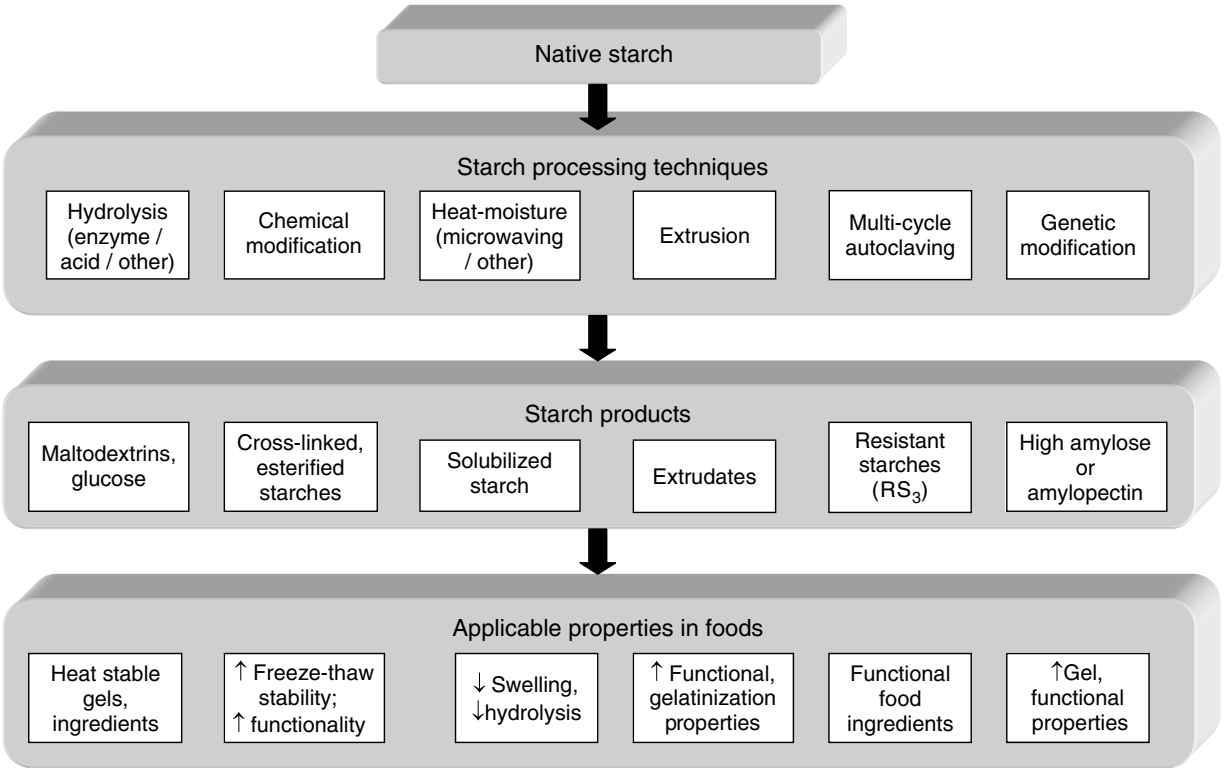

FIGURE 3.5 Outline of starch processing and applications in foods.

management of type II diabetes. The product ensures a slow and sustained digestion of the resistant starch, and minimal absorption of glucose, mitigating the problems of high post-prandial blood glucose levels (Figure 3.5).

VII. STARCH NUTRITIONAL QUALITY

Starch is the primary nutrient involved in energy intake and regulation. Typically, most adults require about 200 g carbohydrate daily to facilitate brain and muscle function. The digestibility and absorption of starch has significant nutritional and physiological implications. As the primary source of energy, starch is rapidly metabolized and absorbed. The extent of starch digestibility is influenced by the nature of the starch, food processing, and physiological status.

There is a dichotomy of starch functionality as a nutrient. On the one hand, it is a source of glucose, the primary substrate for cell metabolism. On the other hand, starch resistant to digestion (resistant starch) is minimally digestible and only minimally absorbed, and therefore is not physiologically available.

A. Starch and Glycemic Index

Starch is the primary source of metabolizable energy, and therefore its availability and digestion are important. High starch foods are rapidly digested and metabolized. Glycemic index (GI), the post-prandial blood glucose response to a particular food, has been used to differentiate the metabolic response to dietary carbohydrates (68). Glycemic index is indicative of the relationship between a food and the implications of starch digestibility, absorption, and metabolism. Foods that are high in readily digestible starch result in high levels of glucose in the blood. These are classified as high GI foods. Typically, most tropical root starchy staples such as cassava and yams have high levels of readily digestible waxy starches (high amylopectin). These are rapidly and readily absorbed, resulting in elevated levels of glucose in the blood. This is, however, modified to a large extent by other factors associated with the nature of the starch, its processing, preparation, and consumption.

Starch is hydrolyzed by salivary and pancreatic amylases to yield monosaccharides such as glucose and fructose, and maltodextrins. These are transported via the hepatic portal vein and available for metabolism. Starch digestion and metabolism has been classified into three categories: rapidly digestible starch, slowly digestible starch, and resistant starch (69). Rapidly digestible starch, which typically is completely digested, is associated with post-prandial glucose response, and hence has effect on insulin levels. Rapidly available glucose meanwhile describes glucose and sucrose obtained as hydrolysis

products of rapidly digestible starch. Rapidly digestible starch occurs most commonly in highly processed foods such as puffed wheat cereal, while slowly digestible starch occurs in foods such as legumes and pasta (69).

Starch digestion and glycemic index also have been associated with satiety. Rapidly digestible starches are quickly absorbed and metabolized, whereas slower digesting starches are only slowly absorbed and therefore improve satiety (70). These have also been shown to improve exercise endurance (71).

There are differences in the metabolic response to dietary carbohydrates. Post-prandial blood glucose and insulin responses vary depending on the nature of carbohydrates, particularly starch. Physiological conditions such as type II diabetes and obesity have been associated with starch metabolism. Other conditions such as coronary heart disease are linked to metabolism of glucose derived from dietary starch. The physiological consequence of starch consumption is influenced by the extent of its digestibility and metabolism. Digestibility of starch is determined by its availability and susceptibility to digestive enzymes. Susceptibility of starch to digestive enzymes is in turn influenced by the chemical nature of the starch and the changes that result from processing.

Starch digestibility is influenced by various factors such as processing, storage, amylose content, and presence of dietary fiber (72). The ratios of amylose to amylopectin are important in starch digestion and metabolism. Consumption of modified high amylopectin starches have been shown to result in an increase in serum free fatty acids and serum glucose levels. This is probably as a result of gluconeogenesis. Conversely, modified amylose cornstarch is highly digestible, and results in lower insulin levels. Starch that is digested and absorbed, however, has physiological effects, some of which have been linked to disease conditions.

Researchers have demonstrated that the consumption of high starch diets in human test subjects apparently leads to an overall decrease in overall energy intake, compared to a high-sucrose (simple sugar) or high fat meals (70,73). This indicates that high starch may have potential for a high satiety value, but with low caloric density, and hence the lowered energy intake.

Type II diabetes, a condition that results from inadequate production of insulin to facilitate glucose uptake, is exacerbated by the presence of glucose in the blood. Clinical manifestations of Type II diabetes include fainting and dizzy spells as a result of low brain glucose levels. Starch and glucose metabolism have been also associated with obesity and accumulation of fat, as glucose is involved in fat metabolism.

The nature of starch and the level of amylose in the starch play a considerable role in the diabetic process and insulin response. Long-term consumption of a high amylose corn starch (70% amylose) by hyper-insulinemic subjects results in a normal insulin response (74). High amylose starch in the diet reduces insulin response (75). Meanwhile legume starches such as pure pea starch have been shown to be even more effective than corn starch in reducing hyperglycemia, as has been demonstrated with purified pea starch (76).

The conversion of sugars, which are starch hydrolysis products, into fat has been implicated in diabetes and cardiovascular disease and obesity. The consumption of simple sugars and refined grain foods has been linked to higher rates of cardiovascular disease and Type II diabetes, particularly in instances of insulin resistance (68,77).

B. Resistant Starch

Resistant starch is non-digestible starch which occurs in foods in various forms.

Resistant starch is described in various ways, including as starch and starch degradation products not absorbed in the gut (78,79).

Resistant starch occurs in four categories, primarily dependent on their mode of origin. These are described as: type 1 (RS_1): physically entrapped starch in the cell matrix of whole or partially milled grains, hence is inaccessible; type 2 (RS_2): native granular starch, mostly B-type legume starches which are may be ungelatinized during processing; type 3 (RS_3): retrograded starch, particularly from food processing; and type 4 (RS_4): chemically modified starch (29,79–82).

Resistant starch levels in food products are influenced by various factors including the nature of the starch, the mode of food processing and preparation, and storage conditions (83). Physical inaccessibility such as cell wall structure and the presence of dietary fiber influences levels of resistant starch, particularly in legumes (72).

Type 3 resistant starch (RS_3), which is retrograded starch, is the most commonly occurring form of resistant starch in processed foods. Starch in cooked then cooled foods such as pasta, rice, and lentils exhibits considerably reduced susceptibility to enzymatic digestion, indicating the formation of resistant starch (72). This is attributable to the retrogradation which occurs following cooling of gelatinized starch. Amylose is more susceptible to retrogradation than amylopectin. Resistant starch formation is therefore influenced by ratios of amylose to amylopectin.

Processing of starchy foods, in addition to factors such as starch amylose: amylopectin ratios and chemical modification, influences their digestibility. This is as a consequence of the disruption of the physical and chemical structure of the starch (84,85). Retrogradation of amylose with processing is mainly thought to be responsible for this alteration in susceptibility to digestive enzymes. In some cases, however, partial damage to starch molecules which would otherwise be physically entrapped

by the cell wall and inaccessible to digestive enzymes, may improve their susceptibility to digestion (86).

Consumption of resistant starch yields physiological effects similar to soluble fiber (82). Fermentation products include short chain fatty acids such as acetate, propionate, and butyrate, which facilitate absorption of minerals, excretion of bile acids, and consequently protect against colorectal cancer.

Resistant starch-containing foods such as legumes, and retrograded starches, however, have been associated with disease prevention. Fermented corn porridge, commonly consumed among some indigenous populations, has been shown to contain considerable amounts of starch that is resistant to digestion and subsequently is protective against various colon conditions (87). Experimental evidence using high resistant starch breakfast cereals in humans shows an improved glucose tolerance (88). In rural South Africa, however, consumption of cold maize porridge, which is high in retrograded starch and has rather low starch digestibility and a low glycemic index, has been associated with low levels of diabetes mellitus (87,89).

High resistant starch foods which have low glycemic index are effective in lowering the concentrations of high-density-lipoprotein (HDL) cholesterol and in improving glucose tolerance in incidence of diabetes and insulin resistance (77,88,90).

Root and tuber starches, unlike grain starches, are high in amylopectin and do not have the same restricting nature of the cell wall. They are, therefore, generally more digestible. Processing techniques such as autoclaving to reduce starch digestibility by increasing resistant starch levels have been suggested in foods (91). Digestibility of legume starch is increased by processes such as soaking and sprouting (30).

VIII. NEW STARCH TECHNOLOGIES

The functionality and applicability of starch in so many food applications and its importance as a food ingredient have led to continuous efforts to improve and optimize properties and versatility of starch. Some techniques currently used include genetic modification to modify starch yields and quality, multi-cycle autoclaving for production of resistant starch, and new processes such as microwave hydrolysis of starch.

A. Genetic Modification

Genetic modification of starch most commonly targets the enzymes of the starch biosynthetic pathway. The activities of these enzymes dictate and determine the quantities of starch synthesized as well as specific characteristics such as ratios of amylose to amylopectin. Their activity therefore influences starch properties: its reactivity, functionality, and applicability in food processing and in food applications.

Genetic modification of cereal starch is commonly employed to modify ratios of amylose to amylopectin, and hence improve functionality and nutritional quality of starch.

The primary enzymes involved in starch synthesis include the starch synthases, starch branching enzymes and adenosine diphosphate-glucose pyrophosphorylase (ADP-glucose-phosphorylase). The starch synthases occur both as a granule-bound synthase (GBSS) or located in the soluble phase, and catalyze the formation of the α-1$\rightarrow$4 glucan chains by adding ADP-glucose to the non-reducing end of the primer. The starch branching enzyme catalyzes formation of the α-1$\rightarrow$6 branches of amylopectin molecules. The ADP-glucose pyrophosphorylase catalyzes the formation of ADP-glucose (56). Other important enzymes are starch debranching enzymes and phosphorylases.

A major contribution of genetic modification is the modification of various cereal starches to reduce amylose content and produce high amylopectin starch. These waxy starches are desirable for various characteristics. They are desirable in various noodles, for modification of amylose characteristics in extrudates, and to extend the shelf-life of baked goods (18).

Waxy starches are produced by modification of the enzyme involved in amylose synthesis, granule-bound starch synthase (GBSS). While naturally occurring mutations in various wheats have resulted in waxy wheat starch, biotechnology to modify the expression of the GBSS genes is used to produce waxy starches, including rice, maize and wheat. Modification by decreasing the levels of enzymes such as starch synthase and starch branching enzyme is employed to increase amylose levels.

Modification by decreasing levels of GBSS results in increased amylopectin levels.

Regular cereal starches (up to 27% amylose) typically form opaque pastes and firm gels. Genetic modification techniques are applied to either decrease or increase the amylose to amylopectin ratios. Low amylose cereal starches (waxy maize, waxy rice, waxy wheat) lack GBSS, and therefore contain less than 1% amylose. These therefore do not effectively form gels but instead clear pastes. Genetically modified high amylose starches form highly resistant and firmer gels (41). Increasing amylose content also increases early onset of gelation. High amylose maize starch — amylomaize — is modified to have high levels of amylose, 50–70%. The granules of amylomaize are more resistant to swelling and therefore form much firmer and more rigid gels (11,92).

Genetically modified potato starch has been shown to be suitable in processing and preparation of starch noodles, as these have greater transparency and higher flexibility (93). This may be due to higher amylose content. Modification of starch synthesis to increase overall yields of starch in food products is carried out by modifying

levels of adenosine triphosphatase (ATPase) and starch branching enzymes (56).

Genetic modification of reactive groups such as phosphates is used to change the composition of starch by decrease of the starch branching enzyme (56).

B. Resistant Starch Production by Autoclaving

Autoclaving and steam processing are used in the production of resistant starch. Resistant starch produced by this technique is retrograded starch (RS_3), as it involves gelatinization and subsequent retrogradation of starch, rendering it resistant to digestive amylases. Autoclaving has been shown to modify resistant starch content in grain sorghum (94). High amylose starches which are most susceptible to retrogradation are therefore preferred for this process.

High pressure autoclaving has been standardized for the production of resistant starch (91,95). Starch with a high volume of water is gelatinized in a high pressure autoclave with stirring until a homogenous gel is obtained. The mixture is then cooled and frozen to facilitate retrogradation.

C. Other Procedures

Other procedures employed in starch modification include microwave solubilization (96,97). Corn starch modified by microwave heating for a short period of time (32–90 seconds) at 900 W has decreased swelling ability (96). Microwave pre-solubilization of starch at 180 W for 10 minutes is employed in food analysis (97). In the presence of dilute hydrochloric acid, there is complete hydrolysis of starch in 5 minutes of microwave processing. This is attributable to the superheating produced by the presence of the ions. These procedures are proposed to substitute for the more expensive and time-consuming enzyme hydrolysis procedures commonly used.

4 Functional Properties of Carbohydrates: Polysaccharide Gums

Steve W. Cui and Qi Wang
Food Research Program, Agriculture and Agri-Food Canada

CONTENTS

I. INTRODUCTION

Gums are long chain polysaccharides widely used in the food and many other industries as thickeners, stabilizers, and texture modifiers. Gums and related polysaccharides are produced in nature as storage materials, cell wall components, exudates, extracellular substances from plants or microorganisms, and in some cases from exoskeletons of shellfish such as lobsters, shrimps and crabs (e.g., chitosan). Some polysaccharides are simple in sugar composition, such as cellulose and β-D-glucans, which contain only one type of monosaccharide (e.g., β-D-glucose), while others are rather complex and may contain up to six types of monosaccharides plus one or two types of uronic acids. Common monosaccharides and uronic acids present in natural polysaccharides include D-glucose, D-galactose, D-mannose, D-xylose, L-arabinose, L-rhamnose, L-fucose, D-galacturonic acid, D-gulucuronic acid, D-mannuronic acid, and L-guluronic acid. The primary structure of a polysaccharide, i.e., monosaccharide composition, linkage patterns, and molecular weight, defines the solubility and conformation of the polymer chains in aqueous solutions, which in turn dictate the functional properties of the gums exhibited in food and other systems.

Polysaccharides can be linear or branched polymers. With the same molecular weight, linear polysaccharides generally have poorer solubility and higher viscosity than branched counterparts due to their extended conformation in solutions (if soluble or dispersible). Perfectly linear homoglycans such as cellulose are either difficult to dissolve or insoluble in aqueous medium due to excessive intra- and intermolecular interactions (mainly through hydrogen bonding), which make them less useful as hydrocolloidal gums. Irregularity introduced by substitution or branching to the linear chain increases solubility. Highly branched polysaccharides are usually very soluble but exhibit lower viscosity in solutions because of their smaller hydrodynamic volumes compared to liner molecules with the same molecular weight. The variations in monosaccharide composition, linkage patterns, molecular weight, and molecular weight distribution of gums contribute to the unique functional properties exhibited by each gum.

The goal of the present chapter is to provide information on the basic structural and functional properties and major applications of all commercial gums and some emerging gums in food and other industries. For detailed descriptions of chemical structure, molecular characterization, physicochemical properties, and applications of these gums, readers are referred to several comprehensive books and chapters (1–5).

II. FUNCTIONAL PROPERTIES OF POLYSACCHARIDE GUMS

A. Viscosity Enhancing or Thickening Properties

When polysaccharide gums are dissolved into solution, one remarkable phenomenon is the considerable increase in solution viscosity; gums restrict the movement of water molecules and in extreme cases gels are formed. The ability of polysaccharide gums to increase viscosity or to thicken the aqueous system is the most important property of such polymers. The shape and conformation of polysaccharides are determined by their primary sequence structure. Once the structure is determined, the shape and/or conformation of a polysaccharide are more or less fixed, and the molecular weight (size) and number of polysaccharide molecules in a given volume (concentration) become important in determining their functional properties. In addition, environmental factors such as solution pH, temperature, presence of certain ions, and ionic strength of the system have significant influences on the conformation of polysaccharide chains, and hence their functional properties.

Solution viscosity of a gum almost always increases with concentration, but not necessarily in a linear manner. At low concentrations, dilute gum solutions normally exhibit Newtonian flow behavior (independent of shear rate) in which polymer molecules are free to move independently without intermolecular entanglements. For most random coil polysaccharides, the relationship between zero-shear specific viscosity (η_{sp}) and concentration (c) follows $\eta_{sp} \propto c^{1.1–1.3}$. When the polymer concentration is increased to a critical point (critical concentration C*), the viscosity of the solution increases sharply due to entanglement of polymer molecules. This is called the semi-dilute region within which polysaccharide gums usually exhibit shear thinning flow behavior where viscosity decreases with increase in shear rate.

The viscosity of most gum solutions decreases with increased temperature, although some gums are more resistant to temperature changes. For example, the viscosity of xanthan gum solution is relatively unchanged over a wide range of temperatures (−4°C to 93°C) (4). There are other extremes, such as methyl cellulose, where the viscosity increases as the temperature increases, and eventually gels are formed at higher temperature. Other factors influencing viscosity include pH, ionic strength, and presence of co-solutes with effects differing in individual gums.

B. Gelling Properties

All hydrocolloids have viscosity enhancing or thickening properties, but only a few are able to gel. Gelation of polysaccharides is caused by the cross-linking (covalently

and/or non-covalently) of long polymer chains to form a continuous three-dimensional network which traps and immobilizes water and forms a firm and rigid structure resistant to flow under force. Gelation of polysaccharides usually involves three stages: 1) Polysaccharide gums have to be dissolved/dispersed at temperature above the melting point. At this stage, polymer chains exist in a coiled conformation. Upon cooling, polymer chains start to form ordered structures such as helices. 2) Formation of a gel network with further cooling. At this stage, helices begin to aggregate by forming cross-links or super-junctions, and a continuous network is eventually developed. 3) Aging stage where existing helices or aggregations are further enhanced and some new helices are formed. Contraction of gel networks may occur with the liberation of free water ("weeping" or syneresis). Most of the polysaccharide gels are thermally reversible below 100°C with defined setting and melting temperature ranges. There is a minimum concentration for each polysaccharide, below which gel cannot be obtained. Some gels exhibit thermal hysteresis where the melting temperature is significantly higher than the setting temperature, e.g., agarose gels (6). However, there are a few gelling gums which do not follow the above rules. Some gums form gels upon heating while others can form gels by changing ionic strengths and pH or introducing specific ions. A wide range of gels with different textures, such as soft, elastic, very firm, and brittle, can be prepared by selecting different types of polysaccharides and by varying gelation conditions.

C. Surface Activity and Emulsifying Properties

Although polysaccharides are hydrophilic compounds not conventionally perceived to be surface active, many polysaccharide gums are used to stabilize emulsions that already contain an emulsifier (proteins or surfactants). The universal role of gums in emulsion systems is to thicken the continuous phase, thereby inhibiting or slowing droplet flocculation and/or creaming. There are a few exceptions of gums that actually exhibit surface activity; these gums play double roles in emulsion systems: as an emulsifier and a thickener. In most cases, surface activity of these gums is attributed to the protein component associated with the polysaccharides, while in other situations, the surface activity is due to the presence of hydrophobic functional groups, such as in the cases of methyl cellulose and propylene glycol alginate. Although it is still controversial regarding what is responsible for the surface activity, fenugreek gum does exhibit excellent emulsifying and emulsion stabilizing properties even at very low protein content (e.g., $<0.5\%$) (7). Detailed applications of these gums as emulsifiers are described in the following sections.

III. CHEMISTRY, FUNCTIONAL PROPERTIES, AND APPLICATIONS OF POLYSACCHARIDE GUMS IN FOOD AND OTHER INDUSTRIES

A. Gums from Exudates

The earliest gum known to humans is from plant exudates. Many plants exude a viscous, gummy liquid when wounded and the liquid will dry to form hard, glassy, tear-drop-like balls or other shapes of masses. The exudates are hand collected, sorted/graded, and further processed to meet the application needs. Gum arabic, tragacanth, karaya, and ghatti are exuded gums that are commercially significant.

1. Gum Arabic

a. Source and structure

Gum arabic, or acacia gum, is prepared from the exudate of *Acacia* trees, mostly from *senegal* species, and sometimes mixed with *seyal* species. Natural gum is in the form of spherical balls resembling tear drops, collected by hand and processed before use. Almost all commercial gum arabic is produced from the Sahelian regions of Africa.

Gum arabic consists of a mixture of a relatively low-molecular-weight polysaccharide ($\sim 0.25 \times 10^6$ daltons, a major component) and a high-molecular-weight hydroxyproline-rich glycoprotein ($\sim 2.5 \times 10^6$ daltons, a minor component) (8). It is a heavily branched polysaccharide; the main chain consists of (1→3)-linked β-D-galactopyranosyl residues. The side chains are two to five units in length made of (1→3)-linked β-D-galactopyranosyl units, joined to the main chain by (1→6)-linkage. Both main and side chains are substituted by α-L-arabinofuranosyl, α-L-rhamnopyranosyl, β-D-glucuronopyranosyl, and 4-O-methyl-β-D-glucuronopyranosyl units. The monosaccharide composition of gum arabic varies with gum sources, e.g., gum from *Acacia senegal* contains about 44% galactose, 27% arabinose, 13% rhamnose, and 16% glucuronic acid of which only 1.5% are 4-O-methylated. In contrast, gum arabic from *Acacia seyal* contains 38% galactose, 46% arabinose, 4% rhamnose, and 12% total glucuronic acid (of which 5.5% are 4-O-methylated) (8). These compositional and structural differences affect their functionalities, e.g., gum arabic from *Acacia senegal* is a much better emulsifier than gum from *Acacia seyal*.

b. Functional properties and applications

Gum arabic is readily dissolved in water to give clear solutions with light colors ranging from very pale yellow to orange brown. It is a typical low viscosity gum and the solutions exhibit Newtonian flow behavior even at concentrations as high as 40%. Higher concentration solutions can be

prepared up to 55%. A major functional property of gum arabic is its ability to stabilize oil-in-water emulsions. The protein-rich high-molecular-weight species are preferentially adsorbed onto the surface of oil droplets while the carbohydrate portion inhibits flocculation and coalescence by electrostatic repulsions and steric forces (8). The major application of gum arabic is in the confectionary and beverage industries for stabilizing emulsions and flavor encapsulation. In the confectionary industry, gum arabic is used to prevent sugar crystallization and to emulsify the fatty components. Examples of such products include pastilles, caramel, and toffee. Gum arabic has also been used in chewing gums, cough drops, and candy lozenges. Good stability under acidic conditions makes gum arabic useful in beverages, e.g., it is used as an emulsifier in the production of concentrated citrus juices and cola flavor oils of soft drinks (3). Gum arabic stabilized flavor oils can be spray-dried to form microencapsulated powders that can be easily incorporated into dry food products such as soup and dessert mixes.

2. Tragacanth Gum

a. Source and structure

Tragacanth gum is dried exudates from branches and trunks of *Astragalus gummifer* Labillardiere or other species of *Astragalus* grown in West Asia (mostly in Iran, some in Turkey). After hand collection, the exudates are graded, milled, and sifted to remove impurities. Tragacanth gum is composed of a water-soluble fraction and a water-insoluble fraction. The water-soluble fraction, accounting for 30–40% of total gum, is a highly branched neutral polysaccharide consisting of L-arabinose side chains attached to D-galactosyl backbones (9, 10). The D-galactosyl residues in the core chains are mostly 1→6-linked, sometimes 1→3-linked, whereas the branching L-arabinosyl residues are mutually joined by 1→2-, 1→3-, and/or 1→5-linkages. The water-insoluble fraction, the major fraction (60–70%), is an acidic polysaccharide consisting of D-galacturonic acid, D-galactose, L-fucose, D-xylose, L-arabinose, and L-rhamnose, and is called tragacanthic acid or bassorin. It has a (1→4)-linked α-D-galacturonopyranosyl backbone chain with randomly substituted xylosyl branches linked at the 3 position of the galacturonic acid residues. Some of the xylosyl residues are attached by an α-L-fucosyl or a β-D-galactosyl residue at the 2 positions (3, 11).

b. Functional properties and applications

Tragacanth gum swells rapidly in both cold and hot water to form a viscous colloidal suspension rather than a true solution. When added to water, the soluble tragacanthin fraction dissolves to form a viscous solution while the insoluble tragacanthic acid fraction swells to a gel-like state, which is soft and adhesive. When more water is added, the gum first forms a uniform mixture; after 1 or 2 days, the suspension will separate into two layers with dissolved tragacanthin in the upper layer and insoluble bassorin in the lower layer. The viscosity of the suspension reaches a maximum after 24 hours at room temperature, and hydration can be accelerated by an increase in temperature. The suspension typically exhibits shear thinning behavior. The ability to swell in water, forming thick, viscous dispersions or pastes, makes it an important gum in the food, pharmaceutical, and other industries. It is the most viscous of the natural water-soluble gums and is an excellent emulsifying agent with good stability to heat, acidity, and aging.

Food applications of tragacanth gum include salad dressings, oil and flavor emulsions, ice creams, bakery fillings, icings, and confectionary. In the pharmaceutical and cosmetic industries, tragacanth gum is used as an emulsifier and stabilizer in medicinal emulsions, jellies, syrups, ointments, lotions, and creams. Gum tragacanth is also a good surface design thickener since it is a good medium for mixing with natural dyes and conveying controlled design onto fabric. It allows easy painting, stamping, and stenciling, and ensures a good control over color placement.

3. Gum Karaya

a. Source and structure

Gum karaya is from the exudates of *Sterculia urens*, trees of the Sterculiaceae family grown in India. It is a branched acidic polysaccharide with high molecular weight. Gum karaya contains 37% uronic acid and 8% acetyl groups. The backbone chain consists of (1→4)-linked α-D-galacturonic acid and (1→2)-linked α-L-rhamnosyl residues with side chains of (1→3)-linked β-D-glucuronic acid, or (1→2)-linked β-D-galactose on the galacturonic acid unit where one half of the rhamnose is substituted by (1→4)-linked β-D-galactose (12, 13). The quality of the gum varies significantly depending on the season of collection: summer usually gives high yields and high viscosity gum. During storage, the viscosity of gum karaya can be lost when exposed to high temperature and high humidity. The decrease in viscosity is more significant when the particle size is small. Preservatives may be added to prevent viscosity loss.

b. Functional properties and applications

Similar to gum tragacanth, gum karaya does not dissolve in water to give a clear solution but swells to many times its own weight to give a dispersion. The type of dispersion is influenced by the particle size of the product. For example, coarse granulated gum karaya produces a discontinuous, grainy dispersion whereas a fine powdered product gives a homogenous dispersion. Dispersion of gum karaya exhibits Newtonian flow behavior at low concentration ($<0.5\%$) and shear thinning behavior at semi-dilute concentrations ($0.5\% < c < 2\%$) (13). Further increase in gum concentration produces a paste resembling spreadable gels. An increase in temperature improves solubility in water, but excessive heat will cause degradation of the polysaccharides, resulting in non-recoverable loss of viscosity. At

extreme pHs and in the presence of sodium, calcium, and aluminium salts, the viscosity of gum karaya dispersion decreases.

Gum karaya is used to stabilize packaged whipped cream products, spread cheeses and other dairy products, frozen desserts and salad dressings, and as acid-resistant stabilizers in acidified products. It is also used as a water binder in bread, processed meats, and low-calorie dough-based products such as pasta (11). Other applications of karaya gum include dental adhesives, bulk laxatives, and adhesives for ostomy rings. Gum karaya is also used in the manufacture of long-fibered, lightweight papers in the paper industry and as a thickening agent in the textile industry to help print the dye onto cotton fabrics.

4. Gum Ghatti

a. Source and structure

Gum ghatti is an amorphous translucent exudate of *Anogeissus latifolia,* a tree of the Combretaceae family grown in India. It contains L-arabinose, D-galactose, D-mannose, D-xylose, and D-glucuronic acid in the ratio of 10:6:2:1:2, plus traces of a 6-deoxyhexose. The detailed structure of gum ghatti has not been clearly established. Its main chain consists of β-D-galactopyranosyl residues connected by (1→6)-linkages and D-glucopyranosyluronic acid units connected by (1→4)-linkages (9).

b. Functional properties and applications

Similar to gum karaya and tragacanth, gum ghatti does not dissolve in water to give clear solutions, but can be dispersed to form a colloidal dispersion. The dispersion exhibits non-Newtonian flow behavior and its viscosity is between those of gum arabic and gum karaya dispersions at the same concentration. Gum ghatti is an excellent emulsifier and can be used to replace gum arabic in more complex systems (13). The pH of gum ghatti dispersions is 4.8, and the viscosity increases with increase in pH, reaching a maximum at pH 8 (3). The viscosity of gum ghatti dispersions increases with time regardless of solution pH; however, addition of sodium salts, such as sodium carbonate and sodium chloride, results in decrease in viscosity. Loss in viscosity also occurs when the gum dispersions are not protected by preservatives against bacterial attack. Gum ghatti is used as an emulsifier and stabilizer in beverages and butter-containing table syrups, and as a flavor fixative for specific applications. Gum ghatti is also used to prepare powdered, stable, oil-soluble vitamins, and as a binder in making long-fibered, lightweight papers.

B. Gums from Plants

Gums of plant origin other than exudates are also important for food use. These include storage polysaccharides from seeds and tubers, mucilages from seed coats, and cell wall materials from fruits and cereals.

1. Galactomannans (Locust Bean, Tara, Guar, and Fenugreek Gums)

a. Source and structure

Galactomannans are a group of storage polysaccharides from various plant seeds. There are four major sources of seed galactomannans: guar (*Cyamopsis tetragonoloba*), locust bean (*Ceratonia siliqua*), tara (*Caesalpinia spinosa* Kuntze) and fenugreek (*Trigonella foenum-graecum* L.). Among these, only guar and locust bean gums are of considerable industrial importance and the use of tara and fenugreek is limited due to availability and price. Most of the guar crop produced worldwide is grown in India and Pakistan. The plant has also been cultivated in tropical areas such as South and Central America, Africa, Brazil, Australia, and the semi-arid regions of the southwest United States. Locust bean is produced mostly in Spain, Italy, Cyprus, and other Mediterranean countries. Fenugreek is grown in northern Africa, the Mediterranean, western Asia, and northern India, and has been recently cultivated in Canada.

The production of commercial guar, locust bean, and tara gums is similar, involving separation of endosperms from the seed hull and germ, grinding and sifting of the endosperm to a flour of fine particle size and sometimes purifying by repeated alcohol washings. The final product is a white to cream-colored powder. The amount and molecular weight of galactomannans found in the endosperm extract can vary significantly depending on the source of seed and growing conditions. Most commercial gums contain >80% galactomannan. Low-molecular-weight grades are produced from acid, alkaline, or enzyme hydrolysis of native gums. Fenugreek gum is extracted from the endosperm or ground whole seed with water or dilute alkali, and yields vary from 13.6% to 38%, depending on the variety/cultivar and extraction methods (14). Commercial fenugreek gum products, such as Fenu-pure and Fenu-life, contain over 80% galactomannas with about 5% proteins. Laboratory-prepared material involves pronase treatment of the gum samples, which produces a product of much higher purity with less than 0.6% protein contaminates (15).

Seed galactomannans consist essentially of a linear (1→4)-β-D-mannopyranose backbone with side groups of single (1→6)-linked α-D-galactopyranosyl units. The molar ratio of galactose to mannose varies with origins, but are typically in the range 1.0:1.0~1.1, 1.0:1.6–1.8, 1.0:3.0, and 1.0:3.9~4.0 for fenugreek, guar, tara, and locust bean gums, respectively. The distribution of D-galactosyl residues along the backbone chain is considered irregular, where there are longer runs of unsubstituted mannosyl units and block condensation of galactosyl units (16, 17).

b. Functional properties and applications

The solubility of galactomannan gums increases with the degree of galactose substitution. Guar and fenugreek gums are readily dissolved in cold water whereas locust bean gum is only slightly soluble in cold water but can be dissolved in

hot water. The hydration rate and solution viscosity depend on factors such as particle size, pH, temperature, etc. Guar gum solutions are reported to be stable over the pH range 4.0–10.5, and the highest hydration rate is reported at ~ pH 8.0 (18). Hydration rates are reduced in the presence of salts and other water-binding agents such as sucrose.

Like many polysaccharides found in nature, these galactomannans are polydisperse, high-molecular-weight polymers. Average molecular weight varies, typically from 1.0 to 2.5 million Daltons. The galactomannan molecules exist as an extended ribbon-like structure at solid state and adopt a flexible coil-like conformation in solution. All four types are highly efficient thickening agents. Given the same molecular weight and polymer concentration, the thickening powder decreases in the order of the increase of galactose contents, i.e., locust bean > tara > guar > fenugreek. The rheological properties of some galactomannan solutions show a considerable departure from classical random coil-like behavior (19). In particular, there is a lower coil overlap parameter $C^*[\eta] \sim 2.5$ in comparison with $C^*[\eta] \sim 4$ for most other disordered coils, and a stronger dependence of specific viscosity on concentration ($\eta_{sp} \propto c^{\sim 4.5}$ in contrast to $\eta_{sp} \propto c^{\sim 3.3}$). This is attributed to intermolecular associations at high concentrations.

Galactomannan gums are compatible with most hydrocolloids. There is a useful synergistic increase in viscosity and/or gel strength by blending galactomannan gums with certain linear polysaccharides including xanthan, κ-carrageenan, and agarose. The synergistic interactions are more pronounced with galactomannans of lower galactose contents.

Fenugreek and guar gums are non-gelling polysaccharides whereas locust bean and tara gum solutions may form weak gels upon freeze-thaw treatment, or by adding large amounts of ethylene glycol or sucrose. Gelation of galactomannans can also be induced by the addition of cross-linking agents such as borax and transition metal ions. The synergistic interactions of locust bean and tara gums with some gelling polysaccharides, such as κ-carrageenan and agarose, may enhance gelation, impart a desirable elastic character, and retard syneresis in these gels. These mixed gels have been used to form sheeted, fruit-flavored snack products and to produce hair gels.

Polysaccharides are generally considered non-surface active agents and the apparent surface activity is frequently attributed to the presence of small amounts of proteins. However, purified fenugreek gum (with less than 0.6% proteins and used in less than 1%) appears to be more efficient than guar and locust bean gums in lowering interfacial free energy. Fenugreek gum is also more concentration-efficient than gum arabic and xanthan gum in stabilizing oil/water emulsions.

Guar and locust bean gums are the most extensively used gums in the world. In the food industry they are widely used as thickening and stabilizing agents, usually in amounts of <1% of the food weight. They are used as stabilizers to improve shelf-life, to prevent creaming or settling in salad dressings, soft drinks, and fruit juices, to influence crystallization, and to improve freeze-thaw behavior of frozen products such as ice-cream and frozen desserts. They are also used as thickener or water-binding agents in pie fillings, icings, meat products, and pet foods. Addition of guar gum to baked products and pastry reduces the degree of starch retrogradation and improves texture and shelf-life. Guar gum is a potential dietary supplement in weight control and treatment of diabetes and hyperlipidemia. Guar and locust bean gums and their derivatives also have wide applications in other industries including pharmaceutical, mining, paper, textile, and construction (18).

2. Pectins

a. Source and structure

Pectin is a generic name for a group of polysaccharides extracted from cell walls of plant tissues. The main commercial pectins are produced from citrus peels and apple pomace, although other raw materials are also used including sugar beet pulp, sunflower seed head, peach pulp, and potato pulp. Pectin is mainly composed of an α-(1→4)-linked D-galacturonic acid backbone chain interrupted by α-(1→2)-linked L-rhamnose residues and the mole-percent of rhamnose varies with the source of pectin (20). The carboxyl groups of galacturonic acids are partly methylesterified and in certain pectins are partially acetylated. The degree of esterification higher than 50% is defined as high methoxyl (HM) pectin; the degree of esterification lower than 50% is defined as low methoxyl (LM) pectin. The molecules have "smooth regions" consisting of blocks of galacturonic acid residues and "hairy regions" with condensation of the side-chains. Often, arabinan, galactan, or arabinogalactan side chains are attached to the C-4 position of the rhamnose residues. Other sugars such as glucuronic acid, L-fucose, D-glucose, D-mannose, and D-xylose are sometimes found in the side-chains.

b. Functional properties and applications

In the solid state, pectin molecules exist as right-handed helices which are stabilized by intra- and intermolecular hydrogen bonding and/or intermolecular calcium ions forming an ordered and fairly stiff structure. It is generally accepted that the backbone adopts a worm-like conformation in solution. Several studies on the solution properties of pectins suggested that pectin molecules are further aggregated into either rods or segmented rods in solution and held together by non-covalent forces (21).

Pectins are highly heterogeneous with respect to their molecular weight. For isolated and purified pectins, the molecular weight is largely determined by the extraction modes and conditions. The average molecular weight from various fruit sources is typically the order of

10^4~10^5 daltons (22). Pectins are generally soluble in water and the solubility usually decreases with increasing ionic strength and molecular weight and decreasing degree of esterification. Aqueous pectin dispersions show rheological behavior similar to many other commercial polysaccharides, and the viscosity decreases with increasing temperature but increases with increasing concentration. The viscosity of aqueous pectin solutions also depends on molecular weight, degree of esterification, electrolyte concentration, type and concentration of co-solute, and pH. Addition of salts of monovalent cations, such as sodium chloride to pectin, dispersions reduces viscosity (23), whereas the addition of calcium or other polyvalent cations increases viscosity of pectin dispersions. In a calcium-free solution, viscosity decreases when pH is increased. Because of its low molecular weight, pectin is not an efficient thickener compared to other high-molecular-weight polysaccharides.

For both high methoxyl (HM) and low methoxyl (LM) pectins, gels can be prepared at concentration above 0.5~1%. Both high molecular weight and high concentration favor gel formation and enhance gel strength. Other intrinsic and extrinsic factors such as pH, amount and type of co-solutes, and the degree of esterification (DE) are also important with different effects on HM and LM pectins. HM pectins form thermally irreversible gels at sufficiently low pH (pH<~3.6) and in the presence of sugars or other co-solutes at a concentration of greater than ~50% by weight. The DE and overall distribution of hydrophilic and hydrophobic groups have major effects on gelation. Commercial HM pectin is classified as rapid-set, medium-set, and slow-set types. Sucrose and other co-solutes also affect gelation although to a lesser extent. The amount of co-solute required increases with increasing DE. LM pectins require calcium or other divalent cations for gelation, and the reactivity to calcium is governed by the proportion and distribution of carboxyl groups and DE. The relative amount of calcium affects the gelling properties of LM pectins considerably. Gelation is favored by increased soluble solids and decreased pH. LM pectin gels prepared at low pH are thermally reversible whereas those prepared at neutral pH are thermally irreversible.

The main uses of pectins are as gelling agents in various food applications including dairy, bakery, and fruit products. HM pectins have long been used in traditional jams and jellies, whereas LM pectins are used in low-calorie, low-sugar jams and jellies. Pectin gels can be used as an alternative to gelatine in fruit desserts and amidated LM pectins are used to prepare milk gels and desserts. Pectins are also used as a protein dispersion stabilizer in acidified dairy products such as yoghurt and milk-based fruit drinks and other protein drinks prepared from soya and whey. The enhanced emulsion stability is caused by interaction between pectin and protein particles (24).

3. Konjac Glucomannan

a. Source and structure

Konjac mannan, or glucomannan, is prepared from the tubers of the konjac plant (*Amorphophallus konjac*). Konjac is a perennial plant unique to Asia and is specially cultivated in Japan. In the production of konjac flour, two-year-old tubers are sliced into thin chips and subsequently dried and milled. Further purification of konjac flour is achieved by washing with ethanol aqueous solutions to remove proteins, lipids, and soluble salts. Purified konjac flour contains typically 88% carbohydrates, 1.7% ash, 0.9% lipids, and 0.5% protein (25). Konjac polysaccharide is a copolymer consisting of random blocks of β-D-glucose and β-D-mannose in the ratio of 2:3. All the monosaccharide units are joined together by 1→4 linkages with occasional substitutions of acetyl group (5–8%) attached at the 3 position of the mannose or both mannose and glucose residues (26, 27).

b. Functional properties and applications

In the solid state, konjac glucomannan has a crystalline structure. X-ray diffraction characterization revealed that it has extended two-fold helices (28). Konjac glucomannan yields a high viscosity solution, but extra efforts such as extensive stirring are needed to dissolve the gum. The solution is a typical non-Newtonian system showing shear thinning behavior. A thermo-irreversible gel is formed when konjac glucomannan solution is heated in alkali conditions. A possible gelling mechanism is that hydrolysis of the acetyl groups under alkali conditions promotes intra- and intermolecular hydrogen bonding leading to "cross-linking" of the glucomannan molecules. However, this hypothesis cannot explain why the gel is thermo-irreversible. Another interesting property of konjac glucomannan is its synergism with other hydrocolloids. Mixture of konjac glucomannan and xanthan gum form gels at a total concentration as low as 0.1%. Thermo-reversible gels can be prepared when konjac glucomannan is mixed with agarose or carrageenan solutions.

Alkali konjac gel is a popular traditional Japanese food (*Kon-nyaku*). Thermo-reversible gels formed from interactions between konjac glucomannan and other gums also have applications in products such as health jellies. Konjac flour is suitable for thickening, gelling, texturing, and water binding. It is a major ingredient for some vegetarian meat products and is also used in fat-free or low-fat meat products.

4. Soluble Soybean Polysaccharides

a. Source and structure

Water-soluble soybean polysaccharide (SSPS) is the cell wall material of the cotyledons of soybeans. Commercial SSPS is extracted with dilute acid from by-products produced from the manufacturing of soy proteins or tofu.

The extract is filtered and/or centrifuged, and dried to give a yield of ~45% (29).

SSPS is a highly branched pectic polysaccharide. The backbone consists of a galacturonan (GN) and a rhamnogalacturonan (RG). The RG structure consists of a diglycosyl repeating unit: (1→4)-α-D-galacturonic acid-(1→2)-α-L-rhamnopyranose units with β-D-galactan side-chains. The side-chains are substituted with L-fucosyl and L-arabinosyl residues, which are linked to the C-4 of the rhamnosyl residues. The degree of polymerization is estimated to be 43–47 which is longer than those of fruit pectins. SSPS is highly polydisperse in molecular weight. Three to four fractions with molecular weights ranging from 4,700 to 542,000 daltons were identified (30).

b. Functional properties and applications

Similar to gum arabic, SSPS is a low viscosity gum. It is soluble in cold water and exhibits Newtonian flow behavior at a concentration as high as 10%. When the concentration is increased to 20%, it exhibits shear thinning flow behavior. Unlike pectins, the viscosity of SSPS solution is not sensitive to salts, including NaCl, $CaCl_2$ and KCl; however, the viscosity increases with increase in sugar concentration (e.g., sucrose). The viscosity is also sensitive to pH and temperature, decreases with decrease in pH and increase in temperature, and the effect is reversible.

SSPS could be used in the food industry as a stabilizing and thickening agent. Addition of 10% SSPS has less effect than wheat bran on color and surface smoothness of Chinese steamed bread but has a stronger detrimental effect on volume and texture (29). Recent applications of SSPS include stabilizing milk proteins under acidic conditions (31).

5. Flaxseed Gum

a. Source and structure

Flaxseed gum is extracted from the seed or hull (seed coat) of the flax plant (*Linum usitatissimum*). Flaxseed gum is composed of a neutral arabinoxylan and acidic pectic polysaccharide. The neutral arabinoxylan has a (1→4)-β-D-xylosyl backbone to which arabinose side-chains are attached to the 2 and/or 3 positions. The acidic polysaccharide has a backbone of (1→2)-linked α-L-rhamnopyranosyl and (1→4)-linked D-galactopyranosyluronic acid residues, with side-chains of L-fucose and D-galactose, with the former at the non-reducing end. The ratio of L-rhamnose, L-fucose, D-galactose, and D-galacturonic acid is 2.6:1:1.4:1.7 (5, 32).

b. Functional properties and applications

Flaxseed gum exhibits Newtonian flow behavior at low concentrations and shear thinning behavior at high concentrations. Flaxseed gum is a low to medium viscosity gum and the viscosity is influenced by pH, with higher viscosity at pH 6–8, and lower viscosity at pH 2–6. Viscosity of flaxseed gum solutions decreases with increase in temperature. Flaxseed gum demonstrates surface activity and the ability to stabilize oil/water emulsions.

In food applications, flaxseed gum has been used as an egg white substitute in bakery products and ice creams. It can be used in medicinal preparations, e.g., ointments and pastes containing flaxseed gum are effective in the treatment of furunculosis, carbunculosis, impetigo, and ecthyma (33). Flaxseed gum is used as a bulk laxative, a cough emollient agent, and a stabilizer in barium sulphate suspensions for X-ray diagnostic preparations (34). Flaxseed gum solution is also used as a saliva substitute because it possesses lubricating and moisture-retaining characteristics resembling those of natural saliva (35). The stringy and fast drying properties of flaxseed gum make it suitable for hairdressing preparations and hand cream formulations. At 2.5% concentration, flaxseed gum is a good base for eye ointments. Other applications of flaxseed gum include printing, textile, and cigar papers.

6. Yellow Mustard Gum

a. Source and structure

Yellow mustard gum is a mucilage deposit in the epidermal layer of yellow mustard seed (*Sinapis alba)*. It is water-soluble and can be extracted from whole seed or seed coat (bran). Yellow mustard gum is a mixture of two polysaccharides, a linear 1,4-linked β-D-glucan with ethyl substitutes and a branched acidic rhamnogalacturonan composed of, disaccharide repeating unit: (1→2)-α-L-Rhamp-(1→4)-α-D-GalpA as backbone chains. The side-chains are composed of a terminal non-reducing end 4-O-Me-β-D-GlcpA, and/or (1→6)-β-D-Galp which is attached at the 4 position of the rhamnose residues in the backbone chain. The ratio of the 4-substituted and unsubstituted rhamnose is 2:1 (5).

b. Functional properties and applications

Yellow mustard gum solution/dispersion is a non-Newtonian system exhibiting shear thinning flow behavior and weak gel structures resembling xanthan gum. It also demonstrates surface activity and emulsifying capacity. The gum solution has a high viscosity over a wide range of pH. Similar to xanthan gum, yellow mustard gum has synergistic interactions with galactomannans leading to considerable increase in solution viscosity or formation of thermo-reversible gels (e.g., with locust bean gum).

Yellow mustard gum is an ideal stabilizer for salad dressings and fruit juice concentrates. It is also used in cosmetics, e.g., a skin care moisturizing lotion prepared using this gum gives a favorable hand feeling (36).

7. Cereal β-Glucan

a. Source and structure

Mix linked (1→3)(1→4)-β-D-glucans are cell wall polysaccharides of cereal endosperm and aleurone cells. The content of β-D-glucans in cereals follows the order of

barley (3–11%), oats (3.2–6.8%), rye (1–2%), and wheat (<1%). It is a linear, unbranched polysaccharide containing a single type of monosaccharide, β-D-glucose. β-D-Glucans from different cereals share a common structural feature: with consecutive blocks of (1→4)-linked β-D-glucose (mostly 2 or 3, and sometimes up to 14) interrupted by a single (1→3)-linked β-D-glucose. The β-(1→3)-linked cellotriosyl unit (trisaccharide) is the major building block (58–72%), followed by β-(1→3)-linked cellotetraosyl unit (tetrasaccharide, 20–34%). The ratio of cellotriose/cellotetraose is about 2.0–2.4 in oats, 3.0 in barley, and 3.5 in wheat (37).

b. Functional properties and applications

β-D-Glucan solution exhibits a wide range of rheological behavior, from viscoelastic fluid, weak gel to real gel, depending on molecular weight and concentration. Solutions of high-molecular-weight β-D-glucans are typically viscoelastic fluids of the "random coil" type. In contrast, low-molecular-weight β-glucans are able to form gels at reduced temperature or favored solvent properties. The gelling property depends on molecular weight and structural regularity (tri-/tetra ratio). The higher the tri-/tetra ratio, the more regular is the structure, and the easier in gel formation. Above the minimum molecular weight for gelation, lower molecular weight favors gel formation (5, 38).

Commercially, there are two β-D-glucan products: Oatrim and Glucagel. Oatrim is made by treating oat bran or flour with a thermo-stable α-amylase at high temperature. Its main component is dextrins, but its functionality appeared to be attributed to β-glucans and dextrins. Oatrim is used in bakery products, frozen desserts, processed meats, sauces, and beverages. Because it mimics the texture of fats, Oatrim is also used as a fat replacer in low-fat or no-fat products (39).

Glucagel is produced by partial hydrolysis of barley β-D-glucan and is a low-molecular-weight product (15,000 to 150,000 daltons) which can form gels at 2% concentration. Glucagel has gelling and fat mimetic properties and is used as a fat substitute in bakeries, dairy products, dressings, and edible films (40, 41).

Oat β-D-glucan is recognized as having important health benefits. It may lower cholesterol levels and reduces glycemic response, and is recommended as a good dietary fiber supplement. Oat β-D-glucan is also used in cosmetics as a moisturizer in lotions and hand creams.

8. Psyllium Gum

a. Source and structure

Psyllium gum is from the seed of *Plantago*, a plant comprising about 200 species of herbs or shrubs widely distributed in the temperate regions of the world. The gum is deposited in the seed coat (husk, hull), and has a long history of medicinal use.

Psyllium gum is a mixture of polysaccharides containing heteroxylans with a (1→3)- and (1→4)-linked β-D-xylopyranosyl backbone with short side-chains attached to position 2 of some of the 1,4-linked β-D-xylopyranosyl residues and to position 3 of other 1,4-linked β-D-xylopyranosyl residues (42). The side-chains consist of β-D-xylopyranosyl and α-L-arabinofuranosyl residues. 1→4-linked α-D-GalpA residues are also present in addition to small amounts of 1,2,4-linked Rha*p* and 1,3-, 1,6-, and 1,3,6-linked Gal*p*. The latter monosaccharides may arise from a small portion of pectic polysaccharides.

b. Functional properties and applications

Psyllium gum does not dissolve completely in water but swells to a mucilagenous dispersion with the general appearance of wallpaper paste (33, 43). A 2.0% psyllium gum dispersion exhibits gel-like structure, similar to that of xanthan gum which generates a "weak-gel" network by entanglement of rigid, ordered molecular structures (44). Increasing the concentration of psyllium gum from 1% to 2% gives a significant increase in gel strength. However, freshly prepared solutions/dispersions of psyllium gum (1%) show flow properties similar to those of disordered coils, with a Newtonian plateau at low shear rate. Upon aging, psyllium gum solutions form cohesive gels and show obvious syneresis. The gels continue to contract on storage over long periods (to about 30% of their original volume after three months). This contraction process can be accelerated by freezing and thawing cycles. However, psyllium gum is stable in high-salt solutions (e.g., 2.5 M NaCl) which are formed by neutralization of the alkaline extract over a prolonged storage, with no evidence of gelation or precipitation.

Psyllium gum is used with other gums in bakeries to replace wheat gluten. Adding psyllium gum and hydroxypropylmethylcellulose (HPMC) at 2% and 1%, respectively, to rice flour gives a loaf volume close to that of hard wheat control (43). The effectiveness of the psyllium-HPMC system arises from the psyllium network stabilizing gas cells formed during proving, and preventing them from collapsing during initial stages of heating in the baking oven. When temperature is further increased, HPMC starts to gel and stabilizes the gas cells.

As a dietary fiber, psyllium gum lowered plasma LDL-cholesterol levels by 6–20% in mildly hypercholesterolemic individuals, although conflicting results were reported (45, 46). Psyllium gum has been used as a demulcent in dysentery, erosion of intestines, dry coughs, burns, excoriations, and inflammations of the eyes (33, 47). It is extensively used as a bulk laxative. When ingested with the proper amount of water, it swells and increases the size of the fecal mass, and has a lubricant effect equal to that of oil but without oil's disadvantages. The water-holding capacity and gelling property of psyllium gum can be used to delay and reduce allergic reactions by holding toxins and allergens in the gel structure.

9. Pentosans/Arabinoxylans

a. Source and structure

Arabinoxylans or pentosans are the primary construction material of the cell wall in some cereals, such as wheat and rye, and are also present in oats and barley. According to solubility, cereal arabinoxylans are classified as water-soluble and water-insoluble. The water-soluble wheat arabinoxylans are present mainly in the flour (endosperm cell walls), while the water-insolubles can be found in both the bran and flour fractions. Insoluble arabinoxylans are cross-linked with proteins through phenolic ester bonds which can be rendered water-soluble by treating with alkali or specific enzymes.

Arabinoxylans consist of a backbone of (1→4)-linked β-D-xylopyranose residues to which α-L-arabinofuranose units are attached through O-3 and/or O-2,3 positions of the xylose residues. The distribution of the α-L-arabinosyl branches along the backbone chain are random with some regions heavily substituted and others unsubstituted (smooth domain) (48). The pattern and degree of substitution vary with cereal sources and tissue locations in the grain.

b. Functional properties and applications

Arabinoxylans are random coil polysaccharides in aqueous solutions, and exhibit Newtonian flow behavior at low concentrations and shear thinning behavior at higher concentrations. Because of the presence of ferulic acid, wheat flour arabinoxylans can form thermo-irreversible gels upon oxidation (48). In comparison, arabinoxylans from wheat bran can form thermo-reversible gels upon cooling (5). Wheat and rye arabinoxylans are important functional ingredients in baked products affecting water binding, dough rheology, and starch retrogradation. They also protect gas retention in dough due to viscous influence on the gluten-starch films (49).

C. Gums from Seaweeds

Seaweed or algae is an important natural source for hydrocolloidal gums. Most seaweed extracts are gelling agents. However, their chemical compositions and structures vary significantly due to the sources of raw material and processing conditions, so do their gelling mechanism.

1. Agar

a. Source and structure

Agar, or agar agar, is extracted from red seaweeds (*Rhodophycae*). It is commercially obtained from *Gelidium* spp. and *Gracilariae* spp. The Japanese are pioneers in processing agar, called "*Kanten*" in Japanese, meaning "cold days" or "cold weather," reflecting the weather conditions used to remove water from agar gels through freeze-thaw cycles which are still being used in modern agar processing plants. The alternative procedure is a syneresis method, in which the absorbed water is eliminated by applying a proper force.

Agar contains a major component, agarose, and a minor component, agaropectin. Agarose is the gelling component which has a molecular weight about 120,000 daltons. It is a linear polymer consisting of a (1→3)-β-D-galactopyranosyl and (1→4)-3,6-anhydro-α-L-galactopyranosyl residues as building units. Agaropectin is a heterogeneous mixture of polysaccharides of lower molecular weights. Their structures are similar to agarose but slightly branched and sulfated, and they may also have methyl and pyruvic acid ketal substituents (6, 50).

b. Functionality and applications

Agar is referred to as the queen of the gelling agents. The gelling property is due to the three equatorial hydrogen atoms on the 3,6 anhydro-L-galactose residues of agarose to form hydrogen bonds. The gel network contains double helices formed from left-handed threefold helices. These double helices are stabilized by the presence of water molecules bound inside the double helical cavity. Exterior hydroxyl groups allow aggregation of these helices to form suprafibers. The gelling temperature is around 38°C and the melting temperature is about 85°C, which gives very high gelling hysteresis. With this enormous gelling power and hysteresis property, agar has found broad applications in food and other industries. It is used in the baking industry because of its heat-resistant gel properties, and is widely used as a stabilizer in pie fillings, icings, toppings, and glazes. The heat-resistant gelling properties help to prevent chipping, cracking or sweating of icings, toppings, and glazes in baked goods. Agar is particularly effective in forming a stiff gel at low concentrations and it is compatible with most other gums. At around 40°C and upon setting, agar gel forms an impervious moisture barrier between icing and wrapping and it has the unique property of not sticking to the wrapping. Agar is also widely used in the confectionary industry as a gelling agent, and in preparing canned meat, fish, and poultry products.

Addition of a small portion of locust bean gum to *Gelidium* agar (1:9) may enhance gel strength and improve gel texture; in particular, it increases the elasticity of the gel (6). This is due to the synergistic interaction between locust bean gum and agar which has practical applications in the food industry where less brittle texture is desired. However, this interaction is only limited to agar from species of *Gelidium* and *Pterocladia.* Due to its excellent gelling characteristics and high resistance to metabolization by microorganisms, agar is used in biotechnology applications such as in microbiological culture media where it forms clear, stable, and firm gels.

2. Algin (Alginates)

a. Source and structure

Alginates or algin are the salts and derivatives of alginic acid, an acidic polysaccharide extracted from the brown seaweeds (Phaeophyceae). The main species of commercial significance include *Laminaria hyperborea*, *L. digitata*, *L. japonica, Macrocystis pyrifera, Ascophyllum nodosum*, *Eclonia maxima, Lessonia nigrescens, Durvillea antarctica*, and *Sargassum* spp. Natural alginate is insoluble due to its salt derivatives obtained during growth in seawater, including calcium, magnesium, and barium salts. In order to extract the material, a pre-extraction treatment is necessary to convert the insoluble cations into protons by treating milled algae tissue with dilute mineral acids. The next step is to neutralize with sodium carbonate or sodium hydroxide, and alginic acid is converted into water-soluble sodium salt. Following the removal of algal particles by sifting, floatation, centrifugation, and filtration, sodium alginate is precipitated by alcohol, calcium chloride, or mineral acids. A derivative of alginate, propylene glycol alginate (PGA), is produced from alginate by an esterification reaction with propylene oxide.

Alginate is an unbranched polymer containing β-(1→4)-linked D-mannuronic acid (**M**) and α-(1→4)-linked L-guluronic acid (**G**) residues (3, 51). It is a copolymer composed of three types of blocks: two homopolymeric blocks consisting of the same residues of M or G, respectively, and a block with strictly alternating residues (i.e., GMGMGMGM). The lengths and sequences of the three blocks vary considerably with the source of algae, place and season of collection, as well as part of the algae from which the alginate is extracted. The differences in chemical structures account for their differences in functionalities and applications.

b. Functional properties and applications

In commercial alginate products, the following factors are important in determining functionality: type of cations, M/G ratio, molecular weight and residual calcium. Sodium salt is the most common form of alginates. Potassium, ammonium, and calcium salts and free alginic acid are also available (3).

The primary function of alginates is to form thermally stable cold-setting gels in the presence of calcium ions. Alginate gels can be heat treated without melting although they may eventually degrade. Gelling properties and gel strengths of alginate gels depend on the type and mode of ion binding ($Mg^{2+} << Ca^{2+} < Sr^{2+} < Ba^{2+}$) (52). Therefore, the control of cation addition is critical for the production of homogeneous gels. High **G** alginates produce strong brittle gels with good heat stability (except if present in low-molecular-weight molecules), but water weepage (syneresis) occurs on freeze-thaw whereas high **M** alginates produce weaker but more elastic gels with good freeze-thaw stability. Two basic methods have been used to control the introduction of cross-linking ions: diffusion and internal setting. The diffusion method lets the cross-linking ion (e.g., Ca^{2+}) diffuse from an outer reservoir into an alginate solution which is used for the restructuring of foods such as artificial berries, pimiento strips, and onion rings. Internal setting differs from the former in that the Ca^{2+} ions are released in a controlled fashion from an inert calcium source within the alginate solution. The controlled release of Ca^{2+} is usually achieved by a change of pH and/or by limited solubility of calcium salt. The internal setting gels found wide applications in food, pharmaceutical, and cosmetic applications, such as cold water dessert gel, instant imitation bakery jelly, and facial masque (52).

The molecular weights of commercial alginates are between 12,000 and 190,000 daltons. Higher-molecular-weight favors gel strength and viscosity enhancement. However, it is sometimes desirable to use a higher concentration of low-molecular-weight alginates to obtain strong gels and to avoid excessively high viscosity prior to gelation.

Chemically modified alginates, e.g., propylene glycol esters of alginic acid (PGAs), are very different from alginates in functionality. They are much more tolerant to calcium ions and acidic environments such as in milk-based products and salad dressings (51). PGAs also exhibit surface activities due to esterification, and can be used as an emulsifier and foam stabilizer.

3. Carrageenans

a. Source and structure

Carrageenans are popular seaweed gums extracted from red seaweed (Rhodophycae). The main species used are *Eucheuma cottonii, E. spinosum. E. cottonii*, and *E. spinosum* which are spiny bushy plants growing along the coasts of the Philippines, Indonesia, and other islands in the Far East. Other species of commercial significance include *Chrondrus crispus* from around the coasts of the North Atlantic and *Gigartina* sp. from the cold deep coastal waters of South America. Based on the origins and processing conditions, three types of carrageenan gums are on the market, namely kappa (κ), iota (ι), and lambda (λ) carrageenans. The process of producing carrageenan gums is rather complex, involving washing and cleaning of the seaweed, alkaline extraction, followed by coarse and fine filtrations, solvent precipitations and/or freeze-thaw cycles and finally, drying, grinding, and blending.

Carrageenan gums consist of alternating (1→3)-linked-β-D-galactopyranose and (1→4)-linked-α-D-galactopyranose sugar units. The three gums differ from one another in their content of 3,6-anhydro-D-galactose and number and position of ester sulfate groups (53).

κ-Carrageenan is composed of alternating (1→3)-β-D-galactopyranose-4-sulfate and (1→4)-3,6-anhydro-α-D-galactopyranose units. It is produced by alkaline elimination of μ-carrageenan isolated mostly from the tropical seaweed *Eucheuma cottonii* (also known as *Kappaphycus alvarezii*). Typical food grade κ-carrageenans contain 25% of ester sulfate and 35% of 3,6-anhydro-D-galactose, which is close to the theoretical maximum.

ι-Carrageenan is composed of alternating (1→3)-β-D-galactopyranose-4-sulfate and (1→4)-3,6-anhydro-α-D-galactopyranose-2-sulfate units. ι-Carrageenan is produced by alkaline elimination of μ-carrageenan isolated from the Philippines seaweed *Eucheuma denticulatum* (also called *Spinosum*). The major difference between κ- and ι-carrageenan amount of 2-sulfate on the 1,4-linked 3,6-anhydro-D-galactose. As the degree of sulfation increases from 25% in κ- to about 50% in ι-carrageenans, there is a noticeable weakening of gelling properties arising from decreased potassium sensitivity.

λ-Carrageenan is mainly composed of (1→3)-β-D-galactopyranose-2-sulfate-(1→4)-α-D-galactopyranose-2,6-disulfate repeating. It is isolated mainly from *Gigartina pistillata* or *Chondrus crispus* and can be converted into θ-carrageenan (theta-carrageenan) by alkaline elimination.

b. Functional properties and applications

All carrageenan gums are highly flexible molecules which, at higher concentrations, interact with each other to form double-helical zones (3). Food-grade carrageenans have molecular weights in the range of 2–4 × 10^5 daltons. Gel formation of κ- and ι-carrageenans requires gel-inducing and gel-strengthening cations, such as K^+ and/or Ca^{2+} and it involves helix formation upon cooling from a hot solution. Carrageenans are used mainly as gelling, thickening, and suspending agents. κ-Carrageenan gels are firm, clear, and brittle with poor freeze-thaw stability. These gels may be softened (and are generally regarded to be synergistically strengthened) by mixing with locust bean gum. Ionic binding of ι-carrageenan is less specific and increasing ionic strength promotes formation of junction zones leading to soft elastic gels with good freeze-thaw stability. λ-Carrageenan is non-gelling as it lacks 3,6-anhydro groups in the 1→4-linked α-D-galactopyranosyl residues which are necessary for forming the initial double helix. λ-Carrageenan can act as a cryoprotectant, and a combination of λ-carrageenan with locust bean gum improves the freeze-thaw behavior of frozen products (54).

κ-Carrageenan stabilizes dairy products due to its interactions with casein micelles (~200 nm diameter), preventing whey separation. It is used in ice creams as a second stabilizer to prevent LBG and β-casein from phase separation (55). Carrageenan is also used as a water binder in cooked meats and as a thickener in toothpaste and puddings.

D. Gums from Microbial Fermentation

Some microorganisms produce slimy materials such as extracellular polysaccharides, structural polysaccharides, or intracellular storage polysaccharides. The extracellular polysaccharides are water-soluble and exhibit unique functional properties, and are hence an important source of hydrocolloids. Since the fermentation process can be controlled and processed in large quantity, gums from microbial production are more consistent than naturally occurring gums.

1. Xanthan Gum

a. Source and structure

Xanthan gum is an extracellular polysaccharide produced commercially by aerobic submerged fermentation from *Xanthomonas campestris* (56). The primary structure of xanthan gum is a β-(1→4)-D-glucopyranosyl backbone with tri-sugar unit side-chains consisting of a β-D-glucuronic acid residue between two D-mannopyranosyl residues, which is attached to the backbone at the 3-position of alternative β-D-glucosyl residues. In the side-chains, the terminal β-D-mannosyl residue is glycosidically linked to the 4-position of the β-D-glucuronic acid, which in turn is linked to the 2-position of the α-D-mannose. About 40% of the terminal mannose residues are 4,6-pyruvated while almost all the inner mannose is 6-acetylated (57).

b. Functional properties and applications

Xanthan is considered a non-gelling gum and is best known for its unique shear thinning flow behavior and weak gel structures. It hydrates rapidly in cold water, but proper hydration depends on particle size, solvent quality, and rate of agitation. Since the viscosity of xanthan gum solutions/dispersions is relatively temperature independent and the polymer is resistant to acids, alkali, and enzymes, it is a popular thickener and stabilizer in the food industry. The most striking property of xanthan gum is the very high low-shear viscosity coupled with its strongly shear-thinning characteristics. The relatively low viscosity at high shear rate provides the advantages of easy to mix, pour, and swallow, and the high viscosity at low shear rate gives good suspension and coating properties to colloidal suspensions at rest. This makes xanthan gum a perfect stabilizer for salad dressings, sauces, gravies, syrups, and toppings. In dairy products, such as ice creams, sour cream, and sterile whipping cream, xanthan gum provides optimal viscosity, long-term stability, improved transfer characteristics during processing, heat shock protection, and ice crystal control. In baked goods, xanthan gum contributes to smoothness, air incorporation and retention, hence improved volume, texture, and moisture retention of refrigerated dough. Blending of xanthan gum with dry cake ingredients helps uniform hydration

and batter mixing, which are important for the overall quality of finished cakes, particularly after storage (58).

Xanthan gum exhibits pronounced synergistic interactions with galactomannans and glucomannans (59, 60). These interactions result in increased viscosity, and in some cases formation of thermo-reversible, soft elastic gels. Experimentally, mixture of xanthan-locust bean gum forms thermo-reversible gels at polymer concentrations as low as 0.1%; in contrast, xanthan-guar gum mixtures only exhibit increased viscosity regardless of the concentration. It is necessary to heat the mixtures to about 90 to 95°C to achieve maximum synergism as this not only unfolds the xanthan structure but also helps to fully hydrate the locust bean gum. The extent of interaction between xanthan gum and galactomannans is reduced at low pH and high salt concentrations. The optimum ratio of interaction is 50:50 for xanthan–LBG mixture and 20:80 for xanthan–guar mixture (4).

2. Gellan Gum

a. Source and structure

Gellan gum is a bacterial exocellular polysaccharide, commercially produced by inoculating a fermentation medium with *Sphingomonas elodea* (ATCC 31461). Gellan gum is composed of a linear tetrasaccharide repeating unit: →3)-α-D-glcp- (1→4)-β–D-glcpA-(1→4)-β-D-Glcp-(1→4)-α-L-rhap-(1→ (61, 62). There are two acyl substitutions on the 3-linked glucose, a L-glyceryl at O(2) and an acetyl at O(6) positions. The average degree of substitution is one glycerate per repeat unit and one acetate every two repeats.

b. Functionality and applications

The functional property of gellan gum is dependent on the degree of acylation and presence of counter ions. High acyl (HA) gellan gum can form soft, elastic, transparent, and flexible gels by cooling the hot solutions when concentration is above 0.2%. The gels set and melt at 70–80°C with no thermal hysteresis and the gelling property is not affected by the presence of counter ions. In contrast, low acyl (LA) gellan gum forms hard, non-elastic brittle gels when binding with a wide variety of ions, such as Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, and H^{+}; the divalent ions are more efficient than the monovalent ions in promoting gelation. The gel strength of LA gellan gum increases with increasing ion concentration until a maximum is reached. Increase of ion concentration also results in increased gel setting and melting temperatures. Sugar has a negative influence on the gelation of LA gellan gum which is often described to have a 'snap set' since gelation occurs rapidly once the setting temperature is reached. In contrast to HA gellan gum, significant thermal hysteresis is observed for LA gellan gels. However, under most conditions, LA gellan gels are not thermo-reversible below 100°C. The minimum gelling concentration of LA gellan gum can be as low as 0.05% in the presence of cations (63).

Both LA and HA gellan gums are commonly used as gelling agents and can be used to prepare dessert jellies with a variety of textures. Gellan gum is used in dairy products and sugar confectionery. LA gellan gum is used to modify traditional gelatin dessert jellies. An interesting application of gellan gum is to prepare structured liquids by applying shear stress either during or after gelation. These structured liquids are extremely efficient suspending agents (61).

3. Curdlan Gum

a. Source and structure

Curdlan gum is an extracellular polysaccharide commercially produced by microbial fermentation of a mutant strain of *Alcaligenes faecalis* var. *myxogenes*. Curdlan is a linear, homopolymer composed entirely of (1→3)-β-D-glucosidic linkages. Native curdlan has a granular structure and is water-insoluble but can be dissolved in sodium hydroxide solutions (64), cadoxen aqueous solution, and dimethyl sufoxide (DMSO).

b. Functional properties and applications

Curdlan gum can form gels by heating the suspensions or reduce the pH of an alkali solution. Heat treatment of curdlan suspensions may produce two types of gels, depending on temperature. A thermo-reversible low-set gel is obtained by heating gum suspensions at 55°C followed by cooling. A thermo-irreversible high-set gel requires heating up to 80°C or higher. The gel strength increases with heating temperature (gelation starts at 55°C) but stays constant between 60–80°C. Further increase in temperature results in steady increase of gel strength (64, 65). At the same heating temperature, gel strength increases with increased concentration. The addition of co-solute also has significant effects on gel strength, e.g., adding borate to curdlan suspension significantly increases gel strength, and adding urea markedly reduces gel strength (65).

Curdlan is a tasteless, odorless, and colorless product with wide food applications. It is used in making tofu noodles and other processed cooked foods as texture modifier, binding, and moisture improvement agents. Curdlan is used in noodle dough to reduce leaching of soluble ingredients, giving a clear broth with improved texture and mouthfeel. Addition of curdlan in processed meats modifies texture and improves water-holding capacity. Other food applications include processed rice cake, ice creams, jellies, sausages, and hams. It is also a popular low-energy ingredient in dietetic foods.

4. Dextran

a. Source and structure

Dextran is a group of α-glucans produced by exocellular bacteria Lactobacillaceae, particularly the genera *Lactobacillus, Leuconstoc*, and *Streptococcus*. Commercially important dextran is produced by *Leuconstoc mesenteroides* B-512 (F) (66). Dextran is a homo-polysaccharide composed primarily of 1→6-linked α-D-glucopyranose units (~95%) with branches at C-3 and/or C-4, occasionally at C-2. About 80% of the branches are single D-glucose. The molecular weight of dextrans can be 40 to 600 million daltons, however, the molecular weight of commercial food-grade dextrans is below 100,000 daltons.

b. Functional properties and applications

Dextran is a fine, white powder, very soluble in both cold and hot water giving clear solutions with low viscosity. A solution can be made to contain up to 50% dextran. The viscosity of dextran solution (2%) is independent of shear rate and unaffected by co-solutes, salts, or changes in the pH (3–10). Dextran has good water-holding capacity and imparts good bodying attributes to liquid systems. It also exhibits effective emulsifying and stabilizing properties.

The most important use of dextran is as a blood plasma extender with strict control of molecular weight (75,000 ± 25,000 daltons). Other pharmaceutical applications include cryo-protective agent to protect cells from freezing damage, suspending agent for X-ray opaque compositions, binder for tablets, stabilizing agent for water-insoluble vitamin preparations and a stomach-irritant preventive, a pharmaceutical taste masking agent, and a drug encapsulating agent in combination with methycellulose.

Dextrans with molecular weight below 100,000 daltons are permitted by the U.S. Food and Drug Administration as Generally Regarded as Safe (GRAS) until their deletion in 1973 due to the lack of use (67). The apparent lack of interest in dextran in foods is probably due to its high solubility and low solution viscosity (66). Bread prepared from yeast-raised dough containing 1–2% dextran was soft with a greater volume and longer shelf-life (68). The addition of dextran (up to 0.5%) to ice cream conferred excellent stability and heat-shock resistance. Dextran can be used as a stabilizer for confectionery to prevent crystallization, improve moisture retention, increase viscosity, and maintain flavor. It can also be used in soft drinks, flavor extracts, milk beverages, and icing compositions. Other food applications include fish products, meats, vegetables, and cheeses.

E. Chemically Modified Gums

Cellulose is the most abundant polysaccharide in plants. Natural cellulose is completely insoluble in aqueous media due to extensive intra- and intermolecular hydrogen bonding. However, certain treatments and chemical modification can render cellulose water-soluble and the derived products exhibit unique functional properties, making them useful as hydrocolloids in many industrial applications. About a third of the purified cellulose is used as base material for water-soluble derivatives and a wide range of products with designed properties, depending on the groups involved and degree of derivatization.

1. Microcrystalline Cellulose (MCC)

a. Source and structure

Microcrystalline cellulose (MCC) is produced by treating purified cellulose with a strong mineral acid, such as hydrogen chloride (69). Acid hydrolysis removes the amorphous regions of cellulose and gives a product consisting primarily of crystallite aggregates. Powdered MCC is produced by drying the acid hydrolysates. Dispersible MCC can be prepared by further processing the hydrolysates by wet mechanical disintegration, which breaks up the aggregates to microcrystals, followed by co-processing with a hydrophilic barrier or other hydrocolloids, such as guar gum, xanthan gum, or carboxylmethylcellulose.

b. Functional properties and applications

Colloidal MCC exhibits thixotropic flow behavior in which viscosity decreases with increase in shear stress, and once the stress is removed, viscosity will recover gradually over time (70). MCC dispersions have good thermo-stability which is useful in the preparation of heat-stable products. MCC can also be used to modify textures, resulting in a cleaner mouthfeel and good flavor release, and making a useful fat replacer in emulsion products. In addition, MCC is a good suspending agent for particles and solids.

MCC has many applications in pharmaceutical, food, and paper industries. Examples include bar mixes to add creaminess and pulpiness. In batters and breadings, MCC improves cling and reduces drying time and fat absorption during frying. MCC also adds creaminess in chocolate drinks in addition to its ability to suspend solids and add opacity to the product (69).

2. Carboxymethylcellulose (CMC)

a. Source and structure

Carboxymethylcellulose (CMC) is produced by reacting alkali cellulose with monochloroacetic acid. The substitution is mostly at 2-O and 6-O, occasionally at 3-O positions. The degree of substitution (DS) is generally 0.6–0.95 per monomeric unit (maximum DS is 3) (62, 71).

b. Functional properties and applications

CMC is readily dissolved in cold water, with maximum viscosity and best stability at pH 7–9. The rheological

properties of CMC are determined by the uniformity of substitution and degree of polymerization (DP). CMC solutions with medium to high DP are pseudoplastic, whereas solutions of low DP exhibit low viscosity and are less pseudoplastic. Medium and high viscosity gum solutions with 0.4–0.7 DS, especially those that are less uniformly substituted, are thixotropic. In contrast, evenly substituted, high DS, medium and high DP gums show no or less thixotropic behavior in solutions (71).

Gelation of CMC can be induced by adding trivalent metal ions (e.g., aluminum) or subjecting the solution to high shear. Gels ranging from soft to very firm can be prepared by selecting different grades of CMC and types of metal ions. The gel structure is also dependent on polymer concentration, DP, pH, and metal cation to carboxylate anion ratio.

Food grade CMC is widely used in the food industry as a thickener, stabilizer, and suspending agent. CMC can be used to improve the volume yield during baking by encouraging gas bubble formation; it is also used in frozen desserts and soft-serve ice creams to control ice crystal growth, and to improve mouthfeel, body, and texture. CMC is used in pet food to bind water, thicken gravy, aid extrusion, and bind fines. Because CMC is insoluble in acidic stomach fluids but soluble in alkaline intestinal fluids, it is a good coating for powders and tablets in the pharmaceutical industry. In the cosmetic industry, CMC is used as a stabilizer for hand lotions and vitamin-oil emulsions. CMC also found applications in textiles and detergents (62).

3. Methylcellulose

a. Source and structure

Methylcellulose (MC) is prepared by etherifying the available hydroxyl groups of cellulose chain by conversion of cellulose into alkali cellulose in sodium hydroxide, followed by reaction with methyl chloride (62). Many MC derivatives are available, but the most important one is hydroxypropylmethylcellulose (HPMC).

b. Functional properties and applications

MC solutions exhibit shear thinning flow behavior at 0.5% concentration and above. The pseudoplastic property is enhanced with increases in concentration and molecular weight. A unique functional property of MC and HPMC is their inverse temperature solubility and thermo-gelling property; they can form gels when the temperature reaches above a critical level due to hydrophobic interactions between high-substituted regions, which consequently stabilizes intermolecular hydrogen bonding. The gels break down upon cooling. Another unique property of MC and HPMC is their surface activity, making them useful emulsifiers for oil-in-water emulsions.

Due to the multifunctional properties, MC and HPMC are used as emulsifiers and stabilizers in French dressings and in low-oil or no-oil salad dressings (72). MC is often used in fried foods to reduce oil absorption through film formation and thermal gelation. In addition, batter adhesion and matrix food cohesion are improved by adding MC and/or HPMC. MC is used in baked goods including cakes, doughnuts, breads, cookies, fruit pie fillings, icings, and glazes. The thermal gelation property prevents boil-over of pastry fillings and aids gas retention during baking. MC retards water migration in frozen baked products during freeze-thaw cycles. MC is also used in non-dairy whipped toppings because of its surface active properties. In the pharmaceutical industry, MC is used in tablet film coating, controlled drug release and ointments. MC and its derivatives are also used as adhesives for wallpapers, controlled release agents for pesticides and fertilizers, and emulsifiers and stabilizers in shampoo and hair conditioners.

4. Hydroxypropylcellulose and Hydroxyethylcellulose

a. Source and structure

Hydroxypropylcellulose (HPC) and hydroxyethylcellulose (HEC) are prepared by reactions of alkali cellulose with propylene oxide and ethylene oxide, respectively, at elevated temperature and pressure (62, 73). The substitution patterns of HPC and HEC are random and lead to significant number of hydroxyl groups unsubstituted along the backbone chain. The molar substitution (MS) of commercial HPC is between 3–4; in comparison, commercial water-soluble grades HEC has a much wider MS value, from 1.8 to 3.8. The molecular weight of HPC and HEC ranges from 50k to 1,300k daltons.

b. Functional properties and applications

HPC is soluble in cold water, but becomes insoluble at temperature above 45°C. It has good film forming and surface active properties and can be used to stabilize toppings, especially at high ambient temperatures. HPC is soluble in ethanol, and has potential applications in alcoholic beverages. It is also used as a thickener in solvent-based adhesives, alcohol-based hair dressings, grooming aids, perfumes, inks, and paint removers. In the polymer industry, HPC is used as a secondary stabilizer in the suspension polymerization of vinyl chloride.

HEC with a DS greater than 1.6 is soluble in hot or cold water. The viscosity decreases with increase in temperature. HEC solutions exhibit Newtonian flow behavior at low shear rate and shear thinning behavior at high shear rate. It is useful as a thickener, viscosity control additive, protective colloid, binder, suspending agent, and film former in many industrial applications, including latex paints, emulsion polymerization, petroleum, paper, and pharmaceutical products. The largest use of water-soluble HEC is

for thickening latex paints because of its solubility, low foaming characteristics, high thickening efficiency, and good compatibility with universal coloring systems.

5. Chitin and Chitosan

a. Source and structure

Chitin is the second most abundant natural biopolymer on Earth and is composed of α-(1→4)-linked 2-acetamido-2-deoxy-β-D-glucose (N-acetylglucosamine). Chitin is found in exoskeletons, peritrophic membranes, and cocoons of insects. Chitin is water-insoluble, but can be converted to water-soluble derivatives such as chitosan. Commercial chitin is prepared from shells of lobster, crab, or shrimp which are grounded and treated with 5% hydrochloric acid to remove minerals. The demineralized shell is further processed with pepsin or trypsin to remove proteins. Alkali deproteinization is also used and preferred if the final product is deacetylated chitin, i.e., chitosan. Chitosan is prepared by N-deacetylation of chitin under strong alkali conditions. The degree of acetylation of commercial chitosans is about 0.20 (74, 75).

b. Functional properties and applications

Chitosan is insoluble in organic solvents but soluble in aqueous acidic media. Following protonation of the amino groups, it forms a unique polycationic structure, while other polysaccharides usually give a neutral or anionic structure. Unlike most gelling polysaccharides, chitosan forms gels through chemical and enzymatic reactions. A thermo-irreversible gel can be prepared by treating chitosan in acetate salt solution with carbodiimide to restore acetamido groups. Gelation is probably attributed to hydrophobic interactions which are thermally favored. Chitosan gel can also be prepared by introducing large organic counter ions, such as 1-naphthol-4-sulphonic acid or 1-naphthylamine-4-sulphonic acid.

Chitosan is also chemically modified for specific applications, e.g., a stable and self-supporting gel can be obtained by enzyme treatment of tyrosine glucan, which is synthesized by reacting chitosan with 4-hydroxyphenylpyruvic acid. The enzyme tyrosinase oxidizes phenol to quinine which forms cross-links with the free amino groups. Chitosan can also be cross-linked with glutaraldehyde in lactic acid to produce a colorless, rigid, and infusible gel up to 200°C (74).

Chitin, chitosan, and their derivatives have a wide range of applications in pharmaceutics, biomaterials, foods, water treatments, biotechnology, cosmetics, textiles, and membranes. Chitosan is a good film former and is recommended for textile finishing, paper sheet formation, glass fiber coating, dye application, shrink proofing of wool, photographic application, and cement setting retardation. Chitosan is also used as a dietary fiber for weight control.

IV. FUTURE PROSPECTS AND NEW DEVELOPMENT

There have been continuous efforts in the field of hydrocolloids to reduce production costs, improve functionality, explore novel applications of existing gums, and discover new gums from natural resources. Although the use of new hydrocolloid gums in foods is limited by extremely high costs required to pass legislative approval, there are gums that have long history of use in foods which could easily get approval for food uses. Currently, we have a good understanding of the basic structures and functional properties of most gums, but problems arise on a daily basis at the production level due to inconsistency of the gum supplies and lack of knowledge on how these gums interact with other food ingredients, such as starch, proteins, oils, etc. Therefore, the following areas are recommended for future research: 1) improve manufacturing practice to produce consistent gum products; 2) further understand the structure-function relationships of hydrocolloids and their interactions with other food ingredients; 3) develop new hydrocolloids from natural sources. Most hydrocolloids, particularly non-starch polysaccharides, are conceived as dietary fibers. Some natural polysaccharides or oligosaccharides are biologically active, such as tissue repairing, anti-carcinogenic, anti-inflammatory, and immuno-modulatory. These polysaccharides are potential ingredients for functional foods or neutraceuticals in addition to their role as thickeners and stabilizers. More research should be directed to these bioactive polysaccharides.

5 Food Protein Analysis: Determination of Proteins in the Food and Agriculture System

Richard Owusu-Apenten
Department of Food Science, Pennsylvania State University

CONTENTS

I. INTRODUCTION

A. Definitions and Perspectives

Protein analysis is the development of methods, instrumentation, and strategies for obtaining information about the quantity and composition of proteins within a sample; analysis also extends to the study of the kinetic and thermodynamic behavior of proteins. A food protein is any protein of interest, in food science and technology, in relation to enhancing the supply of food, which is wholesome, nutritious, affordable, and safe. Two broad areas of food protein analysis are readily recognizable: (i) quantitative analysis – determination of the total amount of protein, and (ii) qualitative analysis – fractionation, characterization, and identification of proteins. Of course, so-called qualitative methods also yield quantitative (i.e., numerical) data related to the concentrations of specific proteins in a mixture, molecular mass, isoelectric point, etc.

The major areas of application for food protein analysis are: (a) protein quantitation, (b) protein speciation – including the detection of cultivars, varieties, genetic polymorphism, and adulteration, (c) tests for physical functionality – defined as protein physicochemical properties of interest in food processing, (d) tests for nutritional quality, and (e) detection of bioactive agents including allergens, inhibitors, microbial toxins, as well as functional ingredients. Figure 5.1 summarizes some of the major techniques for food protein analysis

The aim of this chapter is to provide a brief outline of selected techniques for food protein analysis. The principles behind different techniques are well described in the general literature. Less well discussed are the many practical and scientific issues confronted by food protein analysts. In the remainder of Section I, we consider the scope for food protein analysis. Section II covers protein quantitation methods, Section III deals with protein fractionation analysis by

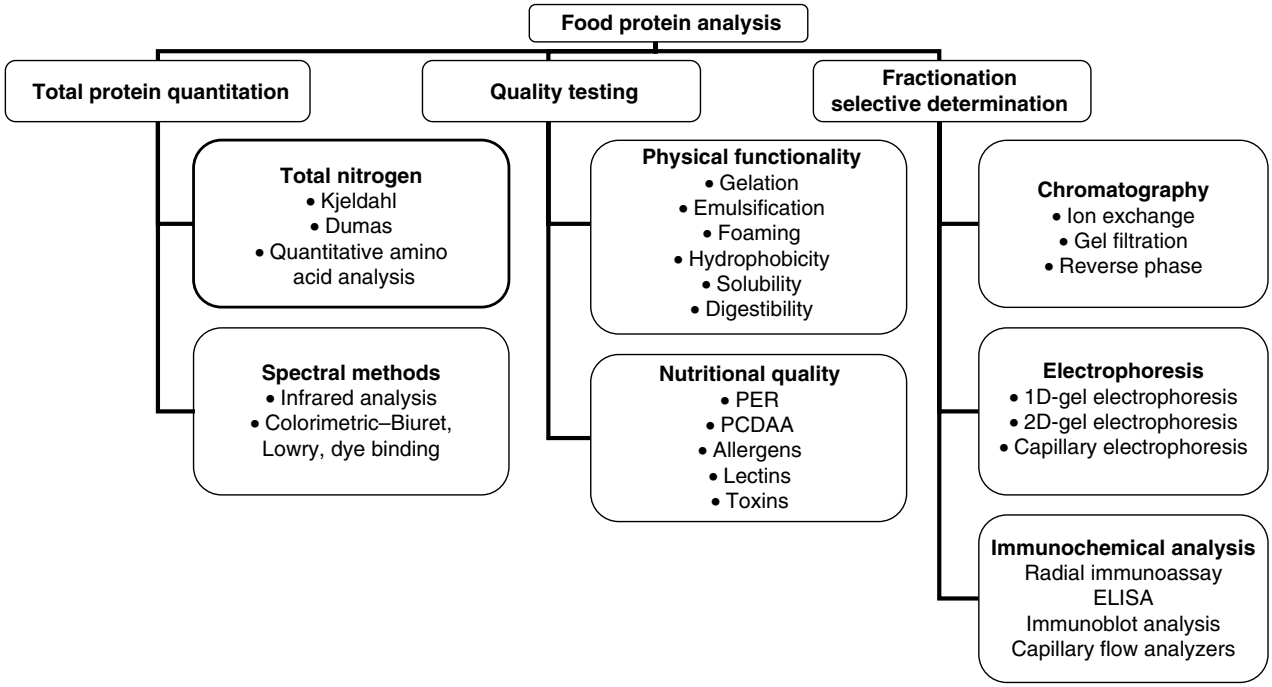

FIGURE 5.1 Some of the major areas of food protein analysis.

electrophoresis, chromatography and mass spectrometry. Section IV provides a brief overview of proteomics, which features high-throughput techniques for protein identification. Food protein analysis is a vast discipline. Only selected themes are introduced in this chapter. Some spectral methods, i.e., colorimetric (e.g., biuret, Lowry, Coomassie blue, bicinchoninic acid, etc.) or spectrophotometric (e.g., ultraviolet absorbance) methods of analysis, were reviewed recently (1) and are not covered here. The following monographs and reviews provide further reading (1–5).

B. Food Proteins

The major food protein groups are listed in Table 5.1. They are mostly industrial proteins produced from well-known food commodities, including milk, wheat, maize, soybean, peanut, canola, fish, egg, meat, some animal by-products. The manufacturing processes involve standard unit operations, e.g., particle size reduction, solubilization, membrane separation, ion exchange, and dehydration. Processing can lead to changes in protein structure, not all of which are "undesirable." Denaturation is effectively harnessed to create interesting high-protein foods (5).

A key requirement for food protein analysis is reproducibility. Consistent protein readings are necessary for fair decision-making about product quality, pricing, and compliance with food legislation. Other desirable assay characteristics include high speed, and low capital and running costs for analysis. Assay sensitivity is not a premium because food samples are readily available. On the contrary, large sample sizes lead to concerns about representative sampling. Accuracy, the closeness of a measurement to a real value, is not of paramount concern because bias (deviation from the true reading) is readily determined by calibration.

TABLE 5.1
Schema for Food Protein Analysis-1

Some Major Protein Ingredients	Specific Proteins
Animal protein ingredients	Specific animal proteins
• Blood proteins	• Blood serum albumins
• Egg protein	• β-Lactoglobulin, α-lactalbumin, casein
• Milk protein	• Ovalbumin
• Muscle – fish, poultry and meat	• Myosin
• Skin & feather – gelatin	• Collagen
• Carcass and by-products, bone meal	
Plant protein ingredients	Specific plant proteins
• Cereals – vital gluten	• Albumins, globulins
• Legume – protein isolates (soy, peas, sesame)	• Prolamins, glutelins
• Tuber – potato protein	• Residue proteins*
• Leaf protein	
Microbial proteins or single cell protein (SCP)	

* Residue proteins refer to cereal storage proteins not extracted using conventional Osborne solvents.

Table 5.2 shows the movement of protein within the food system from agricultural production through to the consumer. Protein analysis is important at all levels of the food system. Farm gate prices for many commodities, e.g., grain and milk, are partly determined by their protein

content. Pricing of farm inputs (e.g., animal feeds) is also affected by levels of protein nitrogen. Recent legislation requires that feed intended for ruminants is free from animal protein. Protein ingredient manufacturers and users require functionality testing, ingredient standardization, optimization, and quality control (Figure 5.1). High protein foods (cheese, milk, meat, fish) are potential targets for adulteration and undeclared substitution – leading to a need for methods to ensure product authenticity. Detection of protein allergens and toxins assumes considerable importance at the consumer end of the food system. Table 5.2 lists also the main food science expertise areas recognized by the Institute of Food Technologists (IFT). All the sub-disciplines in food science offer some opportunity for protein analysis. The schemes in Figure 5.1 and Tables 5.1 and 5.2 provide an indication of the wide scope for food protein analysis.

C. Food Protein Analysis-General Considerations

According to accepted guidelines (6), one should consider the scope and purpose of food protein analysis – type of method (empirical, definitive, screening) and their intended use (research, quality control, surveillance, enforcement). Assay selection should follow desktop research (literature review) and discussions with people having relevant experience. One should obtain some notion of the strengths and disadvantages of different assays (bias, equipment cost, running cost, limit of detection, precision, specificity, speed, etc.). The degree of training necessary is another factor. Initial method development should be followed by optimization. As a rule, most off-the-shelf protein assays are not optimized for specific food samples with regard to interferences (additives, contaminants, flavors) or food matrix effects. Consider whether to use a commercially available ready-made kit. Sample clean-up may be necessary for complex foods, whether raw or processed. Particle size reduction and adequate mixing are important before sampling. Accuracy can be confirmed by comparing the results of one assay with that of an established method. Consider forms of sample storage and transport where protein tests are performed off-site.

II. QUANTITATION OF FOOD PROTEINS

A. Kjeldahl Method

Biological materials are transformed water, carbon dioxide, sulfur dioxide and ammonia when heated at 370–400°C in concentrated sulfuric acid. About 100–250 mg of food material requires 3–10 ml of concentrated sulfuric acid along with potassium sulfate, hydrogen peroxide, or metal oxide catalyst for digestion. There is sample charring followed by decomposition to form a clear-green liquid. Nitrogen (from urea, amino acids, peptides, proteins, nucleic acid, etc.) is converted to ammonium sulfate. Collection and quantitation of ammonia involves (a) neutralization with sodium hydroxide, (b) distillation and absorption by 4% standard boric acid, and (c) titrimetric analysis in the presence of a suitable titration indicator. Sample nitrogen, S_N (g-N per 100 g foodstuff), can be calculated from Eq. 5.1:

$$S_N = \frac{14.01 * V_{TITRANT} * N_{TITRANT} * 100}{Wt(g) * 1000} \qquad (5.1)$$

where $V_{TITRANT}$ is the volume of titrant corrected for blank readings, N is the normality of titrant (0.1M) and Wt(g) is the weight of food sample (grams) digested. Finally, values for S_N are converted to crude protein (cP) by multiplying with K_F (the nitrogen-to-protein conversion factor). For animal proteins K_F has a default value of 6.25 assuming that such proteins contain 16% N.

$$\text{cP (\%)} = S_N \text{ (g-N per 100 g foodstuff)} * K_F \text{(g-protein per g-N)} \qquad (5.2)$$

The accuracy of Kjeldahl analysis is impaired when samples contain high levels of non-protein nitrogen (NPN). For plant foods a default K_F-value of 6.25 overestimates protein content (7). Yeoh & Wee (8) determined K_F for 90 plant species from first principles. Leaf protein content was determined by amino acid analysis (next section). Then S_N was determined via the Kjeldahl method. From Eq. 5.2, we see that $K_F = cP/S_N$. Three distinct K_F parameters were identified: (i) K_A – ratio of protein to amino acid-N excluding amide-N from glutamine and asparagine residues, (ii) K'_A – ratio of protein to amino acid-N and ammonia, or (iii) Kp – Kjeldahl factor; this is protein content (from amino acid analysis) divided by S_N including contributions from NPN. As a matter of interest, the value for K_A, K'_A or Kp was 6.16 ± 0.05, 5.72 ± 0.12 or 4.43 ± 0.4 (g-protein per g-N), respectively.

Plant leaves contained 0.9–12% free amino acid and ≤30% NPN. Ezeagu et al. (9) reported K_F for 13 tropical seeds with a mean protein content of 19.83 ± 6.43% for

10-leguminoseae. They found $K_A = 7.13 \pm 0.23$, $K'_A = 5.94 \pm 0.34$, and $K_p = 4.97 \pm 1.07$. Clearly the default K_p value is not 6.25 for legumes. Multiplying the average value for S_N (4.14%) by K_p gave accurate estimates for cP (20.5%).

Mushrooms and other fungi have high levels of NPN, mostly ammonia, urea, free amino acids, and chitin. Mattila et al. (10) found that K_p was 4.7 ± 0.21 for several mushroom species. Protein levels reported for brown or white *Agaricus bisporus* (27% dry weight) were comparable to values found by Weaver et al. (11), but significantly lower than the value of 7% DW reported by others (12).

Kjeldahl analysis remains one of the most reliable methods for protein quantitation. Further research is needed to address the relation between Kjeldahl and other methods of food protein analysis (13), accuracy issues for K_p (7–10), rapid (colorimetric) methods for ammonia determination (14), and collaborative testing for novel foods (15,16).

B. Dumas Method — Combustion Nitrogen Analyzers

The sample is heated in a combustion nitrogen analyzer (CNA) oven at 950–1000°C within a high (99+%) oxygen atmosphere. Most of the gases produced by combustion (carbon dioxide, sulfur dioxide, and water vapor) are removed using adsorbents. The remaining nitrogen oxide is reduced to elemental nitrogen and measured by a thermal conductivity detector. Instrument output (S_N) is converted to cP after multiplying by K_F (Eq. 5.2). Table 5.3 shows some examples of CNA applications for food analysis. The Dumas method is approved by the CGC (Canadian Grain Commission), AOAC (Association of Official Analytical Chemist), AOCS (American Oil Chemists' Society), ASBC (American Society of Brewing Chemists), AFI (American Feed Industry), BRF-International (Brewing Research Foundation-International), IOB (Institute of Brewing), and EBC (European Brewing Convention).

Williams (21) discussed sources of error during combustion analysis. Equipment error is possible from infrequent or sporadic instrument use, poor maintenance, and instrument malfunction. Common sources of sampling error include incorrect weighing and the presence of trapped air (nitrogen). EDTA (ethylenediaminetetraacetic acid) used for calibration should be highly pure and low in moisture.

C. Quantitative Amino Acid Analysis

Amino acid concentration (C_T; mole per g) is routinely determined during the nutritional evaluation of many foodstuffs. Multiplying C_T by the formula weight for each amino acid (F_i, g per-mole) gives the weight of that amino acid (AA_m) per gram of sample (Eq. 5.3a). Protein content is the sum of all amino acids within the sample (Eq. 5.3b).

$$AA_m = C_T * F_i \tag{5.3a}$$

$$cP = \Sigma (AA_m) \tag{5.3b}$$

Results from quantitative amino acid analysis (QAA) are normally corrected for proline and tryptophan. Such corrections are necessary because acid hydrolysis of proteins destroys tryptophan, and many colorimetric reagents for detection of amino acids fail to react with proline (1). Nowadays, QAA is used mainly to assess values for K_F, which are needed for both the Kjeldahl and Dumas protein assays (7–10). Examples of QAA include the determination of proteins in peanuts (30), vegetables from Japan (31), meat, seafoods, baked goods, and fruits (32).

D. Near Infrared Analysis

Protein determination by near infrared (NI) analysis began in the 1970s (33,34). Protein, moisture, fat, starch, and fiber levels can be determined simultaneously. Other advantages of NI analysis include high sensitivity, high sample throughput, and high precision. NI analysis is non-destructive and the instrumentation is rugged and well suited for on-site operation. The AACC has approved NI analysis for cereals and grains including barley, oats, rye, triticale, wheat of all classes, and soybean (35). More recent developments have led to NI analysis for on-line or real time monitoring. Several monographs (36,37) and reviews (38–40) provide further details about NI analysis. There are very few reviews dealing solely with NI analysis of food proteins.

During near infrared reflectance (NIR) measurements, radiation reflected from the sample is sensed using a lead sulfide detector and an integrating optical sphere (41). Log (1/R) is linearly related to protein concentration. In the NI transmission (NIT) mode, a double beam of radiation passes through the sample and reference cells. Protein concentration is directly proportional to log (1/transmittance). Commercial NIR instruments include the Grain Quality Analyzer (Neotech Corporation, Silver

Spring, MD), Grain Analyzer Computer (Dickey-John, Auburn, IL), Infratec 1225 (Tectator AB, Sweden), Inframatic 8100 & 8144 (PerCon Instruments), InfraAlyzer 300 & 400 (Technicon) and the NIRSystems Model 6500 instrument (NIRSystems,[1] Silver Spring, MD). The following instruments were used in an NIT mode: MilkoScan 104, 203B, 605, etc. (Foss Electric), Multipec M (Shields Instruments, UK) and the NIRSystems Model 6500 instrument (NIRSystems, Silver Spring, MD). Recent developments in NI instrumentation have been reviewed (36,37). Collaborative trials were reported for NI analysis for milk (42), barley (43), wheat (44–46), meat (47), and kernel wheat (48).

1. Near Infrared Analysis of Grain Proteins

A recent example of grain analysis by NIR is described by Corbellini & Canevara (49) using 100 bread wheat (*T. aestivum* L.) samples from Italy. Analysis was performed for ground wheat as well as kernel wheat. Over the range of 7.8–14.7% protein ($S_N \times 5.7$) content, the correlation coefficient (r) for NIR and Kjeldahl results was > 0.98. Other protein-related quality attributes are measurable by NIR (Table 5.4). It is possible to correlate NI instrument output with grain moisture content, kernel hardness, sedimentation value, water absorption, and loaf volume. In addition to multilinear regression analysis, sophisticated multicomponent analysis, such as principal component analysis or partial least squares calibration, enable grain quality assessment by NIR (50, 51).

[a] NIR unless otherwise indicated with (*) for NIT analysis.

[1] A number of corporate takeovers have affected producers of NI instruments. Neotec Corporation (1966–1981) introduced the first commercial NI instrument in 1972 and microprocessor-controlled NI instruments in 1974. The company was bought by Pacific Scientific Corporation in 1981. In 1989, Perstorp Analytical (Sweden) purchased the NIR operations from Pacific Scientific and renamed it NIRSystems. Ownership passed to Foss-Electric (Denmark) in 1997. Foss-NIRSystems is based in Silver Spring, MD, the home of Neotech Corporation. Extract from http://www.foss.dk/c/p/default.asp?width = 1024.

2. Near Infrared Analysis of Meat and Milk Proteins

NIR results for ground lamb and beef were affected by sample homogeneity, particle size, and temperature (62). Results from NIR and Kjeldahl analysis showed only moderate correlation ($r = 0.67–0.8$). Higher correlation of $r \approx 0.99$ was reported in more recent studies for protein determination in fresh chicken (63), mutton (64), trout (65), and meat patties (66). The precision of NIR results appears to match or surpass those from Kjeldahl results. Furthermore, the NIR format leads to greater reproducibility as compared to NIT. However, the coefficient of variation for meat protein analysis (2.71–3.43%) was considered too high for NIR to be adopted for regulatory purposes (67). Sources of error for NIR and NIT measurements (21) include instrumental error, temperature variations, changes in relative humidity, and stray light. Operator error is often the result of inadequate training. NIR was applied for protein determination in milk powder and semi-solid dairy products including whey protein (68), nonfat dried milk (69), cheese (70,71), and fermented products (72,73).

III. FRACTIONATION ANALYSIS OF FOOD PROTEINS

A. Electrophoresis and Chromatography

Electrophoresis and chromatography are the foremost methods for food protein fractionation (74,75). High resolution polyacrylamide gel electrophoresis (PAGE) is available in a range of formats. Chromatography also offers a variety of separation chemistries (Table 5.5). The principles of electrophoresis and chromatography are described in References (76–78). During PAGE analysis, protein molecules migrate under the influence of an applied potential difference. The rate of migration is

dependent on protein charge-to-mass ratio. Protein bands separated by PAGE are visualized by staining (for example, with Coomassie blue dye or silver stain), destaining, and scanning with a densitometer. Native-PAGE is widely applied for identifying genetic polymorphism in milk and cereal proteins. A single amino acid difference for beta-lactoglobulin A and B leads to distinct protein bands during native-PAGE. Acid (acid-PAGE) or urea (urea-PAGE) can be added to gels in order to improve protein solubility. Acid-PAGE allows the identification or differentiation of cereal cultivars based on the analysis of their storage proteins (79,80). Fractionation of milk caseins frequently involves urea-PAGE (81,82).

Addition of ampholyte to native or urea-PAGE formats yields isoelectric focusing-PAGE (IEF-PAGE), which fractionates proteins on the basis of their isoelectric point (pI). IEF-PAGE requires high voltages and consequently the gels are thinner than those used for conventional PAGE to allow increased heat dissipation. Another PAGE format of interest involves sodium dodecylsulfate (SDS). Addition of this detergent encourages protein subunit dissociation, denaturation, and transformation into negatively charged polymers. During SDS-PAGE, proteins are separated on the basis of their molecular mass. Examples of food proteins analyzed by PAGE are provided in References 74, 75, and 83.

Proteins can be transferred from polyacrylamide gels by electroblotting and fixed to synthetic (nitrocellulose, polypropylene, or polyvinylinefluoride) membranes before staining. The membrane-bound protein can also be analyzed using highly specific antibodies as probes. Immunoblotting is an important screening method for food allergens (84,85). Finally, protein zones from PAGE can be excised for analysis using techniques such as mass spectrometry (see below).

Capillary electrophoresis is a relatively recent development in food protein analysis (86,87). Proteins are separated within a small diameter capillary. Various detectors are compatible with CE including fluorescence, refractive index, UV absorbance, and mass spectrometers. A range of protein separation methods is possible, such as capillary affinity electrophoresis (CAE), capillary gel electrophoresis (CGE), capillary isoelectric focusing (CIEF), and hydrophobic interaction capillary electrophoresis (HICE). The principles of CE are described in several reviews (77,86,88,89). Applications to dairy and cereal products are discussed in References 90 and 91, respectively.

B. Mass Spectrometry of Food Proteins

The principles of mass spectrometry (MS) are well known. Only a brief outline is provided here. A food sample is bombarded with high energy electrons in an evacuated chamber. Molecular ions produced by bombardment are accelerated via an electric field, past a set of electromagnets, towards a detector. The detection time for molecular ions is proportional to their mass-to-charge ratio $(m_i/z_i)^{½}$. Techniques for generating protein ions for MS analysis were only developed in the mid-1980s. The best known of these desorption techniques are fast atom bombardment (FAB), matrix assisted laser desorption ionization (MALDI), and electrospray ionization (ESI). The theory, principles, and instrumentation for protein MS analysis have been reviewed (92). Table 5.6 summarizes each desorption method and types of information available from MS analysis of proteins. Process-induced changes in food proteins appear to be readily detectable. For example, ESI-MS analysis of beta-lactoglobulin from 109 cows showed it to be covalently modified by a 324 Da species, probably lactose (93). The mechanism of heme protein denaturation was also examined by ESI-MS (94). Proteolysis of caseins during cheese manufacture and ripening was readily followed by MALDI-MS (95). Virtually all the major food protein groups have been analyzed by MS including milk, egg, meat and cereal proteins as reviewed in References 96–98.

TABLE 5.6
Mass Spectrometric Analysis of Food Proteins

Technique	Comments
FAB	• Protein + glycerol are bombarded by Xe or Cs ions at 8–40 keV. Sample is introduced into MS port.
ESI	• Protein solution disintegrates from the tip of capillary polarized at ±3000–5000 V. Electrospray is fed to MS port.
MALDI	• Protein + large excess of crystalline matrix is irradiated by a laser. The matrix absorbs energy, vaporizes, and ionizes protein.
Application areas*	
Aggregation	Molecular mass analysis
Cheese ripening and maturation	Polymorphism
Denaturation	Post-translational modification
Glycation	Process effects
Heat effects	Proteolysis
Irradiation	Purity
Meat postmortem	Sequence determination
	Sulfur/disulfide exchange

IV. PROTEOMICS

The term proteome was introduced by Wilkins et al. in 1995 to describe the "entire PROTEin complement expressed by a genOME, or by a cell or tissue type" (99). Proteomics is the wholesale identification of proteins comprising a proteome using large-scale, high-throughput technologies, primarily 2D gel electrophoresis and MS. In

the so-called post-genomics era, interest has extended to the subsidiary topics of transcriptomics, proteomics, and metabolomics (Figure 5.2). The transcriptome and metabolome refer to the total profile of RNA and metabolites within a cell, respectively (100). Protein functions other than metabolism – the entirety of enzymatic reactions within a cell – are also of interest. Proteomics is considered a protein-based method for gene expression analysis.

The rationale for proteomics can be seen from the central dogma of molecular biology, postulated by Francis Crick in 1958. The direction of information flow within cells is DNA → RNA → protein → function (101). Transcription of DNA leads to time-dependent expression of cell function. However, the relation between genome and cell function is complicated due to the presence of regulatory mechanism, redundancy, or amplification processes during information transfer. The study of proteomics is clearly essential because (i) proteins are the machinery that perform day-to-day functions within a cell, (ii) there is a low correlation between the number of genes and the number of proteins within a cell, (iii) differential gene expression occurs at different times and in different parts of the organism, and (iv) single genes can encode for more than one protein due to post-translational modification.

There are five essential steps for proteomics research: (i) sample preparation – cells, tissues, or organelles are homogenized to produce a protein extract. Care is needed to avoid protein modification by endogenous proteases, chemical modification or denaturation; (ii) protein separation by 2D electrophoresis. Typically, IEF (1D) and SDS-PAGE (2D) analysis is followed by protein visualization and densitometry leading to a 2D digital representation of the separated proteins. With the new generation of densitometers it is possible to perform a comparative image analysis of hundreds of protein spots resolved by 2D electrophoresis. The key is to discover differences between specific protein (spots) for the control and treatment sample; (iii) protein identification – protein spots of interest are excised from the 2D gel, digested with trypsin, then subjected to HPLC or CE analysis; (iv) peptide sequencing – the products of proteolysis are analyzed by MALDI-MS or ESI-MS as described in Section IIIB. Sophisticated MS instrumentation can now provide protein molecular mass as well as sequence information, (v) Bioinformatics – the application of computerized informatics tools to biological data. Peptide sequences are compared with the DNA- sequence database in order to identify the protein of interest. Digitized 2D gel patterns can also be compared directly with computerized library data for protein identification (99).

(B)

FIGURE 5.2 Information flow in cells is from DNA (genome) to mRNA (transcriptome) to proteins (proteome) to a variety of protein functions (phenome, physiome, and metabolome).

The impact of proteomics on food science and technology could be considerable (100,102). It may be possible to correlate changes in protein expression or post-translational modification with specific treatments, be they developmental, environmental, nutritional, or hormonal. Potential areas for proteomics research in food related areas include the study of protein structure function relations, functional ingredients, food-borne pathogens (103), allergens (104), food adulteration, novel ingredients, starter cultures (105), muscle or meat science (106), and the identification of protein markers for grain quality (107).

V. CONCLUSION

Aspects of food protein analysis are reviewed in this chapter. Food proteins were defined as those proteins which are of interest in food science. Food protein analysis is a vast topic but still emerging as an integrated discipline. Novel techniques for protein quantitation and characterization are being developed. The food system and food science expertise areas (Tables 5.1–5.2) were suggested as schema for defining the perspective of this rapidly evolving subject. The first part of the chapter emphasized "approved" methods for protein quantitation which are used within the food industry (Figure 5.1). Further research on Kjeldahl and Dumas analysis is needed to establish national and international protocols for a wide range of foods. Further developments in NIR analysis are needed in the areas of instrumentation and pattern recognition software. On-line NIR analysis for products on conveyor belts will probably increase (108). An example of a commercially available NIR on-line instrument is the MM170 analyzer from NDC Infrared Engineering (109). The trend towards diode array NIR instrumentation will lead to more rapid acquisition of spectra, increased portability, and more affordable instrumentation. Section III dealt with selected methods for protein fractionation, and the chapter culminated with a discussion of proteomics (Section IV). Though less than 10-years old, high-throughput protein analysis within a proteomics framework is now firmly on the food science agenda.

6 Protein: Denaturation

Srinivasan Damodaran
Department of Food Science, University of Wisconsin–Madison

CONTENTS

I. INTRODUCTION

Proteins perform various functions in processed foods. The functional properties of proteins, such as foaming, emulsifying, gelling, thickening, texturizing, dough forming, whipping, curdling, water binding, flavor binding, and fat binding properties, are important for imparting desirable sensory attributes in a variety of food products. These various functional properties of proteins emanate from two molecular attributes of proteins, namely hydrodynamic properties and physicochemical attributes of the protein's surface (1). While the hydrodynamic properties relate to the size and shape of the molecule, the properties of a protein's surface relate to its topology and to the pattern of distribution of polar and non-polar patches. Although these molecular attributes of proteins in their native state can be determined fairly precisely from their crystallographic structure, it has been difficult to predict their functionality in a complex food milieu. This is principally due to denaturation of proteins that inevitably occurs during food processing, which might alter both their hydrodynamic attributes (shape and size) and surface characteristics. In the denatured state, the intensity of intermolecular interactions between proteins, or between proteins and other constituents in the food milieu, would dramatically alter the proteins' functionality.

The extent of denaturation of proteins in a food milieu depends on the susceptibility of intra-molecular interactions that hold the compact native protein structure to temperature, pressure (shear), pH, ionic strength, types of ions, and specific and non-specific interactions with other food components such as sugars, polysaccharides, lipids, and other additives. It should be recognized, however, that from a food application standpoint, protein denaturation during processing is not always undesirable. In fact, in some cases it is highly desirable. For instance, partial denaturation of proteins at the air-water and oil-water interfaces improve their foaming and emulsifying properties (2, 3), whereas excessive thermal denaturation of soy proteins diminishes their foaming and emulsifying properties (4). In protein beverages, where high solubility and dispersibility of proteins is a necessity, even partial denaturation of protein during processing may cause flocculation and precipitation during storage and thus may adversely affect the sensory attributes of the product. Thus, to develop appropriate processing strategies, a basic understanding of the environmental and other factors that affect structural stability of proteins in food systems is imperative.

II. PROTEIN STRUCTURE

Protein structure is a highly complex architecture. A polypeptide chain containing hundreds of main chain covalent bonds can theoretically assume numerous configurations in three-dimensional space. Yet, under physiological pH, temperature, and ionic strength conditions, proteins always assume a particular native folded conformation. This native conformation represents a thermodynamic equilibrium state in which the free energy of the molecule is usually at the lowest possible level and it is achieved through optimization of various intra-molecular interactions within the polypeptide chain as well as interactions of its constituent amino acid residues with the surrounding aqueous medium.

At the molecular level, protein structure can be defined in terms of four levels. The primary structure denotes the linear sequence of amino acid residues in the polypeptide chain. Intuitively, one would expect this linear structure to possess chain flexibility similar to that of random coil polymers. However, this is not the case. The amide linkage between amino acid residues, which constitute one-third of the covalent bonds in the backbone of a polypeptide chain, possesses a partial double bond character and this substantially restricts the flexibility of the chain. Furthermore, depending on the amino acid sequence, the bulky side chains of amino acid residues impose additional restrictions on local flexibility of polypeptide chains. As a result of such sequence-imposed local restrictions on flexibility, polypeptides do not behave like other natural polymers, such as polysaccharides or nucleic acids, and synthetic polymers in solution. These restrictions on local flexibility play the critical role of guiding the protein toward attaining a particular folded native conformation. Thus, the primary structure of a protein is believed to possess the coded information for its final three-dimensional structure.

The secondary structure refers to regular conformations in polypeptide chains. This regularity of conformation occurs when the dihedral angles of each amino acid residue in a segment of the polypeptide assume the same set of values. The α-helix and β-sheet are the two regular structures found in polypeptides. Segments of polypeptide chain where consecutive amino acid residues assume different sets of dihedral angles tend to be in a disordered state and those regions are termed a periodic structures. The secondary structures in proteins arise as a result of short-range non-covalent interactions that tend to minimize local free energy of the protein chain.

The tertiary structure refers to the overall three dimensional arrangement of the folded polypeptide chain. For most proteins, the folded tertiary structure is roughly spherical in shape with irregular topography. The crevices on the surface, which are inaccessible to solvent water, are non-polar in nature. In food proteins, these crevices act as binding sites for hydrophobic ligands, such as fat and flavor molecules. The tertiary structure of a protein is the net result of optimization of various short and long-range interactions within the polypeptide chain and represents a state that has the lowest possible free energy under physiological conditions. In a monomeric protein, i.e., a protein that contains only one polypeptide chain, the surface of the protein that contacts with surrounding solvent water is predominantly polar and hydrophilic. However, in some proteins, depending on amino acid composition and sequence, some surface regions of the tertiary fold may be non-polar. In such instances, the protein molecules aggregate via hydrophobic interaction; an aggregated structure of the protein, which contains more than one polypeptide chain, is referred to as the *quaternary* structure.

A. Non-Covalent Forces

Folding of a protein from a nascent unfolded state to a folded native conformation is driven by several non-covalent interactions within the molecule. These include van der Waals forces, steric strains, hydrogen bonding, electrostatic, and hydrophobic interactions. The van der Waals interactions are short range in nature and therefore involve interactions between neighboring atoms. Although most of the main chain and side-chain covalent bonds in proteins are single bonds, their rotational freedom is hindered because of steric constraints from side-chain groups. Thus, steric strains indirectly limit the number of configurations accessible to various segments of polypeptides.

Proteins contain several groups that can form hydrogen bonds. The greatest number of hydrogen bonds in proteins occurs between the NH and CO groups of main chain amide bonds. The maximum strength of hydrogen bonds formed between N-H and C=O groups in proteins is about 4.5 Kcal mol^{-1}. The majority of hydrogen bonds in proteins occur in α-helix and β-sheet structures. The stability of these secondary structures is partly attributable to these hydrogen bonds. The vectorial orientation of hydrogen bonds in α-helices renders it to behave like a macro dipole. When two such α-helices come close and orient themselves in anti-parallel directions and form a bundle, the macro dipole-dipole interactions between these helices can stabilize such conformations (5). However, because water itself can hydrogen bond with amide groups in proteins, formation of hydrogen bonds between amide groups in proteins is not thermodynamically stable in an aqueous environment. More importantly, they do not, and cannot, act as the driving force for protein folding. Thus, their existence in α-helix and β-sheet structures might be the result of other interactions that create a non-polar environment where the hydrogen bonding and other macro dipole-dipole interactions become stable. Based on these considerations, it is fair to say that hydrogen bonds in proteins are only pseudo-stable and their stability depends on maintenance of the non-polar environment.

Electrostatic interactions in proteins at neutral pH arise mainly between the positively charged ε-amino groups of lysine, arginine, and histidine residues and the side-chain carboxyl groups of glutamate and aspartate residues. Depending on the relative numbers of these groups, a protein assumes either a net positive or a net negative charge at neutral pH. The stability of electrostatic interactions is dependent on the dielectric constant of the local environment. They are stronger in a non-polar environment than in a polar environment. In aqueous solutions, because of the high dielectric screening effect of water on charged groups, attractive and repulsive electrostatic interactions between charged groups in proteins are very insignificant. Thus, charged groups located on the surface of the protein do not greatly influence the stability of protein structure. On the other hand, if a salt bridge occurs between two buried opposite charges in the interior of a protein, where the dielectric constant is about 2–4, it can contribute very significantly to the structural stability of the protein.

Hydrophobic interactions between non-polar side-chain groups are considered to be the major driving force for protein folding in aqueous solutions. These interactions arise as a result of thermodynamically unfavorable interaction between solvent water and non-polar groups in proteins. The unfavorable free energy change occurs neither because of phobia between hydrocarbon and water nor because of attraction between hydrocarbons. In fact, the negative free energy change for dipole-induced dipole interaction between water and hydrocarbons is greater than the induced dipole-induced dipole interactions between hydrocarbons. The origin of hydrophobic interactions is rooted in the fact that the affinity between water molecules is much greater than between water and hydrocarbon; that is, the negative free energy change for water-water interaction is greater than water-hydrocarbon interaction. Because of this thermodynamically driven preferential interaction, water tends to minimize the surface area of direct contact with hydrocarbon chains and maximize its interaction with other water molecules. Water accomplishes this by forcing the hydrocarbon chains to aggregate. In proteins, this hydrophobic aggregation/association process is the main driving force for the folding of the protein chain. As the non-polar residues are removed from the aqueous environment, the non-polar regions created within the molecule allow formation of hydrogen bonds in such water-deficient regions as the interior of α-helix and β-sheet structures.

From the above discussions, it can be summarized that the folding of a protein from a nascent unfolded state to a folded native state is driven by a simple but fundamental thermodynamic requirement that a majority of non-polar groups be buried in the interior of the protein, away from contact with the aqueous phase, and that a majority of hydrophilic polar and charged groups be located on the surface of the protein in contact with the surrounding aqueous phase in such a manner that the global free energy of the molecule is at the lowest possible level (1). In partial accordance with this dictum, almost all charged and hydrophilic groups are found on the surface of the protein and most, but not all, of the non-polar groups are buried in the interior. The inability to bury all non-polar groups is essentially related to steric constraints imposed by the polypeptide chain. In most globular proteins, about 40% of the protein's surface is non-polar.

The structural stability of the folded state under a given set of solution conditions depends on two opposing forces: the sum of the energetics of hydrophobic interactions and other non-covalent interactions, such as hydrogen bonds, attractive and repulsive electrostatic interaction, and van der Waals interactions which favor folding of the polypeptide chain, and the conformational entropy of the polypeptide chain which opposes folding of the chain. Thus, the net stability of a folded protein molecule is

$$\Delta G_{U\leftrightarrow N} = (\Delta G_{H\text{-}bond} + \Delta G_{ele} + \Delta G_{H\phi} + \Delta G_{vdW}) - T\,\Delta S \quad (6.1)$$

Here $\Delta G_{H\text{-}bond}$, ΔG_{ele}, $\Delta G_{H\phi}$, and ΔG_{vdW} are free energy changes for hydrogen bonding, electrostatic, hydrophobic, and van der Waals interactions, respectively and $T\Delta S$ is the free energy change arising from the decrease in configurational entropy of the polypeptide chain as a result of folding at temperature T. For most proteins the transformation from an unfolded state (U) to the folded state (N) is spontaneous, implying that $\Delta G_{U\leftrightarrow N}$ is negative. The net stability, $\Delta G_{U\leftrightarrow N}$, is in the range of -5 to -20 kcal mol^{-1} (Table 6.1). This marginal stability suggests that the favorable free energy change emanating from numerous non-covalent interactions is greatly offset by the unfavorable free energy change arising from the loss of configurational entropy of the chain.

TABLE 6.1
Free Energy Change for Unfolding of Proteins at 25°C

Protein	$\Delta G_{N\leftrightarrow U}$ (kcal mol^{-1})	Ref.
Actin	6.6	63
Bovine serum albumin	7.2	
Carbonic anhydrase	10.5	64
α-Chymotrypsin (bovine)	12.9	65
Cytochrome c	8.3	65
Lysozyme (chicken)	13.5	65
α-Lactalbumin	5.3	66
β-Lactoglobulin	6.6	67
Ovalbumin	5.9	68
Papain	20.7	69
Pepsin	10.8	70
Ribonuclease A	6.0	65
Alkaline phosphatase	20.0 (30°C)	71
Troponin	4.7 (37°C)	72

The spontaneous transformation of a protein from an unfolded state to a folded conformation in an aqueous medium often resembles that of a hetero-polymer chain collapsing on itself from an expanded state to a compact state driven by the non-covalent interactions (6). This is schematically shown in Figure 6.1. Note that because of the partial double bond character of the amide linkage and local steric restrictions caused by bulky side-chains, protein chains do not behave as a true random coil polymer even in a fully unfolded, denatured state.

III. DENATURATION

The low $\Delta G_{U\leftrightarrow N}$ values indicate that the tertiary structure of proteins is only marginally stable. Any change in the thermodynamic environment of the protein, such as pH, ionic strength, temperature, pressure, or presence of other solutes, can readily cause a shift in the equilibrium in favor of the denatured state. Two terminologies are often used to define alterations in protein structure. Subtle changes in the tertiary structure that do not greatly alter the topographical features of the protein are usually identified as conformational adaptation. This kind of change in structure occurs when a substrate, inhibitor, or a low-molecular-weight ligand binds to a protein. Breakdown of the tertiary fold along with unfolding of the secondary structures is often termed "denaturation."

While the native structure of a protein is a well-defined entity with structural coordinates for each and every atom in the molecule obtainable from its crystallographic structure, it is not the case for the denatured state. Denaturation is a phenomenon wherein a well-defined initial state of a protein formed under physiological conditions is transformed into an ill-defined final state under non-physiological conditions by the application of a denaturing agent. It does not involve any chemical changes in the protein. In the denatured state, because of a greater degree of rotational motions of dihedral angles of the polypeptide chain, the protein can assume several configuration states differing only marginally in free energy (Figure 6.1).

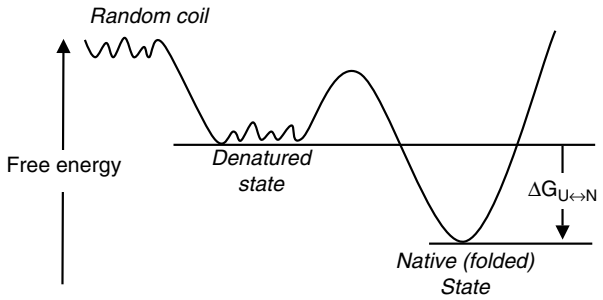

FIGURE 6.1 Schematic representation of the free energy of a protein as a function of its conformational state.

A. Measurement of Denaturation

Since conformation of a protein is not a quantifiable property, and the "denatured state" is not a precisely definable one, the thermodynamics of transformation of a protein from the native state to a denatured state is often determined by measuring changes in physical and chemical properties, such as viscosity, sedimentation coefficient, extinction coefficient, fluorescence, optical rotation, circular dichroism, enzyme activity, and reactivity of sulfhydryl groups of the protein. These intrinsic properties of proteins are conformation-dependent and they are modified significantly as the protein is progressively unfolded from the native state to a denatured state.

The majority of globular proteins so far studied exhibit a "two-state transition" denaturation model. The two-state model stipulates that a protein molecule can only exist either in the native or in the denatured state, but not in an intermediate state. The experimental evidence for this comes from the fact that when changes in a physical property y of a protein are monitored as a function of the concentration of a denaturant or temperature, the property y changes abruptly within a narrow range of denaturant concentration (or temperature), indicating that the transition from the native state to the denatured state is a highly cooperative process. That is, when certain critical intra-molecular interactions in the native state are destabilized by the denaturant, other interactions in the protein become highly unstable, and as a consequence the whole structure unravels within a small range of increment of denaturant concentration. An example of this phenomenon is shown in Figure 6.2 for urea and guanidine hydrochloride-induced denaturation of cytochrome c (7).

For a two-state transition model, the equilibrium between the native and the denatured state is given by

$$N \xleftrightarrow{K_D} D$$

$$K_D = \frac{[D]}{[N]} \tag{6.2}$$

Here K_D is the equilibrium constant. If $y_{(X)}$ is the value of the property y in the presence of a denaturant at concentration X, and $y_{N(X)}$ and $y_{D(X)}$ are the values of the native and denatured states, respectively, at denaturant concentration X, then the equilibrium constant for denaturation can be expressed as

$$K_{D(X)} = \frac{f_{D(X)}}{f_{N(X)}} = \frac{y_{(X)} - y_{N(X)}}{y_{D(X)} - y_{(X)}} \tag{6.3}$$

where $f_{D(X)}$ and $f_{N(X)}$ are the fraction of molecules in the denatured and native states, respectively, at denaturant concentration X. The free energy change $\Delta G_{D(X)}$ is determined from the equation

$$\Delta G_{D(X)} = -RT \ln K_{D(X)} \tag{6.4}$$

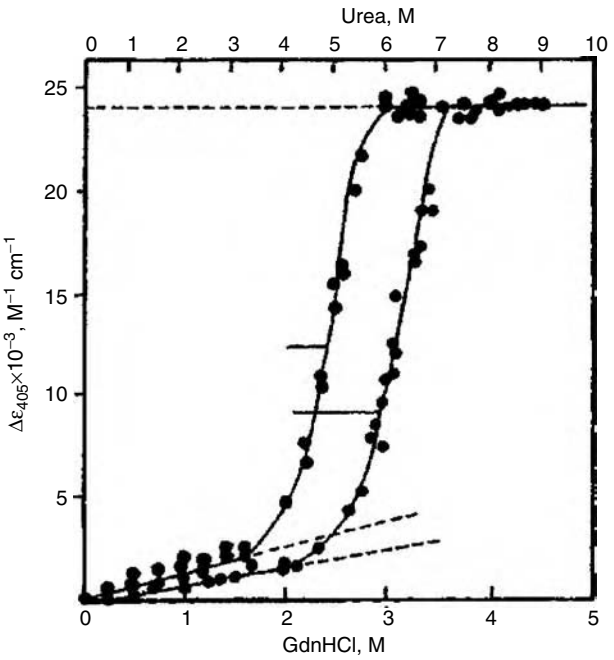

FIGURE 6.2 Guanidine hydrochloride (curve 1) and urea- (curve 2) induced unfolding of cytochrome c at pH 6 and 25°C (from Ref. 7). The ordinate represents change in molar extinction coefficient of the protein at 293 nm as a function of denaturant concentration.

where R is the gas constant and T is the temperature. The effect of the denaturant concentration on $\Delta G_{D(X)}$ generally follows the linear relation (7)

$$\Delta G_{D(X)} = \Delta G_{D(0)} - m_d [X] \qquad (6.5)$$

where $\Delta G_{D(0)}$ is the free energy change in the absence of the denaturant, obtained from the intercept, and m_d is the slope.

Although many proteins follow the two-state denaturation model, recent evidence suggests that certain proteins, such as α-lactalbumin, carbonic anhydrase B, and bovine growth hormone, show deviations from the two-state model (8–11). These proteins, under certain denaturation conditions, follow a three-state transition model

$$N \rightleftharpoons A \rightleftharpoons D \qquad (6.6)$$

where A is a stable intermediate state. The intermediate state is described as the "molten globule" state. The conformation of protein in the molten globule state is neither in the fully folded form nor in the fully unfolded form. The characteristic features of the molten globule state, which is sometimes referred to as the third thermodynamic state (11), are 1) its secondary structure content in terms of α-helix, β-sheet, and aperiodic structures, is very similar to that of the native conformation, 2) its overall shape and dimension is very close to that of the native state such that its intrinsic viscosity is almost the same as that of the native state, 3) the environment of the side-chains, as measured by tryptophan fluorescence, is very similar to that of the native state, and 4) in spite of the presence of secondary structures, the enthalpy of the molten globule is almost the same as that of the denatured state (9).

Acid- or alkali-induced transitions in proteins typically produce an unfolded state characterized as the molten globule state. This phenomenon has been very well studied in the cases of α-lactalbumin, carbonic anhydrase B, and bovine growth hormone. The stability of this state depends on the ionic strength. At low ionic strength, the molten globule, also known as the A state, becomes fully unfolded because of electrostatic repulsion. In addition to acid and alkaline induced transitions, structural states similar to that of molten globule are also produced under other conditions. For instance, complete removal of bound calcium from α-lactalbumin produces a partially unfolded state that is identical to that produced in the acid transition (12, 13). Stable but partially denatured state produced by mild heating, which has a structure different from that of the A state, is also categorized as a molten globule (14, 15). The molten globule state is also formed by reduction of intra-molecular disulfide bonds in proteins (16). Thus, it appears that the molten globule can be defined as any partially unfolded but stable and roughly globular state of a protein formed under a variety of experimental conditions, but having an enthalpy content similar to that of the fully unfolded state.

IV. MECHANISM OF DENATURATION

A. Temperature-Induced Denaturation

Many unit operations in food processing and preservation involve heating and cooling. These processes invariably cause protein denaturation. Typically, most proteins undergo thermal denaturation at elevated temperatures, but certain proteins, e.g., myoglobin, exhibit "cold denaturation" at sub-ambient temperatures as well. In such proteins, the $\Delta G_{N\leftrightarrow U}$ versus temperature profile exhibits a bell-shaped curve with an optimum temperature for maximum stability.

Proteins exhibit vast differences in their thermal stability. For instance, most enzymes are unstable even at 45°C, which is only a few degrees above the physiological temperature at which they function optimally, whereas other enzymes, such as alkaline phosphatase, are stable at higher temperatures. Non-enzyme proteins, especially food proteins such as whey proteins and legume proteins, are usually stable up to 70–80°C. In general, enzymes/proteins from thermophilic and thermotropic organisms are more heat stable than those from psychrophilic and mesophilic species.

The mechanism of temperature-induced denaturation of proteins primarily involves the effect of temperature on the stability of non-covalent interactions. In this respect, the hydrogen bonding and electrostatic interactions, which

are exothermic in nature, are destabilized, and hydrophobic interactions, which are endothermic, are stabilized as the temperature is increased. In addition to non-covalent interactions, temperature dependence of conformational entropy, $T\Delta S_{conf}$, also plays a major role in the stability of proteins. The net stability of a protein at a given temperature is then the sum total of these interactions.

In globular proteins, the majority of charged groups exist on the surface of the protein molecule, fully exposed to the high dielectric aqueous medium. Because of the dielectric screening effect of water, attractive and repulsive electrostatic interactions between charged residues are greatly reduced. For instance, the strength of electrostatic interaction between two charged residues at a distance of 5 Å in water is only about ± 0.8 kcal mol^{-1}, which is comparable to thermal kinetic energy at 25°C. In contrast, in an environment having a dielectric constant of 4, which is comparable to that of protein interior, the strength of the same ion-pair interaction would be about ± 16 kcal mol^{-1}. In addition, at physiological ionic strength, screening of charged groups in proteins by counter ions further reduces electrostatic interactions in proteins. Because of these facts, the influence of temperature on electrostatic interactions in proteins would be negligible. Similarly, hydrogen bonds are unstable in an aqueous environment and therefore their stability in proteins is dependent on hydrophobic interactions that create local low dielectric environment. This implies that so long as a non-polar environment is maintained, the hydrogen bonds in proteins would remain intact when the temperature is increased. These facts suggest that although polar interactions are affected by temperature, they generally do not play a significant role in heat-induced denaturation of proteins. Based on these considerations, the stability of the native state of a protein can be simply regarded as the net free energy difference emanating from hydrophobic interactions that tend to minimize the nonpolar surface area of the protein molecule and the positive free energy change arising from the loss of conformational entropy of the chain ($T\Delta S$). That is,

$$\Delta G_{fold} = \Delta G_{H\phi} + \Delta G_{conf} \tag{6.7}$$

The temperature dependence of the stability of the protein at constant pressure is then given by (17)

$$\frac{\partial \Delta G_{fold}}{\partial T} = \frac{\partial \Delta G_{H\phi}}{\partial T} + \frac{\partial \Delta G_{conf}}{\partial T} \tag{6.8}$$

Hydrophobic interactions are strengthened at higher temperatures; therefore, $\partial \Delta G_{H\phi}/\partial T < 0$. Conformational entropy increases upon unfolding of the protein; therefore, $\partial \Delta G_{conf}/\partial T > 0$. As the temperature is increased, the interplay between these opposing forces reaches a point at which $\partial \Delta G_{fold}/\partial T > 0$. The temperature at which this occurs signifies the denaturation temperature of the protein.

In dilute solutions under certain heating conditions, thermal denaturation of globular proteins is completely reversible. At high concentration, e.g., >1%, protein-protein interaction between unfolded protein molecules hinders refolding of the protein. Prolonged heating of protein solutions at high temperatures, viz., >90°C, can cause irreversible denaturation of proteins regardless of the protein concentration. This is mainly due to chemical changes in proteins, such as destruction of cysteine and cystine residues and deamidation of asparagine and glutamine residues at high temperatures (18, 19).

In addition to denaturation at above ambient temperatures, several proteins have been shown to undergo denaturation at cold temperatures. For instance, myoglobin exhibits maximum stability at about 30°C and is destabilized at lower and higher temperatures (20). Several food proteins also undergo reversible dissociation and denaturation at cold temperatures. For example, glycinin undergoes reversible aggregation and precipitation when stored at 2°C (21). The cold temperature-induced denaturation of proteins is mainly due to a decrease in the stability of hydrophobic interactions at low temperatures.

The fact that the hydrophobic (solvophobic) force and the conformational entropy are the two important forces manifestly controlling thermodynamic stability of proteins tentatively suggests that the stability of proteins might be in some way depend on the amino acid composition. However, studies have shown that thermal denaturation temperature of proteins is not correlated with the mean hydrophobicity of amino acid residues in proteins (22). On the other hand, correlations between certain groups of amino acid residues and thermal stability have been found. For instance, statistical analysis of 15 proteins of known amino acid composition and thermal denaturation temperatures has revealed that the denaturation temperature of these proteins increased linearly with the number percentage of the sum of Asp, Cys, Glu, Lys, Leu, Arg, Trp, and Tyr residues, whereas it decreased linearly with the number percentage of the sum of Ala, Gly, Ser, Thr, Val, and Tyr residues (23). No other combinations of the 20 different amino acid residues in proteins showed a statistically significant correlation with the denaturation temperature. It is likely that attractive interactions between positively and negatively charged groups and the hydrophobic Leu, Trp, and Tyr residues in the first group might be responsible for imparting stability, whereas the highly flexible Gly, Ala, and Ser residues in the second group may tend to increase conformational entropy of proteins and thereby contribute to instability.

Thermal stability of proteins from thermophilic and hyperthermophilic organisms, which can withstand extremely high temperatures, is attributed to their unique amino acid composition (24). These proteins contain lower levels of Asn and Gln residues than those from mesophilic organisms. The implication here is that because Asn and Gln are susceptible to deamidation at high temperatures,

higher levels of these residues in mesophilic proteins may partly contribute to instability. The Cys, Met, and Trp contents, which can be oxidized easily at high temperatures, are also very low in thermostable proteins. On the other hand, thermostable proteins have high levels of Ile and Pro (25, 26). It is believed that the high Ile content might help in better packing of the interior core of the protein (27), which reduces buried cavities or void spaces. Absence of void spaces can reduce mobility of the polypeptide chain at high temperatures and this will minimize the increase in its configurational entropy of the polypeptide chain at high temperatures. A high content of Pro, especially in the loop regions of the protein chain, is believed to provide rigidity to the structure (28, 29). However, comparison of packing volumes of hydrophobic residues in the interior core of homologous glutamate dehydrogenases from mesophilic and hyper-thermophilic organisms has shown no significant difference between them (30), implying that the Ile content and the packing volume may not be really critical for thermostability. On the other hand, examination of crystallographic structures of several proteins/enzymes from thermophilic organisms shows that these thermostable proteins contain a significantly higher number of ion-pairs in crevices on the surface and a substantially higher amount of buried water molecules engaged in hydrogen bonding bridge between segments than in their mesophilic counterparts (30, 31). In other words, it appears that polar interactions (both salt bridges and hydrogen bonding between segments) in the protein interior are responsible for thermostability of proteins from thermophilic and hyper-thermophilic organisms. As discussed earlier, it is conceivable that the presence of 3 to 4 salt bridges between oppositely charged groups in the protein interior could increase the stability of protein structure by about 64 kcal/mol. In spite of these findings, a real understanding of the molecular factors contributing to hyper-thermostability of proteins is still elusive. Apparently, a combination of salt bridges, a strong hydrophobic core, and reduced conformational flexibility seems to be involved in thermostability of proteins.

Water content of dry protein powders affects their thermal denaturation. As the water content is increased from zero to about 0.4 g/g, which incidentally corresponds to monolayer coverage for most proteins, the denaturation temperature of proteins decreases asymptotically and reaches a value that is similar to the denaturation temperature of the protein in a dilute solution (32). This is due to the plasticizing effect of water, which promotes segmental mobility in proteins.

Small-molecular-weight solutes, such as salts and sugars, affect the denaturation temperature of proteins. For instance, addition of 0.5 M NaCl to α-lactalbumin increases its denaturation temperature by about 5°C (33). Sucrose and glucose at 50 wt% level also elevates the denaturation temperature by about 5°C in α-lactalbumin (33). On the other hand, the denaturation temperature of soy glycinin is elevated by about 15°C and that of soy conglycinin by about 12°C in the presence of 0.5 M NaCl compared to the control (34). Interaction of vanillin with ovalbumin decreases both the temperature and the enthalpy of denaturation of ovalbumin (35). Addition of up to 40 wt% sucrose to whey protein isolate solution significantly increased both the denaturation temperature and the gelation temperature (36). The gels formed in the presence of sucrose were more rigid than the control. Addition of calcium at 1–10 mg/g of protein during isoelectric precipitation of soy protein significantly increased the denaturation temperature of soy proteins, especially the 11S fraction; the enthalpy of denaturation, however, was not affected (37). These observations suggest that the magnitude of impact of small-molecular-weight solutes on thermal stability of proteins is dependent on the intrinsic properties of proteins and their response to changes in the external environment.

B. Pressure-Induced Denaturation

Proteins are inherently highly flexible. This high flexibility is the underlying reason for their marginal stability under physiological conditions. This flexibility and marginal stability, which arise due to various competing and balancing forces, are necessary requirements for functioning of enzymes under physiological conditions, because a highly rigid protein cannot exhibit conformational adaptability required for binding of substrates and other ligands.

The flexibility of proteins arises because of void spaces or cavities in the interior of the protein. The void spaces in the interior are created by imperfect packing of the residues as the protein chain collapses on itself during folding. In aqueous solutions, the partial specific volume, $\bar{v}^0$, of a protein consists of

$$\bar{v}^0 = V_c + V_{cav} + \Delta V_{sol} \tag{6.9}$$

Here V_c is the sum of constitutive volumes of atoms in the protein, V_{cav} is the volume of cavities in the protein, and ΔV_{sol} is the volume change due to hydration (38). Among these three parameters, V_c is constant for a given protein molecules since atomic volumes are incompressible. Thus, V_{cav} and ΔV_{sol} are the main parameters that affect partial specific volumes of proteins.

The pressure-induced denaturation is caused by compressibility of the cavities or void spaces in the interior of a protein. Differentiation of Equation 6.9 with pressure under iso-entropic (i.e., adiabatic) conditions results in

$$(\partial \bar{v}^0/\partial \mathrm{P}) = (\partial \mathrm{V}_{cav}/\partial \mathrm{P}) + (\partial \Delta \mathrm{V}_{sol}/\partial \mathrm{P}) \tag{6.10}$$

The adiabatic compressibility is defined as

$$\bar{\beta}_s = -\frac{1}{\bar{v}^0}\frac{\partial \bar{v}^0}{\partial P} \tag{6.11}$$

Thus, Equation 6.10 can be expressed in terms of adiabatic compressibility as

$$\overline{\beta}_s = -\frac{1}{\overline{v}^0}\left[\frac{\partial V_{cav}}{\partial P} + \frac{\partial V_{sol}}{\partial P}\right] \quad (6.12)$$

When hydrostatic pressure is applied, compression of the cavities results in a reduction in volume, i.e., $\partial V_{cav}/\partial P < 0$, but disruption of the hydration shells of charged and polar surfaces causes an increase in volume, i.e., $\partial V_{sol}/\partial P > 0$ (38). Because of these two opposing effects, the net compressibility or decrease in the volume is only marginal. However, if the compressibility arising from $\partial V_{cav}/\partial P$ alone is considered, the compressibility of proteins is an order of magnitude greater than water (38).

The adiabatic compressibility, $\overline{\beta}_s$, of some proteins is shown in Table 6.2. It should be noted that fibrous proteins, such as gelatin, F-actin, myosin, and tropomyosin, have negative compressibility, indicating that the increase in volume due to disruption of hydration shells, i.e., $\partial V_{sol}/\partial P > 0$, is more dominant than the volume decrease due to elimination of cavities. It is possible that these fibrous proteins might be devoid of cavities altogether and therefore $\partial V_{cav}/\partial P$ might be almost close to zero. The positive compressibility values of globular proteins suggest that the negative volume change due to compression of cavities is much greater than the positive volume change from hydration effects. It should be noted that although the partial specific volume of β-casein (0.744 ml g^{-1}) is greater than that of α_s-casein (0.739 ml g^{-1}) and κ-casein (0.739 ml g^{-1}), its adiabatic compressibility is significantly lower than those of α_s- and κ-caseins. This might be related to higher proline content of β-casein (17%) than α_s- and κ-caseins. Because of lack of rotational freedom of the dihedral angle ϕ of the N-C_α bond of proline residues, protein segments containing proline residues often behave like a stiff rod (39). It is conceivable that the uniform distribution of 35 proline residues along the backbone chain in β-casein may render the protein to behave as a stiff rod with only limited flexibility. Among the globular proteins listed in Table 6.2, cytochrome c has the lowest adiabatic compressibility.

TABLE 6.2
Adiabatic Compressibility, $\overline{\beta}_s$, of Proteins[1]

Protein	$\overline{\beta}_s$ ($cm^2\ dyn^{-1}\ 10^{12}$)
Gelatin	−2.5
F-actin	−6.3
Myosin	−18.0
Tropomyosin	−41.0
α-Casein	7.74
α_s-Casein	5.68
β-Casein	3.80
κ-Casein	7.49
Whole casein	6.67
α-Lactalbumin	8.27
β-Lactoglobulin	8.45
Lysozyme	4.67
Myoglobin	8.98
Peroxidase	2.36
Ovalbumin	9.18
Ovomucoid	3.38
Bovine serum albumin	10.50
Cytochrome c	0.066

[1] Compiled from References 73 and 74.

Under very high hydrostatic pressure, the collapse of the cavities formed as a result of imperfect packing of amino acid residues causes unfolding of the protein. In the unfolded state, elimination of the cavities decreases the volume, and hydration of the exposed hydrophobic residues also leads to a reduction in the volume of the solvent. Thus, pressure-induced denaturation usually results in a net reduction in the volume of the system (protein+water).

The free energy change under pressure-induced denaturation of protein is related to its volume change according to the equation

$$\Delta V = d(\Delta G)/dP \quad (6.13)$$

The pressure-induced denaturation of single-chain proteins has been measured by monitoring changes in fluorescence emission and UV absorption spectra of tryptophan residues, and changes in turbidity (40–42). A critical review of the data in the literature suggests the following. In single chain proteins, pressure-induced denaturation occurs only at very high pressures. For most proteins, the midpoint of pressure-induced structural transition is in the range of 4–8 kilobars (43). In oligomeric proteins, dissociation of subunits occurs at 1–2 kilobars, followed by unfolding of the subunits at higher pressures. The volume change in proteins upon pressure-induced unfolding is typically about 0.5% of the total volume of the protein molecule, which is considerably smaller than the theoretically predicted value of about 2%. This tentatively suggests that proteins may retain some residual folded structures even at pressures as high as 10 kilobars. This may partly explain complete reversibility of pressure-induced unfolding in most proteins, including oligomeric proteins. For most single chain proteins, the free energy change at the midpoint of transition at neutral pH and ambient temperature is in the range of 10–20 kcal mol^{-1}. This value is comparable to that obtained from heat-induced or urea and guanidine hydrochloride-induced denaturation. Taken together, the smaller than expected volume change in proteins might indicate that proteins may assume a molten globule state, instead of the completely unfolded state, under high pressure since the enthalpy content of the molten globule state and the fully unfolded state are almost the same.

In addition to causing protein denaturation, high hydrostatic pressure disrupts the integrity of macromolecular assemblies, such as biomembranes, ribosomes, and

bacterial cell walls. Disruption of cell membrane is often irreversible, which results in inactivation of vegetative cells. For this reason, high-pressure treatment of food products is being examined for its effectiveness as a tool for food preservation (44–46). At sufficiently high protein concentration, pressure denaturation can cause non-thermal gelation of proteins (47, 48). Exposure of myosin to pressures up to 800 MPa for 20 min causes denaturation and polymerization of myosin; the polymerized structure contains both hydrogen bonds (as judged from differential scanning calorimetry (DSC)) and disulfide cross-links (49). Pressure-induced gels are softer in texture than the heat-induced gels. However, pressure-induced gels retain color, flavor, and vitamins and other nutrients that are destroyed to some extent in thermally processed foods and in heat-induced gels.

C. Denaturation by Small-Molecular-Weight Additives

Several small-molecular-weight solutes, such as urea, guanidine hydrochloride, detergents, sugars, and neutral salts, affect protein stability in aqueous solutions. While urea, guanidine hydrochloride, and detergents destabilize the native conformation of proteins, sugars tend to stabilize the native structure. In the case of neutral salts, while certain salts, such as sulfate and fluoride salts of sodium, termed as kosmotropes, stabilize protein structure, other salts, such as bromide, iodide, perchlorate, and thiocyanate, termed as chaotropes, destabilize protein structure.

The stabilizing or destabilizing effects of small-molecular-weight additives on proteins is believed to follow a general mechanism. This is related to their preferential interaction with the aqueous phase and the protein surface. Additives that stabilize protein structure bind very weakly to the protein surface but enhance preferential hydration of the protein surface (Figure 6.3). Such additives are generally excluded from the region surrounding the protein; that is, their concentration near the protein is lower than in the bulk solution. This concentration gradient presumably creates an osmotic pressure gradient surrounding the protein molecule, sufficient enough to elevate the thermal denaturation temperature. For instance, studies on protein stabilization by glycerol using the electrospray ionization mass spectrometry (ESI-MS) technique have shown that in glycerol solutions lysozyme assumes a slightly compressed state compared with its state in water (50). This might be due to creation of an exclusion zone around the protein surface for glycerol and development of an osmotic pressure gradient.

In the case of additives that destabilize protein structure, the opposite seems to be true. That is, those additives that decrease the stability of proteins preferentially bind to the protein surface and cause dehydration of the protein. In such cases, water molecules are excluded from the region surrounding the protein and the concentration of the additive in this water-excluded region is higher than in the bulk solvent. Favorable interaction of such additives with protein surface, particularly the non-polar surface, promotes unfolding of the protein so that the buried non-polar surfaces are further exposed for favorable interaction with the additive.

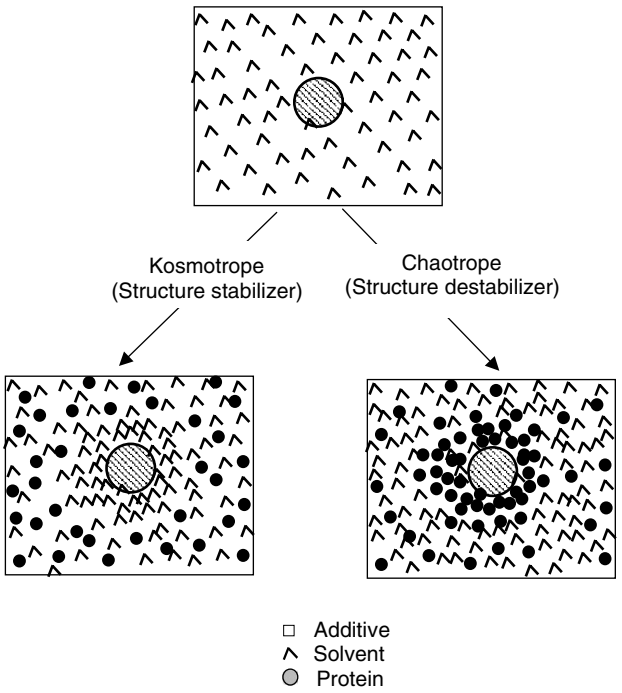

FIGURE 6.3 Schematic representation of preferential binding of solute and solvent molecules with proteins in the cases of kosmotropes (structure stabilizers) and chaotropes (structure destabilizers).

When a protein is exposed to a mixture of stabilizing and destabilizing solutes, the net effect on protein stability generally follows an additivity rule. For example, sucrose and polyols are considered to be protein structure stabilizers, whereas guanidine hydrochloride is a structure destabilizer. When sucrose is mixed with guanidine hydrochloride, the concentration of guanidine hydrochloride required for unfolding proteins increased with increase of sucrose concentration (51). It was also observed that the structure of water was altered in the presence of guanidine hydrochloride and urea. However, addition of polyhydric compounds such as sucrose countered this urea and guanidine hydrochloride-induced change in water structure. Thus, the increase in guanidine hydrochloride and urea concentrations required for unfolding proteins in the presence of sucrose and other polyhydric compounds might be due to mutually opposing effects of these compounds on water structure (51). This also underscores that changes in water structure in the presence of additives are involved in some fundamental way in the

transmission of the effects of additives on protein stability. The exact mechanism is still elusive, partly because "water structure" is not yet a well-defined concept.

Theoretical statistical thermodynamic analyses have shown that the excluded volume of additives has three distinct types of effects on protein stability (52): 1) Small-size solutes strongly denature proteins, 2) medium-size solutes stabilize proteins at low solute concentrations and destabilize them at high concentrations, and 3) large-size solutes stabilize the native state of proteins across the whole liquid region. In agreement with this theory, stabilizers tend to be large-size molecules such as sugars, polymers, polynols, nonionic, and anionic surfactants while denaturants tend to be small-size molecules such as alcohols, glycols, amides, formamides, ureas, and guanidium salts.

The mechanism of preferential binding to or exclusion from protein surface of additives in aqueous solutions is a complex one. Various molecular interactions between the additive and protein (both with the protein surface and protein interior) are involved. These interactions include electrostatic and van der Waals interactions (consisting of Debye-Keesom and London dispersion interactions) with proteins, as well as their interaction with solvent water. It has been pointed out (53, 54) rather convincingly that preferential binding or exclusion of ions from a protein surface in aqueous electrolyte solutions can be fully explained only by including, in addition to electrostatic interactions, dispersion interactions between ions and the protein.

1. Urea and Guanidine Hydrochloride

Both urea and guanidine hydrochloride denature proteins at very high concentrations. Guanidine hydrochloride is a more potent denaturant than urea. For globular proteins the midpoint of unfolding transition occurs at 4–6 M urea and at 3–4 M guanidine hydrochloride concentrations. Generally, globular proteins are completely denatured in 8 M urea and 6 M guanidine hydrochloride. The mechanism of denaturation of proteins by urea and guanidine hydrochloride is related to their solubilizing effect on both polar and non-polar amino acid residues. Solubility studies on non-polar amino acids have shown that the free energy change for transfer of non-polar groups from water to urea and guanidine hydrochloride solutions is favorable (55). This transfer free energy is proportional to the accessible surface area of the non-polar solute, which is about –7.1 cal mol^{-1} $Å^{-2}$ for 8 M urea and –8.3 cal mol^{-1} $Å^{-2}$ for 6 M guanidine hydrochloride (55). Because urea and guanidine hydrochloride interact more favorably with both polar and non-polar groups (via ion-dipole and dispersion interactions) on the protein surface than does water, they preferentially bind to proteins. This preferential interaction further leads to unfolding and solubilization of buried non-polar residues. This shift in equilibrium from native state to the unfolded state is driven by the thermodynamic requirement to increase the area of contact between protein non-polar surfaces and the denaturant.

2. Neutral Salts

Neutral salts affect protein stability via two different mechanisms. At low concentrations (<0.5 M), non-specific electrostatic interactions with charged groups on protein surface results in neutralization of electrostatic (repulsive) interactions within a protein and this often leads to stabilization of protein structure. Salts also affect the pK_a of ionizable groups in proteins, especially the acidic residues, which causes changes in thermal stability of proteins (56). At higher concentrations, neutral salts exert ion-specific effects on protein stability depending on their relative position in the Hofmeister Series (56). The effects of anions on protein stability are greater than the cations and follows the order $F^- > SO_4^{2-} > Cl^- > Br^- > I^- > ClO_4^- > SCN^- > Cl_3CCOO^-$. F^- and SO_4^{2-} actually increase the stability of protein structure (kosmotropes), whereas Br^-, I^-, ClO_4^-, SCN^-, and Cl_3CCOO^- ions destabilize protein structure (chaotropes). The stabilizing and destabilizing effects of these ions on protein structure are manifested in the form of elevation and depression of the denaturation temperature (T_d) of proteins. For instance, Figure 6.4 shows the effect of neutral salts on T_d of β-lactoglobulin (58). At high concentrations, Na_2SO_4 and NaCl significantly raise the denaturation temperature, whereas NaSCN and $NaClO_4$ lower the denaturation temperature of β-lactoglobulin.

Several theories have been proposed to explain the effects of neutral salts on protein structure and stability (57, 59). Experimental evidence indicates that the effects of salts on protein stability are related to their relative ability to bind to proteins and affect its hydration. Salts that stabilize protein structure weakly bind to the protein surface and enhance hydration of the protein, whereas salts that destabilize protein structure bind strongly to protein surface and cause dehydration of the protein (60). However, the fundamental reasons for differential binding of salts, for example monovalent salts, to proteins are not well understood. It appears that ion binding to proteins cannot be simply explained using classical electrostatic potential on the surface. It might also involve dispersion forces between the ion and the apolar interior of the protein (54). The dispersion potential, which relates to ion-dipole polarizability effects, is dependent on ionic radius and concentration and the dielectric susceptibility of the protein. On a more fundamental level, differences in interaction of salts with proteins must be related to free energy differences between interaction with solvent water and protein surface. In this case, ions might affect the thermodynamic state of water and alter its solvent properties. It has been shown that salts that stabilize protein structure also enhance hydrogen-bonded structure of water, and salts that destabilize protein structure also break down the hydrogen-bonded structure of water (59).

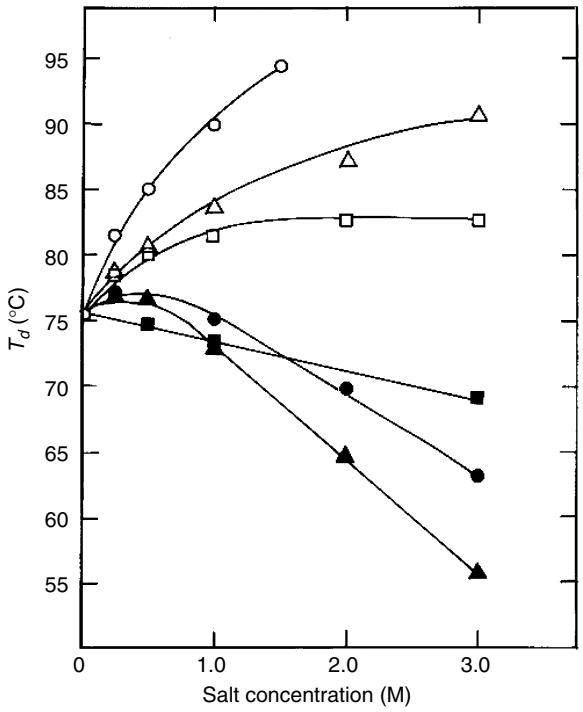

FIGURE 6.4 Effects of various sodium salts on thermal denaturation temperature of β-lactoglobulin. ○, Na_2SO_4; △, NaCl; □, NaBr; ●, $NaClO_4$; ▲, NaSCN; ■, urea (from Ref. 55).

3. Detergents

Detergents, especially anionic detergents such as sodium dodecyl sulfate (SDS), are potent denaturing agents. Unlike urea and guanidine hydrochloride, SDS can denature proteins at 3–8 mM concentration. The mechanism of denaturation involves strong binding of SDS to hydrophobic groups in the crevices of the protein molecule, which results in destabilization and solubilization of buried hydrophobic regions. Proteins bind up to about 1.4 g of SDS per gram of protein. Because of this high binding capacity, proteins in SDS solution become highly negatively charged and consequently electrostatic repulsion between segments also play a role in protein unfolding. Unlike in other denaturing environments, the denatured state of proteins in SDS solution is generally not in a random or aperiodic conformation; invariably they assume a helical rod-type shape. Because of strong binding via hydrophobic interactions, detergent-induced denaturation of proteins is mostly irreversible, whereas denaturation by urea and guanidine hydrochloride is generally reversible under appropriate conditions.

4. Organic Solvents

The mechanism of protein denaturation by organic solvents such as ethanol, propanol, and acetone is complex. This is because these water miscible organic solvents affect various molecular forces, such as electrostatic, hydrogen bonding, and hydrophobic interactions, in proteins differently. However, the effects are mediated mainly via a decrease in the dielectric constant of the solvent medium. First, when a water-miscible organic solvent is added to a protein solution, the decrease in the permittivity of the medium increases electrostatic repulsion between like charges and enhances attraction between unlike charges. The repulsive interactions tend to unfold the protein, whereas the attractive electrostatic interactions tend to stabilize the structure. The latter becomes crucial if the protein contains a salt bridge between a carboxyl and an amino group in a partially exposed crevice on the surface of the protein. Second, because apolar residues in proteins are more soluble in an organic solvent and in an aqueous-organic solvent mixture than in water, the hydrophobic interactions within the protein are weakened and consequently the buried non-polar groups tend to become exposed to the solvent, which results in unfolding of the tertiary structure of the protein. Third, although the tertiary (and quaternary) structure of the protein may unfold, the secondary structures, viz., α-helix and β-sheet, which are stabilized by hydrogen bonds, may not unfold. In the low dielectric environment of the aqueous-organic solvent mixture, strengthening of these dipole-dipole interactions may actually stabilize the secondary structure. In fact, a recent study has shown that in the entire range of aqueous-organic mixtures, that is, from pure water to pure organic solvent, the secondary structure of lysozyme and subtilsin remained essentially intact (61). It is noteworthy that several enzymes retain their activity in neat organic solvents and that is the basis for non-aqueous enzymology (61). Hexane extraction of oil from dry soybeans and other oilseeds at low temperature causes very little denaturation of soy proteins. However, when the moisture content of soybean is high (>10%), hexane extraction often leads to partial denaturation of soy proteins.

Exposure of proteins to polar organic solvents at elevated temperature usually causes extensive denaturation. In the case of food proteins, this results in poor aqueous solubility of the protein. For example, hot aqueous ethanol treatment (55% ethanol at 80°C) caused complete denaturation of pea protein isolate and a large reduction in its protein dispersibility index (62). A significant reduction in the trypsin inhibitory activity of pea protein isolate also was observed. However, treatment with higher ethanol concentration (65%) and lower treatment temperature (65°C) minimized protein insolubility and caused only a marginal reduction in trypsin inhibitory activity.

5. pH-Induced Denaturation

Proteins are either negatively or positively charged at neutral pH. Since this represents the physiological pH, the native structure of the protein represents an equilibrium structure with a global minimum free energy that has

already taken into account the preexisting repulsive and attractive electrostatic interactions. However, at pH values away from the neutral pH, changes in the state of ionization of various charged residues in proteins alter the electrostatic free energy of the protein, resulting in conformational changes. Most proteins are very stable at their isoelectric pH, where the net charge of the protein is zero and electrostatic repulsive interactions are at a minimum. However, many proteins unfold at pH values below 5 and above 10. This unfolding is not simply because of changes in the ionization state of the charged residues on the surface of the protein, but is related to ionization of residues that are partially or fully buried in the protein. Specifically, in many proteins histidine ($pK_a = 6.0$) and tyrosine residues ($pK_a = 9.6$) are buried in the un-ionized form in proteins. When the pH of the solution is decreased below 5.0, ionization of the buried histidine residues can cause unfolding. Similarly when the pH of the solution is increased above 10, ionization of buried tyrosine residues can unravel the protein structure. The pH-dependent ionization of charged residues on the surface of the protein also may contribute to protein denaturation. Protonation of carboxyl groups ($pK_a = 4.6$) at acidic pH eliminates negative charge and the protein becomes highly positively charged. On the other hand, deprotonation of lysine residues ($pK_a = 10.2$) at pH above 10.5 decreases the positive charge and the protein becomes highly negatively charged. In both situations, increased electrostatic repulsion between surface charges may also contribute to unfolding of the protein. If salt bridges between positively and negatively charged residues in partially buried surface crevices of proteins are involved in the stability of native structure of proteins, then protonation (of the carboxyl group) and/or deprotonation (of the amino group) of one of the groups of the salt bridge can significantly perturb protein structure. In many cases, the pH-induced denaturation of proteins is reversible, but prolonged exposure to extreme pH values can cause hydrolysis of certain peptide bonds, deamidation of asparagine and glutamine residues, and destruction of cysteine residues via β-elimination reaction. Such chemical alterations in proteins would result in irreversible denaturation.

V. SUMMARY

Despite the presence of numerous intra-molecular interactions, proteins exist in a metastable state. Thermodynamically, the net stability of the native structure of proteins is only about 5–20 kcal mol^{-1}. Because of this, destabilization of a few critical interactions in a protein by temperature, salts, pH, and other small-molecular-weight denaturants can cause cooperative unraveling of the native structure. In the case of food proteins, the majority of which are oligomeric proteins, the denaturation phenomenon is more complex than that in monomeric proteins. In oligomeric proteins, the denaturation process may follow a three-state model, the first being the dissociation of the oligomer into monomers and the second being unfolding of the monomers. In some proteins these two processes may occur in a de-coupled manner and in other proteins these may be coupled together. Such complex structural transitions in proteins may affect their functional properties as food protein ingredients. They also affect the nutritional properties of proteins, e.g., digestibility. Proteins that are resistant to thermal denaturation also are less digestible, e.g., soy proteins. Thus, a fundamental understanding of the structural stability of food proteins and their denaturation behavior under various environmental conditions as encountered in a food milieu is essential for understanding their structure-function relationships in food systems.

7 Food Protein Functionality

Jeff D. Culbertson
Department of Food Science and Toxicology, University of Idaho

CONTENTS

I. INTRODUCTION

Functionality has been described as the non-nutritive roles that food constituents play in a food system. More formally, functional properties are the physical and chemical properties that affect the behavior of molecular constituents in food systems. Functionality of ingredients is important in the preparation, processing, storage, quality, and sensory attributes of foods (1). Proteins in foods are multifunctional and may be the principal structural component in many food systems, including products from meat and poultry, eggs, dairy, cereals, and legumes. Proteins contribute significantly to the sensory attributes and overall quality of products of which they are a component. Knowledge of protein functionality is critical for the development of new products and the improvement of existing ones. An example is the use of less expensive protein sources as replacements in traditional food products. Use of less expensive proteins not only allows for cost reduction, but also can increase the utilization of food materials that previously might have been considered waste products. As our society increases in complexity,

TABLE 7.1
Important Functional Properties of Proteins in Several Food Systems

Functional Property	Food System(s)
Solubility	Infant formulas, protein beverages, beer, yogurt drinks
Water-holding ability (capacity)	Tumbled hams, deli meats, frankfurters, poultry products, yogurt
Gelation	Frankfurters, custards, gelatin, comminuted meat and poultry products
Emulsification	Ice cream, liquid coffee creamers, salad dressings, milk, mayonnaise, gravies
Foaming	Angel and sponge cakes, meringues, soufflés, marshmallows, whipped cream and toppings

the demand for new food products requires us to understand protein functionality so that we can modify or control their behavior in new food systems.

Functional properties commonly associated with proteins include solubility, gelation, emulsification, foaming, and water-holding capacity. Table 7.1 lists these functional properties and gives examples of foods which commonly exhibit them. Smith (2) classified functional properties into three broad categories: 1) hydration properties such as solubility or water retention, 2) protein-protein interactions such as gelation, and 3) surface properties such as emulsification and foaming.

In many foods systems, proteins are multifunctional in that they might play a number of different functional roles in a given food. Additionally, a given food might require several different proteins so that all of the functional needs of the food are met. Excellent examples of this are highly ground or comminuted muscle foods systems such as frankfurters or bologna. Those products require proteins that exhibit good solubility, gelation, water-holding capacity, and emulsification. Because the naturally occurring proteins in muscle might not perform all of these roles well, it is necessary to add functional proteins to these formulations in the form of food protein ingredients. Protein additives available for use in formulated foods come from many sources and are in high demand by the food industry. As seen in Table 7.2, protein ingredients are extracted and purified (or partially purified) from both plant and animal sources. Besides native source, the major functional protein in each is also listed. Typically, protein ingredients are called concentrates if they contain between 50–80% protein and isolates if their concentration is greater than 90% (2).

The major factors that influence the functional properties of a protein are its biochemical nature and how it was affected by extraction and purification into a food ingredient. Perhaps of paramount importance is the primary structure, or amino acid sequence, of the protein. This sequence dictates how the protein might fold in regular patterns (secondary structure) and how it might appear in three dimensions (tertiary structure). Whether or not a protein is a single unit or contains multiple subunits (quaternary structure) is also a function of primary structure. The tertiary and quaternary structures of proteins are very important to the overall functionality of the proteins. These structures dictate the physicochemical properties of the protein including surface charge, hydrophobicity, stability to heat and chemicals, molecular flexibility, and dissociation behavior. The physicochemical properties of proteins are what determine how it functions in a food system. Thus, if we can understand the physical and chemical properties of a protein we can begin to predict how it might behave in a food. Understanding these principles also allows us to manipulate the physical and chemical characteristics of a protein during food preparation and subsequent processing. We can also use this knowledge to perhaps alter the properties of a protein ingredient to change how it functions in a food.

Figure 7.1 illustrates how the physicochemical properties of a protein might be altered. Food proteins can be altered by processing operations, environmental conditions, or interactions with other ingredients in the food system. Processing conditions that might alter functional properties include heating, drying, freezing, mixing or shearing, and pressurizing. Environmental conditions that influence protein functionality are ionic strength, pH, types of salts present, and oxidation-reduction potential. Environmental conditions tend to overlap with ingredient interactions, since many ingredients have a strong

TABLE 7.2
Major Functional Proteins: Their Sources and Food Use Examples

Major Functional Protein	Source	Use
Gluten: glutenin, gliadin	Wheat	Bakery, pasta, bread
Legumin: 11S and 7S globulins	Legumes	Soy protein isolates, texturized vegetable protein, infant formulas
Casein	Milk	Whipped toppings
Alpha lactalbumin Beta lactoglobulin	Whey	Whey protein isolates, ice cream, infant formula
Myosin	Muscle (beef, poultry)	Frankfurters, deli meats, massaged and tumbled hams, lunchmeats, surimi
Gelatin	Rendering of beef, fish (collagen)	Gelatin desserts, yogurt
Ovalbumin, ovomucin	Egg white	Angel and sponge cakes, soufflés, meringues

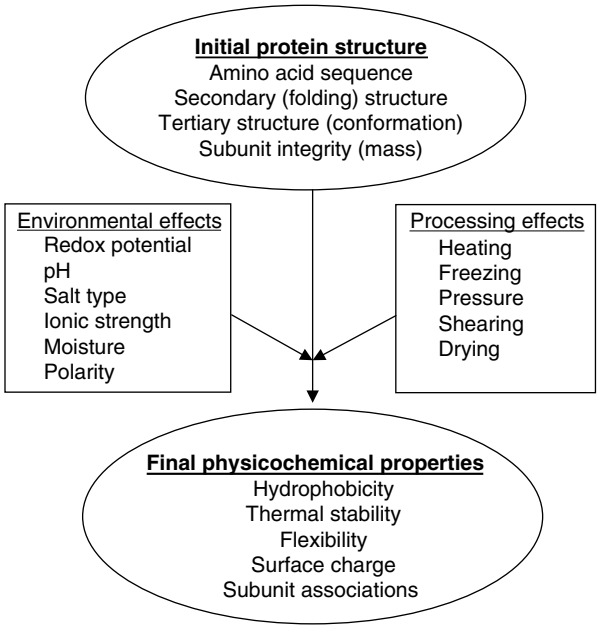

FIGURE 7.1 Effects of environment and processing on the structure and physicochemical properties of proteins.

influence on the environment in which a protein exists. An example is the presence and type of ions and salts that might be added in the form of an ingredient. The presence and types of lipids or fats have a powerful influence on the physicochemical properties of proteins. An example is the inclusion of a small amount of egg yolk in a mixture of egg white proteins that are meant to be foamed. The lipids present in the egg yolk will interact with the egg white proteins and markedly reduce their ability to foam in terms of overall volume and foam stability.

Small changes in formulation (and thus environment) or processing can greatly alter the functionality of food proteins. A classic example is the effect of salt on the functional properties of muscle proteins in processed meats such as frankfurters and lunchmeat (3). The addition of 1.5–2.5% salt solubilizes the meat proteins and allows them to bind water and form an elastic, rubbery gel. This results in the typical texture and sensory quality that we expect in a hot dog or frankfurter. If the salt is not present, the hot dog has poor water binding and gelation, which results in a brittle, tough product.

Storage of food ingredients or finished foods will also influence the functionality of food proteins. Proteins may partially unfold or denature during storage, leading to aggregation and loss of solubility. If a food system contains oxidizing lipid, proteins may react with lipid breakdown products to form unstable aggregates, brown polymers, and otherwise dramatically change in terms of function in the food. When frozen for extended periods, proteins may lose their ability to bind and hold water, thus creating excessive drip in the thawed product.

Because food systems are so complex, protein functionality has been traditionally studied in model systems where many of the interactions with ingredients or processing can be controlled or removed. These studies involve the use of very controlled conditions which are carefully defined so that reproducible results might be obtained. A number of model systems have been developed for each functional property. Functional property tests should be based on a fundamental physical property of a protein. An error that some researchers have repeated is the development of tests that are based solely on equipment available in the researchers' laboratory. In the next section we will examine some of the individual functional properties of proteins that determine their use and application in various foods.

II. FUNCTIONAL PROPERTIES OF FOOD PROTEINS

A. Protein Solubility

The solubility of a protein many times determines its use in foods. Solubility may be the most important aspect of functionality for a protein. In beverages, foams, and emulsions, a protein must be soluble to have functionality. Foaming, gelation, and water binding are also influenced by solubility. In some cases, e.g., water binding, less soluble proteins may function more efficiently. Using classical biochemical terminology, albumins are water-soluble proteins; globulins are salt soluble; glutelins are soluble at high pH values; and prolamines are most soluble in alcohols. The solubility of a protein is determined by its primary structure—the sequence of amino acids in the protein chain. If a protein has a polar surface due to the presence of polar amino acids, it will have good solubility in a polar solvent such as water. Since the pH of a solution will influence the overall charges on a protein, the use of a protein in a given food is many times dictated by the pH of the food system. Proteins with higher contents of hydrophobic amino acids, fewer charges on their surface, or those which contain many subunits tend to have limited water solubility.

As we will see, heat-treated proteins unfold and tend to form less soluble aggregates. Thus, solubility may be used as an index of denaturation of the protein due to exposure to heat, processing or storage. Solubility is markedly affected by pH, polarity of the solvent, temperature, and concentration of dissolved salts.

1. Effect of pH

Surfaces of proteins have net charges due to their amino acid content and the pH of their environment. Amino acid residues such as argenine or lysine can provide positive charges for protein surfaces, while aspartic or glutamic

acids can yield negative charges. The charges present depend on the pH of the food system. When a protein has equal numbers of positive and negative charges on its surface it has minimal solubility. This is called the pI or isoelectric point of the protein. At this point the protein has a net charge of zero. There is minimal solubility because intermolecular repulsion is at a minimum and proteins will tend to aggregate. At pH values above the pI of a protein it has a net negative charge. At pH values below the pI, it will have a net positive charge. In both cases the presence of pronounced surface charges will result in intermolecular repulsion and enhanced solubility.

2. Effect of Salt Concentration

Solubility is also affected by the type and concentration of salts in a food system. As salts increase in concentration proteins become more soluble. This is called "salting in" of a protein and is attributed to the ability of salt ions to enhance the surface charges on proteins. In foods, sodium chloride is commonly used for this purpose. Salt concentrations may be adjusted in a product to enhance the functional properties of the food system. At high salt concentrations, usually above 1 molar, protein solubility decreases. This is thought to be due to salt competing with the proteins for available water for solvation. This effect is called "salting out" and is rarely seen in foods as the concentration of salt required is so high that the food would be inedible.

3. Protein Denaturation

In their natural state, proteins tend to have highly folded structures. Many are "globular" or roughly spherical in shape. This is called their "native" structure. These native structures tend to be very sensitive to conditions which would cause them to change their shape or conformation in a food setting. If a protein unfolds or unravels due to large changes in its surface charges and conformation, it is said to be denatured. For most proteins, denaturation is an irreversible process. Proteins can be denatured by very low or high pH values, organic solvents, high salt concentrations, mechanical shear, and elevated temperatures. Single strands of denatured protein are unstable, leading them to form aggregates which can form gels, foams, or precipitates. The temperature at which proteins denature varies widely due to differences in amino acid sequence and other environmental conditions, such as pH or salt concentration. As denaturation proceeds, protein molecules change in regard to surface charges, shape, size, and hydrophobicity. Most thoroughly denatured proteins are insoluble. When foods are cooked or otherwise thermally processed, the majority of proteins in them become denatured. Denatured protein functions differently from native proteins. Since the solubility of a protein is many times dependent on native structure, denaturation can be simply measured by looking at how soluble a known protein is under certain conditions.

Since denaturation results in loss of solubility, it is undesirable in many food systems where solubility is important. An example is the preparation of protein products for use in foods that rely on protein functionality. Egg whites are pasteurized to destroy pathogenic bacteria; however, the process to do so must be sufficiently gentle so that the finished product can be used in the baking industry to make products such as angel food cake. If the whites were harshly heated, the desired proteins would denature and the ingredient would not function in the finished food. On the other hand, denaturation may cause desirable changes in some food systems, such as in the manufacture of gelatin from collagen or the gelling of egg whites during the cooking of an egg. Some ingredients, such as whey protein concentrates, are available in a variety of degrees of denaturation for application in different products (4, 5). Whey products used for foaming applications have less denaturation than those sold for use as water-binding agents.

4. Measurements of Solubility

One must always remember that any test used to measure a functional property is empirical and thus the results will vary with the test conditions selected. Many solubility tests are based on suspending and stirring a known amount of protein in a buffered solution, followed by centrifugation to remove insoluble components with subsequent protein analysis (colorimetric or Kjeldahl) of the supernatant. The results depend greatly on the protein concentration used, pH, buffer ionic strength, and centrifugal force. Over 70 methods have been published to measure the water-holding capacity and solubility of dairy proteins (6). To obtain results that can be compared to other data and laboratories, it is always best to use a standard method if available. Two commonly used standard methods are published by the American Oil Chemists Society (AOCS) (7) and the American Association of Cereal Chemists (AACC) (8).

B. Gelation

A protein gel is a three-dimensional cross-linked network of protein molecules imbedded in an aqueous solvent (9). Many processed foods are gels such as custards, yogurts, cheeses, frankfurters, and gelatin-based desserts. Most gels are very high in water content (up to 95–98%), yet still have characteristics of solid or rigid food materials. Gelation is based on the denaturation of proteins, followed by their intermolecular association to form matrices which trap water, fat, and other food ingredients. The formation of gels is influenced by heat, pH, pressure or shearing, and the presence of various solvents. The majority of edible food gels based on protein are formed due to heating.

Food gels fall into two categories: thermally reversible and thermally irreversible. Thermally irreversible gels are also called "thermoset" gels and represent the largest group of edible gels. Included in the group are gels based on the muscle protein myosin and ovalbumin, an egg protein. Thermoset gels form chemical bonds that will not break during reheating of the gel and thus remain rigid if reheated. An example would be reheating a cooked egg white. Thermoplastic gels are thermoreversible and will "melt" when reheated due to the reversible nature of the bonds which hold the strands of the gel together. The collagen breakdown product gelatin is the most common example of a thermally reversible gel. Some types of protein, such as alpha-lactalbumin from whey, will form either type of gel depending on the environmental conditions in the food system during heating (5).

1. Properties of Thermoset (Irreversible) Gels

Most thermoset gels are the result of protein unfolding and denaturation followed by aggregation of the molecules into a cross-linked network. During this process, heated proteins partially unfold and form clumps or aggregates. As the "gel-point" temperature is reached, these aggregates unfold further and rapidly cross-link to form a gel (4). This network is generally formed via noncovalent bonds such as hydrophobic interactions and hydrogen bonds. Occasionally, disulfide bonds may be involved. In order for a stable gel to set, there must be a balance between the charges on the denatured protein surfaces and the water molecules in the system. If the protein-protein attraction is too weak, the proteins will remain in solution and a viscous fluid will result. If the attractive forces are too strong, the proteins will aggregate and precipitate. The proper amount of denaturation will result in proteins that interact sufficiently to form a matrix that will also hold a large amount of water.

2. Factors Affecting Thermoset Gel Properties

As one might predict, environmental conditions such as pH and salt concentration, as well as heating rate and final temperature greatly affect the properties of a thermoset gel. Thermoset gels can be opaque and turbid or transparent and clear. Turbid gels are formed when repulsive forces between the protein molecules are low (such as pH values close to the isoelectric point). When heated, the proteins tend to form grape-like aggregate clusters which then are cross-linked together upon further heating (10). Transparent gels are more likely to form when protein molecules are highly charged and repulse each other until denaturation occurs. In transparent gels the protein molecules tend to form structures which resemble "strings of pearls" where individual molecules form chains which occasionally cross-link with other strands. Various researchers have examined the differing properties of gels formed from a single type of protein when conditions of pH, ionic strength, and heating are varied (11). Manipulation of environmental factors can produce turbid, transparent, or hybrid gels from the same protein.

3. Thermoplastic Gels (Thermoreversible)

The most extensively studied protein which forms thermoplastic gels is gelatin, a product of refined collagen. Collagen is a triple-stranded helical protein used in a variety of structural roles in many species. When heated it dissociates into single proteins strands called gelatin that assume random coil configurations. When gelatin is dissolved in hot water, it attempts to reform its original triple helix structure. If the mixture is cooled, gelatin strands will randomly reform sections of the helical structure resulting in the formation of a cross-linked matrix. The sections where intermolecular bonding occurs are called "junction zones." The bonds used to form the matrix are hydrogen bonds, which are thermally reversible. Heating a gelatin gel will cause the hydrogen bonds in a junction zone to dissociate and the matrix/gel will melt. Upon cooling, the gel will reform.

4. Measurements of Gel Properties

As with solubility, a range of functional tests for protein gels exists. Although it might seem appropriate to use a model system where only the protein and water are studied, the impact of other food system components, such as fat or ground particulate matter (such as spices), can be very great and cannot always be ignored. In general, the more simple a model system is, the less likely it will mimic what occurs in a real food, such as a frankfurter (2).

Quality control operations in the food industry have developed a number of empirical tests to relate the properties of gelled products to their acceptability by consumers. An example would be measuring the amount of force required to shear through a cross-section of a frankfurter. Samples of finished product can be gathered off the processing line and sheared as a means of ensuring proper product formulation and processing. However, these types of tests are only valuable for measuring specific products which that particular company produces.

A common test used to test gel strengths is the "torsion test" (12). A gel of appropriate size and shape is twisted in a rheometer until the gel breaks or ruptures. The force required to rupture the cross-sectional area of the gel can be calculated and compared to other properties, such as sensory evaluation results. Several gel strength tests have been widely accepted for use in this manner (13, 14).

C. Water Binding

Water binding is an important functional property for several reasons: 1) most foods contain high amounts of water

and if their chemistry changes in a manner that would cause the formation of free water or drip loss, consumers would be displeased, 2) increasing the amount of water a product can hold effectively can increase the profitability of a given product, and 3) both product yield and sensory quality are highly dependent on the proper moisture content of a finished food. Water-binding capacity is the amount of water that is bound or retained by a protein under highly defined conditions.

Water is usually be bound to the surface of a protein by hydrogen bonding, which is sometimes called dipole bonding. Hydrogen bonding results from water's interaction with the R group of amino acids which are dipoles, such as serine and threonine, or ionic, such as lysine or aspartic acid. Water bound to the surface of proteins in this manner is called "monolayer" water and is very tightly associated with the protein. Other water associated with the protein or protein matrices can be trapped in capillary structures and pores. In food systems, water can also be held in cells and other structural networks. Water that is not associated with the monolayer on the protein surface is called free water and moves unhindered throughout the food system. Depending on the food or model system, water-binding capacity tests measure a mixture of the free and bound water present.

1. Factors Influencing Water Binding

For a given food system, the protein concentration, temperature, salt type and concentration, and degree of denaturation impact on the water binding exhibited. In addition, small polar molecules, such as sugars or sugar alcohols, will enhance water binding by proteins in general. As the protein concentration increases, so does the water binding observed. Generally, water binding increases as temperature increases. In some cases the proteins will form gels, which will enhance the binding of water by the system. Many types of whey protein and soy protein isolates will form gels when heated above 80°C. Enhanced binding in gels is due to water being bound by both hydrogen bonds and by being trapped in pores.

Ions also influence water binding. Sodium chloride binds to charged groups on protein surfaces and weakens intermolecular bonds. This is a positive effect in systems which utilize muscle fibers as part of the structural elements of the food. Salt allows the muscle proteins to distance themselves from others within the muscle fiber and thus increase the number of sites for water to bind. In various muscle types, water binding may be increased 2–3 fold by the presence of salt (15).

The pH of a system markedly influences its ability to bind water. This is due to changes in the surface charges on a protein as the pH is altered. Water binding is lowest at the isoelectric point (pI) of a protein. As the pH is adjusted away from the isoelectric point the ionic charges on the protein increase dramatically and water binding is enhanced. As the pH is lowered from the isoelectric point the protein assumes a net positive charge. Conversely, as the pH is increased, a net negative charge is seen.

2. Methods of Measurement

Water-binding model systems must be carefully defined if reproducible results are expected. Most of the methods are empirical and are usually designed for a specific product or application. At least 15 different methods have been developed to measure the water binding of various muscle/meat proteins (16). In general, two main types of tests exist. One is based on sorption—the adsorptions of water by a dry powder of protein. The other is sometimes called "expressible moisture" where a product is subjected to a force and the amount of moisture expelled is measured. The force is usually pressure or centrifugation. These types of tests must be carefully designed so that the actual internal structure of the gel or food is not destroyed when the pressure is applied. This would lead to an underestimation of the water binding for the system since water that normally would have been trapped in the matrix would be expressed (17).

D. Emulsification

An emulsion is a mixture of two immiscible liquids in which one is dispersed in the other in the form of droplets (18). It is common practice to call the liquid in the droplets the dispersed, internal, or discontinuous phase. The surrounding phase is called the external or continuous phase. Emulsions in which the dispersed phase is a lipid are called "oil in water" emulsions (o/w). Water in oil emulsions contain droplets of water dispersed in a lipid continuous phase. Egg yolk and milk are examples of natural emulsions. Many manufactured foods are intentional emulsions including ice cream, salad dressings, chocolate, mayonnaise, cakes, frosting, butter, and spreads. Food emulsions are far more complex than a droplet of one phase suspended in another. Foods contain many other materials such as air, particulates or other dispersed solids, partially crystallized fat, and gels.

1. Principles of Emulsification

When a liquid is exposed to air, the surface between them is in a state of tension. This so-called "surface tension" is due to the attractive forces between molecules in the liquid that are enhanced by exposure to air. In lay terms, the molecules "bunch" together to decrease their exposure to the air surface. When two immiscible liquids, such as water and oil are in contact, the region of contact is called the interface, with the development of "interfacial tension." As the interfacial area increases, the stability of the mixture decreases. An example would be the creation of

temporary emulsion of oil in water by forming millions of small droplets of oil suspended in the water phase. One can imagine creating this mixture by blending several milliliters of oil into a cup of water in a high speed mixer. This type of mixture is called a "temporary emulsion," for although there would initially be millions of oil droplets, they would rapidly coalesce into a separate oil layer which would form on top of the aqueous phase. Coalesced droplets have less surface area exposed to the water, and thus are more stable. Vinegar and oil salad dressing is a classic example of temporary emulsions.

To stabilize emulsions it is necessary to add molecules which decrease the interfacial tension between mixtures of lipids and water. Surfactants are molecules that contain both hydrophobic (non-polar) and hydrophylic (polar) regions in their structure. When added to a system that contains both lipids and water, surfactants rapidly migrate to the interfaces between the two phases. At the interface, the surfactants orient their polar region towards the aqueous phase and their non-polar region towards the lipid phase. Since proteins contain amino acid residues that can be polar and non-polar they can be excellent surfactants in food systems. Figure 7.2 illustrates the coating of an oil or fat droplet with a protein molecule. Once the droplet or air bubble is coated, the interfacial tension between the two phases is markedly lowered and the tendency to coalesce is greatly reduced. The simplistic illustration in Figure 7.2 shows a single molecule of protein unfolding on the oil surface. In a real emulsion, there are thousands of molecules involved on the surface of a single droplet. If a sufficient reduction in interfacial tension is achieved, the emulsion can be stable for long periods of time.

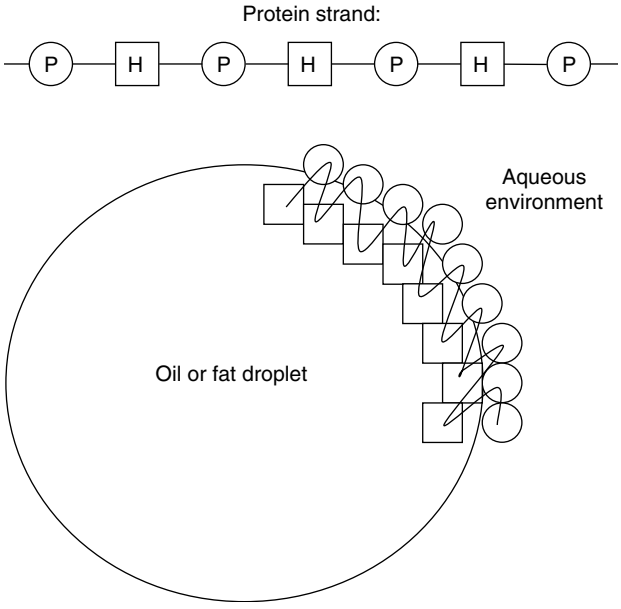

FIGURE 7.2 Formation of a protein stabilized emulsion. The protein is represented by the connected circles and squares, which are defined as follows:
Squares are hydrophobic (H) amino acid residues which orient towards the oil or fat phase.
Circles are hydrophylic (P) amino acid residues which orient towards the aqueous phase.
The continuous line represents the peptide bonds connecting the amino acids.

2. Factors Affecting Protein-Based Emulsions

Food emulsions are complex systems which are normally created by using large amounts of energy to form very small particles of one phase which become suspended in another. Higher energy inputs normally result in smaller droplets and enhanced activity of any surfactants that are present. To work well as a surfactant, a protein must be able to migrate to the interface, orient polar and non-polar side chains into the proper phases, and form a stable film around the droplet. In many cases proteins may partially unfold or denature during these activities. After unfolding and orientation towards the proper phase, proteins form multiple layers on the droplet surface due to intermolecular ionic, hydrogen, and hydrophobic bonding between unfolded protein strands. The formation of superior emulsions by proteins relates to their ability to form viscous yet flexible films around the surface of droplets (19).

Most food emulsions are oil in water. In forming o/w emulsions, the initial water solubility of the protein is very important. Therefore, factors such as protein concentration, pH, salts, ionic strength, and temperature strongly affect the emulsification ability of proteins. Other factors that influence their ability to emulsify are related to the physicochemical properties of the protein, such as surface charge, surface hydrophobicity, molecular flexibility, ease of denaturation, and dissociation behavior of subunits. Table 7.3 lists the factors which can be important to the formation and stability of protein-based emulsions.

Since proteins vary in physicochemical properties, it is not unexpected that researchers have seen varying results when studying the effects of pH, salts, and temperature on the emulsification ability of proteins. Because proteins have unique primary, secondary, and quaternary structures, environmental effects such as pH must be determined for each individual protein. In general, proteins near their isoelectric point (pI) are poor emulsifiers, presumably due to poor solubility. As the pH is adjusted away from the pI, improvement in emulsification is generally seen and is probably due to enhanced solubility. Very low or high pH may lead to poor emulsification even though the proteins might be very soluble. In this case, the proteins are so highly charged they do not interact to form films on the surface of the dispersed phase. If proteins are coated with an excess of charges they will not form cohesive, flexible films (19). Proteins with multiple subunits, such as the soybean storage protein legumin, may exhibit

TABLE 7.3
Factors Affecting Formation and Stability of Protein-Based Emulsions

Environmental factors	Temperature, pH, salt concentration, salt type, ionic strength, other ions, other food components
Protein characteristics	Solubility, ease of denaturation, surface hydrophobicity, surface charge, isoelectric point, flexibility, elasticity of protein film
Processing parameters	Amount and rate of energy input (shear), oil or fat type, oxidative state of lipid, temperature
Aqueous phase	Viscosity

improved emulsification activity at pH values where the subunits are encouraged to dissociate (20).

Several researchers have shown that surface hydrophobicity can be highly related to the ability of proteins to act as emulsifiers (21). In general, proteins that are water soluble but which have large numbers of hydrophobic groups on their surface tend to be superior emulsifiers. With increased surface hydrophobicity, a larger portion of the protein strand might be able to interact with the oil or fat droplet and form stronger protein films (22). Results have shown that proteins with high surface hydrophobicities, such as casein or bovine serum albumin (BSA), are superior emulsifiers compared to proteins with low surface hydrophobicities, such as collagen or gelatin (21).

3. Methods of Measurement

As with other model systems tests, the results of protein emulsification evaluations are often highly empirical. Comparison of results between laboratories is only possible when strict testing conditions are maintained. Although the absolute numbers obtained in these tests may vary from lab to lab, the ranking of different proteins in terms of ability to emulsify or emulsion stability are often similar. The results seen in rapid tests may not give the same results seen in a true food system. Many food companies, however, cannot wait a year for results when they are evaluating proteins for use in products under development and subject to an accelerated development time table.

Emulsions are commonly tested for two parameters: stability and capacity. Emulsification capacity is normally measured as the maximum amount of oil a protein may emulsify. A classic test of emulsification capacity is that of Wang and Kinsella (23), where the maximum amount of oil that a protein can emulsify is determined by a titration method. Oil is added to a protein solution in a blender or mixer until the emulsion fails, which is determined by a rapid decrease in viscosity. Advantages are that the procedure is quick and simple. Disadvantages are that the results are highly dependent on the equipment used to generate the emulsions and the protein:lipid ratios encountered in the test are not commonly encountered in food systems (24). Another widely used technique is the Emulsification Activity Index (EAI) developed by Pearse and Kinsella (25). In this assay, the interfacial area created in an emulsion is measured by a spectrophotometric assay. As the ability of a protein to emulsify increases, smaller and smaller emulsion droplets are formed, which can be measured by light scattering principles. Advantages of this method are that it is a rapid technique that does not rely on the use of an external force to break the emulsion. Disadvantages are: 1) emulsions must be prepared under very standardized conditions (e.g., sample container volume, homogenizer or mixer manufacturer, speed or power settings) and 2) several studies have found poor correlations between EAI and emulsion stability (24).

Emulsion stability can be measured by a variety of methods. Choice of method depends on the type of instability or emulsion breakdown observed in the actual food system where the protein may be used. Separation and clustering of fat or oil droplets on the top of an emulsion is called "creaming" and is a marked sign of emulsion breakdown. A standard test for creaming (26) involves the placement of an emulsion in a graduated cylinder which is held in an environmental chamber. The height of the boundary between the top of the creaming layer and the residual emulsion is measured as it decreases with time. Advantages of the test are that it can be set up rapidly and it can be easily used to determine how pH, ionic strength, and protein concentration impact emulsion stability. Disadvantages are that lengthy storage times under highly controlled conditions are required (24). A more rapid test is the Emulsion Volume Index where centrifugation in microhematocrit tubes is used to accelerate the forces which cause emulsion breakdown (27). Advantages are that analysis times are much shorter and other researchers have found correlations between EVI and longer term stability testing of actual products (24). If time is not essential, it is possible to use a long-term storage test to evaluate emulsion stability by measuring droplet size distribution and concentration in a hermetically sealed container (28). Although the test can duplicate actual storage conditions of products, it may take over a year to complete (24).

E. Foaming

Emulsions and foams are similar types of food systems in that they contain two distinct phases. In foams, the liquid or solid continuous phase surrounds a dispersed gaseous phase which is usually air. Many times a protein which

emulsifies well will also foam well. The first step in the formation of a foam is the migration of proteins to the interface between air bubbles and the aqueous phase. At the interface the protein will unfold and orient their nonpolar regions toward the air phase. As proteins adsorb on the bubble surface, they begin to form layers of partially denatured proteins which encapsulate the air bubble and prevent the foam from collapsing (29). Foams may be produced by mechanical agitation (whipping) or sparging, which is the injection of gas through very small orifices to produce bubbles. Most food foams are produced by whipping and include meringues, soufflés, whipped cream, non-dairy whipped toppings, angel food or sponge cakes, and ice cream. Yeast leavened breads are foams that are produced by the trapping of carbon dioxide bubbles by the gluten protein matrix.

1. Factors Affecting Foaming

As with other functional properties, solubility plays a critical role in foaming. Good foaming proteins also exhibit one or more of the following molecular properties: 1) high rates of diffusion and adsorption at the interface, 2) ability to unfold and denature at the interface, and 3) ability to form intermolecular associations with other molecules that result in the formation of cohesive films around the air bubble (1). The surface hydrophobicity of proteins correlates with its ability to form foams (21). Since it is important for a protein to unfold on the interface, the foaming ability of some proteins can be improved by a mild heat treatment or chemical modification which loosens the protein structure and allows it to unfold more rapidly. Enhanced film formation through increased intermolecular bonding is also generally seen. Excessive denaturation will decrease foam formation and stability by decreasing initial protein solubility and causing protein films to form at the interface that are inflexible and stiff. This is a result of excessive intermolecular interaction between protein strands.

In regard to foaming ability, egg whites (albumen) form some of the highest quality foams due to the properties of the constituent proteins, ovalbumin, globulins, and ovomucoid. During the foaming of egg whites, acids such as cream of tartar (potassium acid tartrate) are added after an initial whipping period. The acid lowers the pH and reduces the net charge on the protein which allows the protein strands to interact more strongly. It also facilitates the denaturation of proteins to increase the elasticity of protein films around the air bubbles. Overall, a more stable film results. Addition of the tartrate before the initial foaming causes the proteins to unfold prematurely and interact before they reach the air bubble surface, which results in decreased foam volumes and stabilities (1).

In most cases, the foaming ability of proteins in inhibited by the presence of lipids. Contamination of egg white with as little as 0.03% egg yolk completely inhibits foaming (30). It is theorized that lipid is absorbed at the air/water interface within the foam and causes the protein film to rupture. Conversely, high concentrations of saturated fat can stabilize foams. An example is whipped dairy cream in which cold coalesced fat droplets can surround protein-encapsulated air bubbles, resulting in a very stable foam.

The amount of energy used during foam formation impacts on foam stability. Energy inputs must be sufficient to create very small air bubbles and assist in the denaturation of proteins due to shear forces. Over-whipping, however, may cause the foam to dehydrate and collapse, leading to decreased foam volume and stability. Energy input must not cause the proteins to denature prior to encountering air bubbles. Denatured protein may fail to reach the air bubble surface and precipitate by interacting with other protein molecules in solution. The denatured protein may also form more brittle films on the air bubble surface.

2. Methods of Measurement

As previously mentioned, the results of functional tests many times are empirical and depend on the methods used and the laboratory in which they are performed. Several methods have been published for foaming proteins, including shaking, sparging (gas injection), and whipping (31). Most food foams are prepared by whipping. Results from a model system test that is based on whipping might be better correlated to actual foods since the method of preparation more closely resembles actual food preparation. Both foam volume and foam stability are important in the manufacture of foods, so it would be valuable to gather data in a model system on those two parameters. Wilde and Clark (29) have published foamability and stability methods that have been widely accepted. The methods use inexpensive equipment but care should be taken to use identical procedures between different laboratories. Another widely used test determines the percent overrun of a foam and involves the removal of samples at various times to determine foam density (32). Stability tests for foams commonly use a "half-life" determination where the time for half of the foam to break down or half the original liquid volume to return to the liquid state is measured.

III. APPLICATION OF FUNCTIONAL PROPERTIES

A. Intentional Modification of Protein Functional Properties

The manufacture of many modern food products relies on the use of proteins for their functionality. The proteins

may be a natural constituent of the food, such as in muscle, or the proteins may be added as an ingredient due to their ability to solubilize, bind water, gel, emulsify, or foam. As we have discussed, the functional properties of proteins are interrelated and associated with the structures of the protein molecule. Although we can obtain protein from a multitude of sources, not all proteins are highly functional due to their primary, secondary, tertiary, or quaternary structures. For example, several yeast proteins and many plant proteins have limited functionality when used in their native conformation. Solubility may be a problem for some types of proteins and require the addition of salts to enhance their functionality. An example is in the manufacture of frankfurters where 0.5–1.5% salt is commonly used to enhance the functionality of myosin in gel formation. Protein modification has the potential to enhance the use of many less functional and less expensive proteins to perhaps make foods more economical and perhaps more desirable in a nutritional sense.

Modification is the intentional alteration of the physicochemical properties of a protein by chemical, physical, or enzymatic means to improve functional properties (33). Many of the alterations simply increase solubility, since it is paramount to most functional properties. For proteins with substantial quaternary structures, such as the legume storage proteins, improvement is related to the disruption of the bonding between individual subunits. In other cases it might be the alteration of amino acids on the protein surface to make them more polar or the disruption of hydrophobic cores of proteins to decrease their molecular density.

As we have learned, a protein's ability to emulsify or foam is related to its ability to migrate to an interface and denature or unfold. Some types of modification will "loosen" up the native structure of a protein through chemical, physical (e.g., heating), or enzymatic means to allow the protein to migrate, unfold, and interact more substantially on the interface in either emulsions or foams. These types of treatments can also enhance the ability of water to bind within a protein or the ability of protein strands to interact to form gels; thus both water-binding and gelation behavior of proteins can be enhanced by modification.

1. Chemical Modification

A variety of chemical modifications have been used to enhance the functionality of proteins from plants, animals, and microorganisms. These generally involve the use of a chemical agent to modify the protein by reacting to covalently alter the amino acid residues on its surface. Acylation reactions that involve the direct addition of chemical groups through the R groups (side chains) of amino acids have the most potential to modify proteins. Researchers have examined modification of surface charge via the creation of esters with acetic, succinic, phosphoric, and a number of fatty acids. Sugars and other oligosaccharides have also been attached to the surfaces of proteins (33).

The common sites for acylation are the epsilon and alpha amino groups of proteins. Lysine is a particularly reactive amino acid, followed by tyrosine and cysteine. Alteration of surface charge and surface hydrophobicity through these modifications is the likely mechanism for functionality improvement.

For chemically altered proteins to be acceptable for human foods they must be nontoxic and digestible (34). Typically, modified proteins can be tested using protocols outlined by the Food and Drug Administration (FDA). A number of different tests can be used to determine the impact on nutritive value (33). Because lysine is an essential amino acid for many species and is also a major site for modification, decreases in nutritive value are seen in chemically modified proteins. Protein Efficiency Ratios (PER) for modified proteins typically range from 40–100% of the values for their unmodified counterparts (33). Since physical and enzymatic methods do not alter amino acid composition dramatically, they are preferred methods for modifying proteins.

2. Enzymatic Modification

Enzymatic modification of proteins includes partial hydrolysis, covalent attachment of functional groups, and the incorporation of cross-links between protein molecules (35).

Protein hydrolysis is the most widely used of these techniques. Proteolysis is easy to control, very rapid, and occurs under ambient conditions. There is very low risk for the formation of toxic residues. Proteolysis is considered by many to be the most cost-effective way to enhance protein functionality (35). Because proteolysis produces peptides that are smaller in size and which contain less secondary structure than the original proteins, their solubility is increased. Enhanced solubility is directly related to the degree of hydrolysis and related to increases in functional properties such as foaming and emulsification. Partial hydrolysis has been used to improve the functionality of a wide variety of proteins from beef, chicken, dairy, fish, yeast, corn, wheat, and peas. Proteolysis is commercially used to prepare functional protein products for use as food ingredients. Depending on the source of protein, optimal peptide size for one functionality, such as foaming, does not always equate to optimal functionality for another, such as emulsification. Proteolysis is quite interesting in that it is possible to fine tune the process to obtain protein ingredients that are optimized for a given functionality.

Enhanced functionality due to cross-linking or covalent attachment of a hydrophylic or hydrophobic residue

is also an area of intense research. Several very functional natural proteins, such as ovomucin, the superior foaming protein from egg white, have surfaces that are highly polar due the presence of glycosyl groups. Researchers have been able to produce protein products with excellent foaming abilities from soy and casein using enzymes which attach very polar groups to their surface (36). Another enzyme, peptidoglutaminase, has also been examined as a means of improving functionality (37). The enzyme increases the negative charges on a protein by converting glutamine and aparagine to their negatively charged counterparts, glutamic and aspartic acids. This technology appears to have potential for widespread use since many insoluble proteins from soy, peas, beans, dairy, and wheat have substantial numbers of glutamine and aparagine residues on their surface.

3. Physical Modification

Heat is the major way in which physical modifications are carried out with proteins. For example, the industry is replete with many soy protein products that have been modified by heating to improve foaming, emulsification, water-binding, and gelation properties (38). Heat causes proteins to partially denature through changes in secondary and primary structure. In theory, this should increase the functionality of the protein by improving its ability to unfold at interfaces and form films around air bubbles or lipid droplets. In particular, the gelling ability of several proteins, such as those from dairy whey, has been substantially improved through heat treatment (4). Many of the procedures used to manufacture heated protein ingredients for use in formulated foods are proprietary. It is known, however, that the procedures used to maximize the functionality of a protein source for one application are usually not the same for another. In other words, heating techniques used to enhance foaming or gelling are not the same as for emulsification (4).

A specific type of modification of plant proteins using heat has widespread application. Texturized Vegetable Protein (TVP) is commonly used in the processed food and food service industry to bind water and fat. Most TVP products are made from soy and are manufactured under very specific environmental conditions of temperature, pH, ionic strength, and pressure. TVP is produced using extrusion techniques where the proteins are subjected to heat, pressure, and shear forces simultaneously. The proteins are extensively denatured and insolublized; however, the resulting matrix is almost sponge-like in its ability to bind other liquids, such as excess fat and moisture, in food systems.

One interesting application of physical alteration of proteins is the manufacture of several fat substitutes through the manipulation of their physical characteristics. Using a process generically called "microparticulation," proteins from milk and/or eggs are denatured and refolded into smaller, denser particles that can act as lubricants during the chewing and swallowing of foods. These materials have the mouthfeel of lipids, but are actually a blend of proteins and water. Simplesse (registered trade name by the NutraSweet Company) is an example. Since these ingredients are proteins, they cannot be used in products that will see extremes of environment, such as heat or pH, since they would most likely denature under such conditions. Their use is probably limited to products that will only see low temperature heating processes, such as pasteurization.

IV. SUMMARY

The functional properties of proteins are defined as their physical or chemical properties that affect foods during their preparation, processing, storage, and consumption. They contribute greatly to the quality and acceptability of a wide range of natural and processed/prepared foods in the food supply. Proteins are considered by many experts to be the most multifunctional components of foods in that they can play many different roles in foods. Natural products made from meat, poultry, dairy, eggs, cereal grains, and legumes, as well as the majority of formulated foods developed and marketed through the food industry, all rely on the functionality of proteins for their acceptability and quality.

The functional properties include solubility, water-holding ability or capacity, gelation, emulsification, and foaming. Solubility is paramount for the successful use of proteins in most food systems. To function in a food the protein must be able to migrate throughout the aqueous phase to seek interfaces (foaming and emulsification), hold water, or form extensive three-dimensional networks (gelation). The solubility of a protein is determined by its amino acid sequence and is greatly influenced by environmental factors such as solvent polarity, pH, temperature, and concentration of dissolved salts.

Food gels are diverse structures primarily composed of immobilized water held within a cross-linked protein matrix. Both thermally reversible (gelatin) and thermally irreversible (frankfurters) gels are important food products. The ability of a protein to gel is primarily evaluated by measuring the texture or strength of the gel using a torsion test.

Water binding by proteins is influenced by temperature, concentration of protein, concentration of salt, degree of protein denaturation, and the presence of other compounds, such as sugars or alcohols. Two main methods, water absorption and expressible moisture, are commonly used to measure the water binding of proteins.

Emulsification and foaming are cousins in the protein functionality family. They both rely on similar properties of the protein in the food system, such as solubility and

ease of denaturation. Proteins must be able to migrate to the interface formed with the second phase of oil in emulsions and air in foams. Proteins must be able to form cohesive, multilayered, flexible films around droplets of lipid or air. The main model tests involve measuring the overall ability of a protein to emulsify or foam, as well as the stability of the emulsion or foam created.

The functional properties of proteins are often measured using model systems that can vary widely from researcher to researcher. To make the results of our research valuable, we must strive to use protocols that are widely accepted and used by our colleagues. In many cases, model systems do not mimic the conditions seen in real food systems. We tend to measure, and correctly so, the fundamental properties that are related to the desired functional property seen in the food.

The modification of proteins by chemical, physical, and enzymatic methods has increased the utilization of less conventional protein sources and decreased the costs of manufacture for a number of food products. Most methods attempt to increase the solubility of proteins. Although chemical methods are effective, there are questions regarding safety and nutritional losses. Enzymatic and physical methods have been adapted for use in the protein ingredients industry. Heating remains the most widely used modification technique and has been very successful in increasing the functionality of a wide range of proteins, particularly those from soybeans and whey. Texturization produces very useful protein ingredients which have the ability to adsorb excess moisture and fat in foods. Lastly, the ability of proteins to be compressed allows them to be used as fat substitutes in foods.

CONTENTS

I. INTRODUCTION

Although the intake of excess fat may result in significant health problems, it is important to note that fats are a critical part of a proper diet. The human body can produce most fatty acids but certain "essential" fatty acids (e.g., linoleic and linolenic acid) are typically derived from lipid-containing foods since the body cannot produce them. In addition, fats in foods are sources of vitamins A, D, E, and K. There is considerable evidence that therapeutic components that can improve human health are endogenous to food fats. Fats also contribute unique

flavors and physical properties to the foods that consumers find desirable.

The two major classes of fats in foods are phospholipids (PL) and triacylglycerols (TAG). Phospholipids are constituents of cell membranes while TAG are fatty globules that exist primarily as coalesced droplets in biological tissues. Other types of fats include sterols, waxes, and carotenoids. Lipid is a term used to encompass all types of compounds that are soluble in organic solvents and therefore classified as fats. Olive oil contains only triacylglycerols while muscle foods contain both PL and triacylglycerols. Food emulsions can contain only TAG (e.g., margarine) or TAG and PL (e.g., mayonnaise). The egg portion of mayonnaise supplies PL, which cause the water phase and the oil phase to be continuous. In other words, yolk phospholipids act as emulsifiers. Phospholipids and TAG are each susceptible to oxidation during storage that results in the formation of off-odors and off-flavors, which effectively end shelf life. Loss of nutritional value can also occur due to oxidation of the lipid and co-oxidation of proteins and vitamins (1). Triacylglycerols and phospholipids can be modified so that desirable functional properties are made available. These functional properties include physical attributes, flavor stability, caloric value, therapeutic effects, and nutrient content. This chapter will primarily focus on 1) factors that promote or inhibit lipid oxidation processes, and 2) chemical modification of lipids that improve their functional and nutraceutical properties. Further, the chemistry involved in food processes such as oil refining, frying, and food irradiation will be addressed.

II. NOMENCLATURE

The core portion of any lipid comprises repeating units of the hydrocarbon group $(-CH_2)_n$. Saturated hydrocarbons are typically named with a numerical prefix and the termination "ane" (e.g., octane is an 8-carbon saturated hydrocarbon). The suffix "ene" indicates the presence of double bonds also expressed as "unsaturation" in the hydrocarbon. Fatty acids contain an acid group (-COOH) bound to the hydrocarbon tail (Figure 8.1). At pH values above the pKa for each fatty acid, the fatty acid will exist mainly in its conjugated base form (COO^-). The charge on the fatty acid will control its reactivity.

The shorthand for c-9 octadecenoic acid (oleic acid) is 18:1ω9. This indicates there are 18 carbons and one double bond. The ω9 indicates that the double bond is nine carbons in from the end of the hydrocarbon portion. c-11 octadecenoic acid (asclepic acid, 18:1ω7) also exists in nature but is less prevalent than oleic acid. This molecule is identical to oleic acid except that the double bond is seven carbons in from the hydrocarbon tail. The omega symbol (ω) is assigned because nutritional and health impact of different fatty acids are related to the locations of the double bonds. Omega-3, ω-3, and n-3 are often used interchangeably. Linolenic acid (18:3ω6 or 18:3 cis-6, cis-9, cis-12) indicates that there are three double bonds. The 6, 9, 12 are the positions where the double bonds begin counting the carboxylic acid group as the first carbon (Figure 8.1). The *cis* conformation is indicative that both alkyl groups adjacent to the double bond are aligned in the same direction. *Trans* fatty acids have the alkyl groups pointing in opposite directions. Most polyunsaturated fatty acids have 1,4-pentadiene structures as illustrated in Figure 8.1. Conjugated fatty acids will have one of the double bonds shifted one carbon closer to the adjoining double bond. Desaturases and elongases cause smaller and more saturated fatty acids (e.g., linoleic acid 18:2ω6) to be converted to longer and less saturated fatty acids (e.g., arachidonic acid 20:4 ω6).

Each membrane phospholipid contains two fatty acids and a single polar head group esterified to glycerol 3-phosphate (Figure 8.2). Typical head groups bound to the phosphate portion include ethanolamine, choline, and serine. These head groups are polar and orient themselves toward the aqueous phase while the fatty acids assemble away from the water phase to form a lamellar membrane bilayer (Figure 8.3). Sterols, proteins, and glycolipids imbedded in the membrane are not illustrated. Other molecular arrangements of phospholipids are possible including inverted micelles (2). Triacylglycerols contain a glycerol backbone on which three fatty acids are esterified. Locations of the fatty acids are designated as sn-1, sn-2, and sn-3. A more extensive review of nomenclature of lipids including different sphingolipids, waxes, sterols, and carotenoids is available (3).

III. LIPID OXIDATION

Lipid oxidation needs to be controlled during storage in order to prevent the formation of off-odors and off-flavors in foods. Desired color and nutritional attributes are also compromised when oxidation of lipids is unimpeded

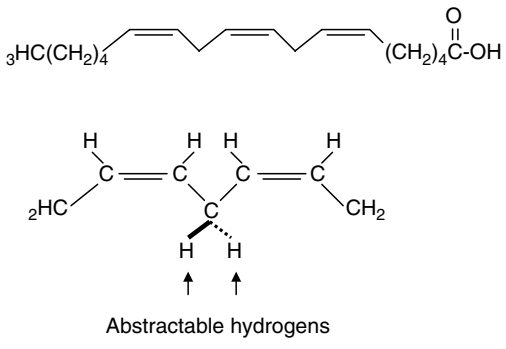

FIGURE 8.1 (Top) Structure of cis-6, cis-9, cis-12 linolenic acid (18:3ω6). (Bottom) The 1,4-pentadiene unit within most polyunsaturated fatty acids.

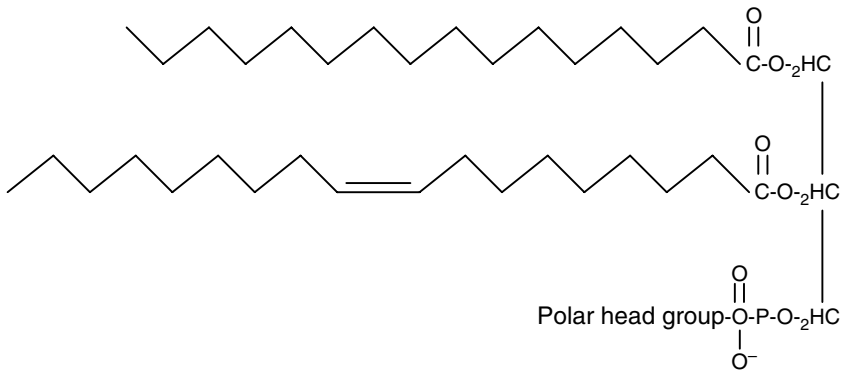

FIGURE 8.2 Basic structure of a glycerophospholipid.

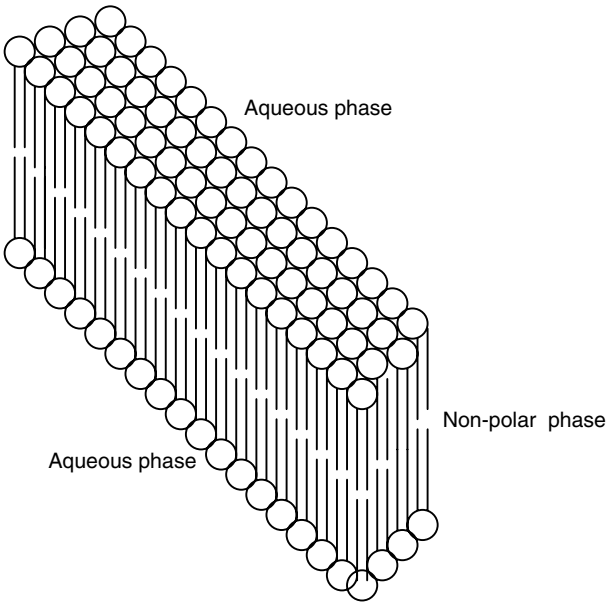

FIGURE 8.3 A simplified representation of a membrane bilayer.

during storage. The mechanism and rate of lipid oxidation will vary depending on the system under investigation. Interfacial properties, processing temperature, particle size, fatty acid unsaturation, and non-lipid constituents will differ among different systems (e.g., a bulk oil, salad dressing emulsion, raw muscle, cooked meat). Therefore the optimal strategies used to inhibit lipid oxidation processes will change from system to system. This should be kept in mind as general principles of lipid oxidation reactions are discussed. Attention to lipid oxidation has rapidly expanded in recent years due to the growing accumulation of evidence that the onset of various disease states may be related to intake of oxidized food lipids and ingesting critical amounts of antioxidants may improve human health (4, 5).

The classical description of lipid oxidation processes begins with the initiation step where a hydrogen atom is abstracted from a polyunsaturated fatty acid (Figure 8.4).

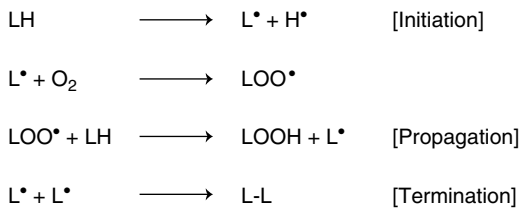

FIGURE 8.4 Initiation, propagation and termination of lipid peroxidation.

This causes the formation of a lipid alkyl radical (L•) that reacts with oxygen to form a peroxyl radical (LOO•). The peroxyl radical can then abstract a hydrogen atom from a different polyunsaturated fatty acid to form a lipid hydroperoxide (LOOH) and another alkyl radical (propagation). It should be kept in mind that small amounts of pre-formed lipid hydroperoxides exist in freshly processed oils, muscle foods and even biological tissues *in vivo* (6, 7). This may decrease the importance of controlling true 'initiators' of lipid oxidation and switch the emphasis to a better understanding of food constituents that break down lipid hydroperoxides. The breakdown of lipid hydroperoxides by metals, heme, heme proteins, and hydroperoxide lyases causes the formation of key volatiles (e.g., aldehydes and ketones) that are responsible for the undesirable odors and flavors associated with lipid oxidation.

Oleic acid (18:1) is generally more susceptible to lipid oxidation than any saturated fatty acids. This is because the lower bond energy of hydrogen atoms adjacent to a double bond allows for more easy abstraction compared to hydrogen atoms in fatty acids lacking double bonds. Most fatty acids with two or more double bonds possess the 1,4-pentadiene structure (Figure 8.1). Hydrogen atoms in the center of the 1,4-pentadiene are around 20 times more abstractable than the abstractable hydrogen of oleic acid (8). Increasing the number of double bonds increases the number of 1,4-pentadiene units and thus increases susceptibility to lipid oxidation. The relative rates of lipid oxidation of oleate (1 double bond): linoleate (2 double bonds): linolenate (3 double bonds) was reported to be 1:12:25 (9).

This was the case in pure lipid systems. In different liposome preparations, oxidative stability decreased as the degree of fatty acid unsaturation increased (10). However, the order of oxidative stability was found to increase with increasing degree of unsaturation when different fatty acids were dispersed in 1% Tween 20 and exposed to iron salts and ascorbate (11). Although atypical, this indicates that under certain conditions highly unsaturated fatty acids are more resistant to lipid oxidation than more saturated ones. In oil-in-water emulsions, fatty acid composition, the physical states of the lipids, content of tocopherols, and activity of transition metals were implicated as factors controlling rates of lipid oxidation (12).

In muscle foods the situation is even more complex. A multitude of components are present that can either accelerate or slow down lipid oxidation processes. Water-washing of muscle fibers from various animal species was used to obtain a wide range of fatty acid unsaturation (13). Washing the muscle removes aqueous antioxidants and pro-oxidants while insoluble myofibrillar proteins and membrane phospholipids remain after washing. Metmyoglobin or iron was added to the washed fibers to stimulate lipid oxidation. The general trend was that lipid oxidation occurred more rapidly in washed muscle containing elevated levels of polyunsaturated fatty acids (fish > chicken > beef). It has also been shown that the ability of fish, poultry, and beef hemoglobins to promote lipid oxidation in a washed muscle system occurred in the following order (fish > chicken > beef) (14). Therefore, the reactivity of different hemoglobins in various muscle foods should be considered as a causative factor in addition to fatty acid unsaturation and endogenous antioxidant capacity.

Compartmentation of cellular and extracellular reactants should be critical in controlling rates of lipid oxidation. Takama et al. (15) suggested that minced flesh of trout was susceptible to rancidity due to the dispersed blood pigments in the flesh caused by the mechanical destruction of the tissue. Crushing plant tissue brings formerly segregated reactants together to stimulate various reactions including oxidation of lipid (16). Critical cellular components and additional factors that control rates of lipid oxidation are discussed below. In any discussion pertaining to lipid oxidation, it is important to realize that any component that accelerates lipid oxidation under one set of conditions can be inhibitory under different conditions.

A. Metals

Low-molecular-weight metals are potent catalysts of lipid oxidation. Copper and iron are two of the more potent metal catalysts in biological systems. Only ferrous ions and oxygen are needed to produce hydrogen peroxide (H_2O_2) as seen in reactions 1 and 2:

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + {}^{-\bullet}O_2 \qquad \text{[reaction 1]}$$

$$^{-\bullet}O_2 + 2H^+ \rightarrow H_2O_2 \qquad \text{[reaction 2]}$$

Ferrous iron (Fe^{2+}) can then react with H_2O_2 or preformed lipid hydroperoxides to produce hydroxyl or alkoxyl and hydroxyl radicals, respectively (reactions 3 and 4). Hydroxyl and alkoxyl radicals are capable of abstracting a hydrogen atom from a polyunsaturated fatty acid and hence initiate/propagate lipid oxidation (17).

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{-}OH + {}^{-\bullet}OH \qquad \text{[reaction 3]}$$

$$Fe^{2+} + LOOH \rightarrow Fe^{3+} + {}^{-\bullet}OH + LO^{-\bullet} \qquad \text{[reaction 4]}$$

Reaction 3 is termed the Fenton reaction. Hydroxyl radical can also be produced via the Haber-Weiss reaction (reaction 5). A "ferryl ion" is produced from Fenton reagents and relevant as an initiator of lipid oxidation (reaction 6); even in the absence of H_2O_2, ferryl ion can be produced from the reaction of Fe^{2+} and the "perferryl ion" complex ($Fe^{2+}O_2$) (18).

$$^{-\bullet}O_2 + H_2O_2 \rightarrow O_2 + OH^- + {}^{\bullet}OH \qquad \text{[reaction 5]}$$

$$Fe^{2+} + H_2O_2 \rightarrow \underset{\text{Ferryl ion}}{Fe^{2+}O} + H_2O \qquad \text{[reaction 6]}$$

Chelators such as ethylenediaminetetraacetic acid (EDTA) and adenosine diphospate (ADP) are widely used to enhance the ability of iron to promote lipid peroxidation (19). Ascorbate increased the ability of iron to stimulate lipid oxidation by reducing ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}) (20). Antioxidant properties of ascorbate and metal chelators are discussed later (Section V.F and V.G). Ferric iron can also be reduced enzymatically (e.g., membrane bound reductase, ADP and NADH). Although Fe^{2+} did eventually stimulate lipid oxidation in sarcoplasmic reticulum, increasing concentrations of Fe^{2+} increased the lag phase prior to lipid oxidation; this suggested that Fe^{2+} initially was an antioxidant by reducing membrane antioxidant radicals to their active form (21). Fe^{2+} could then stimulate lipid oxidation after the antioxidant capacity was exhausted. Lipolysis, cooking temperatures, ascorbate, peroxides and extended storage times have the ability to increase iron concentrations in biological systems by stimulating the release of iron from proteins including ferritin, transferrin, hemoglobin, and myoglobin (22–26).

B. Heme Proteins

Hemoglobin and myoglobin are the predominant heme proteins (HP) in muscle foods. The blood protein hemoglobin is a tetrameric protein while myoglobin from the interior of muscle cells is a monomer (single polypeptide chain). Hemoglobin tetramers dissociate into monomers and dimers upon dilution and with decreasing pH (27, 28).

Certain aquatic and land animals possess multiple hemoglobins with different chromatography characteristics (29, 30). These factors can cause erroneous determination of hemoglobin and myoglobin content in tissue extracts. Heme proteins consist of a globin chain(s) and a heme ring(s), the latter containing an iron atom. The iron is primarily in the ferrous state (HP-Fe^{2+}) *in vivo*. Met heme protein (HP-Fe^{3+}) accumulates post mortem via a proton or deoxygenated HP mechanism (reactions 7 and 8) (31). A general term for the formation of metHP from ferrousHP is heme protein autoxidation.

$$\text{oxy}(+2)\text{HP} + \text{H}^+ \rightarrow \text{met}(+3)\text{HP} + {}^{\bullet}\text{OOH} \qquad \text{[reaction 7]}$$

$$\text{deoxy}(+2)\text{HP} + \text{O}_2 \rightarrow \text{met}(+3)\text{HP} + {}^{-\bullet}\text{O}_2 \qquad \text{[reaction 8]}$$

Met heme protein formation is likely critical to the onset of lipid oxidation since metHP reacts with either H_2O_2 or lipid hydroperoxides to form the ferryl HP radical that is capable of initiating lipid oxidation (reactions 9 and 10) (32). MetHP is much more likely to unfold and release its heme group compared to ferrous HP (33, 34). Released or displaced heme can react with lipid peroxides to form various lipid radical species that have the ability to propagate lipid oxidation processes (reaction 11) (35–37). Bohr effects occur in certain fish hemoglobins (38). This decreases oxygen affinity of the heme protein at post mortem pH values and hence increases met heme protein formation (reaction 8). It is still unclear if ferrous forms of heme proteins can react with lipid hydroperoxides to stimulate lipid oxidation processes although some potential pathways have been suggested involving oxyHP and deoxyHP (39, 40).

$$\text{met}(+3)\text{HP} + \text{H}_2\text{O}_2 \rightarrow \text{HP}^{+\bullet}\text{ferryl}(+4) = \text{O} + \text{H}_2\text{O} \qquad \text{[reaction 9]}$$

$$\text{met}(+3)\text{HP} + \text{LOOH} \rightarrow \text{HP}^{+\bullet}\text{ferryl}(+4) = \text{O} + \text{LOH} \qquad \text{[reaction 10]}$$

$$\text{heme}(+3) + \text{LOOH} \rightarrow \text{Heme}(+3)\text{-O}^{\bullet} + \text{LO}^{\bullet} \qquad \text{[reaction 11]}$$

C. Peroxides

There are numerous sources of hydrogen peroxide in biological systems. Equations 1 and 2 describe an iron, oxygen, and proton-mediated mechanism of formation. NADPH-cytochrome P450 reductase produces ${}^{-\bullet}O_2$ that dismutates to H_2O_2 (19). Production of H_2O_2 in mitochondrial and peroxisomal fractions has been described (41). H_2O_2 production in erythrocytes was mainly attributed to hemoglobin autoxidation (42). H_2O_2 was produced at a rate of 14 nmol/g of fresh weight/30 min in turkey muscle at 37°C (43). High concentrations of H_2O_2 will cause release of iron from the heme ring of heme proteins (25).

Like H_2O_2, lipid hydroperoxides (LHP) react with metals or heme proteins to produce free radical species that propagate lipid oxidation. Further, the collection of volatiles that produce rancid odor result from LHP breakdown. Trace amounts of LHP are required for lipoxygenase activity, converting iron in the active site from the ferrous to ferric form (44). Reduction of lipid hydroperoxides to alcohols with compounds such as ebselen and triphenylphosphine often abolishes any lipid oxidation that was observed prior to reduction (45, 46). Tocopherol-mediated lipid peroxidation was found to require Cu^{2+} and low levels of lipid hydroperoxides (47). Fe^{2+} reacts with lipid hydroperoxides around 20 times faster than with hydrogen peroxide (48). Protein hydroperoxides may also exacerbate lipid oxidation processes (49). Non-lipid surfactant hydroperoxides increased rates of lipid oxidation in oil-in-water emulsions (50).

D. Role of Oxygen

Oxygen not only peroxidizes alkyl radicals to propagate lipid oxidation (Figure 8.4) but also is a source of activated oxygen species (Figure 8.5). Unlike ${}^{-\bullet}O_2$, ${}^{\bullet}OOH$ can cross membranes, which may increase its pro-oxidative character (51). The oxygen concentration in marine oils is fairly constant between 20°C and 60°C but rapidly decreases between 60°C and 80°C (52). The O_2 concentrations in these oils at 20°C (0.44 to 1.25 mM) exceed the O_2 concentration found in water at the same temperature (around 0.30 mM). In 80% oxygen and 20% carbon dioxide packaging, oxygen penetrated 1.7 to 11 mm into different muscle foods (beef > pork > lamb) (53). At high ratios of $[O_2]/[H_2O_2]$, the ferryl ion initiation (reaction 6) is believed to dominate while Fenton reagents (reaction 3) are more prevalent at lower ratios (18). In CCl_4-induced lipid peroxidation of hepatocytes, a distinct maximum was obtained at 7 mm Hg oxygen while iron-mediated lipid oxidation in microsomes differed in oxygen dependence depending on whether initiation or propagation phases were considered (54). Metmyoglobin formation in beef occurred most rapidly at around 11 mm Hg oxygen (55). Non-destructive oxygen sensors are available to measure the oxygen content in headspace of different packaging systems (56). Carotenoids are believed to be more effective antioxidants at low oxygen concentrations compared to higher oxygen concentrations (57).

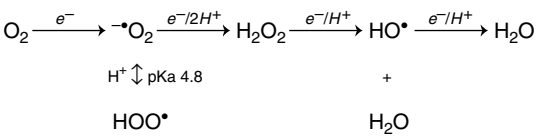

FIGURE 8.5 One-electron reductions of oxygen.

E. Lipoxygenases and Myeloperoxidases

Lipoxygenases are responsible for flavor deterioration in beans during frozen storage (58). Lipoxygenases "initiate" lipid oxidation processes by hydrogen abstraction from a polyunsaturated fatty acid. The off-flavor is due to the volatiles that are produced from breakdown of the lipoxygenase-derived lipid hydroperoxides. Fresh fish aromas are believed to result in part from lipoxygenases that enzymically peroxidize fatty acid substrates (59). These enzymes may also be responsible for formation of rancid odors by providing critical amounts of lipid hydroperoxides that can be broken down by metals or heme proteins to produce rancid odor. Some of the confusion surrounding the presence or absence of lipoxygenases in animal tissues may be due to the quasi- lipoxygenase activities of myoglobin and hemoglobin (60, 61). Esculetin has been utilized as a specific lipoxygenase inhibitor; however, esculetin is a phenolic compound that has general free radical scavenging ability and should not be considered a specific inhibitor of lipoxygenase.

Myeloperoxidases are found in white blood cell neutrophils. Myeloperoxidase catalyzes the reaction of chloride and hydrogen peroxide that produces hypochlorous acid which in turn reacts with $^{\bullet-}O_2$ and yields hydroxyl radical (62). This reaction was found to be six orders of magnitude faster than the Haber-Weiss reaction (reaction 5) and does not require iron.

F. Lipolysis

Lipolysis results in the formation of free fatty acids. Lipolysis occurs due to enzyme action or heat and moisture. Free fatty acids are responsible for both undesirable and desirable flavors (e.g., milk rancidity or positive flavors in cheese, bread, and yogurt). Cabbage phospholipase D decreased the formation of lipid oxidation products in beef homogenates and egg yolk phosphatidylcholine liposomes (63). Adding free fatty acids to fresh salmon flesh, at levels of free fatty acids that accumulated during 6 months at –10°C storage, increased taste deterioration in fresh minced salmon (64). The amount of taste deterioration from each fatty acid was 22:6n-3 > 16:1n-7 > 18:2n-6 > 20:5n-3). This suggested that hydrolysis of triacylglycerols negatively impacted sensory quality. A review on lipolysis effects in fish muscle indicated that triacylglycerol hydrolysis results in increased lipid oxidation while phospholipid hydrolysis was inhibitory (65).

G. Photoactivated Sensitizers (Singlet Oxygen)

Oxygen can exist in the triplet ($^3O_2$) or singlet state ($^1O_2$). Triplet oxygen is the normal state of oxygen while singlet oxygen is generated via photosensitization by natural pigments in food (e.g., riboflavin or chlorophyll). The two electrons in the antibonding 2p orbitals of $^3O_2$ have the same spin and are in different orbitals. This creates a small repulsive electronic state. In $^1O_2$, the two electrons are in a single antibonding orbital and have opposite spins; therefore, electrostatic repulsion will be great. $^1O_2$ is thus at a higher energy state than $^3O_2$, and $^1O_2$ is more electrophillic than $^3O_2$. This causes $^1O_2$ to react readily with moieties of high electron density such as double bonds in unsaturated fatty acids (8). This direct addition of $^1O_2$ to unsaturated fatty acids initiates lipid oxidation without the need for hydrogen abstraction as is the case with free radical-mediated initiation. Nine or more conjugated double bonds (e.g., carotenoids) are required for physical quenching of singlet oxygen (66). Other compounds such as tocopherols and amines can quench singlet oxygen by a charge transfer mechanism (67).

H. Fat Content

Release of c-9 aldehydes into headspace decreased with increasing oil content in oil-in-water emulsions (68). This suggested that the impact of certain odor compounds is decreased by elevated levels of fat via solubilization of the component into the oil phase. A study was conducted that examined the effect of added triacylglycerols on rates of hemoglobin-catalyzed oxidation of washed cod muscle lipids. No difference in rate or extent of lipid oxidation catalyzed by hemoglobin was obtained when washed cod muscle (around 0.7% phospholipids) was compared to the washed cod muscle containing up to 15% added triacylglycerols (69). This indicated that triacylglycerols did not accelerate rates of lipid oxidation during storage. Similar non-effects of added triacylglycerols were obtained in cooked lipid-extracted muscle fibers (70). Increasing fat contents did not increase oxidized oil odor in frozen stored catfish (71).

I. Effect of Cooking

Consumers are finding less time to prepare meals. The food industry is responding to this by increasing the availability of pre-cooked meats. A major problem with pre-cooked meats is the development of an objectionable warmed-over flavor via lipid oxidation (72). This warmed-over flavor occurs more rapidly during refrigerated compared to frozen storage temperatures. It has been suggested that released iron from heme proteins promotes warmed-over flavor in pre-cooked beef (23). The evidence for this was that the low-molecular-weight fraction in an aqueous extract of beef muscle stimulated lipid oxidation of washed muscle fibers much better than the high-molecular-weight fraction (73). On the other hand, in pre-cooked fish, heme proteins were believed to be the active catalysts due to higher pro-oxidative activity in the high-molecular-weight fraction of the fish muscle (74).

Polyphosphates inhibited lipid oxidation in precooked beef, which may be due to iron chelating properties of the phosphates (73). Inhibitors of warmed-over flavor were produced in meat during retorting but could not be extracted from raw beef. This suggests that the high temperature processing caused formation of products that inhibit lipid oxidation (75). Browning reactions that involve carbohydrates and amino acids were believed to impart this antioxidant effect.

Lipid oxidation is much less of a problem in precooked meats that are cured. Cured meats contain nitrite in the formulation. The primary way that nitrite is believed to exert its antioxidant effect is by conversion of nitrite to nitric oxide (NO) that binds to the iron atom in the heme ring of heme proteins. The NO-ligand may be antioxidative by preventing release of heme or iron during cooking and storage or by decreasing heme protein reactivity. Nitrite can also act as an antioxidant by chelating metals and scavenging free radicals. Nitrite may be toxic at elevated levels and therefore it is critical to control the residual nitrite content in the product.

IV. MEASURING RATES OF LIPID OXIDATION IN FOOD SYSTEMS

Lipid hydroperoxides are primary lipid oxidation products that are precursors to rancidity. Lipid hydroperoxides need to be broken down to form the low-molecular-weight volatile compounds (secondary products) that impart rancidity. It is imperative to measure primary and secondary lipid oxidation products. To accentuate this point, tocopherol enriched lipoproteins had higher levels of conjugated dienes (primary product) than lipoproteins containing little tocopherol (76). Standing alone, this errantly suggests that tocopherol was a pro-oxidant. Fortunately, these researchers also measured thiobarbituric reactive substances (TBARS) which indicated less formation of the secondary products in the tocopherol enriched samples. Apparently, tocopherol stabilized the hydroperoxides. Thus, a more complete picture is realized when measuring both primary and secondary lipid oxidation products.

Sensory analysis should be done whenever possible since human subjects can determine the point at which the product becomes undesirable which ultimately determines shelf life. Degree of rancidity or quality perception is harder to pinpoint using chemical indicators of lipid oxidation. Single time point measurements are also discouraged. Primary and secondary lipid oxidation products commonly increase, reach a maximum, and then decrease substantially. This can create a situation where one sample is perceived to be minimally oxidized but in fact had undergone extensive oxidation well before the measurement. Thus, measuring lipid oxidation products at multiple time points during storage is suggested so that a kinetic curve can be obtained which demonstrates a lag phase, exponential phase and plateau, or decrease phase.

Common lipid oxidation indicators that are measured during storage of lipid-containing foods include lipid peroxides, conjugated dienes, headspace volatiles, thiobarbituric acid reactive substances (TBARS), anisidine value, oxygen consumption, and carotene bleaching. A description of these and other methods including those used in fried products is available (8). Very good correlations between TBARS and headspace volatiles (e.g., hexanal, pentenal) were determined in cooked turkey during 4°C storage (77). TBARS are unlikely to provide useful results if the starting material has already undergone considerable oxidation. Rancidity can develop before any detectable change in fatty acid composition occurs. For example, no difference in fatty acid composition was found when fresh mackerel muscle was compared to extensively rancid mackerel muscle (78). This should not be a surprise considering that extremely small amounts of fatty acid precursors are required to produce the amount of volatiles needed for sensory impact (79).

Numerous pitfalls exist when measuring rates of lipid oxidation. Thermogravimetric methods entail weighing the sample until a rapid increase in weight occurs due to oxygen adding to the lipid. This can be done under isothermal conditions or programming from ambient to elevated temperatures. The drawback is that by the time a spike in weight occurs, detection of rancidity had previously occurred. Bulk oils are sometimes heated to 90°C to shorten the storage period needed to produce quantifiable levels of lipid oxidation. The amount of oxygen that is soluble in oil decreases substantially at elevated temperatures. This causes the mechanism of oxidation to be different from that which would occur at lower temperatures. Both the AOM and Rancimat method have been considered unreliable due to the high temperatures that are used (80). More reasonable methods to accelerate the rate of lipid oxidation in oils and emulsions are to store samples at 50°C and add metals or hemin to the system. It is interesting to note that fish held at –10°C was more susceptible to lipid oxidation than muscle stored at around 0°C. The temperature deceleration effect was apparently less substantial than the effect of freeze concentration of reactants (81). The mechanism of lipid oxidation at –20°C (commercial storage) may also be different than –10°C considering that less tissue damage should occur at the lower temperature due to faster freezing rate and smaller sized ice crystals.

V. ANTIOXIDANTS

Food antioxidants are used to inhibit lipid oxidation reactions that cause quality deterioration (e.g., flavor, color, texture, nutrient content). It is important to note that any compound that is antioxidative under one set of conditions

can become pro-oxidative under different conditions. As an example of this point, ascorbate has been found to both inhibit and accelerate lipid oxidation depending on the concentration of linoleate hydroperoxides in the system (82). The main antioxidant mechanisms are free radical scavenging, chelation of metals, removal of peroxides or reactive oxygen species, and quenching of secondary lipid oxidation products that produce rancid odors (83).

A. Free Radical Scavengers

Some typical free radicals that can initiate/propagate lipid oxidation and hence be scavenged by antioxidants include hydroxyl ($^{\bullet}OH$), alkoxyl ($LO^{\bullet}$), peroxyl radicals ($LOO^{\bullet}$), and ferryl heme protein radicals ($HP^{+\bullet}$ferryl(+4)=O) (84). $^{\bullet}OH$ is one of the strongest biological oxidants (Table 8.1) and therefore will react with nearly any molecule that it encounters. This might limit the amount of $^{\bullet}OH$ that will react with fatty acids. Peroxyl radicals are likely prevalent since the reaction of oxygen with alkyl radicals that forms after hydrogen abstraction from a fatty acid is highly favored both thermodynamically and kinetically. Alkoxyl radicals will form due to breakdown of lipid hydroperoxides by heme or reduced metal complexes. Alkoxyl radicals can undergo β-scission reactions that produces a short chain alkyl radical ($RCH_2^{\bullet}$) that reacts readily with O_2 to form peroxyl radicals (17).

There are numerous free radical scavengers (FRS) that are either endogenous to the food or incorporated during processing. The antioxidant effectiveness will depend on hydrogen bond energies (85). The donation of hydrogen from a generic phenolic antioxidant to an alkoxyl radical is depicted in Figure 8.6. The ability of a particular FRS to donate hydrogen to a free radical can be predicted from standard one-electron reduction potentials (17). Any compound that has a reduction potential lower than that of a free radical is capable of donating hydrogen to that free radical (Table 8.1). For example, catechol has a lesser reduction potentials than alkoxyl radical. Thus, catechol can donate hydrogen to the alkoxyl radical. This donating ability of catechol competes with the undesirable reaction of alkoxyl radicals with polyunsaturated fatty acids (PUFA-H) (Table 8.1) and hence inhibits lipid oxidation processes. It should be kept in mind that the reduction potential of a compound changes as a function of pH, temperature, and concentration of the compound(s) of interest.

A potential drawback is that the FRS becomes a free radical itself after donating hydrogen to the alkoxyl radical (Figure 8.6) (Table 8.1). The most efficient FRS exist as low energy radicals after scavenging. The benefit of existing as a low energy radical is that the radical is unlikely to abstract hydrogen from polyunsaturated fatty acids. Low energy radicals result from resonance delocalization (Figure 8.6). The conjugated ring structure of the phenolic allows the phenolic radical to reside at multiple sites on the molecule. As the radical migrates from site to site, a low energy radical results that possesses low reactivity. Evidence of low reactivity can be gleaned from the one-electron reduction potentials. Any radical with reduction potential less than a polyunsaturated fatty acid (e.g., catechol radical) cannot abstract hydrogen from the fatty acid; hence the antioxidant radical cannot initiate/propagate lipid oxidation processes (Table 8.1).

Efficient FRS in their radical form should also not react with oxygen. If reaction with oxygen occurs, a free radical peroxide forms (FR-OOH). The free radical peroxide cannot be regenerated by reducing equivalents as can occur when the FRS is in a resonance delocalized form ($FR^{\bullet}$). The net effect is depletion of the antioxidant upon reaction with oxygen. Further free radical peroxides can decompose to species capable of furthering oxidation. Note that ascorbate has a one-electron reduction potential that is less than tocopherol (Table 8.1) and thus ascorbate can regenerate tocopherol from tocopheroxyl radicals.

Thus, phenolic compounds are efficient FRS due to their hydrogen donating properties and resonance delocalization of the phenoxyl radical. There is a multitude of phenolic free radical scavengers available to food scientists. The synthetic phenolics butylated hydroxy toluene (BHT), butylated hydroxy anisole (BHA), tertiary butyl hydroquinone (TBHQ), and propyl gallate (PG) (Figure 8.7) are commonly used in the food industry due to their low cost of production although consumers prefer natural FRS such as tocopherols and plant phenolics.

TABLE 8.1
Standard One-Electron Reduction Potentials of Components Involved in Free Radical Reactions

[Oxidized / Reduced] Couple	E° ′ (mV)
$HO^{\bullet}$, H^+ / H_2O	2310
$LO^{\bullet}$, H^+/ LOH	1600
$LOO^{\bullet}$, H^+ / LOOH	1000
PUFA$^{\bullet}$*, H*$^+$ */ PUFA-H*	600
Catechol$^{\bullet}$, H^+ / catechol	530
α-Tocopheroxyl$^{\bullet}$, H^+ / α-tocopherol	500
Ascorbate$^{\bullet -}$, H^+ / ascorbate$^-$	282

B. Synthetic Phenolics

Propyl gallate (PG) is poorly soluble in oils and sensitive to heat degradation (e.g., frying temperatures). Substitution of the propyl group with octyl or dodecyl groups provides more heat stability and lipid solubility. Gallates have been used to stabilize meat products, baked goods, fried products, confectionaries, nuts, and milk products (86). Butylated hydroxyanisole (BHA) volatilizes upon frying,

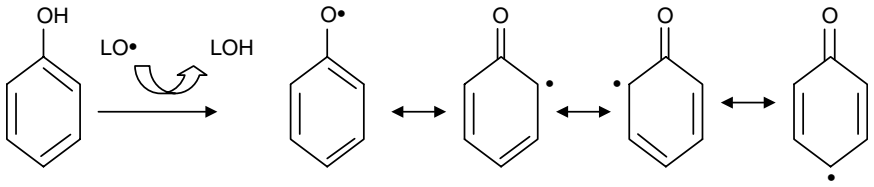

FIGURE 8.6 Free radical scavenging by a phenolic compound and resonance stabilization of the resulting phenoxyl radical. Adapted from Ref. 85.

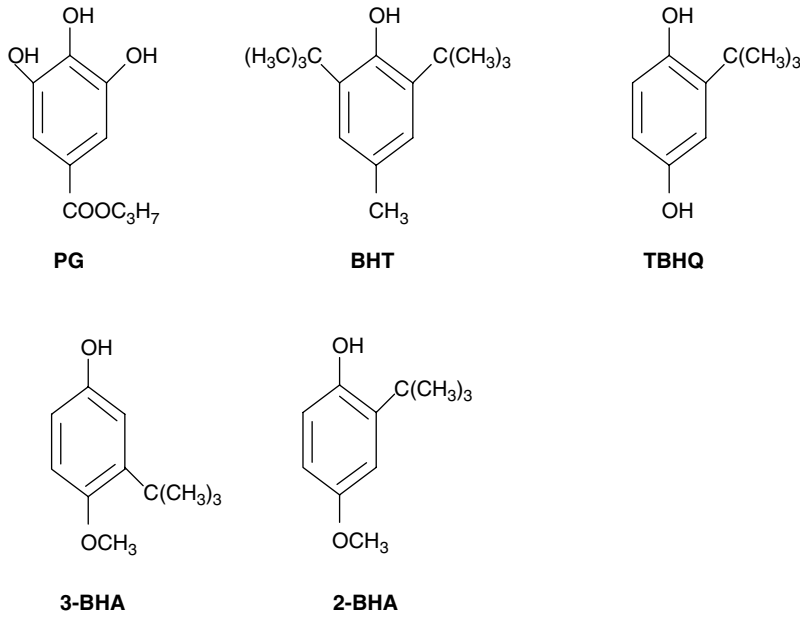

FIGURE 8.7 Structures of various synthetic antioxidants.

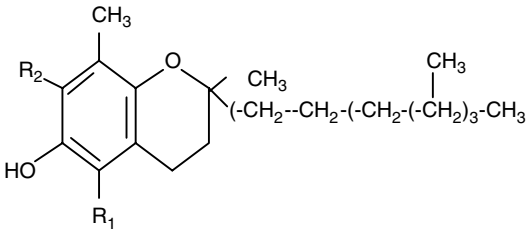
but residual BHA does protect fried foods. BHA is a mixture of two isomers (Figure 8.7). The $-C(CH_3)_3$ group on the conjugated ring increases oil solubility and enhances resonance stabilization of the phenoxy radical. This alkyl group on the conjugated ring also enhances hydrogen-donating properties. Butylated hydroxytoluene is highly soluble in oil due to its two $-C(CH_3)_3$ groups and single methyl group (Figure 8.7). TBHQ has two hydroxy groups and significant solubilities in a wide range of fats, oils, and solvents. The order of antioxidant efficacy in fish oil stored at 60°C was TBHQ> PG=BHA>BHT (87).

C. Tocopherols and Tocotrienols

Tocopherols are of plant origin and exist in four forms (α, β, γ, δ). The structures of the isomers are illustrated in Figure 8.8. Tocopherols are soluble in oils and ethanol. When tocopherol reacts with a peroxyl radical, at least five resonance structures of the tocopherol radical can form (83). BHA, BHT, and PG are considerably more stable to heat treatment than α-tocopherol (86). α-, β-, γ-, and δ-tocopherol inhibited formation of cholesterol oxidation products to different degrees in metal-induced oxidation of unilamellar phospholipid-cholesterol liposomes (88). In beef muscle, tocopherolquinone and 2,3-epoxy-tocopherolquinone were the dominant tocopherol oxidation products and lower amounts of 5,6-epoxy-tocopherolquinone and tocopherolhydroquinone were detected (89). This was consistent with mainly a peroxyl radical scavenging function of tocopherol but also some scavenging of other free radicals. Predominant amounts of the 2,3- and 5,6-epoxy-tocopherolquinone products would suggest a nearly exclusive mechanism of peroxyl-radical scavenging. When examining Atlantic mackerel, a substantial amount of tocopherol was present in stored muscle that was highly rancid (90). This suggested that tocopherol was not an effective antioxidant in the mackerel muscle. Tocotrienols are similar in structure to tocopherols but contain three unsaturated units in the isoprenoid chain. γ- and δ-tocotrienols extended shelf life of coconut fat better or in a manner similar to their corresponding tocopherols during 60°C storage and exposure to frying temperatures (91).



Type	R1	R2
Alpha	$-CH_3$	$-CH_3$
Beta	$-CH_3$	-H
Gamma	-H	$-CH_3$
Delta	-H	-H

FIGURE 8.8 Structures of tocopherols.

D. Plant Phenolics

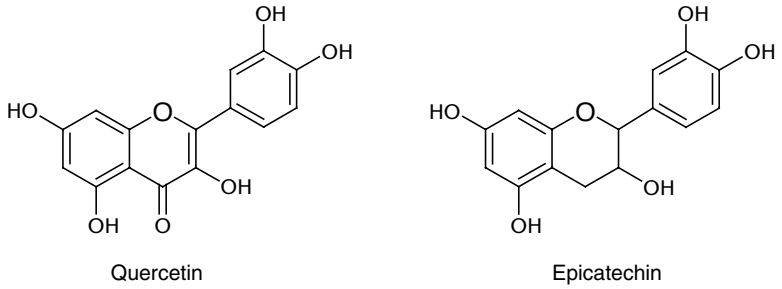
Simple plant phenolics contain a single conjugated ring with various substitutions. These compounds are usually water soluble and examples are gallic acid and hydroxycinnamic acid. Anthocyanidins are 3-ringed structures that exist as protonated cations at acidic pH values, are colorless open-ringed structures at intermediate pH values, and are anions at higher pH values. Glycosylated anthocyaninidins are termed anthocyanins and are the common red pigments in fruits. Flavan 3-ols are colorless compounds that are common in tea. Epicatechin is an example of a flavan-3-ol (Figure 8.9). Quercetin is a flavonol and is one of the most abundant flavonoids (Figure 8.9). Flavonoids is a general term that includes anthocyanins, flavonols, flavones, isoflavones, and chalcones. A quercetin metabolite was found to have antioxidant properties in a liposomal membrane (92). Linked flavan-3-ol repeated molecules are high molecular weight, generally poorly soluble in water, and referred to as proanthocyanidins, procyanidins, tannins, or heteropolyflavans (93). Extensive structural diversity exists in different plant phenolics. In rosemary leaf extract, carnosol, carnosic acid, rosmarinic acid, and rosmaridiphenol have antioxidant potency (86).

The rate of peroxyl radical scavenging by quercetin and epicatechin was greater in non-polar solvents compared to hydrogen bonding solvents (94). In a liposomal model system that generate free radicals during metal-induced peroxidation, 1) antioxidant activity increased with increasing hydroxy substitutions present on the B ring for anthocyanidins but the opposite was observed for the flavan-3-ol, catechin, 2) substitution by methoxyl groups decreased antioxidant activity of anthocyanidins, and 3) substitution of a galloyl group at position 3 of the flavonoid moiety decreased antioxidant activity of the catechin (95).

Many phenolic antioxidants have been characterized in grapes, berries, teas and spices. Beet root pigments were found to have free radical scavenging properties (96). Betanidin 5-O-beta-glucoside in beet was found to inhibit lipid oxidation at low concentrations (97). In pineapple juice, phenolic compounds containing cysteine, glutamyl, and glutathione linkages were identified (98). Proteins (casein or albumin) decreased antioxidant efficacy of tea flavanols (99). Freezing and storage had negligible effects on antioxidant capacity of raspberry phenolics (100). Ferryl myoglobin, a possible pro-oxidant in muscle tissue, was reduced by epigallocatechin gallate from green tea (101). The antioxidant effects of tea catechins in raw chicken muscle were attributed to free radical scavenging ability and iron chelating effects (102).

E. Carotenoids

Carotenoids are fat-soluble pigments. Canthaxanthin and astaxanthin possess oxo groups at the 4 and 4′-positions in the β-ionone ring (Figure 8.10). β-carotene and zeaxanthin do not contain oxo groups and were found to be less inhibitory to methyl linoleate peroxidation than canthaxanthin or astaxanthin (103). β-carotene, however, can scavenge free radicals. Peroxyl radicals either add directly to the hydrocarbon portion of the molecule displacing an unsaturation site or add to the β-ionine ring forming a β-carotene cation radical; these oxidation products, however, are



Quercetin Epicatechin

FIGURE 8.9 Structures of the flavonoids quercetin and epicatechin.

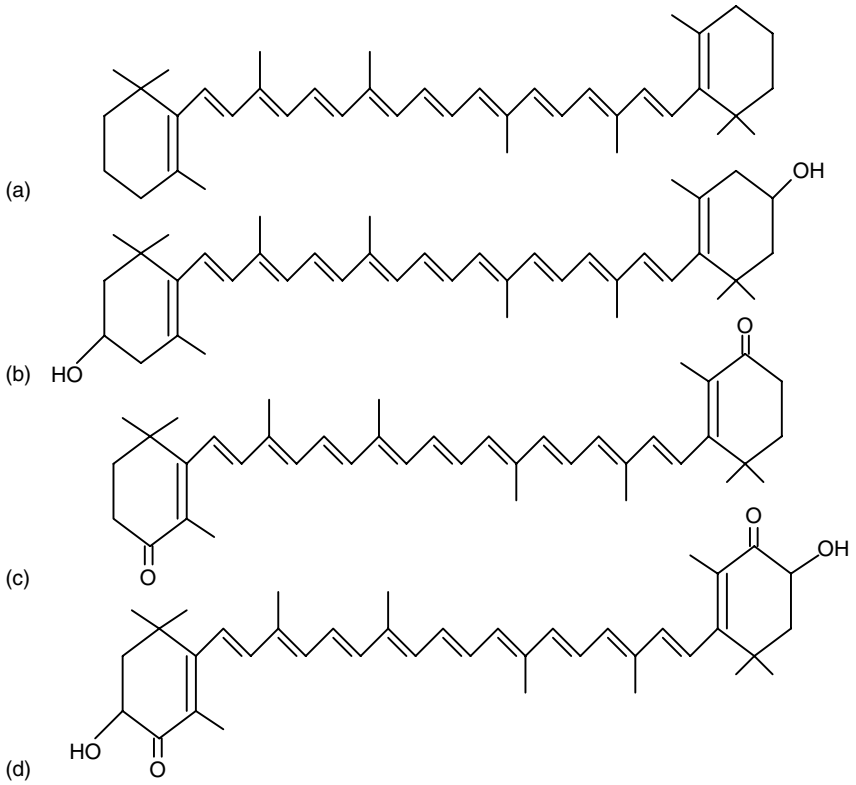


FIGURE 8.10 Structures of various carotenoids. (a) β-carotene, (b) zeaxanthin, (c) canthaxanthin, (d) astaxanthin.

susceptible to breakdown that results in formation of alkoxyl radicals (83). There is evidence that carotenoids are effective antioxidants at low oxygen concentrations but not higher oxygen concentrations (57). Carotenoids including lycopene can inactivate singlet oxygen by physical quenching of the activated oxygen specie (104).

F. Other Free Radical Scavengers and Reductants

Uric acid is present in plasma and can inhibit lipid oxidation by scavenging free radicals or singlet oxygen (105). Ascorbate is believed to scavenge tocopheroxyl free radicals thereby regenerating tocophopherol (17). Ascorbate can also scavenge various free radicals such as $^{\bullet-}O_2$, $^{\bullet}OOH$, and $^{\bullet}OH$ (48). Like flavonoids, ascorbate reduces hypervalent forms of heme proteins to potentially inhibit lipid oxidation in muscle foods (106). Heme oxygenase converts heme into bilirubin. Bilirubin is believed to scavenge free radicals, which results in formation of biliverdin that is reduced back to bilirubin by NADH and biliverdin reductase. This redox cycle was used to explain the high antioxidant power of bilirubin *in vivo* (107). It is not known how effective bilirubin inhibits lipid oxidation in food systems. Ubiquinol is a phenolic compound that is conjugated to an isoprenoid chain and is associated with mitochondrial membranes. Oxidation of ubiquinol results in formation of semiubiquinone radical. Dietary ubiquinone increased ubiquinol levels in lipoproteins and decreased lipid oxidation rates (108). Ubiquinol is considered a weak free radical scavenger due to internal hydrogen bonding that interferes with abstraction of its phenolic hydrogen by free radicals (109).

A potent natural antioxidant from shrimp was tentatively identified as a water-soluble, polyhydroxylated derivative of an aromatic amino acid (110).

G. Metal Inactivators

Ethylenediamine tetraacetic acid (EDTA) can inhibit lipid oxidation by forming an inactive complex with metals. EDTA can either promote or inhibit lipid oxidation depending on the iron/EDTA ratio, which modulates the effective charge in the system (111). EDTA is approved for use in foods at low concentrations. It is poorly soluble in fats and oils but only small amounts are needed for maximum activity. EDTA protected lard better than a combination of BHT and citric acid (86). It should be noted that EDTA indirectly acts as a free radical scavenger. Jimenez and Speisky (112) showed that glutathione scavenged free radicals less effectively in the presence of copper than when EDTA was mixed with copper prior to addition of gluathione. The ability of EDTA to tie up copper or form a chelate with glutathione apparently increased the free radical scavenging ability of glutathione. The carboxylic acid groups of EDTA are protonated at low pH values

(i.e., when pH is below the pKa for the acid groups of EDTA). This interferes with the ability of EDTA to complex metals or other cellular components.

Desferrioxamine is often used as a "metal chelator" in research studies, but this can lead to errant results since desferrioxamine can also act as a free radical scavenger (113). EDTA, tartaric acid and citric acid are other commonly used metal chelators in the food industry. Citrate esters improve oil solubility but at least two free carboxyl groups are needed for effective metal inactivation. Propylene glycol increases solubility of citric acid in oils and fats (86). Sodium tripolyphosphate can act as an antioxidant via metal chelation (114). A disadvantage of using metal chelators in general is that iron bioavailability during digestion may be compromised.

Ceruloplasmin inhibits metal-catalyzed oxidation via its ferroxidase activity. The ferroxidase converts Fe^{2+} to Fe^{3+}, a less catalytic form of iron (115). Transferrin (plasma protein) and ferritin (muscle cell protein) can inactivate metals by chelation of iron but also can release iron causing a pro-oxidant effect; lipolysis and ascorbate, respectively are capable of triggering the iron release (22, 116). Carnosine is a B-alanylhistidine dipeptide found in skeletal muscle at high concentrations. It is capable of chelating copper, scavenging peroxyl radicals, and forming adducts with aldehydes (117). Histidine was found to inhibit non-enzymatic iron mediated lipid oxidation apparently due to formation of an inactive chelate but histidine was also found to activate enzymic pathways of lipid oxidation (118).

H. Enzymes That Inactivate Oxidation Intermediates

Superoxide anion ($^{-\bullet}O_2$) can be produced by heme protein autoxidation or by any process that causes addition of an electron to oxygen (119). Superoxide can reduce Fe^{3+} to Fe^{2+}, the more pro-oxidative form of iron. In addition, the pKa of $^{-\bullet}O_2$ is around 4.5. Thus at pH values below 4.5, the conjugate acid $^{\bullet}OOH$ is the predominant form which can directly initiate lipid oxidation (84). Superoxide dismutase is present in cells and extracellular fluids to remove $^{-\bullet}O_2$ resulting in formation of oxygen and hydrogen peroxide.

Hydrogen peroxide (H_2O_2) can react with either low-molecular-weight iron or heme proteins to form free radicals that initiate/propagate lipid oxidation processes. Biological systems are equipped with antioxidants to deal with this stress. Catalase, a heme-containing enzyme reacts with H_2O_2 to form water and oxygen (120). In plants and algae, ascorbate peroxidase removes H_2O_2 and forms monodehydroascorbate and water. Glutathione peroxidase removes H_2O_2 and forms water and oxidized glutathione. The reaction of glutathione peroxidase with lipid hydroperoxides results in formation of an alcohol, water, and oxidized glutathione. Compounds such as methionine and thiodipropionic acid can also decompose peroxides but at much slower rates than the enzymes.

I. Scavenging of Lipid Oxidation Breakdown Products

Lipid oxidation breakdown products (e.g., aldehydes, ketones, hydrocarbons) form a mixture of volatiles that causes objectionable flavors and odors. Carnosine, anserine, histidine, lysine, albumin, and sulfur or amine containing compounds have the ability to bind aldehydes and therefore decrease rancidity in foods (83). These "scavengers" should be examined in relation to browning of beef considering that lipid oxidation derived aldehydes accelerated the conversion of oxyMb to metMb and hence have the capacity to accelerate browning in beef (121).

J. Other Mechanisms of Antioxidant Action

Spermine was found to inhibit lipid oxidation in hepatocytes of CCL_4-treated rats; a possible mechanism was formation of polyamine-phospholipid complexes (122). Conjugated linoleic acid (CLA) has been shown to decrease rates of lipid oxidation in muscle tissue (123). The mechanism may be related to the ability of dietary CLA to decrease polyenoic fatty acid concentrations in the muscle (124). Organosulfur compounds such as diallyl sulfide and N-acetyl cysteine may exert their antioxidant protection by modulating antioxidant enzymes such as catalase and glutathione-s-transferase (125).

K. Interfacial, Charge, and Location Effects

Deciding which antioxidant(s) to utilize in a particular food system is a formidable task. Having water and lipid soluble antioxidants was found to maximize extension in shelf life of mayonnaise prepared from fish oil (126). However, cost limitation is a factor that limits amounts of antioxidant addition. Most foods have a water phase, lipid phase and water-lipid interface. Location of different antioxidants should affect antioxidant potency. Membrane phospholipids are believed to be more prone to lipid oxidation than triacylglycerols in muscle foods so protecting membrane lipids is desired (127). δ-Tocopherol could be preferentially incorporated into isolated membranes compared to triacylglycerols by proper selection of antioxidant solvent (ethanol instead of corn oil) (128). In minced chicken muscle containing added triacylglycerols, δ-tocopherol could be preferentially incorporated into the membrane fraction if the antioxidant was added to the lean muscle before addition of TAG lipids (129). Hydrophilic antioxidants (trolox and ascorbic acid) were generally more effective than more hydrophobic compounds (tocopherol and ascorbyl palmitate) in bulk oils while the hydrophobic compounds were more effective in oil-in-water emulsions (130, 131). However, when comparing carnosic acid to the more hydrophobic methyl carnosate, the latter was a more effective antioxidant in both bulk oils and emulsions (132). Benzoic acid, a water-soluble phenolic, partitioned into the oil phase of a whey-protein

stabilized emulsion more than could be explained by oil/water partitioning alone (133). This suggested that benzoic acid bound to protein adsorbed at the interface. In oil-in-water emulsions, excess surfactant solubilized phenolic antioxidants into the aqueous phase but the removal of antioxidants from the oil or oil interface phases did not accelerate lipid oxidation (134). The ability of excess surfactant to cause lipid hydroperoxides and iron to partition into the aqueous phase (away from oil droplets) may explain the ability of excess surfactant to inhibit lipid oxidation in oil-in-water emulsions (50, 135). Positively charged protein emulsifiers inhibited lipid oxidation more effectively than negatively charged emulsifiers in oil-in-water emulsions (136). This was attributed to the ability of the positive charge of the protein interface to repel iron away from the oil phase. The ability of Trolox to inhibit lipid oxidation in liposomes was least when the membrane bilayer and trolox molecule were negatively charged and removing the repulsive forces by altering membrane type or pH increased antioxidant efficacy (137). More studies are needed to evaluate the distribution of antioxidants in different phases in conjunction with lipid oxidation kinetics during storage.

VI. PRODUCTION OF FATS AND OILS

Production of fats and oils from plant, animal, fish, and dairy lipids can be broken into four classifications: recovery, refining, conversion, and stabilization. Pressing or solvent extraction are common processes to liberate oil from plant seeds. Care should be taken during transportation of seeds to prevent cell rupture prior to oil extraction. Lipases and lipoxygenases in the cytosol that mix with TAG prematurely due to decompartmentation will be detrimental to oil quality (i.e., formation of free fatty acids and peroxidized lipids prior to extraction will reduce TAG purity and hence yields). Heating during or prior to the pressing step (115°C for 60 min) inactivates lipases and lipoxygenases. Other benefits of heating are rupturing of cell wells, decrease in oil viscosity, and coagulation of proteins. Elevated moisture levels are discouraged due to the ability of excess water to facilitate hydrolysis of esterified lipids. Recovery of animal fat and marine oil is also a high temperature process called rendering. Trimmings, cannery waste, bones, offal, tallow and lard can be subjected to rendering to produce valued added oils and fats.

Refining is the removal of non-TAG components including free fatty acids, phospholipids, pigments, protein, and wax. The degumming step is a water wash that removes phosphatides (e.g., lecithin, phospholipids). Hydration in the presence of heat makes phosphatides insoluble in the oil allowing removal by centrifugation. Heating of oil contaminated with phosphatides can result in foaming and even fire due to the surfactant properties of the phospholipids. The next step in refining is neutralization. Free fatty acids and phosphatides react with sodium hydroxide to form a soap (e.g., saponified material). Subsequent bleaching removes undesirable pigments typically by use of neutral clays. Waxes are then removed by cooling the oil to around 7°C for 4 hours and filtering at 18°C. The final step in refining is deodorizing, which removes hexane, pesticides, and peroxide decomposition products that can potentially impart off-odors and off-flavors. Deodorization is accomplished by steam distillation at high temperatures (180°C to 270°C) under vacuum. Freshly deodorized oils should have a peroxide value of zero and a free fatty acid content of less than 0.03% (138). Ideally fat-soluble antioxidants such as tocopherols are retained in the purified oil. Unfortunately, refining strips antioxidants from the TAG which often requires post-processing addition of antioxidants to pure oil.

The conversion processes winterization and fractional crystallization are physical processes that alter the lipids and thus are out side the scope of this chapter. Various chemical processes of conversion (e.g., interesterification) and stabilization (e.g., hydrogenation) are described later in this chapter. Stabilization techniques for fats and oils are also discussed in the preceding section on antioxidants.

VII. MODIFICATION OF LIPIDS AND PRODUCTION OF SPECIALTY FATS

This section describes the numerous chemical processes that are available to modify the functional properties of food lipids. Functional properties include 1) oxidative stability, 2) plastic range, 3) flavor properties, 4) nutrient content, 5) health promoting effects, and 6) caloric value. Increasing fatty acid saturation or redistributing fatty acids on the glycerol backbone to improve functionality can be accomplished in bulk oils by treatment with low-molecular-weight catalysts. In other cases, more specific alteration of lipids is accomplished through the use of enzymes to improve functionality. Endogenous enzymes in yeasts, molds, and bacteria utilize nonlipid or lipid containing carbon sources to produce a wide array of different specialty lipids (e.g., cocoa-butter substitutes, triacylglycerols rich in omega-3 fatty acids, biosurfactants, polyunsaturated fatty acids, wax esters, and hydroxy fatty acids). A thorough description of the emerging fields of "lipid biotechnology" and "structured lipids" is available (139, 140). Some specific examples that utilize lipases to produce specialty lipids are cited in Section VII.C of this chapter. The opportunity to modify lipids "pre-harvest" is addressed in Section VII.D.

A. Hydrogenation

Hydrogenation is done for two important reasons: 1) provides a semi-solid fat at room temperature from an oil source and, 2) increase oxidative stability during storage. Hydrogenation involves mixing oil with a catalyst such as nickel at elevated temperatures (140°C to 225°C).

Hydrogen gas is then introduced with agitation. Once the desired saturation is obtained, the material is cooled and the catalyst is removed by filtration. Typical products that result include shortenings and margarine. A disadvantage of this process is the formation of trans fatty acids that are considered unhealthy.

B. Non-Enzymatic Interesterification

Factors that contribute to textural properties of fats include not only degree of fatty acid unsaturation and the chain length but also the location of fatty acids on the glycerol backbone. Chemical interesterification "randomizes" the location of the different fatty acids, thereby improving the utility of the fat. Spreadability, melting point, and solid-fat content temperature profile are modified by the randomization. This process typically involves the use of sodium methoxide (0.1%) as a catalyst. The catalyst should function at low temperatures (around 50°C) to avoid polymerization and decomposition of lipids during interesterification. Moisture inactivates the catalyst. Therefore, the water content must be below 0.01%. Free fatty acids and lipid peroxides must be below 0.1% and 1%, respectively. The catalyst must be soluble in the lipid.

The mechanism of interesterification using alkaline bases involves nucleophillic attack by the catalyst towards the slightly positive carbonyl carbon. This attack liberates a fatty acid methyl ester and a resulting glycerate anion (Figure 8.11). The glycerate anion is the nucleophile for subsequent carbonyl attacks. This process continues until all the available fatty acids have exchanged positions. Sodium methoxide also removes an acidic hydrogen from the carbon alpha to the carbonyl carbon. The carbanion produced is a powerful nucleophile.

On occasion randomness is not desirable. If the fat is maintained below its melting point, interesterification proceeds with the formation of more saturated triacylglycerols. This "directed interesterification" produces a product with a higher solids content at higher temperatures, which extends its plastic range.

A practical application of interesterification involves the modification of lard. In its native form, lard has negative attributes including grainy texture, poor appearance, poor creaming capacity, and limited plastic range (141). The graininess is due to a preponderance of palmitic acid at the sn-2 position. Randomization decreases the amount of palmitic acid and the sn-2 position and hence decreases graininess. Directed interesterification resolves the plastic range problem. Improvement in plasticity and stability is due to alterations in the polymorphic behavior. The interesterified lard crystallizes into a β'-2 form that promotes the improved functionality (8).

Fish oils are liquid at room temperature due to their high content of polyunsaturated fatty acids including

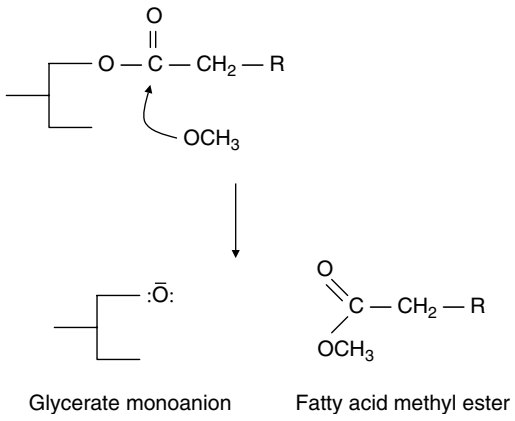

FIGURE 8.11 Proposed mechanism of chemical interesterification. Adapted from Ref. 141.

omega-3 fatty acids (e.g., 22:6 and 20:5). Ingestion of omega-3 fatty acids are noted for their ability to decrease incidences of various diseases but are also highly susceptible to lipid oxidation in foods, which causes off-flavors and off-odors. A possible route to increased consumption of these fatty acids with less quality loss during storage is chemical interesterification. Interesterification of a hydrogenated vegetable oil and the fish oil will produce a mixture of fatty acids on the glycerol backbone ranging from highly saturated to highly unsaturated. The saturated TAGs can be removed by low temperature fractional crystallization and centrifugation. The fraction obtained with intermediate unsaturation (moderately higher temperature crystallization) comprises TAGs containing both saturated fatty acids and the highly coveted omega-3 fatty acids. Compared to the starting fish oil, this results in triacylglycerols 1) with a greater plastic temperature range increasing product applications, 2) more resistance to lipid oxidation due to the incorporation of the saturated fatty acids, and 3) a relatively more stable source of omega-3 fatty acids for incorporation into foods. An area of concern would be the stability of the omega-3 fatty acids at the temperatures used during chemical interesterification. An alternative process that requires lower reaction temperatures is enzymatic interesterification.

C. Enzymatic Modification of Lipids

Enzymatic interestification is accomplished using lipases from bacterial, yeast, and fungal sources. The regio- and stereospecificity obtained through the use of lipases is a marked advantage over chemical interesterification. Enzymatic interesterification requires less severe reaction conditions, products are more easily purified, and produces less waste than chemical interesterification. Enzymatic interesterification is more expensive at the present time although advances are expected to lower costs. In any event, certain processes can be accomplished

with lipases that are not achievable via chemical interesterification. For example, it is optimal to incorporate stearic acid (18:0) at the sn-1 or sn-3 position because stearic acid is least absorbed at these positions compared to the sn-2 position (142). This is advantageous since caloric value is decreased while maintaining a long chain saturated fatty acid that expands the plastic range. An sn-1,3 lipase facilitates the regioselectivity desired whereas chemical interesterification cannot. Since fatty acids at the sn-2 position are more efficiently absorbed than those at the sn-1,3 positions, the ideal location for essential fatty acids is at the sn-2 position. Fatty acids at sn-2 will be shuffled to other positions on the triacylglycerol in chemical interesterification, which is undesirable. The sn-1,3 lipases, however, allow those endogenous fatty acids to remain at the sn-2 site.

The major triacylglycerols in cocoa butter all contain oleic acid at the sn-2 position (1-palmitoyl-2-oleoyl-3-stearoyl-glycerol, 1,3-dipalmitoyl-2-oleoyl-glycerol, and 1,3-distearoyl-2-oleoyl-glycerol). Palm oil is rich in palmitic and oleic acid but lacks appreciable amounts of steric acid. Thus, palm oil has been reacted with stearic acid and an sn-1,3 specific lipase; replacement of palmitic acid with stearic acid at the sn-1 or sn-3 position produced an effective cocoa butter substitute. Chemical interesterification will randomize the location of all the fatty acids and produce a less effective substitute. Cocoa butter is an expensive material due to its limited quantities and unique melting properties (hard and brittle at room temperature but melts as it is warmed in the mouth).

The reaction of fatty acids with esters such as those found in triacylglycerols is termed acidolysis. Another acidolysis reaction involves incorporating capric acid (10:0) and caproic acid (6:0) into an oil stock. This is beneficial since these fatty acids are readily oxidized in the liver and therefore are excellent sources of energy as opposed to normal storage fat for individuals having deficiencies in fat absorption.

Transesterification is the exchange of acyl groups between two esters, specifically between two tricacylglycerols. Mixtures of hydrogenated cotton oil (rich in stearic and palmitic acid) and olive oil (rich in oleic) can be reacted in the presence of the proper lipase and minimal water to create a cocoa butter substitute. To separate the desired TAG from the undesired TAG, trisaturated TAG can be removed by crystallization in acetone or temperature differentials that crystallize out the more saturated triacylglycerols. This process can also be performed using sodium methoxide catalyst instead of lipases but again the randomization of oleic acid from the sn-2 position in the chemical interesterification should produce a less effective substitute than a sn-1,3 lipase-driven interesterification that regiospecifically alters the starting oil stocks, thereby maintaining oleic acid at the sn-2 position.

Alcoholysis is the esterification reaction between an alcohol and an ester. The most common alcoholysis is the production of mono- and diacylglycerol surfactants (e.g., emulsifiers) by reacting glycerol with triacylglycerols. Specifically, this reaction is termed glycerolysis and is usually performed using nonspecific lipases. The newly formed mono- and diacylglycerols are isolated by temperature-induced crystallization. In glycerolysis, Tc is defined as the critical temperature below which monoacylglycerols crystallize out of the reaction mixture (143). This pushes the equilibrium of the reaction to produce more monoacylglycerols. Vegetable oils have low melting points and hence low Tc due to the abundance of polyunsaturated fatty acids compared to animal fats. By reducing the temperature below the Tc for vegetable oils (Tc = 5°C to 10°C), yields of monoacylglycerols can be increased.

D. Modification of Lipids Prior to Harvest

Genetic manipulation of lipid biosynthesis is a possible route to improve functionality of TAG and phospholipids (144). For example, the overexpression of cis-9 desaturase in transgenic tomato results in increases in 16:1(cis 9), 16:2(cis 9,12), and 18:2(cis 9,12) fatty acids, which enhance positive flavor attributes in the fruit mediated by a lipoxygenase/hydroperoxidelyase/isomerase/reductase enzyme system (145, 146). Apparently the enhanced fatty acids are precursors for the desirable flavor compounds in tomato. In cell membranes, phosphatidyl glycerol containing two saturated fatty acids is correlated with decreased chilling injury in plants. Incorporating plastidic sn-glycerol-3-phosphate acyltransferase (GPAT) from a chilling-insensitive species (spinach) into a moderately chilling sensitive species (tobacco) increased disaturated phosphatidyl glycerol and was successful at decreasing chilling injury in the tobacco (147). Oxidative stability of transgenic canola oil was improved by decreasing the activity of a cis 15-endogenous desaturase using antisense technology (148). This lowered the 18:3 (cis 9,12,15) content from 6.9% to 1.4% in the oil. Although lipid stability was improved by this technique, 18:3 is an essential fatty acid so functionality is improved at the expense of nutritional quality. A thorough review of genetic engineering of crops that produce modified vegetable oils is available (149).

E. Fat Replacers

Fat replacers can be primarily carbohydrate, protein, or lipid based. Protein or carbohydrates replacers are called *mimetics* and tend to absorb water readily but cannot carry lipid-soluble flavor compounds. The other category of fat replacers, called *substitutes*, will typically contain fatty acids esterified to a carbohydrate. The fatty acids provide desirable physical properties of fats but are not readily cleaved by lipases during digestion. In other words, the lipids are not metabolized and therefore caloric intake is

reduced per gram or fat ingested. An example of a fat substitute is raffinose polyester. Raffinose is made up of galactose-glucose-fructose units. The eleven available hydroxy groups can potentially be esterified with fatty acids. As the degree of substitution increases the susceptibility to hydrolysis and absorption will decrease (150). Sucrose fatty acid esters act as emulsifiers, texturizers, and protective coatings in various foods products.

Benefat™ consists of short chain fatty acids (e.g., 2:0, 3:0, 4:0) and a long chain saturated fatty acid (stearic acid, 18:0). Short chain fatty acids have low caloric value because they are easily hydrolyzed by digestive lipases and readily converted to carbon dioxide (151). Stearic acid is only partially absorbed, especially if located at the sn-1 or sn-3 position. Benefat is around 5 kcal/g while typical fats are 9 kcal/gram. Currently, Benefat is produced by base-catalyzed interesterification of hydrogenated vegetable oils with TAGs of acetic, propionic, and/or butyric acids (152). The ratios of the short chain fatty acids and the long chain saturated fatty acid can be varied not only providing a low caloric intake but also the physical properties required for specific food applications. Benefat can be used in cookies, baked goods, dairy products, dressings, dips, and sauces (150).

VIII. CHEMISTRY OF FRYING

Frying of oils results in distinctive fried flavors and undesirable off-flavors if the oil is overly deteriorated. Off-flavors are manifested via 1) hydrolysis, 2) oxidation, and 3) polymerization reactions. The interaction of steam, water, and oil will hydrolyze TAG into mono-acylglycerols, di-acylglycerols, and free fatty acids. With increased time even glycerol will be produced due to complete hydrolysis of an individual triacylglycerol. Little glycerol can be detected in frying oils since glycerol volatilizes around 150°C and frying temperatures are typically higher. Factors that control hydrolysis are oil temperature, interface area between oil and aqueous phases, water level, and steam level (153). Metals that contaminate the oil interact with lipid hydroperoxides to form free radical species that initiate and propagate oxidation reactions in the presence of oxygen. Frying temperatures will greatly increase the rate of these fundamental lipid oxidation processes and stimulate reactions that may not occur at lower temperatures resulting in an array of oxidation products including aldehydes, ketones, alcohols, esters, hydrocarbons, and lactones. These low-molecular-weight compounds that form due to degradation of the frying oil are considered "volatile," contributing desirable and undesirable flavors. Polymerization is common in frying where molecules cross-link often as a free radical-free radical reaction. As polymerization increases so too does viscosity of the oil. Most polymerized products are nonvolatile (e.g., dimeric fatty acids, TAG-trimers) and hence do not produce flavor. However, with further heating these non-volatile compounds can be degraded to off-flavor and toxic products. Degradation products negatively affect not only flavor and safety but also color and texture of the fried products.

Antioxidants and antifoam are added to frying oil to extend frying life. Other measures of delaying degradation of oil quality include utilizing fresh oil, using an oil low in polyunsaturated fatty acids and contaminating metals, filtration of oil with adsorbents, turnover of oil, and decreasing exposure of oil to oxygen. Antifoam will aid in reducing exposure of oil to oxygen. Continuous heating is better than discontinuous heating in extending frying life of the oil (153). Not all oxidation that occurs with frying is negative. For instance, 2-4-decadienal is considered a positive flavor compound. Often a preliminary batch of fried foods is prepared and discarded so that the subsequent batches have a desired flavor profile. More unsaturated oils oxidize faster than less saturated oils which decreases the amount of time needed to obtain a proper frying flavor in the food.

Free fatty acid content is an unreliable measure of frying oil quality. There still is not a fully appropriate single test to assess frying oil quality. The FoodOil sensor (FOS) (Northern Instruments Corp., Lino Lakes, MN) measures dielectric constant of frying oil compared to fresh oil and has had some success. The dielectric constant increases with increasing polarity so that once a certain value is reached the oil needs change.

IX. FOOD IRRADIATION

The purpose of food irradiation is to destroy microorganisms and hence extend shelf life. Lipids can be adversely affected. Typical dosages range from 1 to 10 kGy. Sterilization is achieved at doses of 10–50 kGy. When ionization radiation is absorbed by matter, ions, and excited molecules are produced. These ions, and excited molecules can dissociate to form free radicals. Reactions induced by irradiation prefer to react near the oxygen portion of TAG (154). Reaction occurs preferentially near the oxygen due to the high localization of electron deficiency on the oxygen atom. This explains the preponderance of aldehydes with the same chain length as the most abundant parent fatty acid (cleavage at location b) (Figure 8.12). Cleavage at locations c and d results in hydrocarbons that have one and two carbons less, respectively, than the parent fatty acid, which also is more common than a random assortment of hydrocarbons. Alternatively, free radicals can combine. For instance, two alkyl radicals react to form a dimeric hydrocarbon; acyl and alkyl radicals result in a ketone; acyloxy and alkyl radicals produce an ester; alkyl radicals can react with various glyceryl residue radicals to form alkyl glyceryl diesters and glyceryl ether diesters.

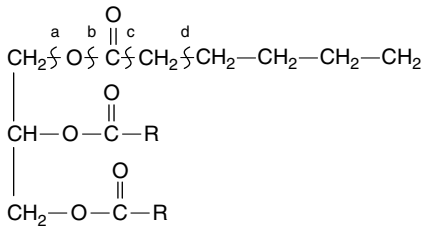

FIGURE 8.12 Cleavage sites on a triacylglycerol due to radiolysis. Adapted from Ref. 8.

Irradiation was found to accelerate lipid oxidation in raw pork patties and raw turkey breast that was aerobically packed (155, 156). Lipid oxidation was accelerated by irradiation (3 kGy) in aerobically packed, pre-cooked chicken (157). Irradiation caused formation of a brown pigment in raw beef and pork, but not turkey (158). Carbon monoxide was implicated as the cause of pinking in irradiated raw turkey breast muscle (159).

9 Fats: Physical Properties

Francisco J. Hidalgo and Rosario Zamora
Instituto de la Grasa

CONTENTS

I. INTRODUCTION

The physical properties of fats and oils are of great practical importance so it is necessary to understand the makeup of these materials and how they should be used (1–9). Thus, many technical applications of fatty materials, including their uses in edible products, depend on the oiliness, surface activity, solubility, melting behavior, or other physical properties peculiar to long-chain compounds (10). Because fats and oils are mainly composed of mixtures of triacylglycerols, the physical properties of these molecules are going to determine the physical characteristics of the oil or fat. Thus, these characteristics are dependent on such factors as seed or plant source, degree of unsaturation, length of carbon chains, isomeric forms of the constituent fatty acids, molecular structure of the triacylglycerols, and processing. This chapter will review the most important physical properties of triacylglycerol molecules as well as of the most common edible fats and oils.

II. CRYSTALLIZATION AND POLYMORPHISM

Crystallization from solution is usually a slow process that first requires supercooling and then leads to nucleation and crystal growth. A high degree of supercooling will be conductive to nucleation, and very small crystals will be formed. At temperatures closer to the crystallization point, crystal growth will be favored and large crystals will be formed (2). Once formed, crystals, which may be stable or metastable, are able either to modify their habit or undergo phase transitions, respectively. Both processes result in polymorphic behavior, a behavior common to fats and other lipids (11–22).

A. Crystalline Structure of Triacylglycerols

In the solid state, molecules adopt the ideal conformation and arrangement in relation to their neighbors in order to optimize intra- as well as intermolecular interactions and achieve close-packing. The smallest building unit of a crystal, the repeating unit of the whole structure, is called the unit cell (Figure 9.1). The crystal structure is obtained by repetition of this unit in the three axial directions (5). Only seven different cells are necessary to include all possible point lattices. These correspond to the seven crystal systems into which all crystals can be classified (Table 9.1).

Of these seven crystal systems, it is now accepted that three predominate in crystalline triacylglycerols (23). Usually, the most stable form of triacylglycerols has a triclinic subcell with parallel hydrocarbon–chain planes ($T_{\parallel}$). A second common subcell is orthorhombic with perpendicular chain phases ($O_{\perp}$). The third common subcell type is hexagonal (H) with no specific chain plane conformation (24). This hexagonal form exhibits the lowest stability.

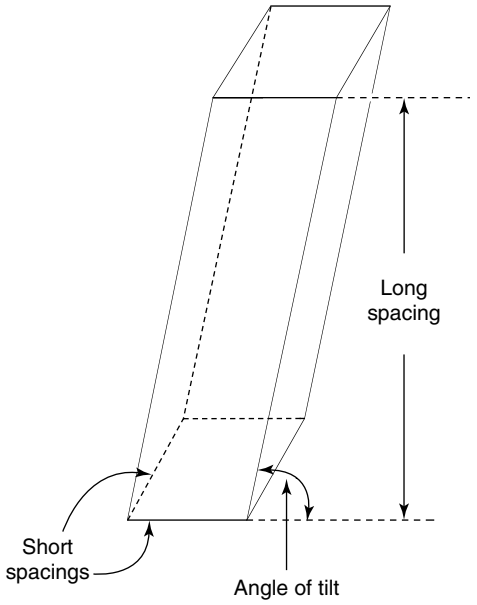

FIGURE 9.1 The triclinic unit cell for long-chain compounds.

TABLE 9.1
The Seven Crystal Systems

System	Angles and Axial Lengths
Cubic	All axes equal and all at right angles $a = b = c$ and $\alpha = \beta = \gamma$ and = 90º
Tetragonal	Two of three axes equal and all at right angles $a = b \neq c$ and $\alpha = \beta = \gamma$ and = 90º
Rhombohedral	All axes equal and none at right angles $a = b = c$ and $\alpha = \beta = \gamma$ and ≠ 90º
Hexagonal	Two axes = 120º and the third at 90º relative to them $a = b \neq c$ and $\alpha = \beta = 90º$ and $\gamma = 120º$
Orthorhombic	All axes unequal and all at right angles $a \neq b \neq c$ and $\alpha = \beta = \gamma$ and = 90º
Monoclinic	Three unequal axes having one pair not equal to 90º $a \neq b \neq c$ and $\alpha = \gamma = 90º \neq \beta$
Triclinic	All axes unequal and none at right angles $a \neq b \neq c$ and $\alpha \neq \beta \neq \gamma$ and ≠ 90º

Source: Ref. 11.

Interpretation of X-ray crystallography data from trilaurin and tricaprin resulted in representation of triacylglycerols in a tuning fork conformation when crystalline (Figure 9.2). The fatty acids esterified at the *sn*-1 and *sn*-2 positions of glycerol are extended and almost straight. The *sn*-3 ester projects 90º from *sn*-1 and *sn*-2, folds over at the carboxyl carbon, and aligns parallel to the *sn*-1 acyl ester. Molecules are packed in pairs, in a single layer arrangement, with the methyl groups and glycerol backbones in separate regions. The main cell is triclinic centered and contains two molecules; the subcell is also triclinic.

In addition to these bilayer structures, triacylglycerols may also be arranged in trilayers (Figure 9.2) (25–27).

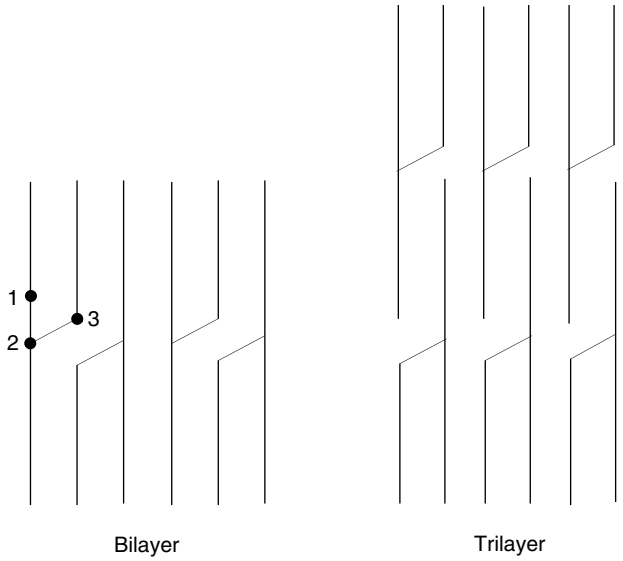

FIGURE 9.2 Double and triple chair arrangements of β form.

Thus, a trilayer structure occurs when the *sn*-2 position of the triacylglycerol contains a fatty acid that is either *cis*-unsaturated or of a chain length different by four or more carbons from those on the *sn*-1 and *sn*-2 positions (28). Also, a trilayer structure has been predicted to arise if the *sn*-2 position contained a saturated acyl ester with unsaturated moieties occupying the *sn*-1 and *sn*-3 positions (29). When unsaturation results in a *trans* configuration around the carbon–carbon double bond, the crystal structure exhibits the normal bilayer appearance (12).

B. Polymorphism and Phase Behavior of Natural Fats

Polymorphism is the ability of fat crystals to exist in more than one crystal form or modification. In the case of natural fats, these crystal forms are α, β′, and β, in order of increasing stability (Table 9.2). The changes among these phases are monotropic, and, therefore, proceeds in the solid phase from lower to higher stability. The forms differ in crystalline structure and in melting points, and correspond to the crystal structures described for natural fats in Section II.A. Thus, the most stable and with highest melting point $T_{\parallel}$ is the β polyform. Another polyform, with variable stability and a melting point lower than β, is β′, which has orthorhombic subcell packing ($O_{\perp}$). Finally, phases with the hexagonal subcell have the lowest melting point and represent the α polymorph.

In addition to these three basic polymorphs, other polymorphs showing subtle differences may be observed. Within groups having the same subcell, lower melting polymorphs are designated with a progressively higher subscript. In addition, the bilayer or trilayer structure of the triacylglycerol is designated with 2 or 3 following the polymorph description. Thus, β'_2-2 designates a bilayer of a β′ polymorph with the second highest melting point.

TABLE 9.2
Characteristics of the Polymorphic Forms of Monoacid Triacylglycerols

Characteristic	α Form	β′ Form	β Form
Chain packing	H	$O_{\perp}$	$T_{\parallel}$
Short spacing (Å)	4.15	4.2, 3.8	4.6, 3.9, 3.7
IR bands (cm-1)	720	727, 719	717
Density	Least dense	Intermediate	Most dense
Melting point	Lowest	Medium	Highest
Morphology	Amorphous-like	Rectangular	Needle shaped

Source: Refs. 10, 12, 15.

The fatty acid makeup and position in the glycerides of the fat solids and temperature history are the two main factors in determining polymorphic behavior (1). Other factors include kind and quantity of impurities, nature of possible solvent, and degree of supercooling. A high level of fatty acids of identical chain length results in a slow conversion rate of β′ to β and a coarsening of crystal structure. The more heterogeneous of fatty acid makeup, the more likely it will be β′ and fine-grained or needlelike crystals. Thus, mixed fatty acid triacylglycerols, such as those in lauric fats, tend to be β′-stable.

If a fat is cooled rapidly, the tendency is to form the small, α-crystals. These generally do not last long and convert rapidly to the β′ needlelike crystals. These β′ crystals are considered highly stiffening and, hence, are the form of choice for plastic shortenings (1). Depending on the glyceride composition and the temperature history, the β′-form may convert to the most stable β-form. This form has large, coarse, platelike crystals. These are not stiffening; hence, those hydrogenated fats exhibiting this behavior are the choice for the solids in fluid shortenings (1). Generally speaking, β′-forms melt about 5–10°C higher than the α-forms, and the β-forms also melt about 5–10°C higher than the β′-forms. Fats that tend to crystallize in β-forms include soybean, corn, olive, sunflower, and safflower oils, as well as cocoa butter and lard. On the other hand, cottonseed, palm, and rapeseed oils, milk fat, tallow, and modified lard tend to produce β′ crystals that tend to persist for long periods.

1. Milk Fat

As with many natural fats, the temperature at which crystallization occurs influences milk fat firmness, crystalline conformation, and percentage of solid fat. Hardness variability in milk results from different thermal treatments and may be better understood considering the presence of three milk fat fractions, which are observed by using differential scanning calorimetry. These fractions are defined as high-, middle-, and low-melting fractions (HMF, MMF,

and LMF, respectively). LMF is liquid at ambient temperature. Stable polymorphs of MMF and HMF were found to be a mixture of β′-2 + β′-3, and β-2, respectively (30,31).

2. Palm Oil

Palm oil is expressed from the pulp of the oil palm (*Elaeis guineensis*) fruit and is unique among vegetable oils because of the large percentage (10–15%) of saturated acyl esters at the *sn*-2 position of the triacylglycerols. In addition, it has almost 5 % of free fatty acids that play a role in the hardness. At room temperature, the oil appears as a slurry of crystals in oil. Three polymorphs have been determined: β'_2, α-2, and the stable β'_1 form (32). The β′ stability has resulted in the addition of palm oil to oils destined for shortening or margarine, since β-tending fats can result in gritty textures.

3. Lauric Fats

Lauric fats are those fats rich in laury acyl esters in the triacylglycerol molecule, mainly coconut oil and palm kernel oil. Two polymorphs have been identified in these fats: α and β′-2. The α form is fleeting and can be recognized only after rapid cooling, as it quickly transforms into the β′-2 polymorph (33–35). The melting point of these fats is sharp at 22°C for coconut and 25°C for palm kernel oil (36).

4. Liquid Oils

Evaluations of polymorphism in fats that are liquid at room temperature are limited. Cottonseed and peanut oils crystallize in a β'_2 form that is transformed into a stable β'_1-2 form. Four other oils (corn, safflower, sunflower, and soybean) show polymorphism similar to that of peanut and cottonseed, but these four fats developed a stable β-2 form (12).

5. Hydrogenated Fats

Complete hydrogenation eliminates the asymmetry, often leading to β stable polymorphs. Thus, soybean, peanut, sunflower, corn, and sesame oils, are converted to hydrogenated fats having stearoyl esters and consequently show the stable β-2 form. For oils rich in palmitic, hydrogenation leads to fats containing a high proportion of 1,3-dipalmitoyl-2-stearoyl-*sn*-glycerol (PStP). Because the rearrangement of PStP into a stable β form is hindered by misalignment of the methyl end plane of the β′ unit cell (23), a fat rich in this triacylglycerol will stay in the β′ form. On the other hand, a hydrogenated fat rich in StPSt can transform into a stable β form. The high PStSt fats have equally stable β′ and β forms, and any transformation to the β form occurs over a long period of time (12).

6. Cocoa Butter

Cocoa butter occupies a special place among natural fats because of its unusual and highly value physical properties. Products containing cocoa butter, such as chocolate, are solid at room temperature; have a desirable "snap"; and melt smoothly and rapidly in the mouth, giving a cooling effect with no greasy impression on the palate. The main characteristic of cocoa butter is the presence of a high content of symmetrical monounsaturated triacylglycerols (1-palmitoyl-2-oleyl-3-stearoyl-*sn*-glycerol (POSt), 1,3-distearoyl-2-oleyl-*sn*-glycerol (StOSt), and 1,3-dipalmitoyl-2-oleyl-*sn*-glycerol (POP) account for about 80% of the total). The polymorphic behavior of cocoa butter is more complex than that of its component glycerides, and a specific system for cocoa butter is often used. This was introduced by Wille and Lutton (37) and recognizes six different polymorphs –I, for the lowest melting form, through VI, for the highest melting form (Table 9.3). Another system in use recognizes only five polymorphs, designated γ, α, β′, β_2, and β_1, in order of increasing stability and melting point (42–45).

The desirable physical properties of cocoa butter and chocolate – snap, gloss, melting in the mouth, and flavor release – depend on the formation of polymorph V or β_2, which has to be obtained under controlled temperature conditions (41,46). After a long storage or unfavorable storage conditions such as extreme temperatures, chocolate may show "bloom." This is a grayish covering of the surface caused by crystals of the most stable β phase (phase VI) (41). Eventually the change progresses to the interior of the chocolate and the resulting change in crystal structure and melting point makes the product unsuitable for consumption.

7. Confectionery Fats

Cocoa butter is the primary fat used in chocolate. Its expense has led to the development of other fats, used alone or in combination, to replace some or all cocoa butter in cocoa-containing confections. These confectionery

Source: Refs. 12, 37–45.

or specialty fats can be classified into cocoa butter equivalents (CBE) and cocoa butter substitutes (CBS) (47). Essentially, a CBE is a mixed fat that provides a fatty acid and triacylglycerol composition similar to those of cocoa butter. A CBS is a fat that provides some of the desired physical characteristics to a confection independent of its dissimilar chemical composition to that of cocoa butter.

Miscibility is an important characteristic of confectionery fats. When fats of different composition are mixed, the melting point or the solid fat content of the blend may be lower than that of the individual components (eutectic effects). This happens when cocoa butter is mixed with a CBS that may lead to unacceptable softening. Mixing of cocoa butter and CBE gives no eutectic effect, and this type of fat can be used in any proportion with cocoa butter, analogously to milk fat (33). However, it has been reported that minor components of milk fats exert a significant influence on the crystallization behavior when milk fat is mixed with cocoa butter and other confectionery fats, having, for instance, a softening effect and antibloom properties (8,48,49). CBEs are generally based on three raw materials – shea oil, illipe butter, and palm – oil and processed by fractionation. CBEs also require the same tempering procedures as cocoa butter, since they will exhibit polymorphism similar to that of cocoa butter. It is also possible to tailor make CBEs to higher solid content and melting point than some of the softer types of cocoa butter. These fats are described as cocoa butter improvers (CBIs).

CBSs are available in two types, lauric and nonlauric. Lauric CBSs are based on palm kernel oil or coconut oil and are not compatible with cocoa butter. They do not need tempering, and the crystals formed are stable. Nonlauric CBSs are produced by hydrogenation of liquid oils, frequently followed by fractionation and/or blending. These products, especially those made from palm olein, are very stable in the β' form. Nonfractionated CBSs are used in compound-coating fats for cookies. The fractionated, hydrogenated CBSs have better eating quality and can tolerate up to 25% cocoa butter when used in coatings.

C. Techniques to Determine Crystallization and Polymorphism

The techniques used to elucidate crystal structures are either spectroscopic or microscopic. Spectroscopic techniques include X-ray diffraction and Raman and infrared spectroscopy. Microscopic techniques include polarized light and electron microscopy (50).

1. Infrared and Raman Spectroscopy

The region of major interest in an IR spectrum for the study of fat polymorphism is the methylene rocking vibration mode which appears between 670 and 770 cm^{-1}. The spectra vary according to the polymorphic form. The nomenclature for polymorphs is as follows: a doublet at 728 and 718 cm^{-1} indicates the presence of the β' form, a singlet at 720 cm^{-1} the α form, and a singlet a 717 cm^{-1} the β modification (51). In addition, vibrational (infrared and Raman) spectra have given fruitful information on molecular conformations of aliphatic chains and olefinic groups, and methyl end packings (52–54).

Raman spectroscopy is also used to identify the different states of order of lipids (55). Two regions are of interest: the C-C stretching vibration region at about 1100 cm^{-1}, and the C-H stretching vibration region at about 2850 cm^{-1}. Lipids with crystalline chains show two sharp peaks near 1065 and 1130 cm^{-1}, whereas these peaks are shifted towards a broad band near 1090 cm^{-1} when the chain melts. The ratio 1080/1130 can be taken as a measure of the degree of a liquid-type order (56). In addition, a peak at 2850 cm^{-1} corresponds to symmetric vibrations of methylene groups characteristic for the liquid state, whereas a peak at 2890 cm^{-1} is caused by antisymmetric vibrations of methylene groups and dominates when hydrocarbon chains are crystalline (57).

2. X-Ray Diffraction

The principle of X-ray diffraction is to excite an anticathode which will emit X-rays being diffracted by the crystal structure at a specific angle. The angle depends on the distance between two crystal planes, d, and d is different for each crystal structure. The chain packing of the triacylglycerol molecules determines the spacing between adjoining molecules. The cross-sectional structures determine the short spacings (Figure 9.1). Each of the chain-packing subcells is characterized by an unique set of X-ray diffraction lines in the wide-angle region between 3.5 and 5.5 Å. The nomenclature used to identify lipid crystal forms was proposed by Larsson (40) and is based on the following criteria: a form that gives only one strong short-spacing line near 4.15 Å is termed α; a form that gives two strong short-spacing lines near 3.80 and 4.20 Å and also shows a doublet in the 720 cm^{-1} region of the infrared absorption spectra is termed β'; a form that does not satisfy criterion two is termed β (Table 9.2).

X-ray diffraction is a powerful analytical technique to identify polymorphic phases unambiguously in both pure triacylglycerol systems and edible fats (43,58–60). In addition, recent developments in high-energy accelerators and X-ray detectors have reduced the exposure times of the sample to the order of milliseconds. Thus, with synchrotron radiation X-ray diffraction, the kinetics of rapid triacylglycerol polymorphic transformations has been elucidated under both isothermal and nonisothermal conditions in pure and mixed triacylglycerol systems (18,61–63).

The complex structure of the crystal network is determined by the fractal dimension, D, which describes the

relation between the number of crystals in a crystal aggregate and its radius, R (64,65). In general, the higher the D value, the more compact the crystal dispersion and, in the case of triacylglycerols, its value changes with ageing of the system after crystallization. In turn, the magnitude of D affects the value of the elastic modulus and, therefore, the texture of the crystal dispersion at a given temperature (e.g., mouthfeel, spreadability). Although the rheology of fat crystal dispersions determines important properties in vegetable oil system (i.e., texture, sedimentation), still more research is needed to understand the structure-property relationship (65).

3. Microscopic Techniques

Polarized light spectroscopy allows under certain circumstances to differentiate the α (platelets), β′ (small needles), and β (larger and growing in clump) forms. This technique makes it possible to view crystals in the range of 0.5–100 μm (66).

In contrast to polarized light microscopy, electron microscopy resolves details in areas of 0.1 μm. However, since fine structures of fats are temperature sensitive, special techniques such as freeze-fracture or freeze-etching are required (66). Structures of liquid and crystallized fat in systems such as butter and margarine can be characterized in micrographs due to the amorphous appearance of the originally liquid fat (67).

III. THERMAL AND RHEOLOGICAL PROPERTIES, AND OTHER PHYSICAL CONSTANTS

A. Melting

1. Melting Points

The melting point is the temperature at which a solid fat becomes a liquid oil. Thus, an individual fatty acid or triacylglycerol has a specific complete melting point for each polymorphic form (Table 9.4 collects the melting points of common triacylglycerols in their three polymorphic forms). Complications arise in fats and oils because they are essentially mixtures of mixed triacylglycerols which crystallize in several crystal forms (Table 9.5 collects triacylglycerol composition of some common fats and oils). These molecules, although of the same chemical structure, differ in chain length, unsaturation, and isomerism. Each component in these products has its own melting point. Fats, therefore, do not have sharp melting points, but a melting range. What is commonly known as the melting point of a fat is in reality the end of the melting range. Table 9.6 collects melting and solidification points of some common fats and oils. In addition, softening points (74) and congeal points (75) are sometimes reported.

The more complex and diversified the mixture of triacylglycerols in the fat, the greater the melting range. If the melting range is less than 5°C, the fat is considered to be non-plastic (cocoa butter, for example). If the melting range is significant (in certain cases it may exceed 40°C) the fat is called plastic. This happens for the majority of natural and processed fats.

The temperature at which a fat or oil is completely melted depends on various factors (12), including the average chain length of the fatty acids (in general, the longer the average chain length, the higher the melting point); the positioning of the fatty acids on the glycerol molecule (as an example, safflower oil, which has a long average chain length, will melt like a medium chain length triacylglycerol); the relative proportion of saturated to unsaturated fatty acids (the higher the proportion of unsaturated fatty acids, the lower the melting point); and the processing techniques employed, for example the degree and selectivity of hydrogenation and winterization.

2. Specific Heat and Heat of Fusion

Specific heat, c_p, is defined as the amount of heat required to increase the temperature of 1 g of material by 1°C. It is believed to be largely independent of the molecular weight for oils, but it does increase with unsaturation (10). In addition, the specific heats of the solid and liquid states of fatty compounds are different. Fats at temperatures just above their melting points have specific heats of ~0.5 cal/g. Their solid forms have lower values. The specific heat of oils has often been observed to increase linearly with temperature (76). Other workers, however, have observed nonlinear increases at higher temperatures (77,78), although these increases may be due to autoxidation reactions (79). Specific heat data for some simple triacylglycerols are given in Table 9.7. Specific heat data of common fats and oils are given in Table 9.8.

The transformation of solid to liquid releases the latent heat of crystallization. Transformation of a lower to a higher polymorphic form also is an exothermic reaction. The heat of fusion (Hf) of a fatty material includes the amount of energy required to melt a gram of material and the heat of crystal transition. Heat (with negative sign) is released when a fat crystal is transformed from a less stable form to a more stable form. Heat of fusion data for several monoacid triacylglycerols are given in Table 9.9 and they increase with chain length. The corresponding values for common fats and oils are collected in Table 9.10.

B. Plasticity

Plasticity is defined as the capability of fats of being molded by largely maintaining the deformation due to a stress after removal of the stress. This is a consequence of the semisolid state of fats at room temperature. Their solid character is the result of the presence of a certain proportion of crystallized triacylglycerols. As the temperature drops, more of the triacylglycerols solidify and the fat becomes progressively firmer. On the other hand, as the temperature rises, most solid triacylglycerols melt and the fat becomes progressively softer until it has practically no "body" or plasticity at all, and eventually it becomes completely melted (82).

If a fat or a shortening that is workable over a wide temperature range is desired, then it should be made up of a combination of triacylglycerols ranging widely in melting points. By the same reason, when a fat or shortening with a narrow temperature range of workability is needed, it is made up of a greater amount of triacylglycerols of similar melting points.

One of the most important properties of fats is the solid fat content (41). It is dependent on temperature and temperature history, and it is related to different physical properties of the fats, including hardness, heat resistance, waxiness, coolness, and flavor release (83). Fats may retain their solid character with solid fat contents as low as 12 to 15%. Below this level, fats become pourable and lose their plastic character. The relationship between hardness and solid fat content indicates that there is only a range of solids that results in a product being neither too hard nor too soft. This is called the plastic range of fats. Shortening is an example of a product that requires an extended plastic range. The solid fat content (SFC) as a function of temperature of some natural fats is collected in Table 9.11.

Plastic fats combine the physical properties of both solids and liquids. This is caused by the presence of a three-dimensional network of crystals in which a considerable amount of liquid oil is immobilized. A plastic fat is usually workable at room temperature when the solid fat content lies between 20 and 40%. Under the influence of weak attractive forces between crystals, mostly due to van der Waals forces, a three-dimensional structure is formed that lends the product a good deal of resistance to deformation. As a result of the presence of this fat crystal network, plastic fats exhibit a yield value. Thus, the product behaves like a rigid solid until the deforming stress exceeds the yield value and the fat start flowing like a viscous liquid. The application of a shear stress to such product is accompanied by structural breakdown and a decrease in strength. This is also known as work softening. The consistency of plastic fats is determined by a number of factors, including solid fat content, crystal size and shape, and polymorphic form.

The earliest developed technique for solid fat content determination was dilatometry. It remains a recommended method of the American Oil Chemists' Society (84) but it has been largely replaced by various nuclear magnetic resonance methods (85,86). Lipid crystallization and, therefore, changes in solid fat content, can also be measured by differential scanning calorimetry (87) or by using ultrasounds (88).

C. Viscosity

Viscosity is a measure of internal friction of a liquid to resist flow. It is usually denoted by η, and defined as the ratio between the shear stress (in force per unit area) and the shear rate (the velocity gradient between the moving and stationary phases). The viscosity, η, carries a dimension of poise (P) or dyne/($cm^2 \cdot s$). Water has a value of 1 centipoise (cP) at 20°C. The viscosities of triacylglycerols or oils (Tables 9.12 and 9.13, respectively) are much higher than that of water, which can be attributed primarily to the intermolecular attractions of the long-chain fatty acids of their triacylglycerols. This is one of the reasons why the oils exhibit their unique oily characteristics and have the ability to form oily or lubricating films. This lubricating action is very important in the preparation of some foods, such as grilled foods (1).

Vegetable oils follow Newtonian flow behavior, i.e., at a given temperature a constant value of viscosity is obtained independent of the force applied to the oil. As a result, oil viscosity (η) is defined as the slope of the shear stress-shear rate curve, also known as the flow curve (65).

In general, the viscosity of oils decreases slightly with an increase in unsaturation, and, therefore, hydrogenated oils are slightly more viscous than original oils (94). In addition, for an equivalent degree of unsaturation, oils and fats containing a greater proportion of fatty acids of relatively low molecular weight are slightly less viscous than those containing a higher proportion of high-molecular-weight acids. Most common oils range in viscosity from 20 to 50 cP at ambient temperature. An exception is castor oil, which has a viscosity exceptionally high because of its high content of ricinoleic acid.

The viscosity of highly polymerized oils is much greater than that of normal oils. For this reason, viscosity is occasionally referred to in determining the conditions of fats used in deep frying. During use in the frying kettle, the viscosity of a frying fat or oil will tend to increase as oxidation and polymerization increase (95). This can be related to polymer development and tendency toward foaming.

Viscosity is also an important parameter in the process of melt crystallization. The dry fractionation of oils to produce a solid and a liquid fraction is greatly influenced by the viscosity of the oil at the fractionation temperature. Toro-Vazquez and Gallegos-Infante (96) have described the relationship between viscosity and crystallization in a system containing saturated triacylglycerols and liquid oil.

D. Vapor Pressure

The vapor pressure, defined as the pressure associated with the vapor in equilibrium with a condensed phase, is very low in triacylglycerols of long-chain fatty acids. Therefore, they can only be satisfactorily distilled by molecular or short-path distillation. These values decrease as chain length increases (Table 9.14). Analogous values and behavior are also observed in fats and oils (Table 9.15).

E. Smoke, Flash, and Fire Points

The smoke, flash, and fire points are important properties when oils or fats are heated in contact with air, as in frying operations. These indices are often used as a quick quality control means for a critical process step such as deodorization. In this case, lower than normal smoke, flash, or fire points indicate the presence of an excess of residual nontriacylglycerol impurities, such as free fatty acids, monoacylglycerols, and other volatiles, which should be largely removed during steam deodorization.

The smoke point is the temperature at which smoking is first detected in a laboratory apparatus protected from drafts and provided with special illumination (98). The flash point is the temperature at which volatile products are evolved at such rate that they are capable of being ignited but do not support combustion. The fire point is the temperature at which the volatile products will support continuous combustion. Smoke, flash, and fire points of common fats and oils are shown in Table 9.16.

The smoke and flash points of fats and oils are greatly dependent on content of free fatty acids and to a lesser degree on partial glycerols. The influence of degree of unsaturation is minimal, but chain length has an important effect. Oils containing short-chain fatty acids (e.g., the lauric acids) have lower smoke and flash points than oils with predominantly longer fatty acids. According to Formo (10), the smoke points of corn, cottonseed, and peanut oils vary from about 232°C at a free fatty acid content of 0.01% to about 94°C at 100% free fatty acid content. The flash points correspondingly decrease from about 329 to 193°C and the fire points from 362 to 221°C.

F. Heat of Combustion

The heat of combustion is defined as the amount of heat released when a definite quantity of a substance is completely oxidized at constant pressure or constant volume. All fats and oils have very similar heat of combustion values and they are about 9.4 kcal/g. These values are collected in Table 9.17.

G. Thermal Conductivity

Thermal conductivity describes the ease with which heat passes through a material. Specifically, it quantifies the

rate of flow of thermal energy through a material in the presence of a temperature gradient, given by the amount of heat transfer across a unit area in a unit amount of time, divided by the negative of the space rate of change in temperature in the direction perpendicular to the unit area. Fats are relatively poor conductors of heat (10) and the thermal conductivity decreases with the temperature (100). Thermal conductivity data for common fats and oils are given in Table 9.18.

H. Thermal Diffusivity

Thermal diffusivity is the thermal conductivity divided by the product of specific heat capacity and density. It is more generally applicable than thermal conductivity in most heat transfer problems. Thermal diffusivity values for some fats and oils are given in Table 9.19.

I. Thermal Expansion

The thermal expansion is defined as the increase in the size of a substance when the temperature of the substance is increased. The thermal expansion coefficients are the proportionally constants that related these increases. Fat and oils have thermal expansion coefficient values in the range $6.6 \cdot 10^{-4}$–$7.8 \cdot 10^{-4}$ mL/g · °C (Table 9.20). These values increase approximately linearly with temperature for liquid oils (79).

J. Dielectric Constant

The dielectric constant is the property of a material that determines how much electrostatic energy can be stored per unit volume of the material when unit voltage is applied. It is quantified as the ratio of electric flux density produced in a material to the value in free space produced by the same electric field strength. In fats and oils, most values are in the range of about 3.0–3.2, and, therefore, dielectric constants are not a particularly distinguishing characteristic. Castor and oiticica oils, however, which contain oxygenated fatty acids (ricinoleic and licanic acids, respectively), have higher dielectric constants (around 4.0). Oxidation increases the dielectric constant of oils by the introduction of polar groups (104). On the other hand, thermal polymerization without considerable oxidation has relatively little effect (10). Dielectric constants for some common fats and oils are given in Table 9.21.

K. Density

The density of a material is a measure of the mass per unit volume. Liquid oils have a density between 0.91 and

0.92 g/mL at 25°C, and this value decreases as the temperature increases (Table 9.22). Oil density generally increases with lower molecular weight fatty acids and by hydrogenation (76,94,107). The densities of solid fats are generally higher than those of their liquid states. In addition, the various types of crystal forms, α, β', and β, melting at progressively higher temperatures, also show increasing densities (Table 9.23).

L. Solubility

Fats and oils are almost completely insoluble in water. When they are held together in systems such as cake batters or butterfat in milk, these systems require the use of food emulsifiers and/or mechanical means such as homogenizers. These same fats, oils, and fatty acids are completely miscible with most organic solvents, such as hydrocarbons, ethers, esters, and so on, at temperatures above their melting points. The solubility of fats in organic solvents increases with temperature, decreases with increasing mean molecular weight, and increases with increasing unsaturation. This last is the basis for fractional crystallization of fats into a number of fractions based on molecular weight and unsaturation. Alcohols from methanol to octanol have the property of being miscible with the liquid portion of plastic fats but not the solid. This has been used as a method for the separation of solid fat (109). The Crismer value is sometimes used to measure the solubility of an oil in a standard solvent mixture, composed of t-amyl alcohol, ethyl alcohol, and water in volume proportion 5:5:0.27. This value is characteristic within a narrow limit for each kind of oil (110). Examples of such values are 68.5–71.5 for olive oil, 67–70 for canola (low erucic rapeseed oil) and 76–82 for high erucic rapeseed oil (111,112). The miscibility of an oil is related to the solubility of glycerides and is affected mainly by the unsaturation and chain length of the constituent fatty acids.

Water is slightly soluble in oil at 0°C, with solubility amounting to about 0.07 and 0.14% at 32°C (2).

Some selected solubility data of nitrogen, oxygen, hydrogen, and carbon dioxide are shown in Table 9.24. With the exception of carbon dioxide, the solubilities of these gases in oil usually increase with temperature.

M. Surface Tension, Interfacial Tension, and Emulsification

Surface tension is the force acting on molecules at the surface of the oil that tends to pull them into the bulk of the

liquid. The interfacial tension is the surface tension at the surface separating two non-miscible liquids. Surface and interfacial tensions against water for different oils are given in Tables 9.25 and 9.26, respectively, and are similar among them (114).

Interfacial tensions may be decreased by the use of emulsifiers (115). Thus, the presence of monoacylglycerols and lecithin decreases the interfacial tension between oil and water from 30 to <10 dyne/cm. This reduction of interfacial tension lowers the energy required to homogenize the oil/water mixture, thus making possible the fine oil-in-water or water-in-oil dispersions.

Acylglycerols with three fatty acids attached to a glycerol molecule have minimal emulsification properties. However, fats and oils are important constituents of emulsions (116–124). An emulsion consists of a three-phase system composed of a continuous phase (the phase or medium in which the disperse phase is suspended), a disperse phase (the phase which is disrupted or finely divided within the emulsion), and an emulsifier (16). The emulsifier is present at the interface between the dispersed phase and the continuous phase, and keeps them apart; it reduces the interfacial tension between the two liquids, enabling one liquid to spread more easily around the other; and it forms a stable, coherent, viscoelastic film that prevents or delays coalescence of the dispersed emulsion droplets.

These properties of the emulsifiers are a consequence of their structure: the molecules contain two distinct sections, one having polar or hydrophilic character, the other having nonpolar or hydrophobic properties. The relative sizes of the hydrophilic and hydrophobic sections of an emulsifier mostly determines its behavior in emulsification. To make the selection of the proper emulsifier for a given application and to predict the type of emulsion that will be formed, the so-called hydrophile-lipophile balance (HLB) system has been developed. It is a numerical expression for the relative simultaneous attraction of an emulsifier for water and for oil. Emulsifiers with HLB in the range 2–6 tend to form water-in-oil (W/O) emulsions, those with HLB in the range 7–9 are good wetting agents, and those with HLB in the range 10–18 tend to form oil-in-water (O/W) emulsions (115). HLB values of some commercial nonionic emulsifiers are given in Table 9.27. These values can be estimated from experimental measurements of its cloud point or can be calculated from a knowledge of the number and type of hydrophilic and lipophilic groups that it contains, according to the equation:

$$\text{HLB} = 7 + \Sigma \text{ (hydrophilic group numbers)} - \Sigma \text{ (lipophilic group numbers)}$$

Hydrophilic and lipophilic group numbers have been tabulated (115,116,125).

Foods contain many natural emulsifiers, of which phospholipids and proteins are the most common (126,127). Mono- and diacylglycerols are examples of emulsifiers that are added to products in order to provide ease of mixing. They absorb at the interface, reducing interfacial tension, and increasing the spreadability of the continuous phase, or the wettability of the dispersed phase.

Many natural and processed foods exist either partly or wholly as emulsions, or have been in an emulsified state at some time during their existence (117,128–132). Milk is the most common example of a naturally occurring food emulsion (133). Mayonnaise, salad dressing, cream, ice cream, butter, and margarine are all examples of manufactured food emulsions. Powdered coffee whiteners, sauces, and many desserts are examples of foods that were emulsions at one stage during their production but subsequently were converted into another form (116).

N. Ultrasonic Properties

Ultrasonic velocity in triacylglycerols or oils is a measure of the speed of sound in these food components. It is related to its fatty acid composition and the supramolecular lipid structure. This is one of the most important variables in predicting the velocity of sound in an emulsion. The speed of sound in oils decreases monotically with temperature (134), is similar for oils and water at 20°C (79), and is lower in solid fats than oils. Ultrasonic velocities for some triacylglycerols as well as for some common oils are given in Tables 9.28 and 9.29, respectively.

The ultrasonic attenuation coefficient is a measure of how much ultrasound is dissipated in an oil per unit distance. This coefficient has little direct value beyond predicting the ultrasonic properties of an emulsion. However, in this application, a precise value is essential. The attenuation coefficient increases with frequency at a single temperature (79). Attenuation and its frequency dependence tend to decrease with increased temperature. Ultrasonic attenuation coefficients for some common oils are given in Table 9.29.

IV. OPTICAL AND SPECTROSCOPIC PROPERTIES

A. Color

Fatty acids and triacylglycerols, are colorless and essentially transparent to visible light. Natural fats and oils, however, often contain pigments that partially absorb transmitted light. Most of these pigments are removed from fats and oils by the refining and bleaching process,

but some of them remain and most oils have their specific color, which is a consequence of the type and amount of natural pigments present. Therefore, some oils are naturally darker than others (68).

Carotene is the predominant red/yellow color pigment in soybean, safflower, and sunflower oils, among others. Carotene becomes colorless when subjected to the temperatures encountered in the edible oil processing steps. The oxidation products and other pigments found in these refined oils can be removed by adsorption on diatomaceous earth in the edible oil processing step referred to as bleaching. Most of the red color found in cottonseed oil, on the other hand, comes from a minimal residual level of gossypol and gossypol derivatives, especially a complex gossypurpurin. While some of the pigments that contribute to oil colors can be removed by adsorption on bleaching earths and any carotene is rendered colorless by heating, the gossypol can only be removed by alkali refining. The level of color removal that can be achieved is, to a great extent, dependent on the handling and storage of the seed and crude oil prior to refining.

In addition, poor grade of crude oil or improper processing and handling may produce oils and fats which are darker than usual. Thus, insufficient refining may leave residual phospholipids that will darken the oil during deodorization. Vegetable oils and shortening will also darken after being stored for a long time or at elevated temperatures due to the oxidation of tocopherol to tocoquinones. During frying, oil darkening is further complicated by the polymerization of oil and interaction between the oil and other components of the food being fried (95).

Color may be determined by a number of procedures. The Lovibond method determines color by matching the color of the light transmitted through a specific depth of liquid fat or oil to the color of the light originating from the same source, transmitted through glass color standards (140). Results are given in red and yellow units describing the combination that matches the sample color. By using this methodology, the maximum accepted values for edible oils are collected in Table 9.30. Other methods that also determine color by comparison with permanent color standards or glasses of known color characteristics have also been described (142,143).

Color can also be determined spectrophotometrically. In this case the oil or fat is dissolved in the required solvent and the transmittance or the extinction of the solution is then determined at the specified wavelengths with reference to pure solvent (144). These absorptions may be expressed as specific extinctions (the extinction of 1% solution of the oil in the specified solvent, in a thickness of 1 cm), conventionally indicated by K (145). K values are usually employed to define olive oil quality (146).

B. Refractive Index

The refractive index of a fat is a measure of the relative velocities of light in air and in the material to be tested. It is defined as the ratio of the sine of the incident angle of light from air and the sine of the refractive angle in the medium. This index, which can be easily measured, is influenced by wavelength, temperature, density, and constitution, and it is employed to examine the purity and concentration of a liquid sample, and to control the progress of some reactions such as hydrogenation and isomerization. For lipids, the refractive index normally increases with the hydrocarbon chain length and with the number of double bonds and conjugation, and decreases with an increase in the temperature (the refractive index for an oil drops by 0.00035 per °C). The refractive indices of some triacylglycerols and common fats and oils are given in Tables 9.31 and 9.32, respectively.

C. Ultraviolet Spectroscopy

Monoene and methylene-interrupted polyene acids and their triacylglycerols absorb ultraviolet light at wavelengths too low for convenient study. Therefore, the use of ultraviolet spectroscopy in the study of fats and oils is confined to systems containing or generating conjugated unsaturation. Thus, ultraviolet spectroscopy is a valuable tool and it is broadly employed for detecting fatty acids and their corresponding triacylglycerols with conjugated double bonds. Conjugated dienes show a single absorption peak at 230–235 nm, whereas conjugated trienes show three peaks at ~260, 270, and 280 nm. Methylene-interrupted polyenes undergo double bond migration to produce compounds with conjugated unsaturation in reactions such as oxidation or hydrogenation and the appearance of absorption at appropriate wavelength has been employed in the study of such processes. Thus, the edible oil industry estimates spectrophotometrically at 233 nm the amounts of conjugated dienes in the finished fats and oils (148), and the K234 and K270 are indexes of olive oil quality (146,149).

D. Infrared (IR) Spectroscopy

The infrared spectra has been applied to solid lipids to provide useful information about polymorphism, crystal

structure, conformation and chain length of fats and oils, and it is also frequently employed for identification and quantitative analysis of fats and oils. Most oils containing the usual mixture of saturated and unsaturated acids have similar infrared spectra. Superimposed on this there may be additional absorption bands associated with less common functional groups. A selection of the bands of interest in the study of fats and oils is collected in Table 9.33.

The most frequent use of infrared spectroscopy is in the recognition of *trans* isomers. The *trans*-double bond

produces a characteristic absorption at 968 cm^{-1} that does not change for additional double bonds unless these are conjugated, when there are small changes from this value. Therefore, this absorption can be employed to estimate the percentage of *trans* of the total amount of double bonds (146,150,151). There is not a similar diagnostic infrared absorption band for *cis* unsaturation, but Raman spectra show strong absorption bands at 1665 ± 1 cm^{-1} (*cis*-olefin) and 1670 ± 1 cm^{-1} (*trans*-olefin).

Carbonyl compounds have a strong absorption band in the region 1650–1750 cm^{-1}. The wavelength varies slightly with the nature of the carbonyl compounds (Table 9.33) and this may be of diagnostic value. Thus, this band has been suggested for free acidity determination in oils (152) and it is usually employed for measurement of fat content in automatic analyzers (153). Other applications of infrared spectra are the determination of iodine value, saponification value, free acid, oxidative stability, and carotene content, among others (3,154–156). By using Fourier transform infrared spectrometers (FTIR), these parameters can be measured by simple menu-driven procedures in a few minutes. The results are not only obtained more quickly, but without recourse to solvents or laborious titrimetric methods.

Near infrared spectroscopy, covering the region 800–2500 nm, is also being employed in fat and oil analysis. Thus, methods to determine fatty acid composition, peroxide value, oil content of individual seeds, recognition of individual vegetable oils, oil oxidation and in-line measurement of tempered cocoa butter and chocolate, among others, have been developed (3,157–160).

E. Raman Spectroscopy

As commented above, Raman spectroscopy may be appropriate to use for the simultaneous analysis of the *cis* and *trans* content of oils, since *cis* and *trans* carbon-carbon double bond stretching bands can be observed simultaneously. By using this technique, the *cis*/*trans* isomer ratios were determined with a precision of 1% (161). The carbon-carbon double bond stretch and the methylene scissor intensity ratios have also been used to determine iodine values. In addition, the total unsaturation in oils and margarines can also be determined (162).

F. Nuclear Magnetic Resonance (NMR) Spectroscopy

NMR spectroscopy is used in two ways in the study of fats and oils. With low-resolution instruments, it is possible to determine the proportion of solid and liquid in a fat and the content of oil in a seed. High-resolution spectrometers, on the other hand, are used to mainly examine solutions and give information about the solute.

1. Low-Resolution NMR

Differently to high-resolution NMR, broad band NMR does not distinguish among hydrogen nuclei in different atomic environments. Two techniques can be employed, namely wide-line NMR or pulsed NMR, and both distinguish between hydrogen atoms in liquid and solid environments. Nowadays, the most widely used technique is pulsed NMR. By using this technique, a measurement related to the total number of hydrogen nuclei is followed by a second measurement after 70 μs to determine only those hydrogen nuclei in a liquid environment. This determination depends on the fact that the signal for hydrogen nuclei in solid triacylglycerols decays much more quickly (less than 1% remains after 70 μs) than that of hydrogen nuclei in a liquid environment (which requires about 10000 s).

These measurements require only about 6 seconds and are used routinely for the study of margarine and other confectionery fats and of cocoa butter and similar substances. However, though the measurement is so quick, it may have

[a] Assignments are abbreviated by fatty acid and carbon number. 1(3)- and 2-Positions of glycerol are designated by the Greek symbols α and β, respectively. Labeling of acyl chains: S, saturated; P, palmityl; St, stearyl; O, oleyl; L, linoleyl; Ln, linolenyl chain. Depending on the oil composition and experimental conditions, a lower number of signals is usually observed.

to be preceded by a lengthy tempering routine. Without controlling tempering the results would not be reproduced from day to day or between laboratories. The tempering regime varies with the kind of fat but a typical procedure for cocoa butter involves melting at 100°C then holding at 60°C (1 h), 0°C (1.5 h), 26°C (40 h), 0°C (1.5 h), and finally at the measuring temperature for 1 h. For many fats the long tempering at 26°C can be omitted (3).

For oilseed breeders, the NMR method is often used to estimate the oil content of oilseeds in a nondestructive manner. This information is of commercial value and can assist seed breeders and agronomists in their studies to develop improved varieties. Pulsed NMR is also employed in lipid crystallization studies (163).

2. High-Resolution ^1H NMR

The use of ^1H NMR in the study of oils, fats and food lipids has increased particularly because of the great amount of information that high field instruments can provide in a very short period of time (164). The NMR spectrum consists of a series of sharp signals whose frequencies and multiplicities can be related to the chemical nature of the different hydrogen atoms (methyl, methylene, olefin, etc.) and whose intensities are directly related to the number of hydrogens producing the signal (165,166). In this spectrum, all hydrogen atoms having the same chemical surroundings produce signals at the same frequency. The position of a resonance signal in the

spectrum is called the chemical shift (δ). In the ^{1}H NMR spectra of fats and oils the resonances appear between δ 4.10 and 5.40 ppm for glycerol and unsaturated protons, and saturated protons signals appear between δ 0.80 and 2.80 ppm. Table 9.34 collects the assignation of most common signals.

By using the information contained in the spectra, ^{1}H NMR has been employed, among others, to determine the iodine value, number of double bonds, average molecular weight, proportion of acyl groups in the triacylglycerol molecule, *n*-3 polyunsaturated fatty acid proportion, and docoxahexahenoic acid content (167–176). Some attempts to apply ^{1}H NMR spectroscopy to oil authenticity have also been carried out (177).

^{1}H NMR spectroscopy may also be employed to determine minor oil components, but the signals of these components should not overlap with those of the main components, their concentration be high enough to be detected, and high field equipment be employed. Thus, the determination of saturated and unsaturated aldehydes in virgin olive oils as well as diacylglycerols have been described (170,177,178).

3. High-Resolution ^{13}C NMR

High-resolution ^{13}C NMR spectra are more complex than ^{1}H spectra and they do not provide quantitative information so easily. Nevertheless, they contain much more structural information (chemical shifts and intensities) if this can be teased out of the data provided with each spectrum. ^{13}C NMR resonances of fats and oils can be grouped into four well-defined spectral regions: carbonyl carbons ranging from 173.3 to 172.8 ppm; unsaturated carbons ranging from 132.0 to 127.1 ppm; glycerol carbons ranging from 69.1 to 61.6 ppm; and aliphatic carbons ranging from 34.3 to 14.0 ppm. The assignation of the different signals has been the objective of many studies and it is nowadays clearly resolved (179–181). The main resonances observed in the ^{13}C NMR spectra of fats and oils are collected in Table 9.35.

Information contained in these spectra has been employed for edible oil authenticity determination and quality controls, including the analysis of fatty acid composition and distribution of fatty acids in the triacylglycerol molecule, the free fatty acid, iodine value, and diacylglycerol determination, the analysis of minor components, the oil stability prediction, the determination of polar components and oil colors, etc. (182–198). All these data suggest that with only one analysis, NMR allows the determination of a large number of components with very little or without any manipulation of the oil samples that nowadays need many different analyses. In addition, the application of multivariate statistics to NMR spectral data increases considerably the potential of the technique. However, and because minor components of the oils are playing an essential role in defining oil authenticity and quality, concentration of these compounds (either by using a chromatographic procedure or by the use of unsaponifiables) or their observation during routine analysis by using special probes seem to be a necessary requisite to achieve a routine application of NMR to most aspects of oil analysis.

I. INTRODUCTION

The water-soluble vitamins consist of a mixed group of chemical compounds. Their classification into specific chemical groups depends on both chemical characteristics and functions. The letter designations (vitamins B_1, B_2, B_3, etc., C) represent in part remnants from the past as the discovery of given dietary growth or curative factors were given letter designations.

Vitamins are novel in their roles as "external" or dietary regulatory agents. They have largely evolved to serve: 1) specific cofactor and/or co-substrate functions, 2) as regulatory agents, or 3) as antioxidants. All of the vitamins undergo specific and metabolically controlled modifications before activation or conversion into their functional forms. The most limiting events that control function are often a specific step(s) in cofactor formation, e.g., a phosphorylation reaction or ATP addition.

The use of broad functional categories as headings to organize this chapter was chosen. For example, niacin, riboflavin, and ascorbic acid serve primarily as redox cofactors. The roles of thiamin, pyridoxine (vitamin B-6) and pantothenic acid (as a component of coenzyme A) are distinguished because of their importance to carbohydrate, protein and amino acid, and acyl and acetyl transport, respectively. Folic acid, vitamin B-12 (cobalamin), and biotin will be discussed in relationship to their roles in single-carbon or CO_2 transfer reactions.

II. VITAMINS IMPORTANT IN REDOX REACTIONS

A. Ascorbic Acid (Vitamin C)

Ascorbic acid functions primarily as a cofactor for microsomal mono-and dioxygenases (hydroxylases) and oxidases. In most animals, ascorbic acid is synthesized from glucose in the liver. In birds and reptiles, ascorbic acid synthesis takes place primarily in the kidney. In animals that require ascorbic acid, e.g., humans, it is a deficiency of gulonolactone oxidase, the last step in ascorbic acid synthesis, which results in the need for a dietary source (Figure 10.1; 12).

1. Chemistry

Ascorbic acid (2,3-enedial-glulonic acid) is a powerful cellular reducing agent and is of general importance as an antioxidant because of its high reducing potential. Both of the hydrogens of the enediol group dissociate, which result in the acidity of ascorbic acid ($pK_1 = 4.2$). When ascorbic acid plays a role in reductions, the reaction usually occurs in a stepwise fashion with monodehydroascorbic acid, as a semiquinone intermediate. This intermediate then disproportionates to ascorbic acid, and dehydroascorbic acid (Figure 10.1).

2. Absorption, Tissue Distribution, and Metabolic Functions

Dietary ascorbic acid is absorbed from the duodenum and proximal jejunum. Measurable, albeit small, amounts of ascorbic acid also cross the membranes of the mouth and gastric mucosa. Although some controversy exists regarding the relationship between dietary intake and the intestinal absorption of ascorbic acid, studies indicate that within the physiological ranges of intake (40–200 milligrams per day for humans or ~5–25 mg/kJ of diet); 80–90% of the vitamin is absorbed. Uptake at apical membranes involves a specialized Na^+-dependent, carrier-mediated system. Exit of ascorbic acid from enterocytes utilizes a Na^+-dependent carrier system. To date, two Na^+-dependent L-ascorbic acid transporters have been cloned and partially characterized. The preference for these transporters is for L-ascorbic acid. Dehydroascorbic acid uptake is facilitated by hexose transporters (3, 12).

In tissues, the highest concentration of ascorbic acid is found in the adrenal and pituitary glands followed by the liver, thymus, brain, and pancreas. In diabetic animals, the ascorbic acid content of tissue is often depressed, which may be due to competition for uptake between dehydro forms of ascorbic acid and glucose (3).

Ascorbic acid is maintained in cells by several mechanisms. Ascorbic acid reductases maintain L-ascorbic acid in the reduced form, which is less susceptible to easy diffusion. Within most cells, measurable amounts of ascorbic acid are also maintained as the 2-sulfate derivative. The ability to maintain ascorbic acid in the reduced state and as ascorbic acid-2-sulfate appear important in maintaining cellular ascorbic acid levels (12).

In the neonate, glutathione is also very important to ascorbic acid recycling. In this regard, an argument can be made for a dietary need for ascorbic acid in the neonates of some animal species in which the adult does not have a dietary requirement. For example, the levels of glutathione are relatively low in neonate rat and mouse tissues. As ascorbic acid is oxidized to dehydroascorbic acid, there is the need for conservation, because dehydroascorbic acid is easily degraded. Glutathione in its

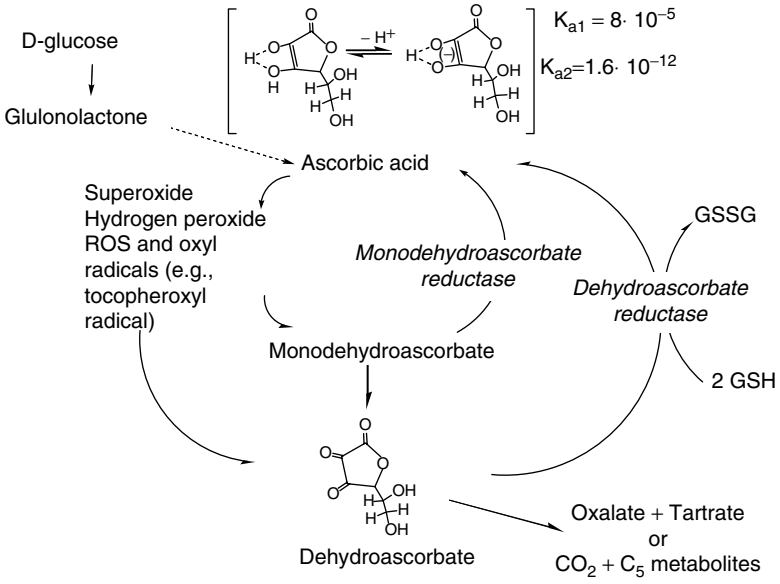

FIGURE 10.1 Ascorbic acid. In most animals ascorbic acid is derived from glucose. Gulonolactone is produced from glucose and its oxidation to ascorbic acid is catalyzed by gulonolactone oxidase (dashed line). The K_as for the two dissociable protons in ascorbic acid are indicated. At pH 7, dehydroascorbic acid can be reduced to ascorbic acid with a $Eo' = 0.08$, e.g., dehydroascorbate $+ 2e^- + 2H^+ \leftrightarrow$ ascorbate. In a biological system, reduction of the monodehydroascorbic acid to ascorbic acid occurs by the NADH-requiring enzyme, monodehydroascorbic acid reductase. Reduction of dehydroascorbic acid utilizes reduced glutathione and is catalyzed dehydroascorbic acid reductase, also known as glutaredoxin.

reduced form serves as the reducing substrate for glutaredoxin, an enzyme that can maintain ascorbic acid in a reduced state (3, 12).

As a cellular reducing agent, ascorbic acid plays a number of very important roles. It serves as a cofactor for mixed-function oxidations that result in the incorporation of molecular oxygen into various substrates. Examples include the hydroxylation of proline in collagen, elastin, C1q complement, and acetylcholine esterase. Some of the P-450-dependent hydroxylases that carry out the hydroxylation of steroids, drugs, and other xenobiotics also have a need for ascorbic acid (12).

Ascorbic acid-dependent hydroxylation steps also occur in the biosynthesis of carnitine and the hydroxylation of tyrosine in the formation of catecholamines. Most of the enzymes involved in these processes are metal-requiring enzymes, in which the role of ascorbic acid is to maintain the metal (usually Cu or Fe) in a reduced state.

3. Requirement, Deficiency, and Toxicity

Most animals with the exception of primates, guinea pigs, some snakes, fruit-eating bats, birds such as passerines, and salmonid fish synthesize ascorbate (Figure 10.1). Impaired collagen synthesis is a principle feature of ascorbic acid deficiency, which is evidenced in capillary fragility, bleeding gums, delayed wound healing, and impaired bone formation. Connective tissue lesions are primarily a result of under-hydroxylated collagen (at specific prolyl and lysyl residues). This can result in abnormal collagen degradation and, as a consequence, decreased collagen production. In addition, the inability to deal with metabolic stress requiring normal adrenal gland function and abnormal fatty acid metabolism (carnitine synthesis) can be signs of scurvy.

The current requirement for humans is 75 mg per day (U.S. RDA for the healthy adults) or 30–60 mg per 1000 kcal or 4 MJ of diet (4; Table 10.1). Because of the mechanisms in place to homeostatically regulate ascorbic acid, evidence of toxicity, other than gastric upset, is seldom reported (e.g., diarrhea, gastric irritation). Evidence of toxicity, however, may be manifest, when ascorbic acid is consumed in gram quantities per day. Of interest, ascorbic acid intake in this range can result in decreased histamine production and facilitate reduction of nitrosamines and other putative cancer promoting agents with similar chemical characteristics. The interaction with nitrosamines occurs primarily in the stomach, and is chemical in nature owing to ascorbic acid's potential to function as an excellent reducing agent. The anti-histamine effects from pharmacologic exposure of ascorbic acid are in part the basis for its use as an analgesic in the treatment of "common colds."

When fed in excess of metabolic need, tissue levels of ascorbic acid are homeostatically maintained. Homeostasis occurs by the induction of ascorbic acid decarboxylases, which initiates enhanced degradation of ascorbate to CO_2 and C-4 or C-5 fragments (12).

[a] Dietary Reference Intakes (DRI) — Reference values that are quantitative estimates of nutrient intakes to be used for planning and assessing diets for apparently healthy people. There are 4 reference values: the EARs, RDAs, AIs, and UIs.

[b] Estimated Average Requirement (EAR) — The nutrient intake value that is estimated to meet the requirement of half of the healthy individuals in a group. The EAR is used to assess the adequacy of dietary intakes within a population and it is used to develop the RDAs.

[c] Recommended Dietary Allowances (RDA) — The average daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a designated group.

[d] Adequate Intake (AI) — AI is used when the RDA for a nutrient is not available. It is a recommended daily intake that is based on observed or experimentally determined approximations of nutrient intake by a group of healthy people. An AI is developed when there is no EAR or research to help develop the RDA for a nutrient.

[e] Tolerable Upper Intake Level (UL) — Highest level of daily nutrient intake that is likely to pose no risks of adverse health effects to almost all individuals in the general population.

4. Food Sources and Stability

Ascorbic acid is widely distributed in fruits and vegetables, with foods such as citrus fruits, berries, kiwi, peppers, Brussels sprouts, and broccoli being particularly high in this vitamin. Ascorbic acid is relatively unstable and easily destroyed during processing and storage of foods. It is labile to neutral and alkaline conditions, heat, light, and exposure to oxygen. The rate of decomposition is accelerated by the presence of metals, especially iron and copper, and by enzymes such as peroxidases. Food preservation techniques that act to limit losses of ascorbic acid are blanching of vegetables, pasteurization, and deaereation of juices to limit oxygen and inactivate the enzymes. Additionally, packaging in containers that limit exposure to light and oxygen will maintain ascorbate concentrations. Erythorbic acid, a biologically inactive analog of ascorbic acid, is often added to foods as an antioxidant to preserve freshness. A summary of chemical characteristics for ascorbic acid and other B-vitamins is given in Table 10.2 (4, 13).

III. THE B VITAMINS

A. Niacin

Throughout the 18th and 19th centuries, the disease pellagra was prevalent in Western Europe and the southern region of the United States. This disease would eventually became associated with the vitamin, niacin, and the consumption of corn (maize), as a principle source of dietary energy. The nutritional availability of niacin in corn is relatively low bioavailability. Corn also has a low content of tryptophan. As shown in Figure 10.2, niacin can be generated upon tryptophan degradation.

Normally, niacin is derived from foods, such as corn, by hydrolysis of NAD (nicotinamide adenosyl dinucleotide) and NADP (nicotinamide adenosyl phosphodinucleotide) by the action of pancreatic or intestinal nucleosides and phosphatases. As most human diets now contain adequate tryptophan, and available NAD and NADP, niacin deficiency is seldom observed (6).

1. Chemistry

NAD and its phosphorylated form, NADP, are two coenzymes derived from niacin. Both contain an unsubstituted pyridine 3-carboxamide that is essential to function in redox reactions with a chemical potential near –0.32 V. Virtually all cells are capable of converting niacin to NAD. Most enzymes that require NAD are oxidoreductases (dehydrogenases).

NAD catalyzes a diverse array of reactions, such as the conversion of alcohols and polyols to aldehydes or ketones. The most common mechanisms involve the sterospecific abstraction of a hydride ion [H: (-)] from the substrate with its subsequent transfer. It is of interest that cells generally delegate NAD to enzymes in catabolic

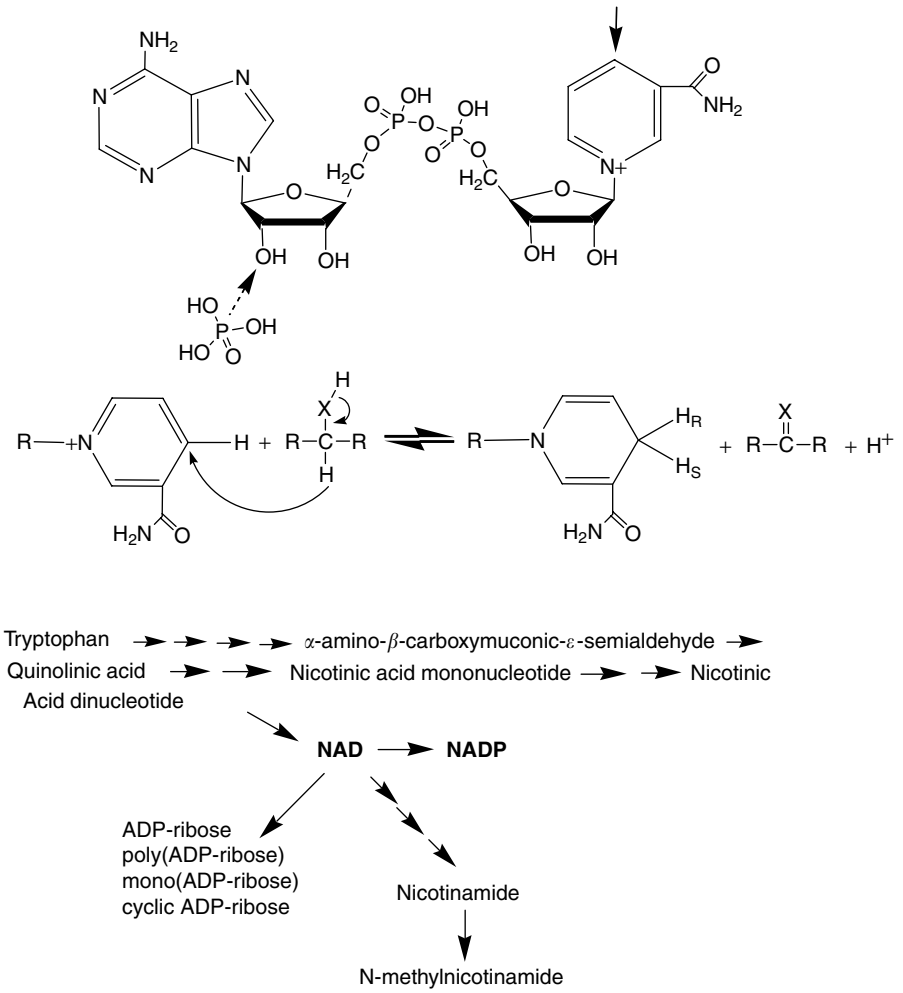

FIGURE 10.2 NAD and NADP. The structures for NAD and NADP (via ATP-derived phosphate addition to NAD, cf. dashed arrow) and their site of hydrogen transfer (solid arrow) are indicated along with a mechanism of hydrogen transfer. The HR and HS designations are shown to indicate that the transfer occurs with stereospecificity. NAD and NADP are products of tryptophan degradation through the quinolate portion of the tryptophan degradation pathway. In addition to acting as a reductant, NAD is precursor to ribosylations and cyclic ribosylated products that are important to cellular regulation.

pathways, whereas NADP is utilized in synthetic pathways. An additional and equally important function of NAD is its role as a substrate in poly- and monoribosylation reactions. Mono and polyribosylation post-translational chemical modifications are important in many cellular regulatory functions (see next section).

2. Absorption, Tissue Distribution, and Metabolism

Transporters for niacin uptake have been identified, but are not as well characterized as some of the other vitamin transporters. As noted, NAD may be derived from tryptophan through the so-called quinolinate pathway (Figure 10.1). About half the niacin as NAD or NADP is associated with enzymes; the remainder is available as a substrate for mono- and polyribosylation reactions that are important in the regulation of a broad range of enzymes. In the nuclei of cells, polyribosylation of specific histones precedes the normal process of DNA repair. When niacin is in excess, most mammals convert it to N-methylnicotinamide, which has a low renal threshold and is excreted (6).

3. Requirements, Toxicity, and Pharmacology

Niacin is needed in amounts corresponding to 14 to 16 mg per day or 4–6 mg per 1000 kcal or 4 MJ of diet (4; Table 10.1). Niacin requirements are often expressed as equivalents, where one equivalent corresponds to 1 mg of niacin. The conversion of tryptophan to niacin produces about 1 mg or equivalent of niacin for every 60 mg of tryptophan degraded (Figure 10.2).

There are a number of therapeutic uses for pharmacologic doses of niacin-derived compounds, when increased blood flow is desirable. Nicotinic acid can cause vasodilatation when consumed in amounts of 100 mg or more. Niacin in gram quantities is an effective lipid-lowering agent (increases HDL). However, in some individuals, flushing, gastric irritation, and other similar side effects caused by pharmacologic doses of nicotinic acid or niacin may preclude use (6).

4. Food Sources and Stability

Niacin is found in high levels in animal tissues (chicken, fish, beef – especially liver), and peanuts, and in moderate amounts in whole grains such as wheat and barley, enriched cereal products, mushrooms, and some vegetables such as corn and peas. Niacin is very stable in a variety of conditions. Indeed some treatments such as moderate heat and alkali treatment of corn can result in greater niacin availability (Table 10.2). An excess of water used in cooking and processing of foods can result in leaching of the vitamin, as is similar for all water-soluble vitamins (4).

B. Riboflavin

Riboflavin was one of the first of the B vitamins identified (10). Originally, it was thought to be the heat stable factor responsible for the prevention of pellagra. Riboflavin is present in tissue and cells as FAD (flavin adenine dinucleotide) and FMN (flavin adenine mononucleotide). FAD and FMN are cofactors in aerobic processes, usually as cofactors for oxidases, although FAD can also function in anaerobic environments as a dehydrogenase cofactor.

1. Chemistry

Flavins, such as riboflavin derivatives (Figure 10.3), are ideally suited to catalyze one electron, one-proton transfer reactions. Oxygen is often utilized as a co-substrate in the redox reactions catalyzed by FAD- and FMN-containing enzymes. Carbon-carbon double bond formation and redox of sulfur-containing compounds, e.g., lipoic acid, are catalyzed also by flavoproteins. $NADP(H) + H^+$ commonly serves as a reductant in processes to regenerate FAD and FMN. Riboflavin has a number of designations, some of which are still in use (vitamin B-2, vitamin G, ovoflavin, uroflavin, lactoflavin, heptoflavin).

Riboflavin was separated and identified from other B vitamins, because it is heat stable, but light instable and fluorescent. The chemical name for riboflavin is 6,7-dimethyl-9-(d-1′-ribityl) isoalloxazine. Deviations in structure can markedly affect activity (10). For example, the polyol side-chain must be in the D-form and substitution in other positions causes loss of activity or gives rise to compounds that have inhibitory activity, e.g., 5,6-dimethyl (isoriboflavin).

2. Absorption, Tissue Distribution, and Metabolism

Like most water-soluble vitamins, riboflavin is absorbed in the proximal part of the small intestine by a carrier-mediated process. Riboflavin is not particularly soluble. There are upper limits to riboflavin's availability, which are dictated in part by solubility. In this regard, an important chemical characteristic that is attributed to the ribose moiety is improved water solubility. Isoalloxazines are not particularly water-soluble.

Intestinal riboflavin uptake is adaptively regulated by dietary levels, and by specific intracellular protein kinase-mediated regulatory pathways. Over-supplementation with pharmacological amounts of riboflavin can lead to a significant and specific down-regulation in riboflavin uptake; riboflavin deficiency causes a significant and specific up-regulation in intestinal riboflavin uptake. Factors that have been shown to interfere with the normal intestinal riboflavin uptake process include alcohol and certain tricyclic drugs (e.g., chlorpromazine).

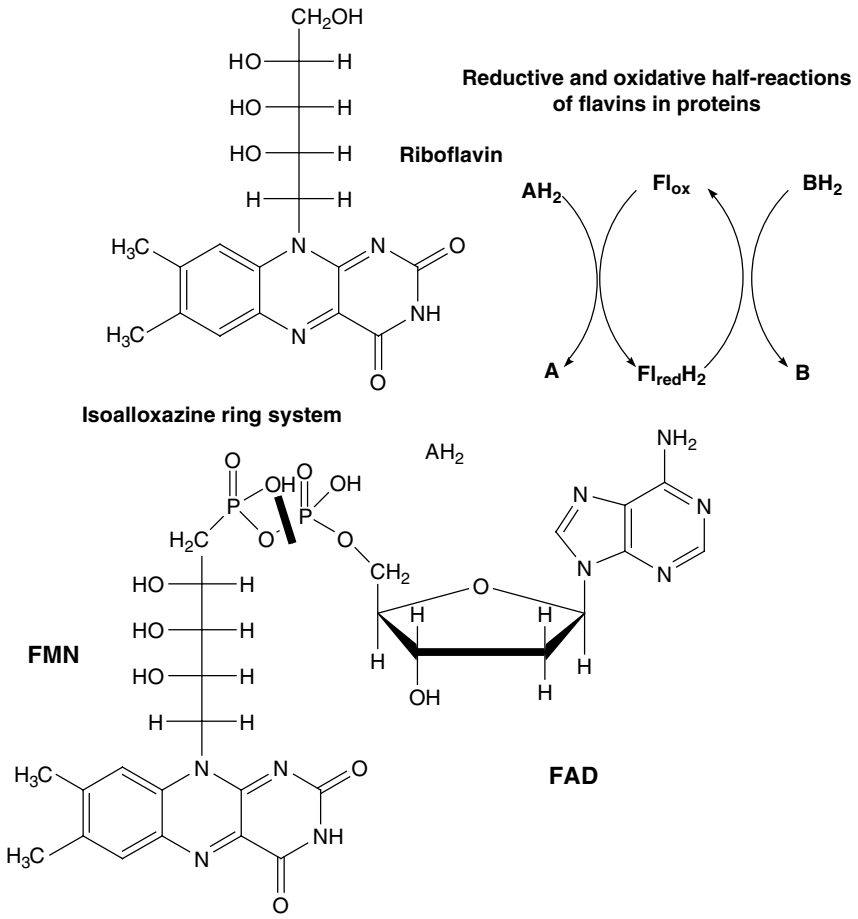

FIGURE 10.3 Riboflavin, FMN, and FAD. When associated with flavoproteins, the reductive and oxidative half-reactions for FMN and FAD occur wherein the nitrogens at positions 1 and 5 are involved. Redox of the isoalloxazine ring involves the following transition: $-N^1H-C=C-N^5H- \leftrightarrow -N^1=C-C=N^5-$.

Transport to tissues can be perturbed by boric acid and certain drugs, e.g., theophylline and penicillin, which displace riboflavin (or FMN) from known binding proteins (e.g., albumin > globulins > fibrinogen).

Once in cells, riboflavin is phosphorylated to FMN. In most cells about 20% of the riboflavin is present as FMN and of the remainder, over 70% is present as FAD with 1 or 2% as free riboflavin. Urine is the major route of excretion for riboflavin, although some FMN is excreted in bile (10 and refs. cited therein).

3. Metabolism and Requirements

The requirements for riboflavin, 1.1 to 1.3 mg/day, are lower than those for niacin or ascorbic acid because riboflavin is tightly associated with the enzymes that serve as a cofactor, and accordingly turns over much slower than niacin or ascorbic acid (Table 10.1; 4). In some cases, FMN is covalently bound (e.g., as in succinic dehydrogenase). Riboflavin is not toxic, primarily because of its regulated uptake at the intestinal level, and its relatively low solubility compared to other B-vitamins.

In humans, signs of riboflavin deficiency include lesions of the oral cavity, the lips, and the angle of the mouth (cheilosis), inflammation of the tongue (glossitis) and accompanying seborrhic dermatitis. Like other severe B-vitamin deficiencies, the filiform papillae of the tongue may also be lost with changes in color from pink to magenta. Anemia and increased vascularization of the eye are present in some animals with riboflavin deficiency.

4. Food Sources and Stability

The best sources of riboflavin are milk and dairy products. Other good sources are meats, especially liver, eggs, dark green leafy vegetables, and fortified breakfast cereals (4). Today, milk and breakfast cereals make the greatest contributions to riboflavin intake in the U.S. and the U.K. Riboflavin is stable to acid pH, heat, and oxygen, but is very susceptible to destruction by light, resulting in the inactive compounds lumiflavin and lumichrome (Table 10.2; 13). These compounds and other oxidative products can contribute to off-flavors due to oxidative

damage to milk lipids. Milk exposed to visible spectrum light will lose 50% of its riboflavin content after two hours, thus the importance of packaging milk in opaque containers.

IV. B-VITAMINS IMPORTANT TO SPECIFIC FEATURES OF CARBOHYDRATE, PROTEIN, OR LIPID METABOLISM

A. Thiamin

Studies on thiamin played an important role in the development of early concepts on the function and importance of vitamins. For example, the demonstration by the Dutch medical officer, Christian Eijkman, that polyneuritis could be produced in an experiment animal by dietary manipulation was conceptually very important. Eijkman and his colleagues fed a diet of polished rice, presumably low in thiamin, to chickens (one of the first uses of an animal model to study disease) and observed characteristic features of beriberi, such as head retraction, a common neurological sign in animals. The focus on rice and the observation that there appeared to be a curative principle in rice bran led to the eventual isolation of thiamin. This sequence of events and experimental protocols provided the underpinnings that led to the discovery of vitamins as precursors to cofactors (19).

1. Chemistry

The five-member (thiazole) ring of thiamin contains an arrangement of atoms (-N=CH-S-) called an *ylid*. The central carbon has carbanion character that acts as an electron-rich center for reactions that are commonly characterized as decarboxylations and transketolations (Figure 10.4). Thiamin is not stable to heat or alkali.

2. Absorption, Tissue Distribution, and Metabolism

Thiamin occurs in the human body as free thiamin and its mono-, di-, and triphosphorylated forms: thiamin monophosphate, thiamin pyrophosphate (TPP), which is designated as thiamin diphosphate, and thiamin triphosphate (TTP), which is found mostly in neural tissue. TPP and TTP are the cofactor forms of thiamine.

Thiamin is essential to the utilization of carbohydrates as energy sources, because of roles in TCA cycle regulation, and perturbations in the pentose phosphate – related carbohydrates pathways. In the TCA cycle, the principle enzymes are pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. These enzymes catalyze the decarboxylations of pyruvate and α-ketoglutarate. TPP is also a cofactor for transketolase reactions. Transketolation is a central activity in the metabolic sequence known as the pentose phosphate pathway. One of the most important intermediates of this pathway is ribose-5-phosphate, a phosphorylated 5-carbon sugar, required for the synthesis of the high-energy ribonucleotides, ATP, GTP, the nucleic acids, DNA and RNA, and the niacin-containing coenzyme NADPH, which is essential for a number of biosynthetic reactions. A deficiency of thiamin can lead to decreased production of NADPH, which impacts synthetic processes, such as fatty acid biosynthesis. In addition, it is evident from the neurological disorders caused by thiamine deficiency that thiamin plays a vital role in nerve function. In the brain, TTP is proposed to function in ion transport. The concentration of thiamin in the brain is resistant to changes in dietary concentration. Stimulation of nerves results in the release of thiamine monophosphate and free thiamine with accompanying decrease of cellular thiamine pyrophosphate and thiamine triphosphate and changes in Na^+ and K^+ gradients (19).

Human thiamin deficiency, beriberi, is termed dry, wet, or cerebral, depending on the systems that involved. The main feature of dry (paralytic or nervous) beriberi is peripheral neuropathy, including abnormal (exaggerated) reflexes, diminished sensation, and weakness in the legs and arms. Muscle pain and tenderness are also features. When cardiovascular manifestations occur, the term wet beriberi is used. Signs include a rapid heart rate, cardiac enlargement, and edema. Ultimately, congestive heart failure may be the cause of death. Cerebral beriberi can lead to Wernicke's encephalopathy and Korsakoff's psychosis. Signs include abnormal eye movements, stance and gait abnormalities, and abnormalities in mental function, e.g., confusion (19).

3. Requirements, Pharmacology, and Toxicity

The requirement for thiamin is 1.1 to 1.2 mg per day or 0.5 mg per 1000 kcal or 4 MJ of diet (4; Table 10.1). Factors that influence requirements are inadequate intake, strenuous physical exertion, fever, pregnancy, breastfeeding, and adolescent growth, or exposure to antagonists, such as tannins, alcohol (sufficient to cause inflammatory bowel conditions), and thiaminases, enzymes in many foods, particular mollusks, and the muscle of fish. Individuals who habitually eat raw freshwater fish, raw shellfish, and ferns are at higher risk of thiamin deficiency because these foods contain a thiaminase. For example, an acute neurological syndrome (seasonal ataxia) in Nigeria has even been associated with thiamin deficiency precipitated by a thiaminase in African silkworms, a traditional high-protein food for some Nigerians.

Antagonists include pyrithiamine and oxythiamine, which act to inhibit the phosphorylation of thiamin. Amprolium (coccidiostat) inhibits thiamin absorption.

4. Food Sources and Stability

Thiamin is present in most animal and plant foods, but is especially prominent in whole grains, organ meats, pork,

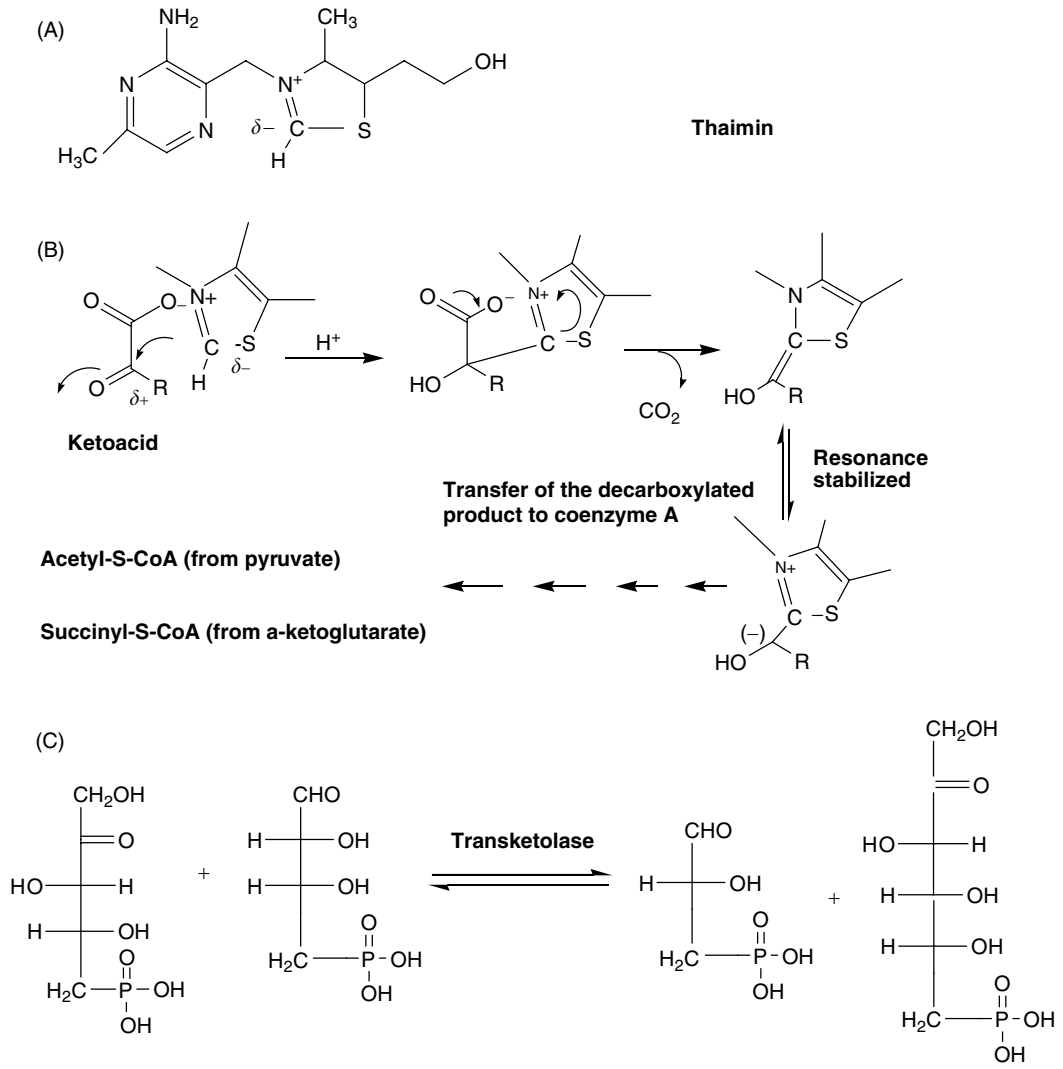

FIGURE 10.4 Thiamin. The carbanion character of thiamin **[A]** facilitates the non-oxidative and oxidative decarboxylation of α-ketoacids **[B]** and transketolase reactions **[C]**.

eggs, nuts, and legumes. Many food cooking and processing conditions will negatively affect thiamin content, as it is unstable in neutral and alkaline conditions, and with heat, oxygen, and sulfur exposure (Table 10.2). Milling of whole grains will remove the bran where thiamin and other B vitamins are in greatest concentrations; however, the current practice of fortification has restored thiamin levels in flours and grain-based products (13).

B. Pantothenic Acid

Roger William discovered pantothenic acid in 1933, and observed that it was an essential growth factor for yeast and lactic acid bacteria. Over the next 15 years, pantothenic acid was shown to be essential in animals. Pantothenic acid serves as a component of coenzyme A (Figure 10.5) and as a part of phosphopantotheine, e.g., at the acyl carrier site in acyl carrier protein (ACP) (18). Recently, pantothenic acid has been shown to be present in a number of other enzymes where thioesters facilitated transfer reactions are essential (5).

1. Absorption, Tissue Distribution, and Metabolism

Both Coenzyme A (CoASH) and ACP are present in foods. Consequently, absorbed pantothenic acid must first be released from CoASH and ACP, steps that involve the actions of peptidases and nucleosidases. The mechanism of absorption of pantothenic acid in the small intestine involves the same carrier-mediated Na^+-dependent system that transports biotin (15). Similarly, colonic absorption of pantothenic acid was found to involve the biotin-Na^+-dependent, carrier-mediated system. The interaction between biotin and pantothenic acid transport has also been described in other tissues such as the blood brain barrier, the heart, and the placenta, but the importance of this interaction is not understood.

2. Metabolic Functions and Requirements

CoASH is the principle moiety for the vectoral transport of acyl and acetyl groups in synthetic and catabolic reactions. A deficiency is characterized by impaired acetyl and acyl metabolism. The ability to utilize fatty acids as fuels is clearly compromised in experimental pantothenic acid deficiency. There is also an increased production of short chain fatty acids and ketone bodies, which can lead to severe metabolic acidosis. Dermal lesions occur because of impaired fatty acid metabolism. Selected aspects of pantothenic acid utilization and CoASH regulation are given in Figure 10.5.

The requirement for pantothenic acid is about 5 mg per day or 2 mg per 1000 kcal (~4 MJ) of diet. Even at gram intakes, pantothenic acid does not appear to be toxic (4).

3. Food Sources and Stability

Good dietary sources of pantothenic acid are meats, organ meats, eggs, nuts and legumes, cereals and some vegetables such as broccoli. The vitamin is stable in neutral pH, but unstable outside of this range, and also susceptible to degradation by heat treatment.

C. Pyridoxine

Pyridoxine or vitamin B-6 is a collective term for pyridoxine, pyridoxal, and pyridoxyl amine. Pyridoxine is most abundant in plants; pyridoxal and pyridoxyl amine are most abundant in animal tissues. The active form of vitamin B-6 is phosphorylated at the 5 position, e.g., pyridoxal-5-phosphate (7).

1. Chemistry

The most common of the reactions catalyzed by vitamin B-6 containing enzymes is the transaminase reaction. Transaminations are essential to the interconverson of amino acids to corresponding α-keto acids. The mechanism is also useful for reactions important to producing racemic amino acid mixtures (e.g., the conversion of L-alanine to D-alanine) and α, β–addition or elimination reactions. An example of an α, β–elimination reaction is the conversion of serine to pyruvic acid or the conversion of homocysteine plus serine to cystathionine. The basic feature of the transamination mechanism is electron withdrawal from the α-carbon resulting in a proton liberation, which sets the stage for subsequent substitution and additional reactions (Figure 10.6; 7).

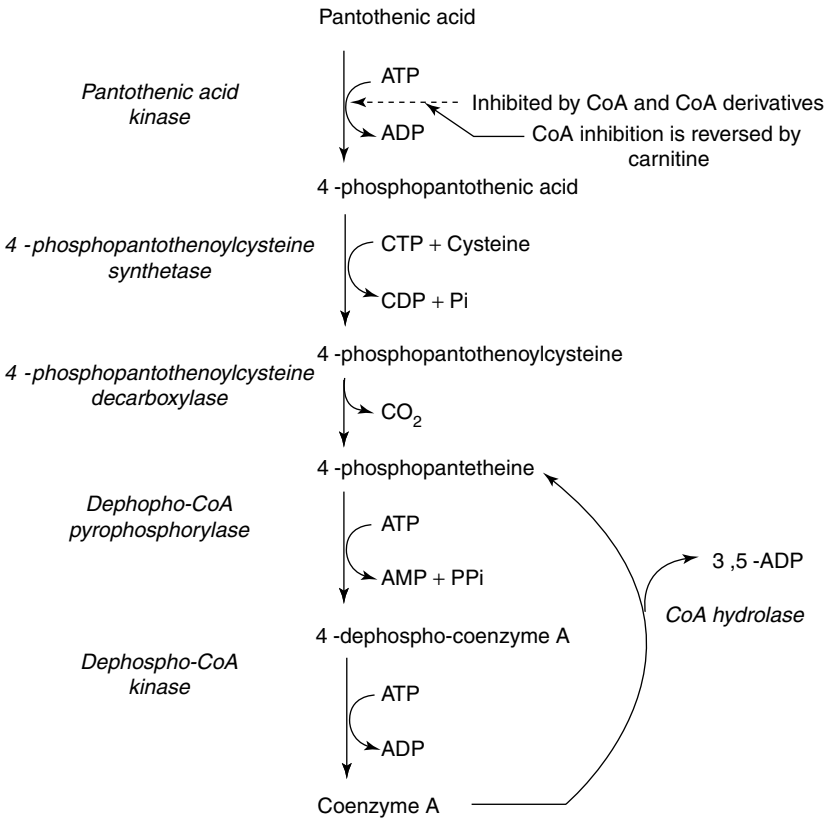

FIGURE 10.5 Synthesis of Coenzyme A (CoASH) from pantothenic acid. The synthesis of CoASH from pantothenic acid is regulated in part by feedback inhibition, e.g., by CoA derivatives at the step catalyzed by pantothenic acid kinase. Carnitine also plays a role in regulation.

The second most common reaction involves electron withdrawal from the α-carbon and carboxylic acid group carbon, which results in decarboxylation (Figure 10.6). Decarboxylation reactions include the conversions of tyrosine to tyramine, 5-hydroxytryptophan to serotonin, histidine to histamine, and glutamate to γ–aminobutyric acid (GABA). Signs of convulsions associated with vitamin B-6 deficiency are attributed to insufficient activity of pyridoxal-5″-phosphate-dependent, L-glutamate decarboxylase.

A third type of reaction involves electron withdrawal from the β,γ-carbons of amino acids (Figure 10.6). This sets the stage for hydride condensations or aldol reactions. A good example of an aldol reaction is the conversion of serine to glycine with the transfer of the β-carbon (as formaldehyde) to another vitamin cofactor, tetrahydrofolic acid in single carbon reactions (see the next section). Another example of a hydride condensation is the formation of α-aminolevulinic acid, the first step in heme biosynthesis.

Another important function of vitamin B-6 (as pyridoxal-5′-phosphate), independent of amino acid metabolism, is its role in glycogen phosphorylase. Glycogen phosphorylase catalyzes the hydrolysis of ether (α-1 to 4 C-O-C) bonds in glycogen to form glucose-6-phosphate. Ether bonds are best catalyzed through acid-mediated mechanisms. The acid proton in this instance is derived from the phosphate group of pyridoxal-5′-phosphate. This important mechanism was only elucidated recently. Previously, it was speculated that the association of vitamin B-6 with glycogen phosphorylase was primarily some type of storage mechanism for B-6.

2. Absorption, Tissue Distribution, and Metabolism

Vitamin B-6 is absorbed in the upper gut by energy-dependent pathways. Muscle, kidney, and liver are rich in pyridoxal enzymes, e.g., glycogen phosphorylase (in

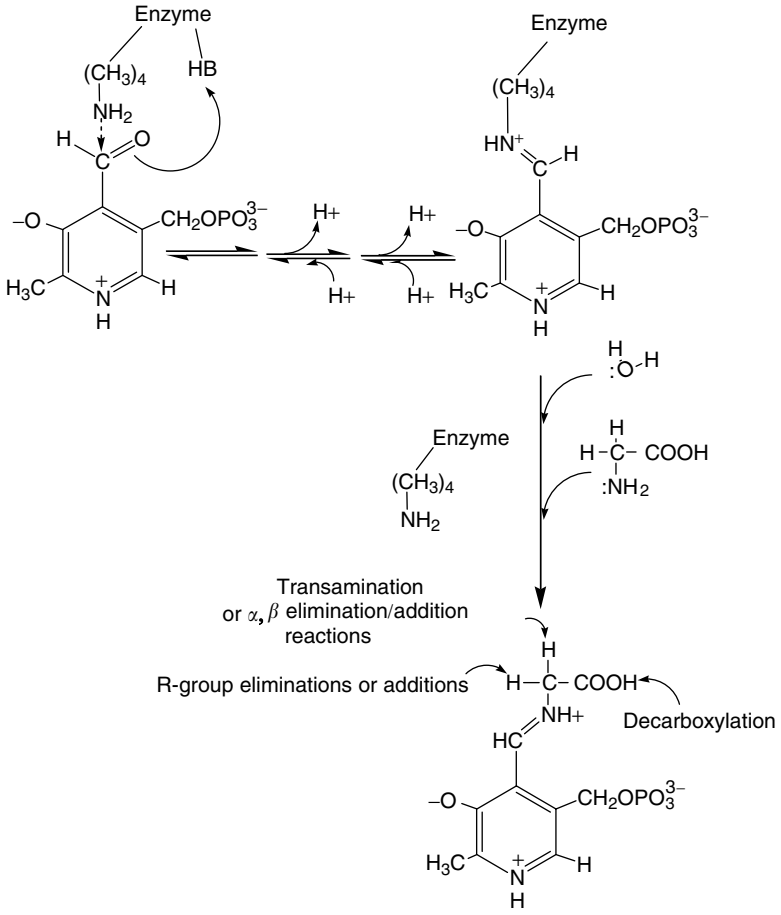

FIGURE 10.6 Pyridoxal-5′-phosphate. Vitamin B-6, as pyridoxal-5′-phosphate, is linked to pyridoxal-5′-phosphate containing enzymes by an dissociable imine linkage with a lysyl residue at the enzyme's active site. By a process of transamination given amino acids are transferred to pyridoxal-5′-phosphate. Depending on the enzyme and nature of the enzymatic process, transamination reactions, α,β-elimination/addition, R-group elimination/addition, or decarboxylation reactions can occur.

muscle) and amino acid catabolizing enzymes and transaminases (in liver and kidney).

The major form of vitamin B-6 in cells is pyridoxal –5′-phosphate. The conversion of the pyridoxal form of the vitamin to pyridoxic acid signals elimination from the body (7 and refs. cited).

3. Requirements, Pharmacology, and Toxicity

Vitamin B-6 deficiency is rarely seen as most diets provide adequate amounts. Normally, the vitamin B-6 is met at 1.3 or more mg per day or about 0.3 mg per 1000 kcal (4MJ) of diet (Table 10.1; 4). Drug-induced vitamin B-6 deficiency can occur following administration of the tuberculostatic drug, isoniazid (isonicotinic acid hydrazide). This drug forms hydrazone derivatives with pyridoxal or pyridoxal phosphate, which can then act to inhibit pyridoxal-containing enzymes. Patients receiving long-term isoniazid therapy respond to the administration of supplemental vitamin B-6. Penicillamine (β-dimethylcysteine) used in the treatment of Wilson's disease also can interfere with normal B-6 metabolism due to the formation of thiazole derivatives. A naturally occurring antagonist to vitamin B-6, linatine (1-amino-D-proline) is present in flax seed, which forms a stable product with pyridoxal phosphate (7).

The most important signs of B-6 deficiency relate to defects in amino acid metabolism. Neurologic signs occur because of reduced synthesis of important biogenic amines from amino acid precursors (7), and anemia is a consequence of decreased heme synthesis. Adverse effects have only been documented from vitamin B-6 supplements and never from food sources. Chronically high doses of pyridoxine can result in painful neurological symptoms known as sensory neuropathy. Symptoms include pain and numbness of the extremities, and in severe cases difficulty walking. Sensory neuropathy typically develops at doses of pyridoxine in excess of 1,000 mg per day. At intakes below 200 mg/day, sensory neuropathy is not observed.

4. Food Sources and Stability

The richest sources of vitamin B-6 are meats and whole grains. Heat and light are the two primary treatments that negatively affect the stability of the vitamin (Table 10.2). Similar to other B vitamins, milling of whole grains and removal of the bran will result in significant losses of pyridoxine. Fortification of cereal products will restore B vitamin levels (4).

V. B-VITAMINS INVOLVED IN SINGLE CARBON AND CO_2 TRANSFER REACTIONS

A. Biotin

Biotin was discovered following a long search for factors important to the understanding of the condition, egg white poisoning, which was associated with poor growth, alopecia, and dermatitis in animals exposed to raw eggs and egg whites as a primary source of dietary protein. It was eventually found that biotin-binding factors in eggs could reduce biotin availability (see below).

1. Chemistry

Biotin functions in enzymatic carboxylation reactions as a cofactor for CO_2 – fixing enzymes. Examples include: acetyl CoA carboxylase, which is essential for fatty acid synthesis; propionyl CoA carboxylase, which participates in odd chain fatty acid metabolism; pyruvate carboxylase, which is involved in the formation of oxaloacetate, an important obligatory step in reverse glycolysis and gluconeogenesis; and β-methylcrotonyl CoA, important in leucine metabolism (9).

Biotin is covalently bound in carboxylases and transcarboxylases by peptidyl linkage between the carboxylic acid moiety of biotin and the ε-amine function of peptidyl lysine (extends from the side chain associated with the sulfur-containing ring of biotin, which is only partially depicted in Figure 10.7). The biotin-lysine adduct is called biocytin. Biocytin can be cleaved by the enzyme biocytinase to generate free biotin.

2. Metabolism and Requirements

Biotin is found in highest concentrations in the liver. In plant foods, biotin is present in relative high concentrations in most cereals. Dietary biotin exists in free and protein bound forms. The latter form is digested first by gastrointestinal proteases and peptidases to generate biocytin (N-biotinyl-L-lysine) and eventually free biotin plus lysine. Like the other water-soluble vitamins, biotin is taken up by specialized Na^+-dependent carrier-mediated mechanisms. At the basolateral membrane, biotin exits cells via a Na^+-dependent carrier system. In adult humans, biotin uptake is significantly higher in the duodenum and jejunum compared to ileum. As noted previously, biotin shares the transporter with pantothenic acid (15, 18).

When biotin-containing carboxylases are degraded in cells, biotin is also released as biocytin. Cellular biocytinases catalyze its cleavage to release free biotin for reutilization. In the absence of this enzyme, biotin reutilization is compromised. Re-biotinylation requires ATP to catalyze the formation of a peptide bond between biotin and a lysyl group at the active center of targeted carboxylases (9).

The nutrition need for biotin is expressed as an "Adequate Intake" and amounts to ~25 micrograms per day (Table 10.1; 4). Reasons for the relatively lower requirements are: biotin is covalently attached to a limited number of enzymes that it serves as a cofactor; biotin is extensively reutilized; significant amounts of biotin are produced by the gut microflora.

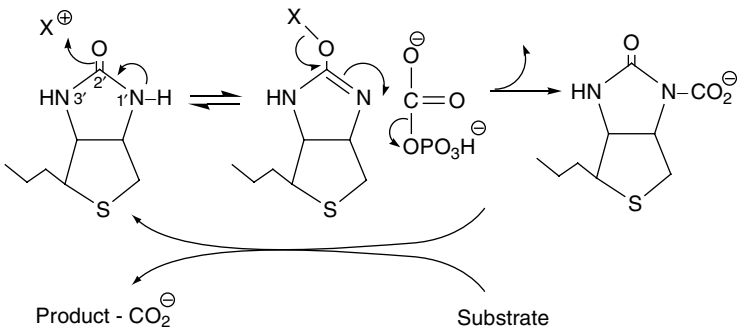

FIGURE 10.7 Biotin.

Nevertheless, nutritional problems associated with biotin status can occur. Biotin and biocytin have a high affinity for certain proteins, particularly avidin in egg white. The consumption of raw egg albumin can induce biotin deficiency, due to the strong association of biotin with avidin rendering dietary biotin unavailable. Ingestion of significant quantities of raw egg white by fur-bearing animals and pigs has led to the condition initially described as "egg white injury."

Biotin deficiency leads to impairment of gluconeogenesis and fat metabolism. Biotin deficiencies can also induce severe metabolic acidosis. The inability to carry out fat metabolism, also markedly affects the dermis. Alopecia and dermatitis are characteristics of biotin deficiency in most animals (9).

3. Food Sources and Stability

Biotin in animal foods is found in highest concentrations in the liver, but also in meats, milk, and egg yolk. In plant food, biotin is present in relative high concentrations in most cereal grains, as well as nuts, mushrooms, and some green vegetables. It is relatively stable to most treatments, with the exception of heat and alkaline conditions, which result in minor losses.

B. Folic Acid and Vitamin B-12

Vitamin B-12 and folic acid will be discussed together, because their functions and metabolism are uniquely linked (Figure 10.8). Knowledge regarding folic acid and B-12 evolved from efforts to better understand macrocytic anemias and certain degenerative neurologic disorders (8). The Scottish physician, Combe, recognized in the early 1800s that certain forms of macrocytic anemia appeared related to a disorder of the digestive organs. In classic studies by Minot, Murphy, Castle, and others, it became clearer that the disorder was associated with gastric secretions and in some cases could be reversed by consuming raw or lightly cooked liver.

In parallel studies, folic acid was also associated with macrocytic anemia. Large-scale efforts throughout the 1940s and 1950s and careful clinical and basic studies eventually led to the isolation of folic acid and vitamin B-12.

1. Chemistry Folic Acid

The folates are a group of heterocyclic compounds composed of 4-(pteridin-6-ylmethyl)-aminobenzoic acid conjugated with one or more L-glutamate units. Folate and folic acid are the preferred synonyms for pteroylglutamate and pteroylglutamic acid, respectively, and designate any members of the family of pteroylglutamates having various levels of reduction of the pteridine ring, one-carbon substitutions, and differing numbers of glutamate residues (Figure 10.8; 2).

The reactions that involve folic acid include the generation and utilization of formaldehyde, formimino, and methyl groups. For these conversions to occur, folic acid must be reduced in the form of tetrahydrofolic acid (THFA). Reduction brings the nitrogen at positions 5 and 10 closer together and changes their electrochemical properties, which facilitates the formation of the various THFA single carbon derivatives.

The formyl, methanyl, and methylene forms of THFA are utilized for purine synthesis and in thymidylate (i.e., DNA-related) synthesis. These reactions are essential to cell division and proliferation. Folate also participates in reactions involved in the interconversion and catabolism of amino acids. Much of the folate in the body is also in the form of methyl-THFA for eventual methyl transfer reactions. Removal of the methyl group from methyl-THFA and its eventual irreversible transfer to methionine by the vitamin B-12 requiring enzyme, methionine synthetase, represents an important interaction between folic acid and vitamin B-12 (1, 2).

2. Chemistry: Vitamin B-12

Vitamin B-12 consists of a porphyrin-like structure of tetrapyrrole rings with a monovalent cobalt metal at the center (Figure 10.9; 1). A 5′,6′-dimethylbenzimidazolyl nucleotide is also linked to the tetrapyrrole rings via a phosphate sugar linkage. Vitamin B-12 catalyzes the

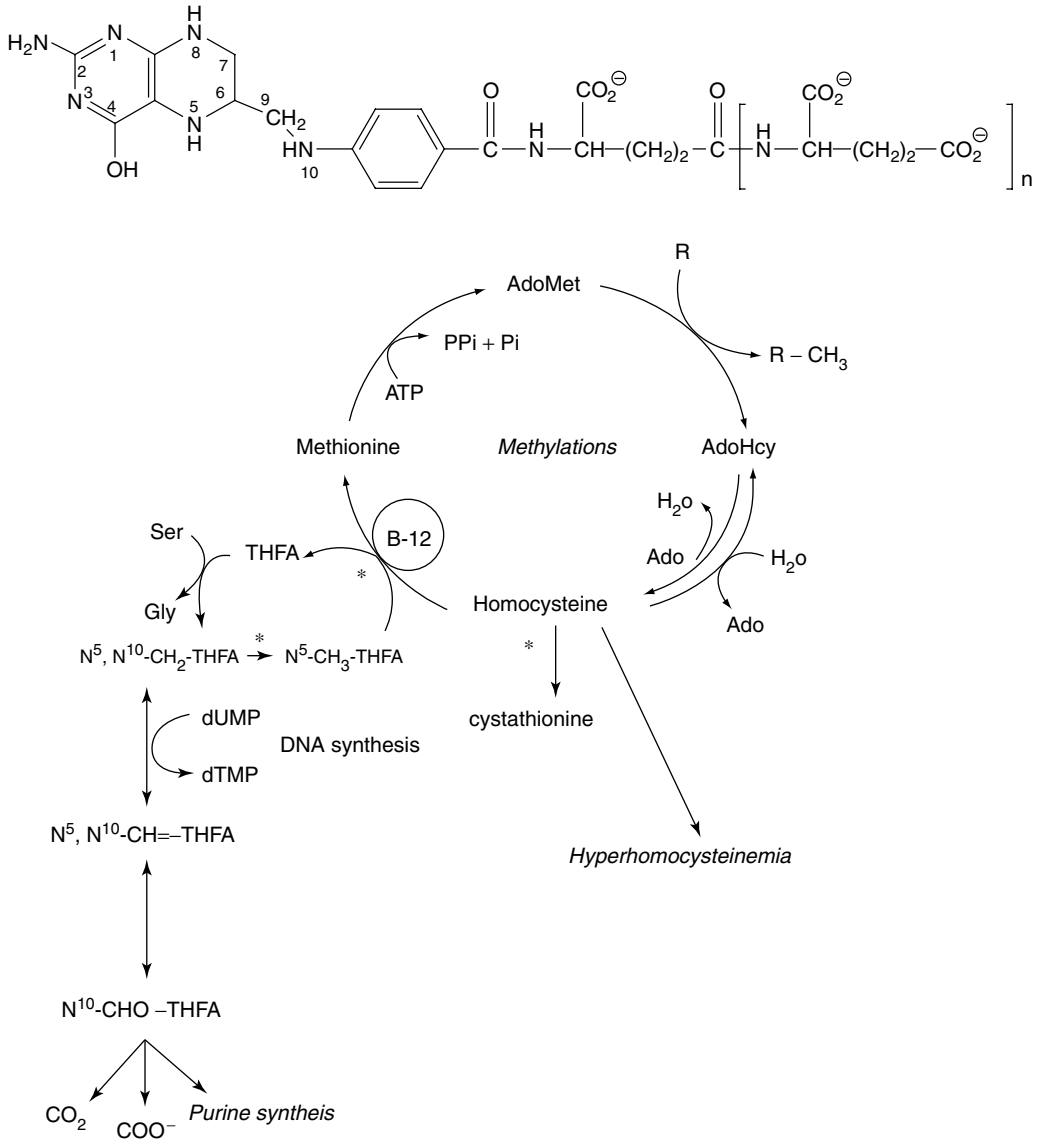

FIGURE 10.8 Folic acid. Basic features of the folic acid structure are shown. Folate is essential to: 1) methylation reactions (via the vitamin B-12-dependent methionine synthetase step), 2) DNA synthesis (via single carbon transfer from N^5, N^{10}-methylene-THFA in the conversion deoxyuridylate to deoxythymidylate), 3) purine synthesis (via transfer of a single carbon from N^{10}-formyl-THFA into the purine pathway). Not shown are reduction steps that result in the regeneration of THFA (at positions 5 and 8) from oxidized folic acid.

conversion of homocysteine to methionine via transfer of a methyl moiety derived from methyl-THFA. Vitamin B-12 in the form of the adenosyl derivative can also catalyze the conversion of methylmalonyl CoA to succinyl CoA. Deficiency of vitamin B-12 leads to intracellular accumulation of metabolites of these two reactions, homocysteine and methylmalonic acid (1, 2, 8, 13, 16).

3. Digestion, Metabolism, and Tissue Distribution

Folate absorption requires processing of food-derived folates from poly- to monoglutamyl forms. The proximal part of the small intestine is the main site of absorption of dietary folate. A specialized carrier-mediated system is involved in folate uptake across the apical membrane of the absorptive cells, as well as other cells. The factors that negatively affect intestinal folate absorption are alcohol consumption and the use of certain pharmacological agents like sulfasalazine and phenytoin (Dilantin). An important step in the digestive process is the conversion of polyglutamyl folate to monoglutamyl folate by intestinal polyglutamyl hydrolase.

There are a number of substances in unprocessed foods (e.g., uncooked beans) that act as folate hydrolase inhibitors. In plasma, there are specific carrier proteins, which take folic acid to targeted cells. In this regard,

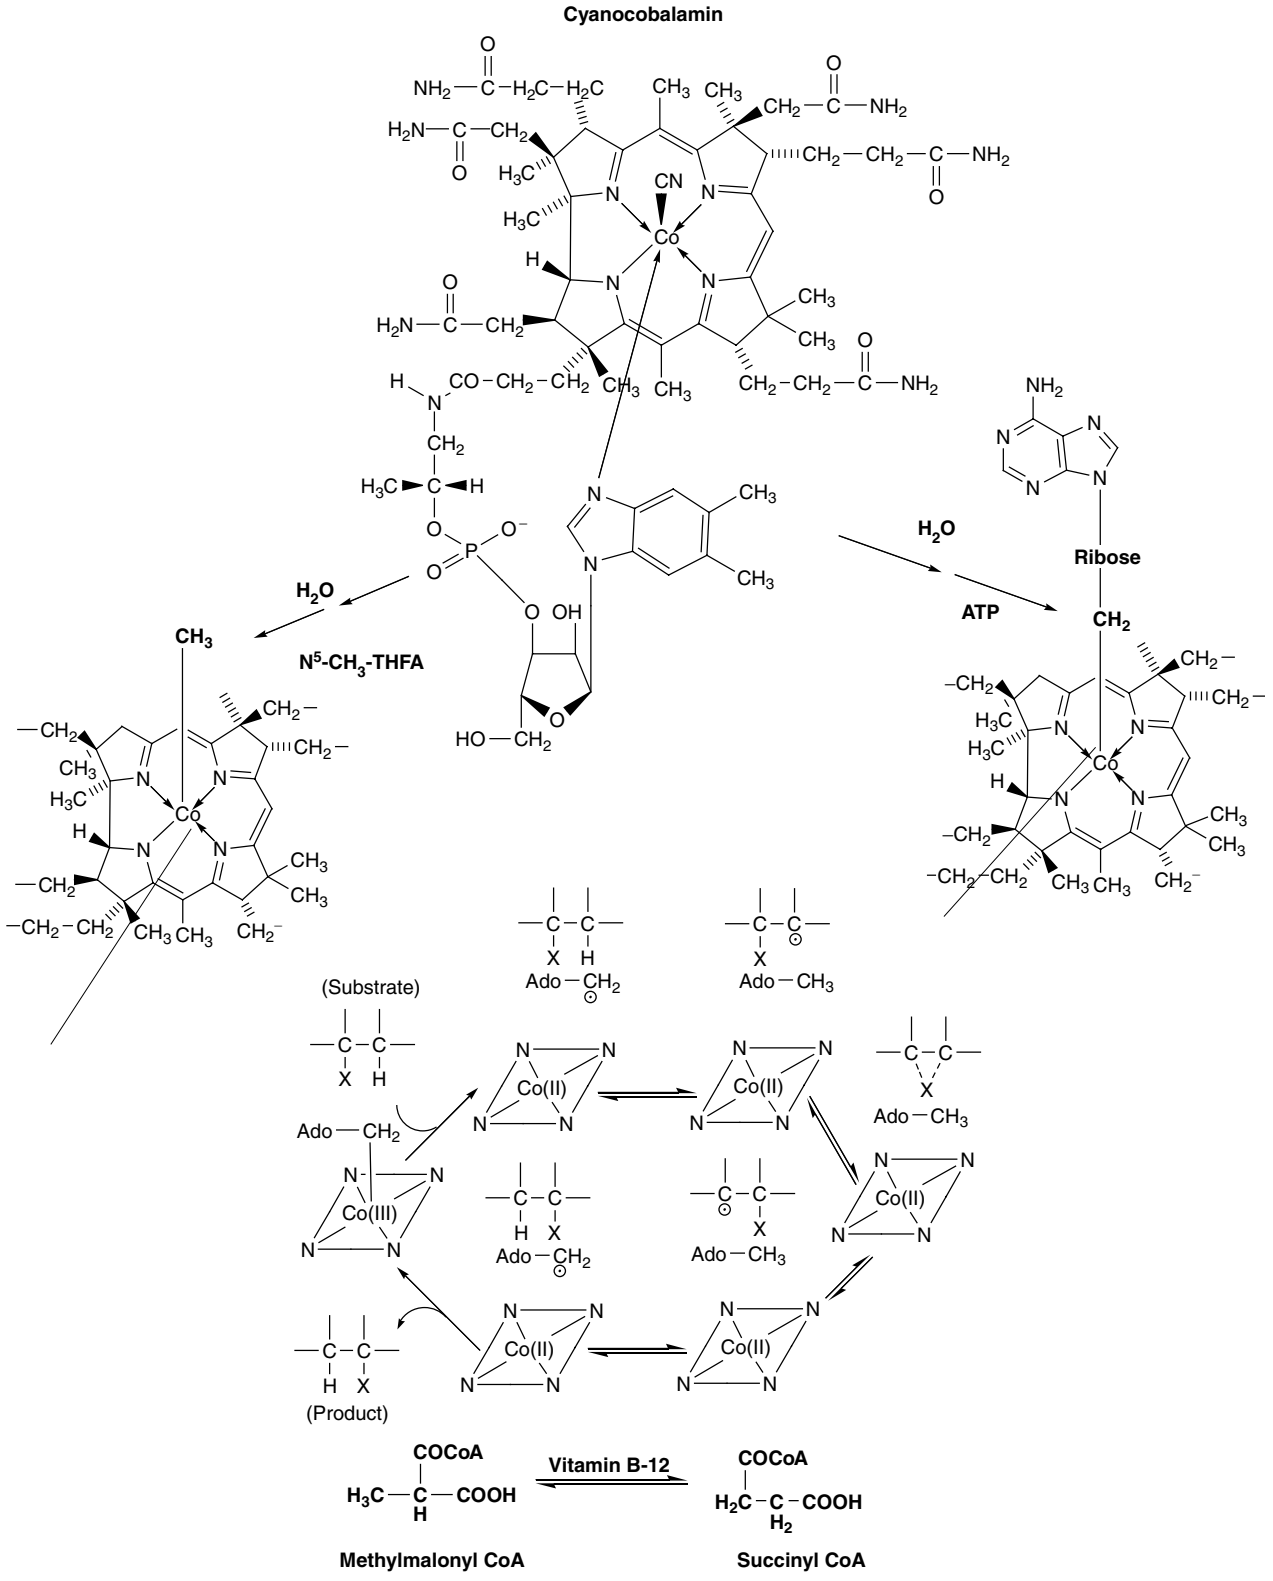

FIGURE 10.9 Cyanocobalamin. Commercial preparations of vitamin B-12 usually have a cyano group coordinated with the cobalt (associated with the corrin ring of vitamin B-12). In an aqueous environment the cyano group can be displaced by water for the eventual transfer of a methyl group (donated by N5-methyl-THFA) or an adenosyl moiety (from ATP). Methylated vitamin B-12 serves as a cofactor for methionine synthetase (see Figure 10.7). Adenosylated vitamin B-12 serves as a cofactor for unusual isomerase reactions, such as the conversation of methylmalonyl CoA to succinyl CoA. A mechanism for this process is shown, which involves the redox of cobalt in the corrin ring of cobalamin (Co+3«Co+2).

ethanol can also markedly decrease folate biliary secretion, thereby reducing availability to body tissues from liver. In tissues, the distribution of folates is largely dependent on the concentration of folate dependent enzymes. Methyl-THFA mono glutamate is rapidly transported (bound to carrier proteins) to liver. Uptake proceeds through a receptor-mediated endocytotic process and is then quickly converted to folate in various polyglutamyl forms (2).

Steps important to processing of vitamin B-12 involve first release from foods under acidic conditions. Vitamin B-12 then binds to proteins produced by cells of the gastric fundus, pancreas, and salivary gland. Two proteins have been identified, which are designated as R protein and intrinsic factor. Vitamin B-12 first binds to R protein and is released in the intestinal lumen by the action of pancreatic and intestinal proteinases and peptidases, to allow vitamin B-12 to bind to intrinsic factor. Intrinsic factor is a small-molecular-weight glycoprotein, which is made in stomach parietal cells (1). The vitamin B-12 – intrinsic factor complex then interacts with receptors on the intestinal brush border localized in the midgut (i.e., ileum). Interference with R protein or intrinsic factor production, or inflammatory disease affecting the ileum, or overproduction of intestinal microflora can adversely affect the availability of vitamin B-12 (1).

After vitamin B-12 is taken up by luminal cells, it is transported into the lysosomes where the vitamin B-12 – intrinsic factor complex is degraded and the vitamin B-12 is released and vectorally directed for release into plasma. Vitamin B-12 is transported in plasma by one of three specific transport proteins, transcobalmin I, II, or III. Transcobalmin I carries vitamin B-12 to the liver. Transcobalmin II carries vitamin B-12 from the liver to peripheral tissues. Note that the processing of folate and vitamin B-12 in and out of tissues differs from that for other water-soluble vitamins. The process is receptor mediated and endocytotic, in contrast to involvement of an active sodium-dependent transporter (1).

4. Requirements, Pharmacology, and Toxicity

Decreased production of methanyl and methylene forms of folate can result in decreased purine synthesis and thymidylate formation from uridylate. The latter can cause replicating cells to arrest in the S-phase of the cell cycle. Epithelial cells are often most affected by folate deficiency (2, 8). The consequences range from megaloblastic anemia to growth retardation. Accordingly, aggressive supplementation of folic acid has been associated with a decrease in the appearance of certain developmental defects, e.g., abnormal neutral tube closure (2, 11, 13, 16).

As noted, the most important link between folate and vitamin B-12 occurs at the methionine synthetase step, where 5-methyl THFA serves as a substrate with homocysteine to form methionine. In this regard, recent studies have suggested that low folate levels may play a role in the etiology of coronary artery disease because of the association of elevated homocysteine as a risk factor in vascular disease (8).

The movement of single carbon units from folate through methionine synthetase in the formation of methionine is also important for S-adenosylmethionine (SAM) formation. SAM is essential to methylation of phospholipids, and production of methylated forms of various amino acids and carbohydrates. SAM also serves as the methyl source in DNA methylation.

Deficiencies of both vitamin B-12 and folic acid produce clinical signs of macrocytic anemia and disynchronies in growth and development owing to the importance of folic acid to purine and DNA synthesis. Chronic deficiencies of either folic acid or B-12 can also promote fatty liver disease and indirectly influence extracellular matrix maturation stability by causing abnormal elevations in homocysteine (1, 2, 8, 11, 13, 16). Such signs and symptoms are attributable to both THFA and B-12 deficiencies, because of the integral relationship of vitamin B-12 to THFA regeneration. Dietary intakes of folic acid, sufficient to maintain functional THFA levels, can mask the initial signs of vitamin B-12 deficiency (e.g., macrocytic and megaloblastic anemia). Prolonged vitamin B-12 deficiency in humans results in serious neurologic disorders due to degeneration of the myelin sheath (1).

The requirement for folic acid is 400 µg per day (Table 10.1; 4). However, there are some conditions in which the folic acid requirements are conditionally high, e.g., when either natural or pharmacological folic acid agonists are present in the diet. A range of genetic polymorphisms in proteins important to folate metabolism can also influence the folic acid requirement. Alterations in folate hydrolase, folate reductase, or methionine synthetase that cause changes in the affinity for folate binding are all known to impact folate requirements (2).

The requirement for vitamin B-12 is 2.4 µg per day or 1 µg per 1000 kcal (~4 MJ) of diet (Table 10.1; 4). Although vitamin B-12 deficiency is rare, disease of the stomach, proximal duodenum, or ileum and pancreatic insufficiency can affect folic acid and vitamin B-12 absorption, respectively.

5. Food Sources and Stability

Folic acid: Foods that are particularly high in folate are oranges, green leafy vegetables, and whole grains. Fortification with folic acid to all enriched cereal grain foods was begun in the U.S. in 1998 by mandate of the Food and Drug Administration (11). The primary objective of this program was to provide increased folic acid to women of childbearing age in order to decrease the occurrence of neural tube defects (NTD). The fortification program has successfully decreased NTDs by 19%, but any longer term health benefits on other diseases is unknown at this time. Folic acid is stable in acid pH, but is rapidly

10 The Water-Soluble Vitamins

Science and Nutrition, University of California

CONTENTS

destroyed in neutral or alkaline conditions and is unstable to prolonged heat, oxygen, and light exposure.

Dietary sources of B-12 are meats with liver being the highest followed by dairy products and some seafoods (1, 2, 4). B-12 is also present in yeast and fortified cereals. The reliance on primarily animal products for vitamin B-12 means that strict vegetarians are potentially at risk for B-12 deficiency. B-12 is relatively stable and destroyed only by extended heat treatments and exposure to light and oxygen (Table 10.2).

VI. CONCLUDING COMMENTS

Additional compounds, mostly derived from carbohydrate and amino acid metabolites, are listed with the vitamins, because of conditional dietary needs or functions in metabolic regulation. Many of these compounds typically perform specialized transport function, particularly in relation to fatty acids. Examples include choline (a major source of methyl groups in the diet), inositol (important in signal transduction), and carnitine (required for the transportation of fatty acids from the cytosol into the mitochondria). Taurine, queuine, the ubiquinones (coenzyme Q), the tetrahydrobiopterins, pyrroloquinoline quinone (17), and lipoic acid could also be added to the list, because of their novel roles in metabolism.

Regarding the need for vitamins, acute deficiencies for most water-soluble vitamins can be induced under experimental conditions. Frank deficiency diseases are rarely seen in most populations unless specific food sources are severely limited due to food distribution problems, environmental problems such as drought, or severe economic constraints that limit access to food. However, marginal deficiencies can be observed when individuals consume a monotonous diet in which relatively few foods constitute a source of calories. Genetic polymorphisms in proteins involved in vitamin metabolism may also affect vitamin nutriture and result in increased needs. When a defect is associated with a vitamin deficiency, what often defines why the defect occurs is the K_m for the association or binding of the vitamin with proteins associated with the defect (e.g., a specific enzyme). In such cases, the K_m or related constants is usually high. In addition, disturbances of absorption (e.g., pancreatic insufficiency, biliary obstructions, alcohol, enteropathies), antagonists (e.g., antibiotics, tannins, caffeic acid, alcohol), or metabolic conditions (e.g., pregnancy, diabetes) may contribute to the increased need for given vitamins (14).

11 Fat-Soluble Vitamins

Lin Ye and Ronald R. Eitenmiller
Department of Food Science and Technology, University of Georgia

CONTENTS

I. INTRODUCTION

The fat-soluble vitamins include vitamin A, vitamin D, vitamin E, and vitamin K. Knowledge of their roles in metabolism and maintenance of health has greatly expanded over the recent past decades. Consumer interest has been energized by many diet-health relationships that, in some cases, have been well documented. Such interest and the expanding knowledge base has led to rapid growth of the use of fat-soluble vitamins in supplements and functional food products, increased fortification of food, the need to improve global food composition data banks, technology improvements in synthesis and food technological aspects, and increased need for accurate analytical methods both for scientific and regulatory use. Recent publication of the Dietary Reference Intakes (1–3) has added new perspectives on human requirements and diet planning. This chapter provides an overview of chemistry and nutrition of the fat-soluble vitamins.

II. VITAMIN A AND CAROTENOIDS

Night blindness resulting from vitamin A deficiency represents one of the earliest recognized dietary deficiency diseases (4). Scientific studies began in the early 20th century, and McCollum and Davis reported (1913) the presence of a lipid-like substance in butter and egg yolk required for the growth of young rats. The factor was named fat-soluble A in 1916, and the name vitamin A was first used in 1920 to emphasize the discovery of the first fat-soluble vitamin, differentiating it from the water-soluble vitamins. The structure of vitamin A was determined in 1931. The vitamin A activity of β-carotene was identified in 1929, and the term "provitamin A" was then used to differentiate carotenoid precursors of vitamin A from carotenoids without potential to form vitamin A. Plant carotenoids are, therefore, the precursors of all vitamin A found in the animal kingdom. Dietary vitamin A, by convention, is called preformed vitamin A when all-trans-retinol or its esters are consumed as a dietary constituent of animal products or through use of supplements (5). Identification of roles for vitamin A in gene expression, embryonic development, and immunological function (1) has greatly expanded interest in the nutritional significance of vitamin A to human well-being. Likewise, identification of functions other than as a precursor for vitamin A for both provitamin A carotenoids and other carotenoids such as lutein and lycopene have confirmed their significance as health-promoting components of a well-balanced diet (6).

A. CHEMISTRY

1. Vitamin A

Vitamin A refers to all isoprenoid compounds from animal products with the biological activity of all-trans-retinol (Figure 11.1). All-trans-retinol is the parent structure to most retinoids and contains a substituted β-ionone ring (4-{2,6,6-trimethyl-2-cyclo-hexen-1-yl}-3-buten-2-one) (5) with a side chain of three isoprenoid units linked at the 6-position of the β-ionone ring. The conjugated double-bond system includes the 5,6-β-ionone ring carbons and the isoprenoid side chain. Retinoids include all substances with vitamin A activity and many structurally similar synthetic compounds without vitamin A activity (7). Various retinoids are identified as significant for cell differentiation, immunity, and embryonic development. All-trans-retinoic acid, retinol esters, and various cis-isomers are significant metabolites (Figure 11.1). 13-cis-Retinol is frequently found in food extracts as a result of isomerization of all-trans-retinol during the extraction process (8). Acetate and palmitate esters of all-trans-retinol are the primary commercial forms of vitamin A used by the pharmaceutical and food industry in supplements and fortified foods. Esterification stabilizes the vitamin toward oxidation. Availability of the esters in beadlet or encapsulated products adds further stability during processing and marketing of supplements and fortified foods. The USP standard is retinyl acetate. Physical properties of all-trans-retinol, retinyl esters, and closely related retinoids are provided in Table 11.1.

2. Carotenoids

Carotenoids comprise an extensive family of plant pigments, and as many as 1000 occur naturally in the plant kingdom (6, 9). In the plant, carotenoids function in photosynthesis as light harvesting pigments that supplement the ability of chlorophyll to capture light energy (10, 11). They protect the photosynthetic apparatus by quenching reactive oxygen species ($^1O_2$, $^3O_2$, O_2^{2-}) and acting as free radical interceptors, thus preventing oxidative events which can irreversibly damage cell membranes and DNA (11).

Carotenoids are formed by the head-to-tail linkages of eight isoprene units to provide a C_{40} skeleton. Nomenclature for the carotenoids specified by the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Biochemistry (IUB) was reviewed by Weedon and Moss (12). Structures of common provitamin A carotenoids and other significant carotenoids to the human are given in Figure 11.2. Lycopene, which shows the acyclic hydrocarbon backbone chain, is considered the parent compound (12). Modifications of lycopene produce the diverse family of the carotenoids found throughout the plant kingdom. β-carotene (Figure 11.2) is characterized by the presence of β-ionone rings on both ends of the hydrocarbon chain. Oxygenation produces the xanthophylls. Oxygen functions include hydroxylation at the 3- or 4-position to produce lutein and β-cryptoxanthin, respectively, and ketolation to yield canthaxanthin. Other structural variants include aldehydes, epoxy, carboxy, methoxy, and

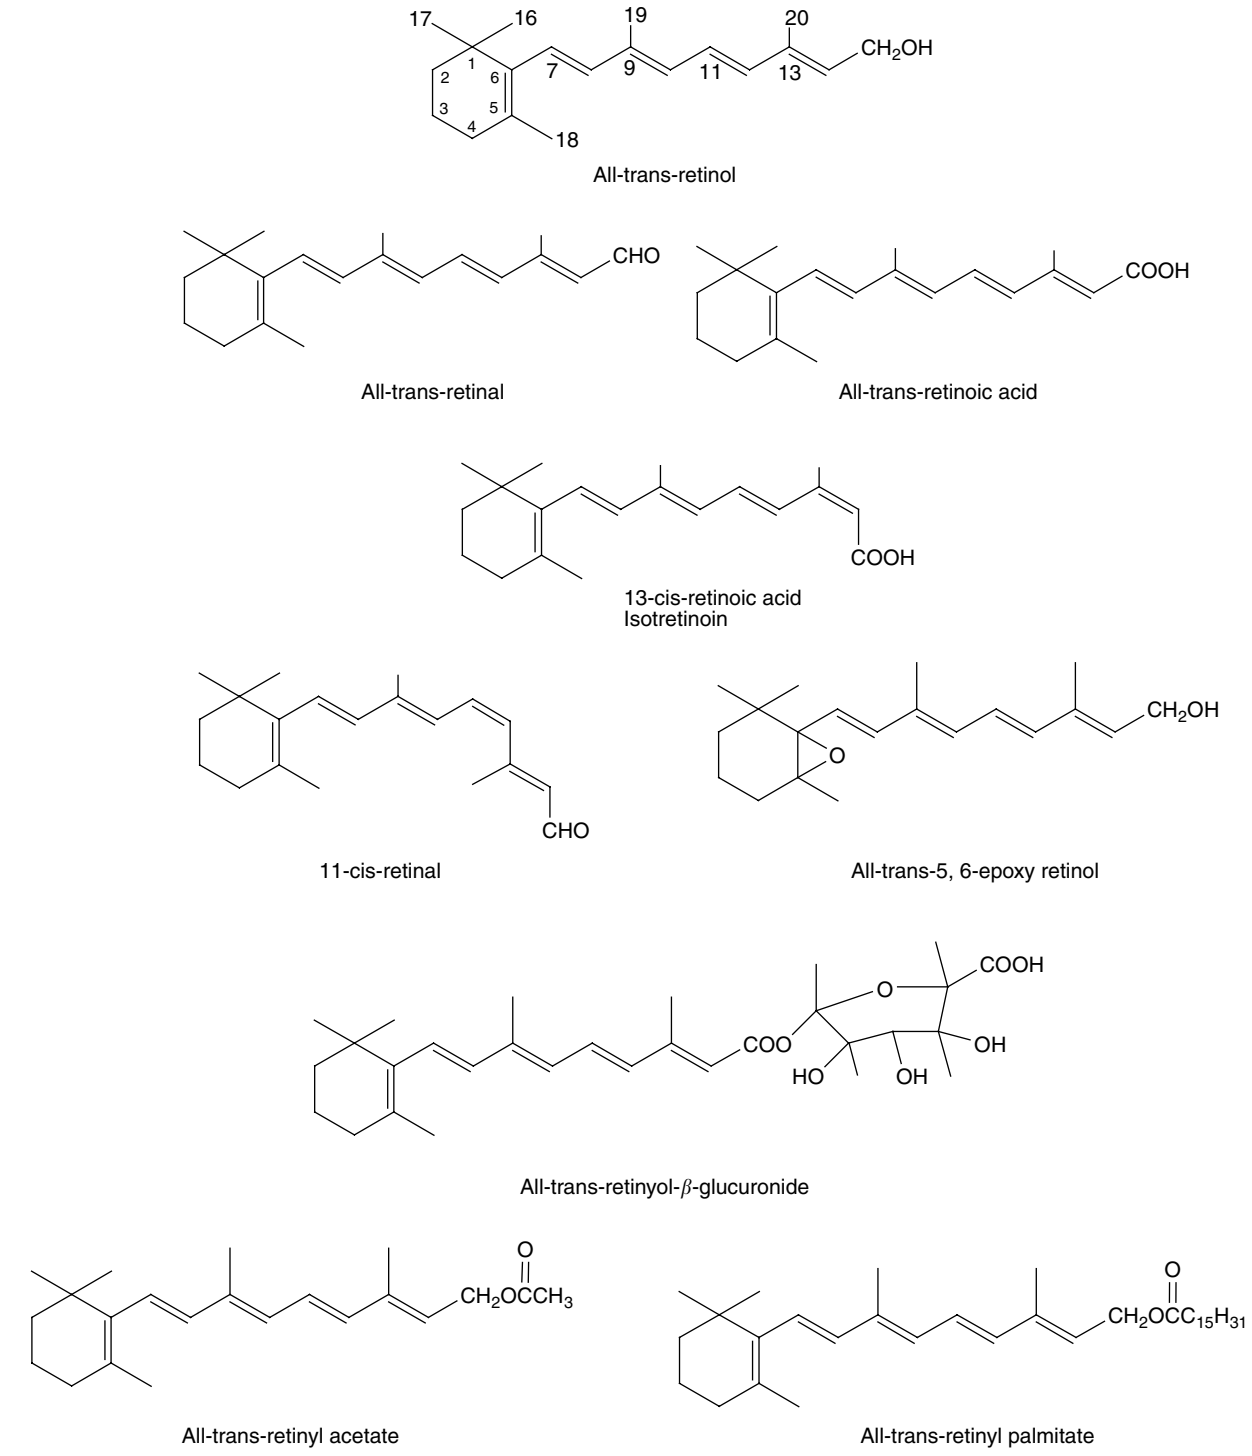

FIGURE 11.1 Structures of vitamin A, its metabolites and esters.

various other oxygenated forms. Some of the most frequently occurring carotenoids include the hydrocarbons lycopene, phytoene, and phytofluene, carotenal esters, and carotenol fatty acid esters (5).

The most commonly occurring provitamin A carotenoids in plant foods are β-carotene, α-carotene, γ-carotene, and β-cryptoxanthin. cis-Isomers are biologically not as active compared to the all-trans naturally occurring carotenoids. Vitamin A activity depends on the presence of one, non-hydroxylated β-ionone ring in the provitamin A structure. Presence of the β-ionone ring allows conversion to all-trans-retinol (6). Acyclic hydrocarbons (lycopene,

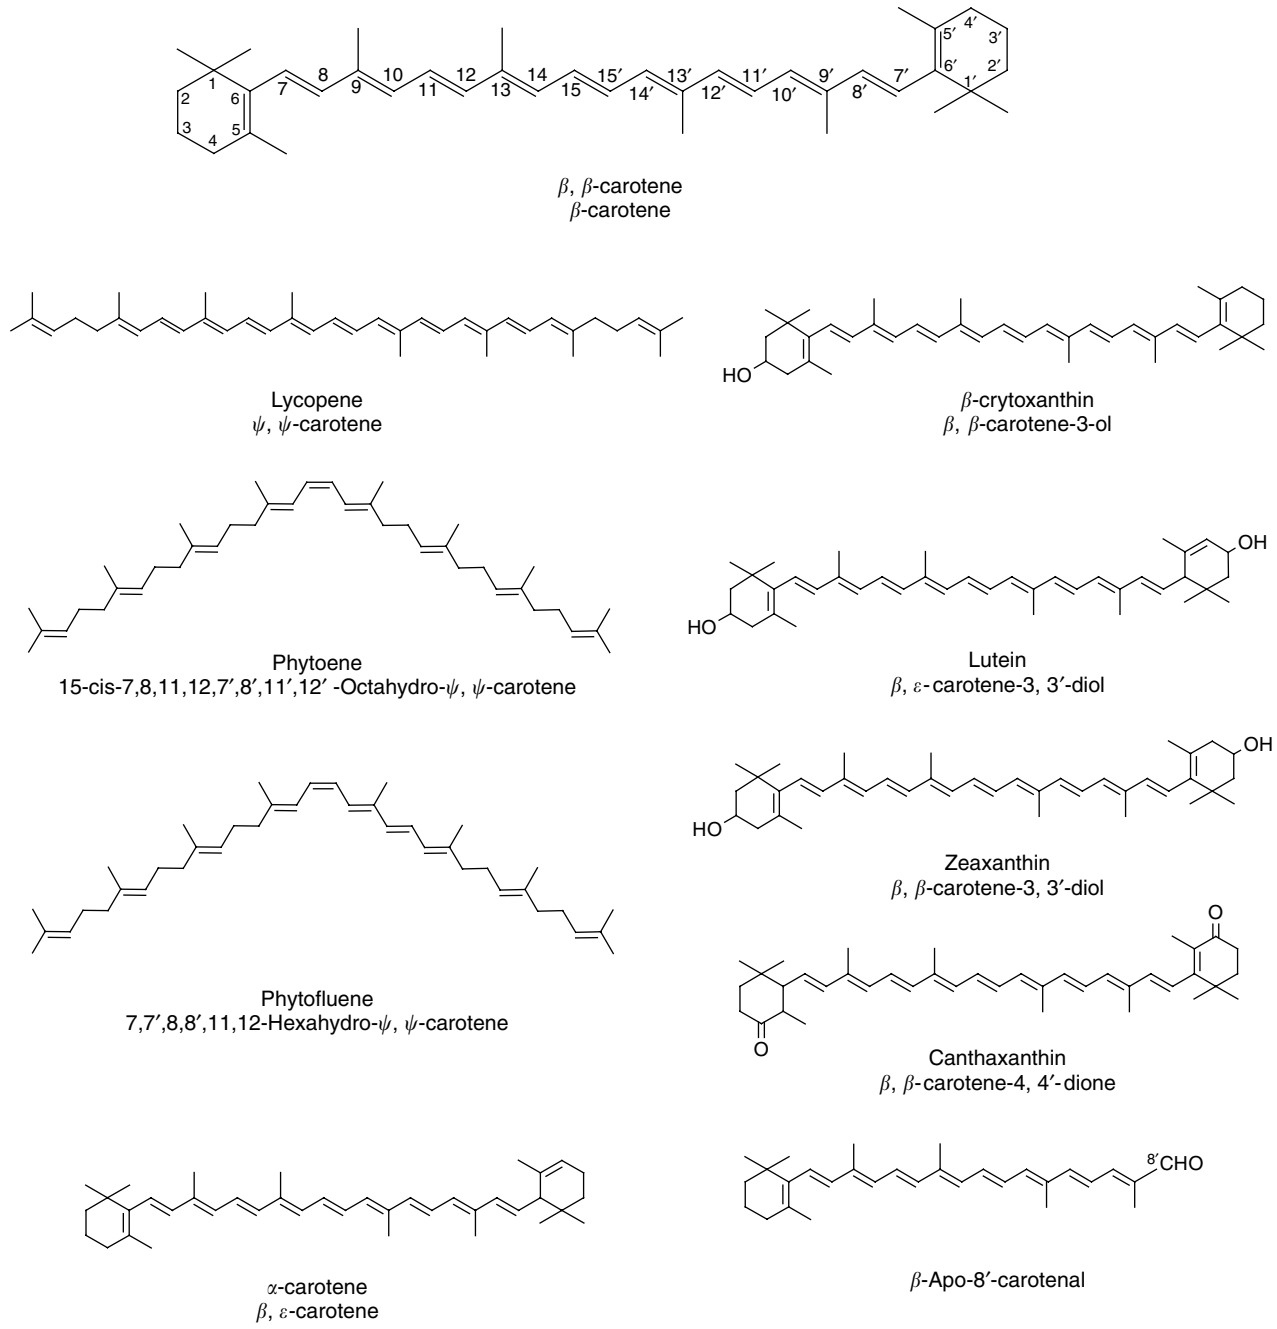

FIGURE 11.2 Structures of commonly occurring carotenoids.

phytoene, phytofluene), therefore, are not provitamin A carotenoids. Carotenoids with one hydroxylated ring or other oxygen function on one ring usually possess less than 50% of the biological activity of β-carotene (β-cryptoxanthin). Hydroxylation of both β-ionone rings (lutein) leads to a complete absence of vitamin A activity. Conversion of the provitamin A carotenoids to all-trans-retinol can occur by central oxidative cleavage at the 15,15′ double bond to yield two moles of vitamin A per mole of β-carotene or by random oxidative cleavage that yields only one or two moles of vitamin A per mole of β-carotene, depending on the point of cleavage (13–15). Central cleavage is accomplished by β-carotene-15,15′-dioxygenase within the intestinal absorptive cells (1).

Physical properties of various carotenoids are provided in Table 11.1. β-Carotene and β-apo-8′-carotenal are added to margarines, salad dressings, and other foods to enhance color as well as to fortify the products. In the

poultry industry, xanthophyll concentrates derived from the marigold are added to rations to enhance yellow to red pigmentation in the skin and in egg yolks. The xanthophylls deposited in the skin and yolks do not add to the vitamin A activity of the products, since xanthophylls lack vitamin A activity.

3. Spectral Properties

The conjugated double bond system of the retinoids gives the compounds strong UV absorption properties. UV absorption maxima (Table 11.1) vary with structural modification of the all-trans-retinol. Effects on UV absorption by structural variations of the retinoids indicate that maximal absorption ranges from 318 to above 360 nm. Absorption maxima vary with solvent and the presence of cis-isomers (Z-). Isomerization to the cis-form decreases the absorption maxima and $E^{1\%}_{1cm}$ values relative to all-trans-retinol (Table 11.1) (17, 20).

All-trans-retinol and retinyl esters fluoresce strongly at λ_{ex} from 325 to 490 nm. Fluorescence intensity is greater in non-polar solvents; therefore, fluorescence is an ideal detection mode for normal-phase liquid chromatography-based analytical systems compared to UV detection (5, 21). Most other retinoids other than retinol and its esters do not fluoresce and oxidation of the alcohol results in lower fluorescence (20).

Carotenoids contain eleven π electron conjugated double bonds and, thus, possess strong primary absorption in the visible region due to the long conjugated double bond system. The bright and varied pigmentation of the carotenoids characterize the strong, visible region absorption. Published absorbance maxima are given in Table 11.1. Spectra commonly show two to three absorption maxima between 400 and 500 nm. A characteristic UV absorption peak occurs in cis-isomers approximately 142 nm below the longest-wavelength absorption maxima of the all-trans carotenoid (22). cis-Isomers show UV maxima between 330 to 340 nm and a downward shift of the entire spectrum (20, 22). Absorption intensity is affected by solvent or mobile phase composition (23, 24). Detection at 450 nm is commonly used as a detection mode for β-carotene after LC resolution.

4. Stability

Eitenmiller and Landen (5) summarized studies that exist in the literature on the stability of all-trans-retinol and β-carotene in foods during processing and storage. Little information exists on the stability of other retinoids or carotenoids such as lycopene and lutein. However, due to similarities in chemical properties, stability characteristics would be somewhat similar. Ball (25) provided an excellent review of the stability of all-trans-retinol and β-carotene with many specific literature citations. Significant facts regarding the stability of all-trans-retinol and carotenoids presented by Eitenmiller and Landen (5) include the following:

1. Conversion of all-trans to cis-isomers is easily induced by light, acids, metals, lipoxygenase action, and heat processing, acting independently or synergistically.
2. All-trans-retinol and the carotenoids are oxidatively unstable. Autoxidation of lipids can induce rapid loss of vitamin A activity. Some carotenoids are active singlet oxygen quenchers. This ability is directly related to the number of double bonds in the conjugated double bond system. β-Carotene, lutein, and other carotenoids preferentially react with singlet oxygen, converting it to the triplet state (26). The excited triplet state carotenoids can thermally disperse excess excited state energy through chemical reactions that destroy the carotenoids (27). Degradation products include various cleavage products.
3. Carotenoids scavenge free radicals at low oxygen pressures (<155 mm Hg) and act as primary chain-breaking antioxidants. Carotenoids, like β-carotene, trap peroxyl radicals through the addition of the radical at the 5,6-double bond of the carotenoid with conversion to peroxides (27).
4. All-trans-retinol and the carotenoids become more unstable as the food matrix is disrupted or the compounds are removed from the matrix by extraction prior to analysis. Destruction of the food matrix can liberate lipoxygenases that catalyze isomerization.
5. Blanching of plant products prior to freezing inactivates lipoxygenase and removes oxygen from the tissue. Thus, carotenoids are protected from lipoxygenase-initiated oxidative degradation during freezer storage.
6. Air drying or freeze drying can produce large losses in all-trans-retinol or the carotenoids. Storage of freeze-dried foods, because of the open, porous nature of the product, requires removal of oxygen with inert gas or vacuum to stabilize the vitamin A activity. Losses can be considerable during the drying process.
7. All-trans-retinol and the carotenoids are relatively stable at alkaline pH. Therefore, saponification can be used for sample extraction if the reaction vessel is evacuated and protected from light. Saponification at ambient temperature can be used to slow isomerization reactions that are more predominant at elevated temperatures.
8. All-trans-retinyl palmitate and all-trans-retinyl acetate are the commonly available commercial

forms of vitamin A used for food fortification and by the pharmaceutical industry. The ester forms are more stable to oxidation. However, conversion of all-trans to cis-isomers can readily occur. Most LC procedures will resolve the all-trans from the cis-isomers, which is essential to accurately assess biological activity. Encapsulation of concentrates in a matrix of gelatin, microcrystalline cellulose, or modified starch inhibits oxidation and isomerization. Antioxidants including tocopherols and other free radical interceptors are usually added to vitamin A preparations to inhibit oxidation.

Due to the lability of all-trans retinol and the carotenoids to oxidation and isomerization, precautions must be taken during analysis of foods and other biological samples to avoid conditions adverse to the analytes. Precautions to minimize destruction during extraction and determinative chromatography include the following (5, 28):

1. During all phases of sample handling, exclude oxygen. Air should be replaced by vacuum or inert gas.
2. Addition of antioxidants such as butylated hydroxytoluene (BHT), pyrogallol, ascorbic acid, or combinations is necessary prior to saponification. Low levels of antioxidants in extracting solutions and mobile phases are often added to protect the retinoids and carotenoids from oxidation.
3. Trans- to cis-isomerization ($E \rightarrow Z$) is promoted at elevated temperatures. Therefore, use of the lowest practical temperature is recommended. Use of solvents with low boiling points is preferred. For rotary evaporation, 40°C should not be exceeded. Solutions should be stored at −20°C, preferably lower.
4. All sunlight should be avoided. Analytical steps and extractions should be completed in dim light, diffused sunlight, or under gold fluorescent light. Solutions of sample analytes and standards should be stored in low actinic glassware whenever possible. Isomerization rapidly occurs through light activation and is a common source of cis-isomer formation in biological sample extracts.
5. Acid must be avoided. All solvents must be acid free. Addition of Triethylamine (TEA) at 0.001% is useful to neutralize low acid levels in some solvents.
6. Alkaline conditions can lead to base-catalyzed isomerization, especially if exposure to light occurs.

B. Nutrition and Biochemistry of Vitamin A

1. Functions of Vitamin A

Functional roles of vitamin A continue to be identified as the scientific basis of its relationship to cell growth and differentiation and immunological function becomes better understood. Specifically, vitamin A is required for normal vision, gene expression, reproduction, embryonic development, growth and immunological function.

The role of vitamin A in maintenance of eye health and the visual cycle is quite well understood. Retinoic acid is required for normal differentiation of the cornea, conjunctival membranes, and photoreceptor rod and cone cells of the retina (1, 7). In the visual cycle, all-trans-retinol is isomerized to 11-cis-retinol which is oxidized to 11-cis-retinal (29). In the rod cells, 11-cis-retinal is bound to opsin to form the visual pigment, rhodopsin. Absorption of light by rhodopsin isomerizes 11-cis-retinal to all-trans-retinal which triggers signaling to neuronal cells in the visual cortex of the brain (1). All-trans-retinal is released from the protein, converted back to all-trans-retinol, and stored as all-trans-retinyl esters, completing the cycle (1, 7, 29).

Identification of two families of nuclear receptors, retinoic acid receptors (RAR) and retinoid receptors (RAX), has helped explain the role of vitamin A in cell differentiation. In the nucleus, all-trans- and 9-cis-retinoic bind with RAR and 9-cis retinoic acid binds with RAX. The activated receptors regulate gene expression significant to embryonic development and integrity of epithelial cells (1, 7, 29).

The relationship of vitamin A deficiency to decreased disease resistance and increased child mortality in areas of the world lacking proper food supplies has been recognized for decades. Vitamin A influences immune response through maintenance of circulating natural killer cells with anti-viral and anti-tumor activity, by increasing phagocytic activity, and by increasing production of cytokines which regulate production of T and B lymphocytes (1). Fortunately, in vitamin A deficient individuals, immune function can be improved through supplementation of the diet with vitamin A.

2. Vitamin A Deficiency

Vitamin A deficiency is characterized by changes in the eye that can cause irreversible blindness. Clinical symptoms are referred to as xerophthalmia. The initial stage of development of xerophthamia is night blindness or the inability to adapt to dim light due to decreased ability to regenerate rhodopsin. At this stage, addition of supplementary vitamin A will reverse the disease. Progression of the disease leads to corneal and conjunctival xerosis (dryness) due to a decreased amount of globlet cells and to the appearance of Bitot's spots on the conjunctiva. Final stages are referred to as keratomalacia or ulceration and

scarring of the cornea that leads to loss of vision. Other symptoms include skin lesions, loss of appetite, epithelial keratinization of epithelial tissue, impaired embryonic development, lack of growth and increased susceptibility to infections (1, 30–32).

While vitamin A deficiency in developed countries is not prevalent and is limited to individuals with fat absorption abnormalities, chronic liver disease, and alcoholics (32), it continues to be the leading cause of blindness world-wide and greatly contributes to infant and child mortality. Recent estimates indicate that 250,000 to 500,000 children go blind annually due to lack of vitamin A (1, 33, 34). Although fortification programs can be successful in improving vitamin A status at low cost, large segments of the world's population can still benefit from fortification of staple foods or through provision of supplements. The role of the food industry and public health organizations in this regard can still dramatically improve human well-being.

3. Hypervitaminosis A

Vitamin A toxicity can occur from high intake of foods high in vitamin A or high potency supplements. Toxicity to retinoids has been classified as acute, chronic, and teratogenic (1, 29). Acute toxicity results from a single dose or a limited number of large doses over a short time period. A single dose greater than 200 mg (>200,000 RAE (retinol activity equivalent), >660,000 IU or 0.7 mmol) or all-trans-retinol can result in acute toxicity in adults. For children, 50% of the adult dose can cause acute toxicity (29). Symptoms include nausea, vomiting, headache, increased cerebrospinal fluid pressure, vertigo, blurred vision, muscle incoordination, and bulging fonanel in infants (1). Chronic toxicity results from ingestion of large doses at or above 30 mg (30,000 RAE) per day for months or years (1). Symptoms of chronic toxicity include alopecia, ataxia, liver abnormalities, membrane dryness, bone and skin changes, visual impairment, and nervous system effects (1, 29). Most symptoms are reversible when vitamin A intake is decreased (29). Teratogenic effects can result from single, large doses (30–90 mg) or long-term intakes that result in chronic toxicity (29). Common teratogenic defects include physical malformations, heart, kidney, and thymic disorders, and central nervous system disorders (29).

4. Dietary Reference Intakes

Based on newer information on absorption of dietary carotenoids, the Institute of Medicine (1) established the retinol activity equivalent (RAE) to replace the retinol equivalent (RE) as a measure of the vitamin A activity of dietary provitamin A carotenoids. One RAE is defined as 1 μg of all-trans-retinol, 12 μg of all-trans-β-carotene and 24 μg of other provitamin A carotenoids (usually limited to α-carotene and β-cryptoxanthin). International units (IU) are used for labeling pharmaceuticals, supplements, and foods. One microgram of all-trans-retinol equals 3.33 IU of vitamin A activity. The Reference Daily Intake (RDI) set by the Nutritional Labeling and Education Act of 1990 (NLEA) is 5000 IU.

Establishment of the RAE was based on the accepted carotene: retinol equivalency ratio (μg) of a low dose of purified β-carotene in oil of 2:1, indicating that 2 μg of β-carotene in oil yields 1 μg of retinol (1). Differences between RE conversion factors and RAE factors stem from absorption studies that show that 6 μg of dietary β-carotene is equivalent to 1 μg of purified β-carotene in oil (1). Since previous data indicated 3 μg of dietary β-carotene was equal to 1 μg of β-carotene in oil ($6 \times 2{:}1 = 12{:}1$), the RAE calculation doubles the amounts of dietary provitamin A carotenoids required to provide 1 μg of retinol or 1 RAE as compared to calculation of RE values. The Institute of Medicine report (1) emphasizes that vitamin A intake from provitamin A carotenoids has been overestimated by previous assumptions made on carotenoid absorption from mixed meals including fruits and vegetables. Implications to the presentation of food composition databank information are significant in that reliable data on carotenoid composition of fruit and vegetables are still somewhat limited.

The ability of the scientific community to reliably quantify carotenoids from fruits and vegetables has greatly improved with the introduction of a C_{30} stationary phase designed to provide high absolute retention, enhanced shape recognition of carotenoid isomers, and to moderate silanol activity of the support (35). This LC support has gained wide acceptance, with utilization for multi-analyte analyses including the tocopherols (36, 37). With a LC reversed-phase method based on the C_{30} support, Darnoko et al. (37) quantified tocopherols and 13 carotenoids in red palm oil. The C_{30} support adds a new dimension to LC assay of fat-soluble vitamins from foods and supplements and expands the capability to use reversed-phase systems, in general, for fat-soluble vitamin assay.

Dietary Reference Intake (DRI) values for vitamin A range from an Adequate Intake (AI) of 400 μg RAE/day (RAE, retinol activity equivalents) for the 0- to 6-month infant to Recommended Dietary Allowance (RDA) values of 700 μg RAE/day for adult women and 900 μg RAE/day for adult men. The RDA increases to 1300 μg RAE/day for lactating women (19–50 years) (1). The Tolerable Upper Intake Level (UL) is 3000 μg RAE/day for adults (Table 11.2).

5. Food Sources and Dietary Intake

Significant dietary sources of preformed vitamin A include organ meats (liver), fish oils, butter, eggs, whole milk, and fortified reduced fat and skim milk, other dairy products, and high fat species of fish including tuna and sardines (8). Fortification of foods with retinyl palmitate and/or

[a]EAR=Estimated Average Requirement. The intake that meets the estimated nutrient needs of half of the individual in a group.

[b]RDA=Recommended Dietary Allowance. The intake that meets the nutrient need of almost all (97–98%) of individuals in a group.

[c]AI=Adequate Intake. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such a growth rate, normal circulating nutrient values, or other functional indicators of health. The AI is needed if sufficient scientific evidence is not available to derive an EAR. The AI is not equivalent to an RDA.

[d]UL=Tolerable Upper Intake Level.

Source: Refs. 1–3.

β-carotene helps to prevent vitamin A deficiency in countries that require fortification. Commonly used food vehicles for delivery of vitamin A include fluid milk, dry milk, margarine, and some edible oils. Choice of the proper food for delivery of vitamin A depends on which foods are consumed by the target population. In the United States, milk is fortified with not less than 2,000 IU of vitamin A (retinyl palmitate), and margarine is fortified with no less than 15,000 IU per pound (by a combination of retinyl palmitate and β-carotene) (38).

Provitamin A carotenoids are widely distributed throughout the plant kingdom. However, reliable quantitative data only exist for β-carotene, α-carotene, and β-cryptoxanthin in some fruit and vegetables. Minor carotenoids with provitamin A activity provide only small amounts to the total vitamin A in human diets because of lower natural levels compared to the primary provitamin A carotenoids. Color or color intensity cannot be used to predict the vitamin A activity of a food due to the complexity of carotenoid profiles and the fact that most carotenoids such as lycopene have zero vitamin A activity. The red color of ripe tomatoes is primarily due to lycopene and most tomato cultivars are quite low in vitamin A activity (5). An excellent database exists that was formulated through efforts of the United States Department of Agriculture and the National Cancer Institute. The database contains compositional information on 2400 fruits and vegetables for β-carotene, α-carotene, β-cryptoxanthin, lutein plus zeaxanthin, and lycopene (39–41). The database provides the most easily applied tool to estimate dietary intake (42). Estimation of dietary intake of non-provitamin A carotenoids has become more significant to public health as new, functional roles are identified for carotenoids such as lutein and lycopene. Although β-carotene and several other carotenoids are clinically associated with lower risk of several chronic diseases, the DRI Panel on Antioxidants and Related Compounds (3) supported increased consumption of fruits and vegetables but did not set DRIs for β-carotene or other carotenoids. The Panel did not recommend use of supplemental β-carotene other than as a source of provitamin A for the control of vitamin A deficiency.

The Institute of Medicine report on DRIs for vitamin A (1) gives quite good, documentable data on vitamin A intake in the U.S. based upon the Third National Health and Nutrition Examination Survey (NHANES) (43). The following facts pertaining to vitamin A intake were delineated:

1. The median dietary intake of vitamin A is 744 to 811 μg RAE for men and 530 to 716 μg RAE for women.
2. For adults, 25 to 50% had vitamin A intakes less than the estimated average requirement (EAR) of 500 μg RAE/day for women and 625 μg RAE/day for men.
3. The data suggest that many adults in the U.S. have lower liver stores of vitamin A than is considered optimal. However, intake is sufficient to avoid clinically measurable deficiency.
4. Conversion factors based upon the RAE factors give dietary intake levels that are lower compared to older estimates calculated using retinol equivalent (RE) factors. Therefore, greater amounts of provitamin A carotenoids are needed to meet vitamin A requirements.
5. Carrots provide 25% of the β-carotene in the U.S. diet.

6. Cantaloupe, broccoli, squash, peas, and spinach are major contributors of β-carotene.
7. Carrots contribute 51% of the α-carotene in the U.S. diet.
8. Fruits are the only sources of β-cryptoxanthin.
9. All provitamin A carotenoids contribute 26 and 34% of vitamin A consumed by men and women, respectively. Previous estimates indicated that approximately 75% of the vitamin A in the U.S. diet originated as preformed vitamin A from animal products.

III. VITAMIN D

Rickets was initially identified in 1919 as a deficiency of a fat-soluble factor in dogs fed fat-free diets and kept indoors in the absence of sunlight (44). The deficiency state was cured by feeding cod liver oil. The fat-soluble, antirachitic factor was named vitamin D in 1925 by McCollum's research group and proven to be produced in the skin by ultraviolet irradiation. Vitamin D was isolated as ergocalciferol or vitamin D_2 from irradiated ergosterol from yeast in 1931. The structure was identified in 1932. Cholecalciferol or vitamin D_3 was later characterized and shown to be the antirachitic factor in cod liver oil. Better understanding of the intermediary metabolism of vitamin D occurred in the 1970s with the identification of the hydroxylated metabolites, 25-hydroxyvitamin D_3 ($25(OH)D_3$) and 1 α, 25 dihydroxy D_3 (1 α, $25(OH)_2D_3$). Biologically, 1 α, $25(OH)_2D_3$ is the primary metabolically active form known as calcitriol. Vitamin D, as a general term, is referred to as calciferol (2).

A. Chemistry

Vitamin D refers to steroids that are antirachitic. Structures of vitamin D_3 (cholecalciferol) and the steroid nucleus are given in Figure 11.3. The International Union of Pure and Applied Chemists – International Union of Biochemistry (IUPAC-IUB) nomenclature rules for steroid structure are used to characterize the ring system (45, 46). The rings (A, B, C, D) are derived from the cyclopentanoperhydrophenanthrene steroid structure. Cholesterol serves as the parent compound (Figure 11.3) (46). In nature, 7-dehydrocholesterol and ergosterol are the provitamin forms for cholecaliferol (D_3) or ergocalciferol (D_2). Previtamin D_2 requires opening of the D ring at the 9,10 bond. The open-ring vitamin D forms are secosteroids. Accepted IUPAC-IUB systematic names are 9,10-seco(5Z,7E)-5,7,10(19) cholestatriene-3β-ol for vitamin D_3 and 9,10-seco(5Z,7E)-5,7,10(19),22 ergostatetraene-3β-ol for vitamin D_2. Conversions of the provitamins to previtamins D_2 and D_3 by irradiation to vitamin D_2 and vitamin D_3 are shown in Figure 11.4 along with the structures of the hydroxylated vitamin forms ($25(OH)D_3$ and 1 α, $25(OH)_2D_3$). Vitamin D_2 and vitamin D_3 structurally vary by a double bond at C-22 and a methyl group at C-24

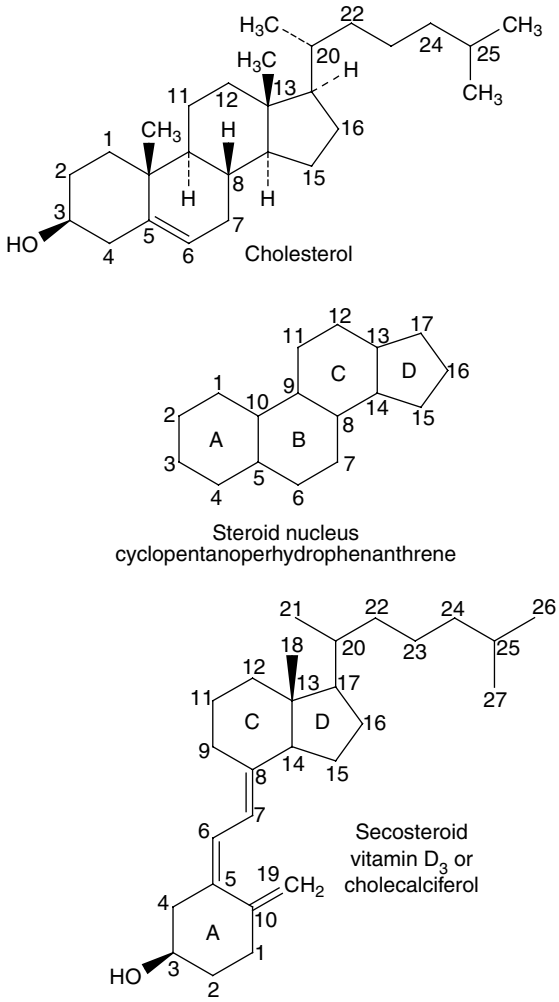

FIGURE 11.3 Structures of vitamin D_3, cholesterol, steroid, nucleus.

in vitamin D_2. Since the structures are quite similar, chemical and physical properties are similar (Table 11.3).

1. Spectral Properties

Vitamin D has a characteristic broad UV spectrum with maximum absorption near 264 nm and a minimum near 228 nm (47). The vitamin does not fluoresce. Because vitamin D is present, even in fortified foods, at quite low concentrations, most methods of quantification by LC rely on extract clean-up and concentration prior to determinative chromatography (5). With proper sample treatment, UV detection at 264–265 nm is sensitive and specific enough to provide reliable data. UV detection is generally not sensitive enough to quantify hydroxylated metabolites in serum or biological tissues.

2. Stability

Stability of vitamin D is excellent in the absence of water, light, acidity, and at low temperatures (47). The

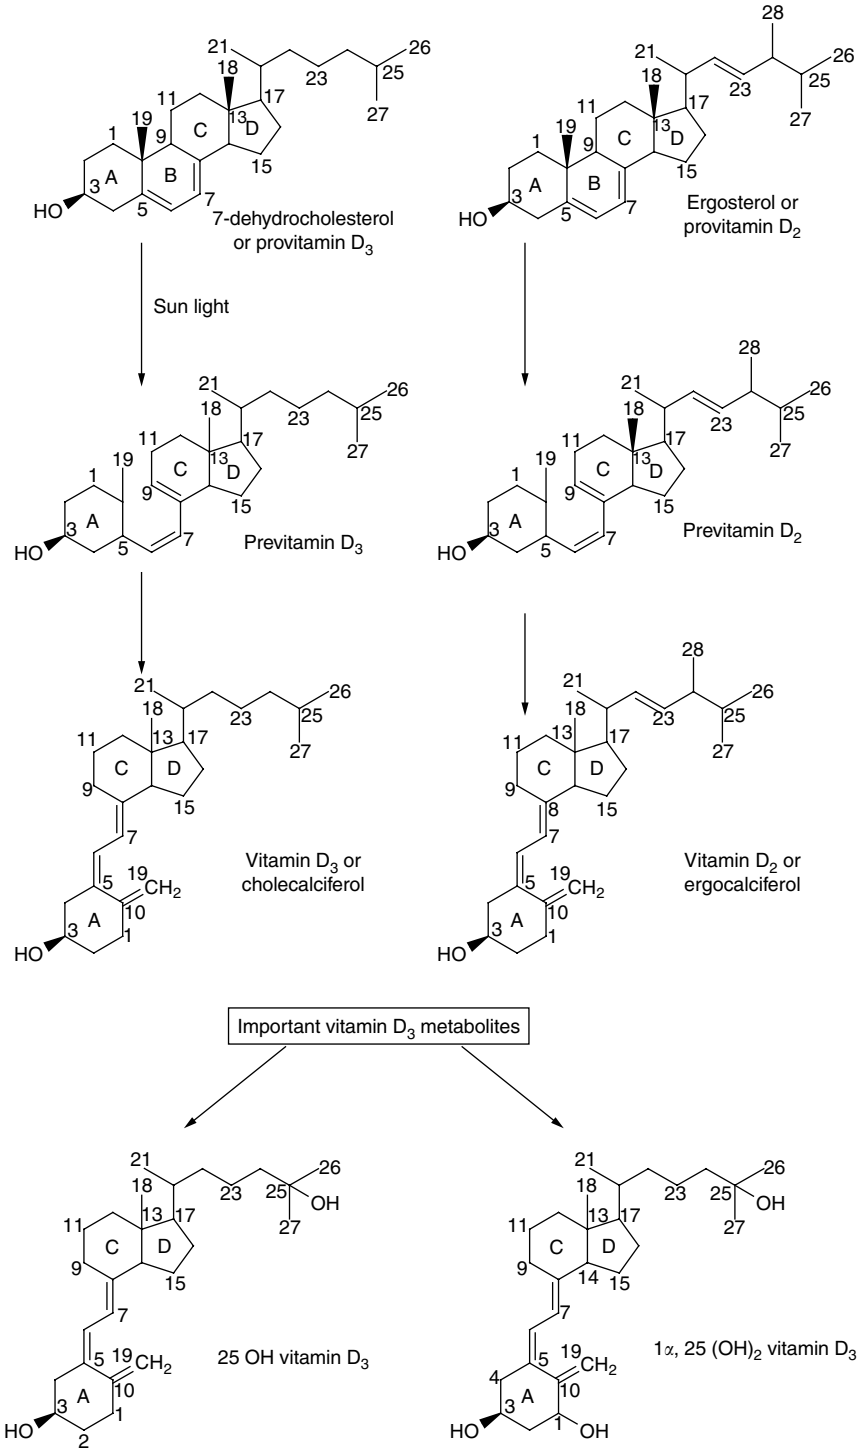

FIGURE 11.4 Structures of vitamin D, its precursors and metabolites (from Ref. 8).

5,6-trans-isomer and isotachysterol can form when exposed to acid or light (48). For food samples, saponification provides a convenient first step in extraction of vitamin D, since the stability under alkaline conditions is quite good. Precautions discussed in the vitamin A-carotenoid section of this chapter must be adhered to for extraction of vitamin D even though vitamin D is considered to be much more stable to oxidation compared to vitamin A. Oxidation can be a predominate route for decomposition at the conjugated double bond system at the 5,6 and 7,8 positions of the secosteroid structure. However, vitamin D is less susceptible to oxidative losses than vitamin A, carotenoids or vitamin E (47). Since various environmental conditions can lead to isomerization of vitamin D_2 and vitamin D_3 to the previtamin

forms, analytical methods must be capable of measuring all biologically active forms, including the previtamins, to accurately assess vitamin D activity. Thermal interconversion is difficult to completely avoid during sample preparation prior to quantification.

Vitamin D is quite stable to food processes used for fluid milk or in the production of nonfat dry milk. Research has shown that light and air exposure of fluid milk in the marketing channel results in only small losses of vitamin D (48). Documentation of degradation during the production of spray-dried, fortified whole milk showed that vitamin D was stable to the preheating by direct steam injection to 95°C, five-stage evaporation and spray-drying. No significant losses were noted (49).

B. Nutrition and Biochemistry of Vitamin D

1. Functions of Vitamin D

Vitamin D functions as a steroid hormone. In this respect, vitamin D_2 and D_3 undergo conversion through hydroxylation to the biologically active 1 α, $25(OH)_2D$ form. 25(OH)D is initially formed in the liver by the action of vitamin D 25-hydroxylase. The 25(OH)D constitutes the primary circulating form of vitamin D, and circulating levels can be used as an indication of overall vitamin D status. In the kidney, 25(OH)D is hydroxylated by 25-hydroxyvitamin D-1 α-hydroxylase to 1 α, $25(OH)_2D$ (50, 51). The dihydroxy form is then transported to target tissues where receptor binding occurs. Hydroxylation in the kidney also forms 24R, $25(OH)_2D$, although actions for this dihydroxy form of vitamin D are not clearly established (51). Overall, the actions of 1 α, $25(OH)_2D$ include maintenance of serum calcium and phosphorous concentrations and mobilization of monocytic stem cells in the bone marrow to become mature osteoclasts (2). In this regard, 1 α, $25(OH)_2D$ regulates mineral homeostasis by stimulation of the intestinal lumen-to-plasma flux of calcium and phosphorous, stimulation of renal resorption of calcium and phosphorous, and stimulation of bone resorption to increase calcium and phosphorous levels in the serum (51). Osteoblast formation is controlled at the bone cell differentiation level. In the kidney, regulation of

the overall vitamin D endocrine system occurs through control of activity of the $25(OH)_2D$-1 α-hydroxylase. Other accepted roles for 1 α, $25(OH)_2D$ include general effects on cell regulation and differentiation, regulation of protein synthesis, essentiality for insulin secretion, neural function and brain metabolism, immunological function, estrogen synthesis (52), and antiproliferative effects on various cancers (53–60). Detailed discussion on the complex vitamin D endocrine system has been presented by Norman and colleagues (44, 51).

2. Vitamin D Deficiency

Inadequate intake of vitamin D, lack of exposure to sunlight or metabolic failure to convert vitamin D to 1 α, $25(OH)_2D$, or a combination of the factors leads to deficiency (2). Deficiency states are characterized by inadequate mineralization or demineralization of the skeleton. These states are referred to as rickets in children and osteomalacia in adults. Deficiency due to inadequate intake or exposure to sunlight responds to supplementation of the diet but vitamin D-resistant rickets does not. Vitamin D-resistant rickets arises through genetic disorders and includes loss of the renal resorption system for phosphate, absence of the 25-hydroxy-vitamin D-1 α-hydroxylase in the kidney and through disruption of the vitamin D receptor gene (61). Rickets in children produces widening at the end of long bones, rachitic rosary, deformations in the skeleton (bowed legs, knocked knees, curvature of the spine, and others) (2). Osteomalacia in adults results in loss of calcium from the bone with bone pain, muscular weakness, and development of a porous bone structure (2, 44). Absence of sufficient 1 α, $25(OH)_2D$ leads to decreased circulating calcium levels and an increased production of parathyroid hormone (PTH). PTH stimulates calcium mobilization from the bone, conserves calcium excretion and increased excretion of phosphorous with the effect of bone demineralization and osteoporosis (62–64).

3. Hypervitaminosis D

Hypervitaminosis D can occur through improper use of supplements, excessive intake of foods fortified with vitamin D or rarely through manufacturing errors of supplements or food resulting in improperly labeled products with excessively high vitamin D levels. Current Upper Tolerable Intake Levels (UL) range from 25 to 50 μg/day (Table 11.2); however, severe effects have been noted at intakes of 250–1,250 μg/day or higher (2). Symptoms include increased intestinal absorption of calcium and increased resorption of calcium from bone resulting in hypercalcemia. Hypercalcemia can lead to loss of renal function. Other symptoms include anorexia, nausea, vomiting, thirst, polyuria, muscular weakness, joint pain, and general disorientation with eventual death (44).

4. Dietary Reference Intakes

Dietary Reference Intakes (DRIs) for vitamin D are limited to Adequate Intakes (AI) and Tolerable Upper Intake Levels (UL) (2). AIs range from 5 μg/day for infants through 50 year adults and 15 μg/day (600 IU/day) for older adults (>70 year). The AI recommendations assume that no vitamin D is available from synthesis in the skin by exposure to sunlight (2). UL values range from 25 μg/day for infants (0–6 months) to 50 μg/day for all other age groups (Table 11.2). Regarding development of hypervitaminosis D, only a small degree of safety exists between the AIs and the levels that can produce symptoms of hypervitaminosis D. For infants (AI-5 μg/day) 45 μg of vitamin D per day has been established as the NOAEL (highest level at which no adverse effects have been observed) (2). This level represents an intake only 9 times higher than the AI. The UL for infants is set at 25 μg/day (5 times the AI). For adults, the UL is 50 μg/day or 10 times the AI.

5. Vitamin D Sources for the Human

a. Synthesis in the Skin

The availability of vitamin D from unfortified foods is limited, and the major source to the human is synthesis in the skin upon exposure to sunlight. Synthesis is completely dependent upon exposure to the sun and varies with season, climate, and environmental conditions that can limit exposure to the sun (65). 7-Dehydrocholesterol from cholesterol is photoconverted to previtamin D_3 by exposure to UV irradiation between 290 and 315 nm (Figure 11.4). The previtamin D_3 is then isomerized to vitamin D_3. Likewise, ergosterol can be converted to previtamin D_2 by photoconversion. However, plant foods are generally devoid of vitamin D activity. Variability of sunlight exposure, particularly during winter months, makes dietary supply of vitamin D essential to avoid deficiency.

b. Food Sources and Dietary Intake

Vitamin D content of food and supplements is reported on an international unit (IU) or microgram basis (2). One IU of vitamin D is defined as the activity of 0.025 μg of cholecalciferol (vitamin D_3) measured by the rat or chick bioassay. The United States Pharmacoepial (USP) standard is either vitamin D_2 or vitamin D_3 since biological activity for the human is equal. Applications are developing for the use of 25(OH)D in supplements and for food fortification (66). The activity of 25(OH)D is 5 times that of vitamin D_3 (1 IU=0.005 μg) (2).

Fortified foods represent the only concentrated dietary sources of vitamin D other than some fatty fish (salmon), liver of some aquatic mammals, some fish oils and eggs from hens that have been fed rations containing high levels of vitamin D (2). The lack of many naturally occurring significant vitamin D sources, and the fact that consumption of higher vitamin D-containing foods

requires large intake levels to meet the vitamin D requirement places a significant emphasis on the role of food fortification in ensuring an adequate dietary supply of vitamin D. In the United States, the primary vehicle for food fortification is fluid milk. Although fortification of fluid milk is optional (38), most fluid dairy products are fortified with 400 IU/quart (10 μg/quart or 9.6 μg/L). Margarine fortification in the United States is optional, and most commercial margarines are only fortified with retinyl palmitate and β-carotene (8). Vitamin D_2 and vitamin D_3 can be used interchangeably for food fortification; however, for fluid milk products, most are fortified with vitamin D_3. Synthetic vitamin D_2 or D_3 is readily available to the food and supplement industries.

Since food fortification with vitamin D requires the addition of μg levels to the food on a per serving basis, problems have occurred with both over- and underfortification of fluid milk and infant formulas which must contain 40 IU/100 kcal. Surveys have noted wide variability in vitamin D content of milk and infant formula products arising from processing errors (67–69).

Dietary intake in the United States was estimated at a median level of 2.9 μg/day for young women from the second National Health and Nutrition Examination Survey (NHANES II) (2). However, it is recognized that reliable intake data do not exist (2). Lack of reliable data results from analytical difficulties, variable composition of fortified foods, and because food intake surveys have not emphasized vitamin D (2). Recommendations pertaining to the dietary reference intakes (DRI) were limited to average intake values (AI) due to the lack of reliable data required to set estimated average requirements (EARs) and recommended dietary allowances (RDAs). Average intake values range from 5 μg/day for infants to 15 μg/day for adults 70 years or older with the assumption that no vitamin D is available from sunlight exposure. Further, it is recognized that older individuals are more susceptible to conditions leading to vitamin D deficiency (2).

IV. VITAMIN E – TOCOPHEROLS AND TOCOTRIENOLS

Evans and Bishop discovered and characterized a fat-soluble nutritional factor necessary for reproduction and fetal death in rats (70). Published in 1922, the factor was designated "Factor X" and the antisterility factor. The name, vitamin E, was given since its discovery closely followed the discovery of vitamin D. A vitamin E active compound was isolated from wheat germ oil by the Evans' research group and named α-tocopherol (α-T) from the Greek words *tocos* (birth) and *ferein* (bringing) to denote the essentiality of the vitamin to reproduction in rats (71). The "ol" ending denoted that the compound was an alcohol (72). Other significant early historical events of vitamin E research include the isolation of β- and γ-tocopherol (β-, γ-T) from vegetable oil in 1934 (73), determination of the structure of α-T in 1937 (74, 75), synthesis of α-T in 1938 (76), recognition of the antioxidant activity of the tocopherols (77), recognition that α-T was the most effective tocopherol in prevention of vitamin E deficiency (73), isolation of δ-tocopherol (δ-T) from soybean oil in 1947 (78), and identification of the four naturally occurring tocotrienols (α-T3, β-T3, γ-T3, δ-T3) (79, 80). Quantification of the vitamin E content of the diet was initiated in the late 1940s. Publication of the paper "Vitamin E Content of Foods" in 1950 (81) represents one of the earliest documentations of dietary levels.

A. Chemistry of Vitamin E

Vitamin E is the collective term for fat-soluble 6-hydroxychroman compounds that exhibit the biological activity of α-T measured by the rat resorption-gestation assay. Tocol (Figure 11.5) (2-methyl-2-(4′,8′,12′-trimethyltridecyl)-chroman-6-ol) is generally considered the parent compound of the tocopherols. Accepted nomenclature has been set by the IUPAC-IUB Joint Commission on Nomenclature (82–84). Naturally occurring vitamin E consists of α-, β-, γ-, and δ-T and the corresponding α-, β-, γ-, and δ-T3 (tocotrienol), (Figure 11.5). The tocopherols are characterized by the 6-chromanol ring structure methylated to varying degrees at the 5-, 7-, and 8-positions. At position 2, there is a C16 saturated side chain. The tocotrienols are unsaturated at the 3′, 7′, and 11′ positions of the side chain. The specific tocopherols and tocotrienols, therefore, differ by the number and positions of the methyl groups on the 6-chromanol ring. α-Tocopherol and α-T3 are trimethylated; β-T, β-T3, γ-T, and γ-T3 are dimethylated; and δ-T and δ-T3 are monomethylated (Figure 11.5). Trivial and chemical names are given in Figure 11.5.

The tocopherols possess three asymmetric carbons (chiral centers) at position 2 of the chromanol ring and at positions 4′ and 8′ of the phytyl side chain. Synthetic α-T (all-rac-α-T) is a racemic mixture of equal parts of each stereoisomer. Therefore, each tocopherol has eight (3) possible optical isomers. Only RRR-tocopherols are found in nature. The eight isomers of all-rac-α-T (RRR-, RSR-, RRS-, RSS-, SRR-, SSR-, SRS-, and SSS-) are depicted in Figure 11.6. Only the 2R-stereoisomeric forms (RRR-, RSR-, RRS-, and RSS) of α-T are considered active forms of vitamin E for the human (3). The tocotrienols arising from 2-methyl-2-(4′,8′,12′-trimethyltrideca-3′,7′,11′-trienyl) chroman-6-ol (non-methylated ring structure) have only one chiral center at position 2. Consequently, only 2R and 2S stereoisomers are possible. Unsaturation at position 3′ and 7′ of the phytyl side chain permits four cis/trans geometric isomers. The eight potential tocotrienol isomers are given in Table 11.4. Only the 2R, 3′ trans, 7′ trans isomer exists in nature. Isolation and elucidation of the structural properties of the tocotrienols

was accomplished in the 1960s (80, 85). Physical properties of various vitamin E forms are given in Table 11.3.

1. Spectral Properties

UV and fluorescence properties of vitamin E compounds are given in Table 11.3. Maximal UV absorption for tocopherols, tocotrienols and their esters occurs between 292 and 298 nm. Minimum absorption is between 250 and 260 nm (25, 89–92). Esterification at the C-6 hydroxyl shifts the absorption to shorter wavelengths. For example, all-rac-α-tocopheryl acetate has maximal absorption at 286 nm (88, 91, 92). Intensity of absorption decreases with esterification. Reported $E^{1\%}_{1cm}$ values for all-rac-α-tocopheryl acetate range from 40 to 44 compared to 75.8 to 91.8 for the tocopherols and tocotrienols (88).

Vitamin E alcohols possess strong native fluorescence that provides an ideal and very specific mode of detection for LC-based methods. Excitation of the chroman ring near or at maximal absorption produces maximal emission at 320 nm or slightly higher wavelengths. Many quantitative methods are based on excitation at 292 nm and emission at 320 nm (88). Vitamin E esters show only weak fluorescence compared to the alcohols. Older literature (prior to 1985) often states that α-tocopheryl acetate does not fluoresce. However, the ester shows weak fluorescence sufficient to quantify the ester that is easily detected by currently available fluorescent detectors. By measuring the α-tocopheryl acetate as the ester and avoiding saponification of the sample, accurate measure of the biological activity is possible. Biological activity of all-rac-α-tocopheryl acetate is lower than that of RRR-α-T.

2. Stability

Vitamin E is a natural antioxidant, acting as a chain-breaking, primary antioxidant to intercept peroxyl free radicals in biological systems. As an antioxidant, α-T, or other vitamin E alcohols, is, thus, converted into the α-tocopheryl radical and to termination products consisting of dimers and trimers and various oxygenated forms. Since it is active in any fat system undergoing oxidation, oxidative losses can become substantial quite rapidly. Losses are accelerated by light, heat, irradiation, alkali pH, lipoxidase activity, metals, and by the presence of other proxidants in the fat system, including pre-formed free radicals (88). Tocopherols and tocotrienols are stable to heat and alkaline conditions necessary for saponification of lipids. Therefore, saponification is routinely used for extraction of vitamin E prior to analysis by LC.

Frying of foods normally results in loss of the native vitamin E components in the edible oil. Heat combined with incorporation of air with the food, the polyunsaturated nature of the oil and introduction of proxidants into the oil provides an ideal environment for oxidation. Vitamin E through its antioxidant action, combined with some loss through volatilization, leads to rapid loss of vitamin E from the frying oil. Refining of edible oil produces some loss of native vitamin E, primarily at the

deodorization stage. However, loss is not enough to destabilize the oil to oxidation. Deodorizer sludge, once a by-product of edible oil refining with little value, now represents the raw material source for isolation of natural vitamin E. Natural vitamin E is in demand world-wide for use in supplements, feeds, and cosmetics (72).

B. Nutrition and Biochemistry of Vitamin E

1. Functions of Vitamin E

Vitamin E is the primary, lipid-soluble, chain-breaking antioxidant that combines actions with other lipid and water-soluble antioxidants to provide cells an efficient defense against free radical damage. Free radicals are chemical species capable of independent existence that contain one or more unpaired electron (93). Free radical generation occurs when organic molecules undergo homolytic cleavage of covalent bonds and each fragment retains one electron of the original bonding electron pair. Two free radicals are produced from the parent molecule with net negative charges. The free radicals have the ability to react with an electron of opposite spin from another molecule. Free radical generation also occurs when a nonradical molecule captures an electron from an electron donor. During normal metabolism, many reactive oxygen species (ROS) and reactive nitrogen species (RNS) are produced (94). ROS and RNS include both radicals and oxidants capable of generation of free radicals (95, 96). Common ROS and RNS are given in Table 11.5.

Oxidants and oxygen radicals formed from triplet oxygen by reaction with other radicals or by photoexcitation, metabolism, irradiation, metal catalysis, or heat are the major inducers of oxidative stress in living systems. They also initiate antioxidative events in raw and processed foods. RNS, particularly nitric oxide ($NO^{\cdot}$) contributes to oxidative stress along with ROS. Nitric oxide acts as a biological messenger with regulatory functions in the central nervous, cardiovascular, and immune systems (97). It is synthesized through the oxidation of arginine to $NO^{\cdot}$ by nitric oxide synthetase (NOS:EL 1.14.13.39). Nitric oxide synthetase is highly active in macrophages and neutrophilis where $NO^{\cdot}$ and superoxide anion ($O_2^{\cdot -}$) are produced during the oxidative burst triggered by inflammation (98).

TABLE 11.5
Reactive Oxygen and Nitrogen Species

Radicals	Nonradicals

	Peroxynitrous acid, ONOOH
	Nitronium cation, NO_2^+
	Alkyl peroxynitrates, ROONO

α-Tocopherol is located in the cell membranes and protects lipoproteins. It scavenges peroxy free radicals, protecting unsaturated fatty acids. Lipid-generated free radicals have greater affinity for reaction with α-T than with unsaturated fatty acids located within the cell membrane. It is an efficient chain-breaking antioxidant since it can rapidly transfer the phenolic H^+ at C-6 to lipid peroxy radicals. The α-T becomes the α-tocopheroxyl radical, which is stabilized by resonance.

Potency of α-T as an antioxidant depends upon its molecular properties and orientation within the cell membrane. In the membrane, the phytyl side chain is embedded within the bilayer (Figure 11.7) with the chromanol ring and the 6-hydroxyl positioned toward the surface of the membrane. Hydrogen bonding and hydrophobic interactions between the chromanol ring, the phytyl tail, and fatty acids stabilize the membrane and position the chromanol ring to facilitate hydrogen atom donation to lipid peroxy radicals. The α-tocopheroxyl radical migrates from the lipid bilayer to the surface of the membrane, facilitating regeneration of α-T by ascorbic acid and other water-soluble reducing agents that act as hydrogen donors to the α-tocopheroxyl radical.

Non-autoxidative roles for α-T have been recently delineated which cannot be fulfilled by other tocopherols or tocotrienols. These functions at the molecular level appear to be highly significant to understanding the onset of many chronic diseases. Several critical reviews exist that indicate that the molecular control aspects of vitamin E are just beginning to be understood (98–103). α-Tocopherol acts as a cell signaling molecule at the posttranscriptional level or at the gene expression level. Many of these cell signaling functions of α-T are operative through inhibition of protein kinase C (PKC). PKC enzymes are phospholipid-dependent serine/threonine kinases that participate in regulation of cell growth, death, and stress responsiveness (104). α-Tocopherol acts at the posttranscriptional level by activating protein phosphatase PP_2A which dephophorylates PKC (105, 106). Some specific physiological responses regulated by PKC include cell proliferation, platelet adhesion and aggregation, immune response, free radical production and gene expression. Now regulation of gene expression at the transcriptional stage is accepted as a primary regulatory function of α-T.

Specific non-antioxidant functions for α-T3 have been identified that are not fulfilled by α-T. Hendrich et al. (107)

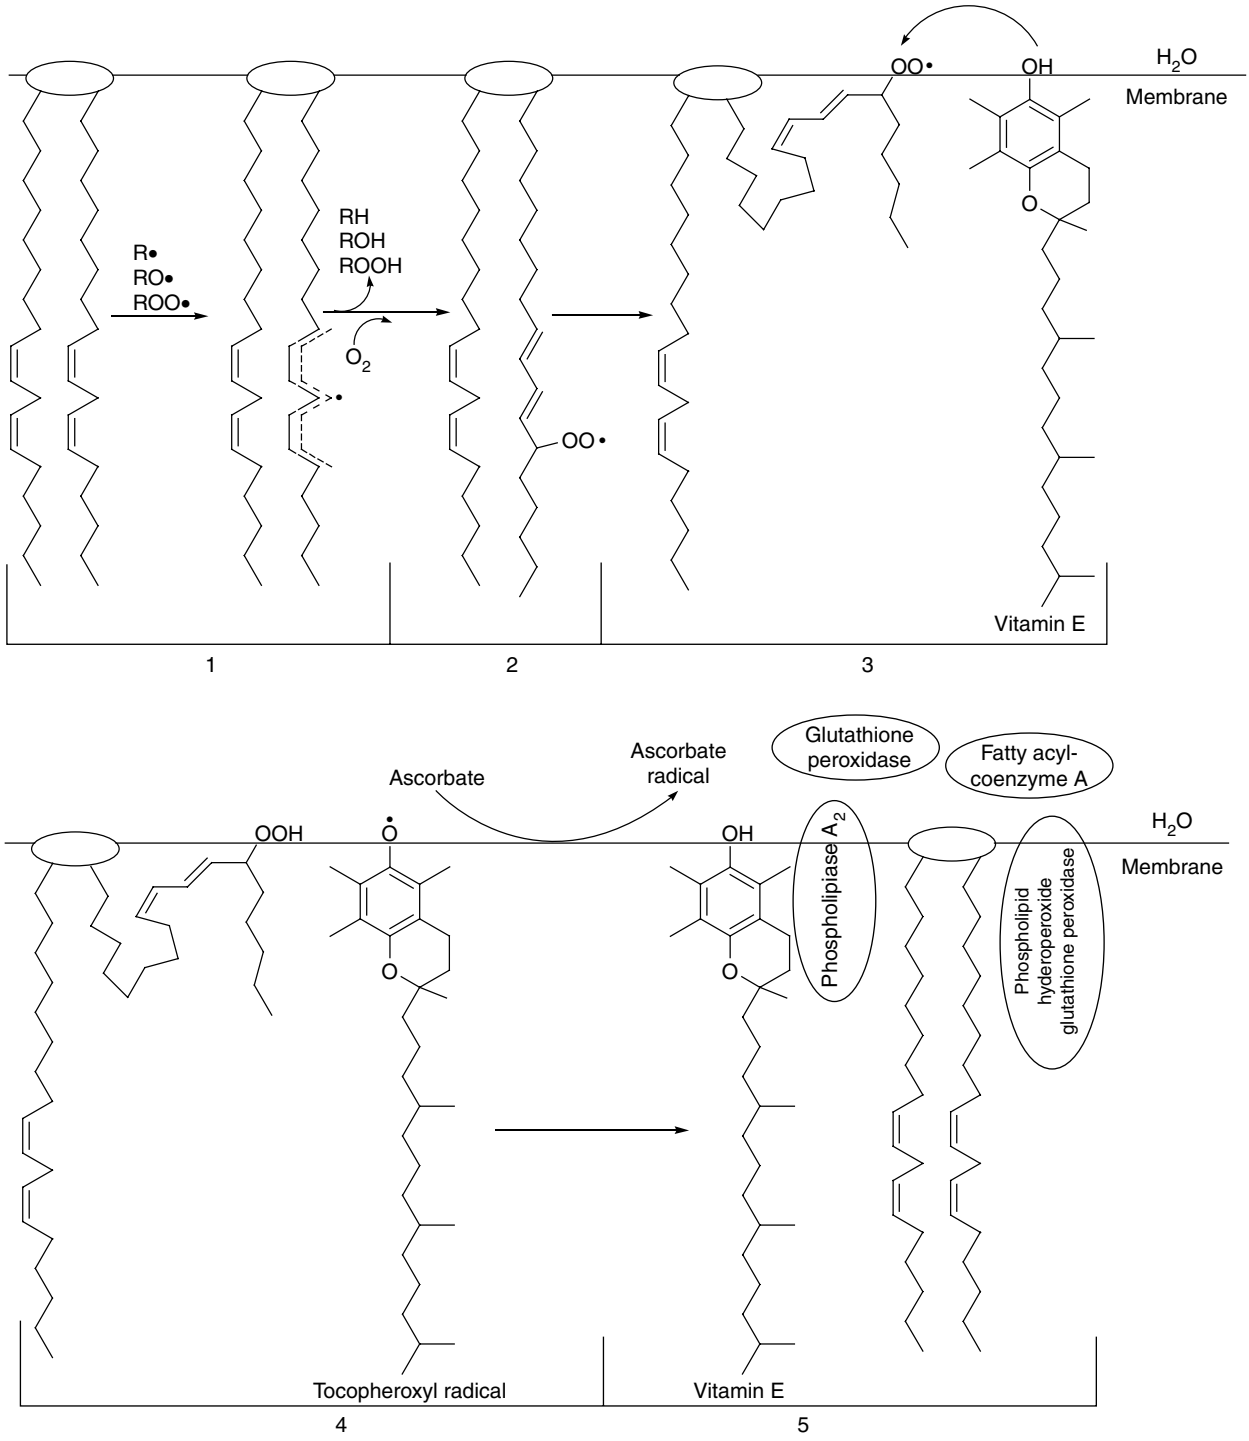

FIGURE 11.7 Representation of the positions of α-T and ascorbic acid at the membrane-water interface.

suggested that tocotrienols should be considered as a specific group of food components independent of the tocopherols due to specific differences in action that differ from actions of α-T. Such specific actions include posttranscriptional suppression of 3-hydroxy-3-methylglutaryl Co A reductase (HMG-Co A reductase) through a cell signaling event (108, 109). The ability of tocotrienol supplements to lower human total serum cholesterol levels is currently controversial (110).

2. Vitamin E Deficiency

Vitamin E deficiency in humans is almost always due to factors other than dietary insufficiency. Deficiency results from

genetic abnormalities in production of the α-tocopherol transfer protein (α-TTP), fat malabsorption syndromes, and protein-energy malnutrition (3). Fat-malabsorption can be related to pancreatic and liver abnormalities that lower fat absorption, abnormalities of the intestinal cells, length of the intestine and defects in the synthesis or assembly of the chylomicrons (61). Genetic abnormalities in lipoprotein metabolism can produce low levels of cylomicrons, very low density lipoproteins (VLDL) and low density lipoprotein (LDL) that affects absorption and transport of vitamin E (111). Abetalipoproteinemia is an autosome recessive genetic disorder leading to mutations in the microsomal triglyceride transfer protein (112). The disease is associated with ataxia and impaired intestinal absorption of lipids and vitamin E, since the triglyceride transfer protein participates in the transport of lipids and other fat-soluble substances. Defects in the gene that codes for α-TTP leads to an inherited autosomal recessive disease referred to as familial isolated vitamin E deficiency or ataxia with vitamin E deficiency (AVED) (112–114). Changes in α-TTP result in inefficient transfer of RRR-α-T from the liver and recycling of plasma RRR-α-T.

Clinical symptoms include many neurological problems stemming from peripheral neuropathy with degeneration of the large-caliber axons in the sensory neurons (3). Common symptoms are ataxia, muscle weakness and hypertrophy, neurological abnormalities, reproductive disorders, abnormalities of the liver, bone marrow, and brain (61). At the cellular level, increased oxidation can occur due to increased oxidative stress.

3. Dietary Reference Intakes

When establishing the dietary reference intakes (DRIs) for vitamin E, the Institute of Medicine, Panel on Dietary Antioxidants and Related Compounds decided that human requirements should only be based on the 2-R isomers of α-T (RRR-, RSR-, RRS-, RSS-) (3). This decision stems from the accumulated evidence of the strong selectivity of α-TTP for the 2-R isomers in the liver which leads to preferential secretion of the 2-R isomers into nascent VLDL. Other forms of vitamin E (2-S isomers of α-T, β-T, γ-T, δ-T, tocotrienols) are primarily secreted into the bile and excreted. The selection process is not 100% effective; however, only small amounts of other dietary and supplemental vitamin E forms are delivered to the cells.

For adults, EAR and RDA are 12 and 15 mg of α-T per day, respectively (Table 11.2). The UL value includes all forms of α-T from supplemental intake of all-rac-α-T. The UL is 1000 mg/day.

Since the DRI values refer only to 2R-α-T forms, discussion is necessary on the units used to report vitamin E concentrations in foods and pharmaceuticals. Currently used units include the following:

1. International Units (IU) and USP Units

$$\textit{Molar Conversion Factor (μmol/IU)} = \frac{\textit{USP Conversion Factor (mg/IU)} \times \textit{1000 (μmol/mol)}}{\textit{Molecular Weight (mg/mol)}}$$

Calculation for RRR-α-tocopheryl acetate:

$$\textit{Molar Conversion Factor (μmol/IU)} = \frac{\textit{USP Conversion Factor (mg/IU)} \times \textit{1000 (μmol/mol)}}{\textit{Molecular Weight (mg/mol)}}$$

$$= \frac{\textit{0.735 (mg/IU)} \times \textit{1000 (μmol/mol)}}{\textit{472 (mg/mol)}} = \textit{1.56 (μmol / IU)}$$

$$\textit{α-T Conversion Factor (mg/IU)} = \frac{\textit{Molar Conversion Factor (μmol/IU)} \times \textit{430 (mg/mol)}}{\textit{1000 (μmol/mol)} \times R}$$

Where R=2 for synthetic vitamin E and esters, R=1 for natural vitamin E and esters.
So, the α-T conversion factor for RRR-α-tocopheryl acetate is determined as follows:

$$\textit{α-T Conversion Factor (mg/IU)} = \frac{\textit{Molar Conversion Factor (μmol/IU)} \times \textit{430 (mg/mol)}}{\textit{1000 (μmol/mol)} \times R}$$

$$= \frac{\textit{1.56 (μmol/IU)} \times \textit{430 (mg/mol)}}{\textit{1000 (μmol/mol)} \times \textit{1}} = \textit{0.067 (mg/IU)}$$

The United States Pharmacopeia (USP) (115) defined the IU of vitamin E as 1 mg of all-rac-α-tocopheryl acetate based on biological activity measured by the rat fetal absorption test. Biological activities of various vitamin E forms in relation to the activity of all-rac-α-tocopheryl acetate are given in Table 11.6. After 1980, the USP discontinued use of the IU and replaced it with USP units based on the same basis of biological activity as the IU (3). One USP unit is defined as the activity of 1 mg of all-rac-α-tocopheryl acetate. Therefore, USP units and IUs are equivalent (116).

The Institute of Medicine, Panel on Dietary Antioxidants and Related Compounds (3) recommended that USP units be redefined by USP to take into account the fact that all-rac-α-T has only 50% of the activity of RRR-α-T present in nature or with other 2R stereoisomers found in all-rac-α-T preparations that are used for food fortification and in supplements (3). Factors to convert USP units (IUs) to RRR-α-T or other 2R-isomers of α-T are given in Table 11.7.

Derivation of the conversion factors given in Table 11.7 follows the general formula:

2. α-Tocopherol Equivalents

TABLE 11.6
Biological Activity of Natural and Synthetic Vitamin E Forms[a]

Vitamin E Forms	Biological Activity	
	USP Units (IU)/mg	Compared to RRR-α-T (%)
Natural Vitamin E (RRR-)		
α-Tocopherol	1.49	100
β-Tocopherol	0.75	50
γ-Tocopherol	0.15	10
δ-Tocopherol	0.05	3
α-Tocotrienol	0.75	50
β-Tocotrienol	0.08	5
γ-Tocotrienol	Not known	Not known
δ-Tocotrienol	Not known	Not known
Synthetic		
2R4′R8′R α-tocopherol	1.49	100
2S4′R8′R α-tocopherol	0.46	31
All*rac*-α-tocopherol	1.10	74
2R4′R8′S α-tocopherol	1.34	90
2S4′R8′S α-tocopherol	0.55	37
2R4′S8′S α-tocopherol	1.09	73
2S4′S8′R α-tocopherol	0.31	21
2R4′S8′R α-tocopherol	0.85	57
2S4′S8′S α-tocopherol	1.10	60
RRR-α-tocopheryl acetate	1.36	91
RRR-α-tocopheryl acid succinate	1.21	81
All*rac*-α-tocopheryl acetate	1.00	67
All*rac*-α-tocopheryl acid succinate	0.89	60

[a]*Source*: Ref. 8.

α-Tocopherol Equivalents (α-TEs) were defined for recommending dietary intakes of vitamin E based on biological activity of tocopherols and tocotrienols determined by the rat fetal absorption test (Table 11.6) (117). One mg of α-TE is the activity of 1 mg of RRR-α-T. Total α-TEs (mg) of mixed diets containing only RRR-isomers is determined by multiplying the amount (mg) of α-T by 1.0, β-T by 0.5, γ-T by 0.1, α-T3 by 0.3, and γ-T3 by 0.05. In fortified foods, the conversion factors for all-rac-α-T and all-rac-α-tocopheryl acetate are 0.74 and 0.67, respectively. Use of the α-TE unit has been the accepted way of reporting vitamin E concentration in foods for approximately the past two decades. The Panel on Antioxidants and Related Compounds (3) determined from USDA food intake survey data that 80% of the α-TE from foods arises from RRR-α-T. Therefore, to convert α-TE mg to RRR-α-T, the conversion factor is 0.8.

The following conversions are fully explained in the Dietary References Intake report (3):

a. mg of α-T in a meal = mg of α-TE × 0.8
b. mg of α-T in a food, fortified food, or multivitamin = IU (USP unit) of RRR-α-T × 0.67 or IU (USP Unit) of all-rac-α-T × 0.45

Anytime both natural and synthetic forms of α-T are present, analytical procedures must be capable of resolution of the specific compounds in order to apply the above formulas. Almost always in a fortified food, both RRR-α-T and all-rac-α-tocopheryl acetate will exist together.

4. Food Sources and Dietary Intake

The second National Health and Nutrition Examination Survey (NHANES II) has been extensively evaluated to show dietary sources of vitamin E in the United States. Major food groups contribute the following percentages of total vitamin E: fats and oils, 20.2; vegetables, 15.1; meat, poultry, and fish, 12.6; desserts, 9.9; breakfast cereals, 9.3; fruit, 5.3; dairy products, 4.5; mixed main dishes, 4.0; nuts and seeds, 3.8; soups, sauces, and gravies, 1.7 (3, 117). Data collected from the Continuing Survey of Food Intakes by Individuals (CSFII, 1994) are given in Table 11.8 (D. Haytowitz, personal communication, 2003). The tabulation shows that high oil content foods are major sources but cereals fortified with α-tocopheryl acetate are also significant sources. Raw tomatoes and tomato products, due to high consumption, are significant sources of vitamin E in the U.S. diet.

Using the CSFII and NHANES data as well as other studies, the DRI committee estimated the median intake of α-T from food and supplements at 9.8 mg for men and 6.8 mg for women (3). It was emphasized that data on vitamin E intake from food intake surveys might be low due to potential for underreporting of energy and fat intake, problems with assessment of fats and oils added during food preparation, uncertainty about the types of fats added, and the variability of food composition tables.

TABLE 11.7
Conversion Factors to Calculate α-Tocopherol from International Units or USP Units to Meet Dietary Reference Intakes for Vitamin E[a]

	USP Units (IU)/mg	mg/USP Units (IU)	μmol/USP Unit (IU)	α-Tocopherol mg/USP Unit (IU)
Natural Vitamin E				
RRR-α-tocopherol	1.49	0.67	1.56	0.67
RRR-α-tocopheryl acetate	1.36	0.74	1.56	0.67
RRR-α-tocopheryl acid succinate	1.21	0.83	1.56	0.67
Synthetic Vitamin E				
All-*rac*-α-tocopherol	1.1	0.91	2.12	0.45
All-*rac*-α-tocopheryl acetate	1	1	2.12	0.45
All-*rac*-α-tocopheryl acid succinate	0.89	1.12	2.12	0.45

TABLE 11.8
Significant Sources of Vitamin E in the Diet in the United States[a]

		% Vitamin E in U.S. Diet[b]
1	Margarine, regular stick, 80% fat	5.5
2	Salad dressing, mayonnaise, soybean oil, with salt	4.3
3	Oil, soybean, salad or cooking	3.1
4	Cereals, ready-to-eat, Total	2.8
5	Oil, corn, salad or cooking	2.7
6	Shortening, composite, household	2.5
7	Salad dressing, Italian, commercial, regular, with salt	2.4
8	Peanut butter, smooth, with salt	2.3
9	Snacks, potato chips, plain, salted	2.3
10	Eggs, whole, raw, fresh, frozen	2
11	Sauce, pasta, spaghetti/marinara, ready-to-serve	1.6
12	Oil, canola	1.4
13	Tomato products, canned, sauce	1.2
14	Shortening, composite, institutional	1.1
15	Rolls, hamburger or hot dog, plain	1
16	Margarine-like spread, tub, composite, 60% fat, with salt	1
17	Milk, cow, whole, fluid, 3.3% fat	1
18	Oil, cottonseed, salt or cooking	0.9
19	Tomato products, canned, puree, without salt	0.9
20	Fast foods, chicken, breaded, fried, boneless, plain	0.9
21	Broccoli, cooked, boiled, drained	0.9
22	Tomatoes, red, ripe, raw	0.7

[a] *Source*: D. Haytowitz, 2003.

[b] Calculated on the basis of mg α-tocopherol equivalents (mg α–TE).

Although the estimated median intakes for men and women are below the RDA of 15 mg of α-T per day (Table 11.2) and many clinical studies exist that indicate beneficial responses to supplemental vitamin E, the panel believed that clinical evidence was too limited to recommend use of vitamin E supplements for the general population.

V. VITAMIN K

Vitamin K was characterized through the efforts of several research groups in the 1930s. Observations by Dam in Denmark showed that chicks developed blood with poor clotting properties and fatal hemorrhages when fed diets extracted with ether (118). Addition of the ether extract back to the diet alleviated the deficiency. The fat-soluble factor was named vitamin K by Dam in 1935 based on the word "koagulation." In 1939, the vitamin K form (2-methyl-3-phytyl-1,4-naphthoquinone) was isolated by research groups led by Dam and Doisy (119, 120). The vitamin K_1 designation was given along with the generic name of phylloquinone. Vitamin K_2, the menaquinone-n (MK-n) form, was isolated from fermented fish meal by Doisy's group in 1939. Vitamin K_1 was synthesized by Doisy's group in 1939. In 1943, both Dam and Doisy were awarded Nobel Prizes for their work on isolation and synthesis of vitamin K.

A. CHEMISTRY

Vitamin K compounds consist of 2-methyl-1,4-naphthoquinone and all derivatives providing antihemorrhagic activity of vitamin K_1 (phylloquinone). 2-Methyl-1,4-naphthoquinone (Figure 11.8) is the parent compound of the family but does not occur in nature (120). It is commonly used in animal rations and is commercially referred to as menadione (vitamin K_3, MK-0) and, formerly, as menaquinone. Naturally occurring vitamin K forms include vitamin K_1 and the vitamin K_2 series. Vitamin K_1 is phylloquinone (2-methyl-3-phytyl-1,4-naphthoquinone) (Figure 11.8). Vitamin K_1 is synthesized in the plant kingdom and constitutes the primary food source of vitamin K activity (120). Alkylation at carbon-3 of the 2-methyl-1,4-napthoquinone ring with five-carbon isoprenoid units produces the vitamin K series. Vitamin $K_{1(20)}$, the most common phylloquinone, contains four isoprenoid units of which three are reduced. The reduced side chain or phytyl side chain at carbon-3

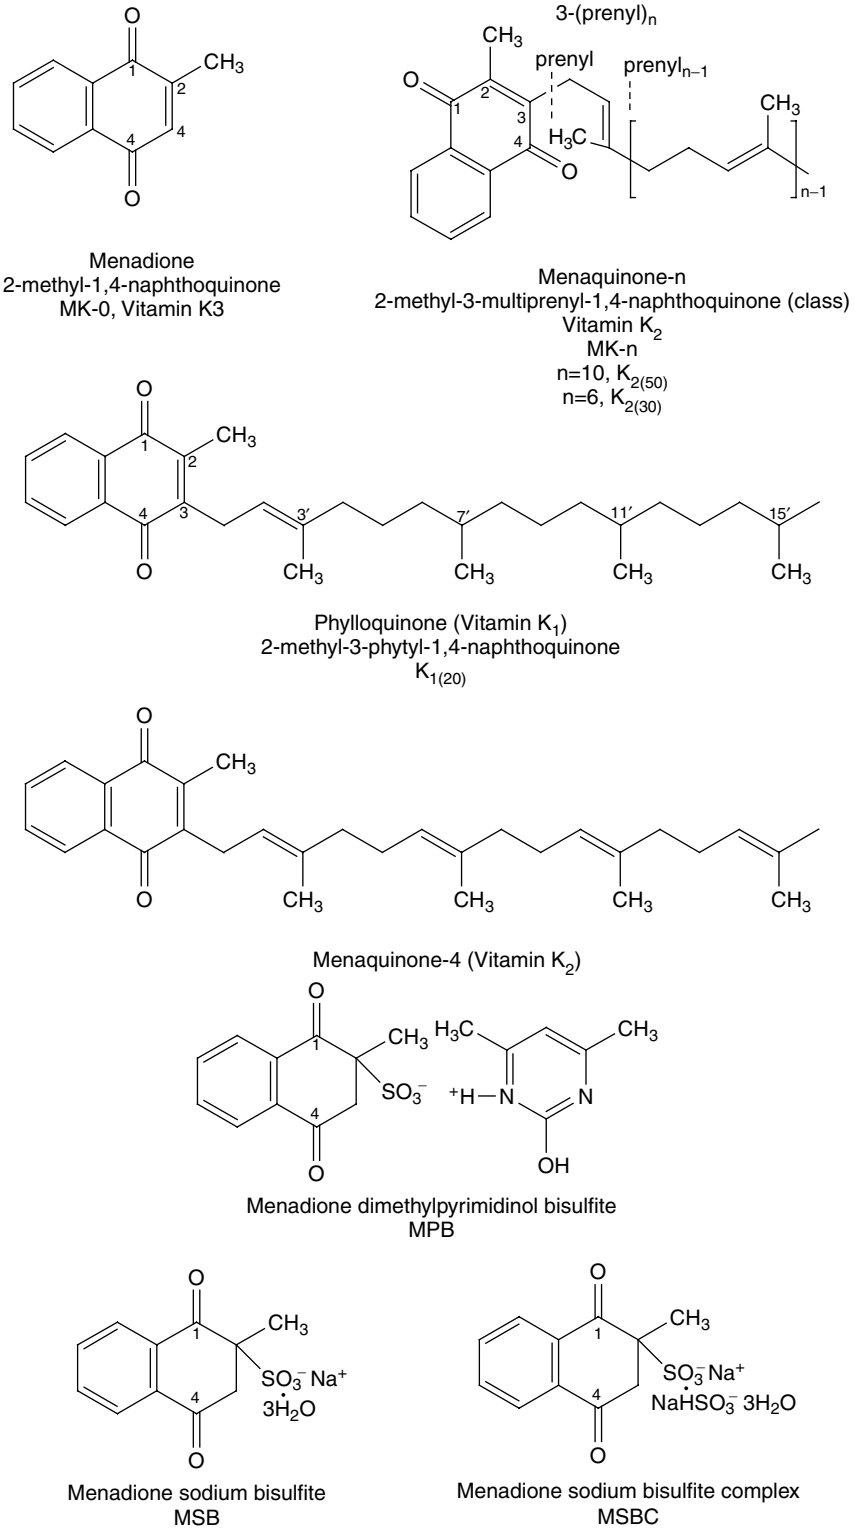

FIGURE 11.8 Structures of vitamin K and water-soluble menadione forms.

of the 2-methyl-1,4-naphthoquinone ring with one double bond characterizes the phylloquinones. The United States Pharmacopeia (USP) designates vitamin K_1 as phytonadione. USP phytonadione is a mixture of E and Z isomers with not more than 21% Z isomer content (115). Natural phylloquinone is 2′-E, 7′R, 11′R (118).

Vitamin K_2 (menaquinone-n series, MK-n) (Figure 11.8) have polyisoprenoid side chains at carbon-3 of the

2-methyl-1,4 naphthoquinone ring. Vitamin K_2 compounds are synthesized by bacteria except MK-4 is synthesized by birds and animals from menadione (119). Side chains are unsaturated and usually contain 4–13 isoprenoid units. The MK-n designation gives the number of prenyl groups in the side chain. One or more of the isoprenoid units may be reduced. Reduction usually occurs at the second isoprenoid units from the naphthoquinone ring (118). Physical properties of vitamin K compounds are given in Table 11.3.

Vitamin K compounds other than menadiones that are modified to increase water solubility are lipid-soluble and soluble in non-polar solvents. Vitamin K_1 (20) is synthesized and used by the food and supplement industries and for use in olestra-containing products (121). Menadione is toxic and not used for human supplements. It is an important nutritional additive to poultry and animal rations. Vitamin K_1 is not used in animal feeds due to cost (25). In poultry rations, chemotherapeutic agents inhibit intestinal synthesis of vitamin K and, therefore, increase dietary requirements (25). Stabilized forms of menadione with increased water solubility are available to the feed industry. These include menadione sodium bisulfate (MSB), menadione sodium bisulfite complex (MSBC), and menadione dimethyl-pyrimidol bisulfite (MPB) (Figure 11.8). The menadione salts are absorbed more efficiently than menadione and show greater stability due to their water solubility.

1. Spectral Properties

Both phylloquinones and menaquinones show UV spectra characteristic of the naphthoquinone ring. Phylloquinone shows absorption maxima at 242, 248, 260, 269, and 325 nm in hexane. The UV spectrum of menadione in hexane has an absorption maximum at 252 nm (25). Vitamin K compounds do not fluoresce. Conversion of the quinone to the hydroquinone induces strong fluorescence. Post-column reduction to the hydroquinone forms the basis of excellent quantitative procedures currently used for assay of vitamin K in foods, supplements, and other biological samples (122). The hydroquinone shows maximal fluorescence at $\lambda_{ex} = 244, \lambda_{em} = 418$.

2. Stability

Vitamin K is quite stable to oxidation and food processing and preparation conditions (122). It is unstable to light and alkalinity. Instability to alkalinity eliminates the use of saponification for extraction from foods; so, it is difficult to include extraction of vitamin K with multi-analyte procedures that rely on saponification as the initial step of the assay. Reducing agents destroy the biological activity of vitamin K_1. Isomerization of trans- to cis-isomers leads to loss of biological activity. Presence of variable quantities of the cis-isomer in vitamin K concentrates requires that quantitative methods be capable of resolving cis- and trans-forms to accurately estimate biological activity (122).

B. Nutrition and Biochemistry of Vitamin K

1. Functions of Vitamin K

Vitamin K is a cofactor for vitamin K-dependent carboxylase required for the posttranslational conversion of glutamic acid to gamma-carboxy-glutamyl residues (Gla) (120, 123). Numerous Gla-containing proteins are known. These include the blood coagulation proteins consisting of prothrombin (factor II, factors VII, IX, and X, and proteins C, S, and Z) (120). Three Gla proteins including osteocalcin, matrix Gla protein, and protein S (120, 123) are bone matrix components. Various other Gla proteins have been identified, but the functions for such vitamin K-dependent proteins are not clearly understood (120).

2. Vitamin K Deficiency

Deficiency of vitamin K in the adult is rare. It is defined as vitamin K-responsive hypoprothrombinemia characterized by an increase in prothrombin time (PT) (1). It usually results from fat malabsorption syndromes, liver disease, and antibiotic treatments that inhibit synthesis of vitamin K_2 by the gut microflora. Anticoagulant treatment with coumarin produces a secondary deficiency by disruption of vitamin K function and inhibition of synthesis of vitamin K-dependent clotting proteins.

In human infants, deficiency of vitamin K commonly occurs and is named hemorrhagic disease. The deficiency occurs through poor placental transfer of vitamin K from the mother to the fetus and lack of bacterial synthesis in the gut of the newborn baby. Other factors include the low concentration of vitamin K in breast milk and low concentrations of blood clotting factors at birth (120). Hemorrhages occurs in the skin, subcutaneous tissue, GI tract, umbilical cord, and intracranially. Central nervous system disorders can occur if untreated. Hemorrhagic disease is prevented by intramuscular injection of vitamin K_1 (0.5–1 mg) or oral dosage (2.0 mg) within 6 hours of birth (120). Breast-fed infants develop hemorrhagic disease more frequently than formula-fed infants because human milk is low in vitamin K. Infant formula is fortified at a minimum of 4 μg per 100 kcal as specified by the Infant Formula Act of 1980 (124).

3. Dietary Reference Intakes

The panel on DRIs for vitamin K was unable to establish average requirements for vitamin K because of lack of data; therefore, only Adequate Intake (AI) values were set (1). The AI levels are 120 and 90 μg/day for adult men and

women, respectively (Table 11.2). Tolerable Upper Intake Levels (ULs) were not established, since no adverse effects have been reported at high intake levels (1).

4. Food Sources and Dietary Intake

Leafy green vegetables, certain legumes, and vegetable oils are considered good sources of vitamin K. Vitamin K_1 is the primary food source, and green leafy vegetables provide 40 to 50% of the total intake (125). Milk and dairy products, meats, eggs, cereals, fruits and vegetables, are low but consistent sources of vitamin K to the U.S. diet (122). Reliable data did not exist for the vitamin K content of the diet until excellent LC procedures were developed during the 1990s by Sadowski and colleagues (126–129). Establishment of methodology and collection of reliable data led to the development of a reliable database to estimate intake of vitamin K_1 (130). The database was based on vitamin K_1 intake in women's diets collected from the 1990 Food and Drug Administration Total Diet Study (130). Major food sources were spinach, collards, broccoli, iceberg lettuce, and coleslaw with salad dressing. Addition of fats and oils to mixed dishes is a significant source of vitamin K_1 (125). The panel on DRIs for vitamin K estimated the median intakes of vitamin K_1 for men and women to be 89 to 117 μg and 79 to 88 μg per day, respectively (1). Data from the Third National Health and Nutrition Examination Survey (NHANES III) (43) were used to estimate the intakes.

12 Fundamental Characteristics of Water

Chung Chieh
Department of Chemistry, University of Waterloo

CONTENTS

I. INTRODUCTION

Water, a natural occurring and abundant substance that exists in solid, liquid, and gas forms on the planet Earth, has attracted the attention of artists, engineers, poets, writers, philosophers, environmentalists, scientists, and politicians. Every aspect of life involves water as food, as a medium in which to live, or as the essential ingredient of life. The food science aspects of water range from agriculture, aquaculture, biology, biochemistry, cookery, microbiology, nutrition, photosynthesis, power generation, to zoology. Even in the narrow sense of food technology, water is intimately involved in the production, washing, preparation, manufacture, cooling, drying, and hydration of food. Water is eaten, absorbed, transported, and utilized by cells. Facts and data about water are abundant and diverse. This chapter can only selectively present some fundamental characteristics of water molecules and their collective properties for readers when they ponder food science at the molecular level.

The physics and chemistry of water are the backbone of engineering and sciences. The basic data for the properties of pure water, which are found in the CRC Handbook of Chemistry and Physics (1), are useful for food scientists. However, water is a universal solvent, and natural waters contain dissolved substances present in the

environment. All solutes in the dilute solutions modify the water properties. Lang's Handbook of Chemistry (2) gives solubility of various gases and salts in water. Water usage in the food processing industry is briefly described in the Nalco Water Handbook (3). For water supplies and treatments, the Civil Engineering Handbook (4) provides practical guides. The Handbook of Drinking Water Quality (5) sets guidelines for waters used in food services and technologies. Wastewater from the food industry needs treatment, and the technology is usually dealt with in industrial chemistry (6). Most fresh food contains large amounts of water. Modifying the water content of foodstuffs to extend storage life and enhance quality is an important and widely used process (7).

A very broad view and deep insight on water can be found in "Water – A Matrix of Life" (8). Research leading to our present-day understanding of water has been reviewed in the series "Water – A Comprehensive Treatise" (9). The interaction of water with proteins (10, 11) is a topic in life science and food science. Water is the elixir of life and H_2O is a biomolecule.

II. WATER AND FOOD TECHNOLOGY

Water is an essential component of food (12). Philosophical conjectures abound as to how Earth evolved to provide the mantle, crust, atmosphere, hydrosphere, and life. Debates continue, but some scientists believe that primitive forms of life began to form in water (13). Complicated life forms developed, and their numbers grew. Evolution produced anaerobic, aerobic, and photosynthetic organisms. The existence of abundant life forms enabled parasites to appear and utilize plants and other organisms. From water all life began (14). Homo sapiens are integral parts of the environment, and constant exchange of water unites our internal space with the environment.

The proper amount of water is also the key to sustaining and maintaining a healthy life. Water transports nutrients and metabolic products throughout the body to balance cell contents and requirements. Water maintains biological activities of proteins, nucleotides, and carbohydrates, and participates in hydrolyses, condensations, and chemical reactions that are vital for life (15). On average, an adult consumes 2 to 3 L of water: 1–2 L as fluid, 1 L ingested with food, and 0.3 L from metabolism. Water is excreted via the kidney, skin, lung, and anus (16). The amount of water passing through us in our lifetimes is staggering.

Aside from minute amounts of minerals, food consists of plant and animal parts. Water is required for cultivating, processing, manufacturing, washing, cooking, and digesting food. During or after eating, a drink, which consists of mostly water, is a must to hydrate or digest the food. Furthermore, water is required in the metabolic process.

Cells and living organisms require, contain, and maintain a balance of water. An imbalance of water due to freezing, dehydration, exercise, overheating, etc. leads to the death of cells and eventually the whole body. Dehydration kills far more quickly than starvation. In the human body, water provides a medium for the transportation, digestion, and metabolism of food in addition to many other physiological functions such as body temperature regulation (17).

Two thirds of the body mass is water, and in most soft tissues, the contents can be as high as 99% (16). Water molecules interact with biomolecules intimately (9); they are part of us. Functions of water and biomolecules collectively manifest life. Water is also required for running households, making industrial goods, and generating electric power.

Water has shaped the landscape of Earth for trillions of years, and it covers 70% of the Earth's surface. Yet, for food production and technology it is a precious commodity. Problems with water supply can lead to disaster (5). Few brave souls accept the challenge to stay in areas with little rainfall. Yet, rainfall can be a blessing or a curse depending on the timing and amount. Praying for timely and bountiful rainfall used to be performed by emperors and politicians, but water for food challenges scientists and engineers today.

III. WATER MOLECULES AND THEIR MICROSCOPIC PROPERTIES

Plato hypothesized four *primal substances*: water, fire, earth, and air. His doctrine suggested that a combination and permutation of various amounts of these four *primal substances* produced all the materials of the world. Scholars followed this doctrine for 2000 years, until it could not explain experimental results. The search of fundamental substances led to the discovery of hydrogen, oxygen, nitrogen, etc., as chemical elements. Water is made up of hydrogen (H) and oxygen (O). Chemists use H_2O as the universal symbol for water. The molecular formula, H_2O, implies that a water molecule consists of two H atoms and one O atom. However, many people are confused by its other chemical names such as hydrogen oxide, dihydrogen oxide, dihydrogen monoxide, etc.

A. Isotopic Composition of Water

The discoveries of electrons, radioactivity, protons, and neutrons implied the existence of isotopes. Natural isotopes for all elements have been identified. Three isotopes of hydrogen are protium (^1H), deuterium (D, ^2D or ^2H), and radioactive tritium (T, ^3T or ^3H), and the three stable oxygen isotopes are ^{16}O, ^{17}O, and ^{18}O. The masses and abundances of these isotopes are given in Table 12.1. For radioactive isotopes, the half-lives are given.

Random combination of these isotopes gives rise to the various isotopic water molecules, the most abundant

TABLE 12.1
Isotopes of Hydrogen and Oxygen, and Isotopic Water Molecules Molar Mass (amu), Relative Abundance (%) or Half Life

Isotopes of Hydrogen			Stable Isotopes of Oxygen		
^{1}H	^{2}D	^{3}T	^{16}O	^{17}O	^{18}O
1.007825	2.00141018	3.0160493	15.9949146	16.9991315	17.9991604
99.985%	0.015%	12.33 years	99.762%	0.038%	0.200%

Isotopic water molecules molar mass (amu) and relative abundance (%, ppm or trace)

$H_2{}^{16}O$	$H_2{}^{18}O$	$H_2{}^{17}O$	$HD^{16}O$	$D_2{}^{16}O$	$HT^{16}O$
18.010564	20.014810	19.014781	19.00415	19.997737	20.018789
99.78%	0.20%	0.03%	0.0149%	0.022 ppm	trace

one being $^{1}H_2{}^{16}O$ (99.78%, its mass is 18.010564 atomic mass units (amu)). Water molecules with molecular masses about 19 and 20 are present at some fractions of a percent. Although $HD^{16}O$ (0.0149%) is much more abundant than $D_2{}^{16}O$ (heavy water, 0.022 part per million), D_2O can be concentrated and extracted from water. In the extraction process, HDO molecules are converted to D_2O due to isotopic exchange. Rather pure heavy water (D_2O) is produced on an industrial scale especially for its application in nuclear technology, which provides energy for the food industry.

A typical mass spectrum for water shows only mass-over-charge ratios of 18 and 17, respectively, for H_2O^+ and OH^+ ions in the gas phase. Other species are too weak for detection, partly due to condensation of water in mass spectrometers.

The isotopic composition of water depends on its source and age. Its study is linked to other sciences (18). For the isotopic analysis of hydrogen in water, the hydrogen is reduced to a hydrogen gas and then the mass spectrum of the gas is analyzed. For isotopes of oxygen, usually the oxygen in H_2O is allowed to exchange with CO_2, and then the isotopes of the CO_2 are analyzed. These analyses are performed on archeological food remains and unusual food samples in order to learn their origin, age, and history.

B. Structure and Bonding of Water Molecules

Chemical bonding is a force that binds atoms into a molecule. Thus, chemists use H-O-H or HOH to represent the bonding in water. Furthermore, spectroscopic studies revealed the H–O–H bond angle to be 104.5° and the H–O bond length to be 96 picometers (pm = 10^{-12} m) for gas H_2O molecules (19). For solid and liquid, the values depend on the temperature and states of water. The bond length and bond angles are fundamental properties of a molecule. However, due to the vibration and rotational motions of the molecule, the measured values are average or equilibrium bond lengths and angles.

The mean van der Waals diameter of water has been reported as nearly identical with that of isoelectronic neon (282 pm). Some imaginary models of the water molecule are shown in Figure 12.1.

An isolated water molecule is hardly static. It constantly undergoes a vibration motion that can be a combination of any or all of the three principal modes: symmetric stretching, asymmetric stretching, and bending (or deformation). These vibration modes are indicated in Figure 12.2.

Absorption of light (photons) excites water molecules to higher energy levels. Absorption of photons in the

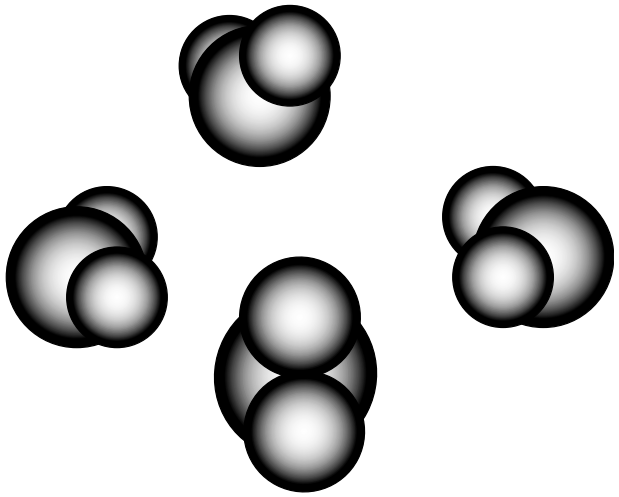

FIGURE 12.1 Some imaginative models of water molecules.

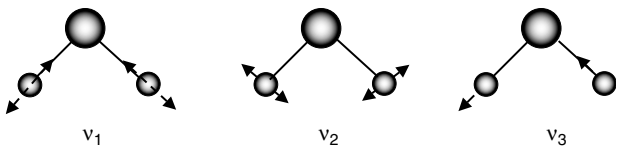

FIGURE 12.2 The three principal vibration modes of the water molecule, H_2O: ν_1, symmetric stretching; ν_2, bending; and ν_3, asymmetric stretching.

infrared (IR) region excites the vibration motion. Photons exciting the symmetric stretching, bending, and asymmetric stretching to the next higher energy levels have wave numbers 3656, 1594, and 3756 cm^{-1}, respectively, for H_2O (20). These values and those for other water molecules involving only ^{16}O are given in Table 12.2.

The spectrum of water depends on temperature and density of the gaseous H_2O. A typical IR spectrum for the excitation of only the fundamental vibration modes consists of three peaks around 1594, 3656, and 3756 cm^{-1}. Additional peaks due to excitation to mixed modes appear at higher wave numbers.

Rotating the H_2O molecule around the line bisecting the HOH angle by 180° (360°/2) results in the same figure. Thus, the molecules have a 2-fold rotation axis. There are two mirror planes of symmetry as well. The 2-fold rotation and mirror planes give the water molecules the symmetry point group C_{2v}.

Rutherford's alpha scattering experiment in 1909 showed that almost all atomic mass is in a very small atomic nucleus. In a neutral atom the number of protons in the nucleus is the same as the number of electrons around the nucleus. A proton and an electron have the same amount, but different kinds of charge. Electrons occupy nearly all of the atomic volume, because the radius of an atom is 100,000 times that of the nucleus.

Electrons, in quantum mechanical view, are waves confined in atoms, and they exist in several energy states called orbitals. Electrons in atoms and molecules do not have fixed locations or orbits. Electron states in an element are called electronic configurations, and their designation for H and O are $1s^1$, and $1s^2 2s^2 2p^4$, respectively. The superscripts indicate the number of electrons in the orbitals 1*s*, 2*s*, or 2*p*. The electronic configuration for the inert helium (He) is $1s^2$, and $1s^2$ is a stable core of electrons. Bonding or valence electrons are $1s^1$ and $2s^2 2p^4$ for H and O, respectively.

The valence bond approach blends one 2*s* and three 2*p* orbitals into four bonding orbitals, two of which accommodate two electron pairs. The other two orbitals have only one electron each, and they accommodate electrons of the H atoms bonded to O, thus forming the two H–O bonds. An electron pair around each H atom and four electron pairs around the O atom contribute stable electronic configurations for H and O, respectively. The Lewis dot-structure, Figure 12.3, represents this simple view. The two bonding and two lone pairs are asymmetrically distributed with major portions pointing to the vertices of a slightly distorted tetrahedron in 3-dimensional space. The two lone pairs mark slightly negative sites and the two H atoms are slightly positive. This charge distribution around a water molecule is very important in terms of its microscopic, macroscopic, chemical, and physical properties described later. Of course, the study of water continues and so does the evolution of bonding theories. Moreover, the distribution of electrons in a single water molecule is different from those of dimers, clusters, and bulk water.

The asymmetric distribution of H atoms and electrons around the O atom results in positive and negative sites in the water molecule. Thus, water consists of polar molecules.

The **dipole moment, μ**, is a measure of polarity and a useful concept. A pair of opposite charge, *q*, separated by a distance, *d*, has a dipole moment of $\mu = d\ q$ with the direction pointing towards the positive charge as shown in Figure 12.4.

The dipole moment of individual water molecules is 6.187×10^{-30} C m (or 1.855 D) (21). This quantity is the vector resultant of two dipole moments due to the O–H bonds. The bond angle H–O–H of water is 104.5°. Thus, the dipole moment of an O–H bond is 5.053×10^{-30} cm. The bond length between H and O is 0.10 nm, and the

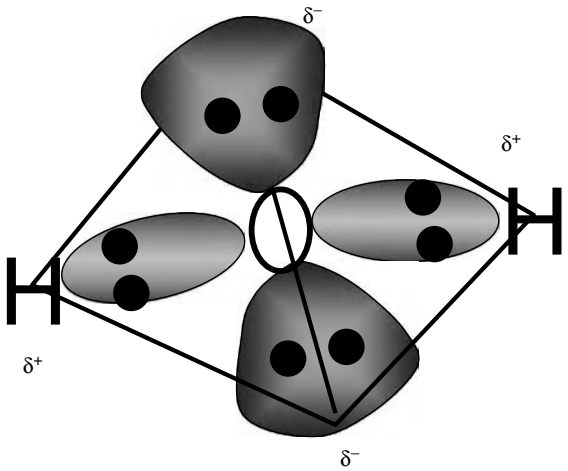

FIGURE 12.3 A tetrahedral arrangement of the Lewis dot-structure and charge distribution of the H_2O molecule.

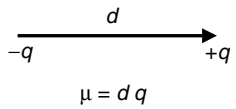

FIGURE 12.4 Separation of a positive and a negative charge *q* at a distance *d* results in a dipole, $\mu = d\ q$.

partial charge at the O and the H is therefore $q = 5.053 \times 10^{-20}$ C, 32% of the charge of an electron (1.6022×10^{-19} C). Of course, the dipole moment may also be considered as separation of the electron and positive charge by a distance 0.031 nm.

It should be pointed out that the dipole moments of liquid and solid water appear to be higher due to the influence of neighboring molecules. For the liquid and solid, macroscopic properties need be considered.

C. Hydrogen Bonds

Attraction among water molecules is more than polar-polar in nature. The O atoms are small and very electronegative. As a result, the positive H atoms (protons) are very attractive to the negative O atoms of neighboring molecules. This O- - -H – O strong attraction is called a **hydrogen bond**, a concept popularized by L. Pauling (22). Furthermore, hydrogen atoms bonded to atoms of N and F, neighboring elements of O in the periodic table, are positive, and they form hydrogen bonds with atoms of N, O, or F. The strength of hydrogen bonds depends on the X–H - - - Y (X or Y are N, O, or F atoms) distances and angles; the shorter the distances, the stronger are the hydrogen bonds.

When two isolated water molecules approach each other, a dimer is formed due to hydrogen bonding. The dimer may have one or two hydrogen bonds (Figure 12.5). Dimers exist in gaseous and liquid water. When more water molecules are in close proximity, they form trimmers, tetramers and clusters. Hydrogen bonds are not static, they exchange protons and partners constantly. Hydrogen bonding is a prominent feature in the structures of various solid phases of water usually called ice as we shall see later.

Water molecules not only form hydrogen bonds among themselves, they form hydrogen bonds with any molecule that contains N–H, O–H, and F–H bonds. Foodstuffs such as starch, cellulose, sugars, proteins, DNA, and alkaloids contain N–H and O–H groups, and these are both H-donors and H-acceptors of hydrogen bonds of the type N- - H–O, O- -H–N, N- -H–N, etc. A dimer depicting the hydrogen bond and the van der Waals sphere of two molecules is shown in Figure 12.6 (23).

Carbohydrates (starch, cellulose and sugars) contain H–C–O–H groups. The O–H groups are similar to those of water molecules, and they are H-acceptors and H-donors for hydrogen bonds. Proteins contain O–H, R–NH_2 or $R_2 >$ NH groups, and the O–H and N–H groups are both H-donors and H-acceptors for the formation of hydrogen bonds. Thus, water molecules have intimate interactions with carbohydrates and proteins.

IV. MACROSCOPIC PROPERTIES OF WATER

Collectively, water molecules exist as gas, liquid, or solid depending on the temperature and pressure. These **phases** of water exhibit collective or macroscopic properties such as phase transitions, crystal structures, liquid structures, vapor pressures, and volume-pressure relationships of vapor. In addition, energies or enthalpies for melting, vaporization, and heating are also important for applications in food technology.

Thermodynamic constants for phase transitions given in Table 12.3 are those of pure water. Natural waters, of course, contain dissolved air, carbon dioxide, organic substances, microorganisms, and minerals. Water in food or used during food processing usually contains various organic and inorganic substances. These solutes modify the properties of water and caution should be taken to ensure proper values are applied in food technology.

The triple point of water defines the temperature of 273.16 K in the SI unit system. The division of 1/2 73.16 in thermodynamic temperature scale is approximately 1°C.

Water has many unusual properties due to its ability to form hydrogen bonds and its large dipole moment. As a result, the melting, boiling, and critical points for water are very high compared to substances of similar molar masses. In general, the higher the molar masses, the higher are the melting and boiling points of the material. Associated with these properties are its very large heat of melting, heat capacity, heat of vaporization, and heat of sublimation. Moreover, its surface tension and viscosity are also very large. Thermodynamic energies and volume changes for phase transitions of H_2O are summarized in Table 12.3. These data are mostly taken from the Encyclopedia of Chemical Technology, Vol. 25 (1991) (24).

A. Crystal Structures and Properties of Ice

Hydrogen bonding is prominent in the crystal structures of various solid phases of H_2O. The triple point of water is at 273.16 K and 4.58 torr (611 Pa). The melting point at 1.00 atm (760 torr or 101.325 kPa) is 273.15 K in the Kelvin scale. When water freezes at these temperatures and atmospheric pressure or lower, the solids are hexagonal ice crystals usually designated as I_h. Properties of I_h are given in Table 12.4. Snowflakes have many shapes because their growth habit depends on temperature and vapor pressure, but they all exhibit hexagonal symmetry, due to the hexagonal structure of ice (25).

However, from a geometric point of view, the same bonding may also be arranged to have cubic symmetry. The existence of cubic ice has been confirmed. When water vapor deposits onto a very cold, 130–150 K surface or when small droplets are cold under low pressure at high altitude, the ice has a cubic symmetry usually designated as I_c. At still higher pressures, different crystal forms designated as ice II, III, IV, … etc., up to 13 phases of cubic, hexagonal, tetragonal, monoclinic, and orthorhombic symmetries have been identified (26). The polymorphism of solid water is very complicated. Some of these ice forms are made under very high pressures, and water crystallizes into solid at temperatures above the normal melting or even boiling temperatures. Ice VII is formed above 10 G Pa (gigapascal) at 700 K (26).

When liquid water is frozen rapidly, the molecules have little chance of arranging into crystalline ice. The frozen liquid is called **amorphous ice** or **glassy ice**.

The basic relationships between nearest neighboring water molecules are the same in both I_h and I_c. All O atoms are bonded to four other O atoms by hydrogen bonds, which extend from an oxygen atom towards the vertices of a tetrahedron. A sketch of the crystal structure of hexagonal I_h is shown in Figure 12.7 (27). In I_h, hydrogen positions are somewhat random due to thermal motion, disorder, and exchanges. For example, the hydrogen may shift between locations to form H_3O^+ and OH^- ions dynamically throughout the structure. In this structure, bond angles or hydrogen-bond angles around oxygen atoms are those of the idealized tetrahedral arrangement of 109.5° rather than 104.5° observed for isolated molecules. Formation of the

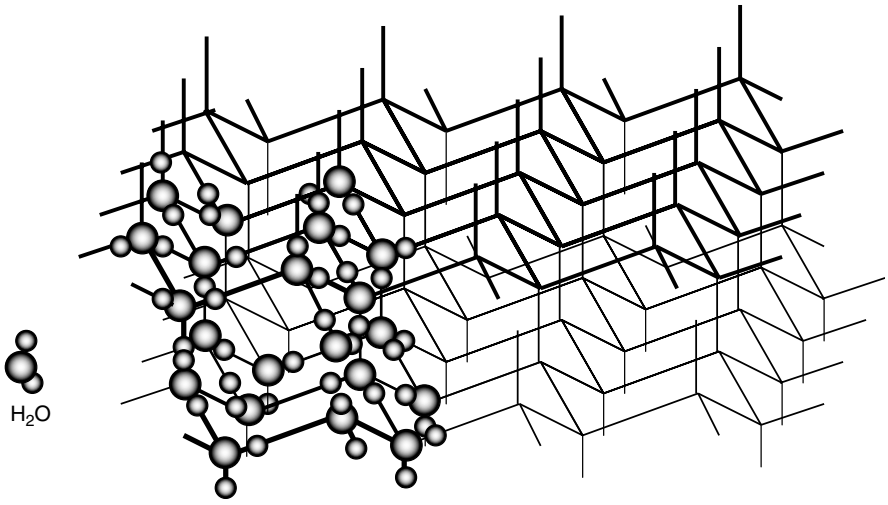

FIGURE 12.7 Ordered crystal structure of ice, bond distance: O–H, 100 pm; H- - -O, 175 pm; and O–H- - -O, 275 pm.

hydrogen bond in ice lengthens the O–H bond distance, 100 pm compared to 96 pm in a single water molecule. The diagram illustrates a crystal structure that is completely hydrogen bonded, except for the molecules at the surface.

Each O atom of hexagonal ice I_h is surrounded by four almost linear O–H - - O hydrogen bonds of length 275 pm, in a tetrahedral fashion. Each C atom of cubic diamond is also surrounded by four C–C covalent bonds of length 154 pm. Thus, the tetrahedral coordination can either be cubic or hexagonal, from a geometrical viewpoint. Indeed, the uncommon cubic ice and hexagonal diamond have been observed, giving a close relationship in terms of spatial arrangement of atoms between ice and diamond (26). Strong hydrogen bonds make ice hard, but brittle. The structure is related to its physical properties, which vary with temperature.

The pressure of H_2O vapor in equilibrium with ice is called the **vapor pressure of ice**, which decreases as the temperature decreases. At the triple point or 0°C, the pressure is 611.15 Pa. When ice is slightly overheated to 0.01°C, the pressure increases to 611.657 Pa. However, at this temperature, the vapor pressure of liquid water is lower. The vapor pressures of ice between 0°C and – 40°C are listed in Table 12.5 at 1°C interval. Various models can be used to estimate the vapor pressure at other temperatures. One method uses the Clausius-Clapeyron differential equation

$$\frac{dp}{dT} = \frac{H}{T\,\Delta V}$$

where p is the pressure, T is the temperature (K), H is the latent heat or **enthalpy** of phase transition, and ΔV is the difference in volume of the phases. The enthalpy of sublimation for ice depends on the temperature. At the freezing point, the enthalpy of sublimation for ice is 51 (51.06 in Table 12.3) kJ mol^{-1}, estimated from the vapor pressure at 0 and –1°C. The enthalpy of sublimation is required to overcome hydrogen bonding, dipole, and intermolecular attractions. The energy required in freeze-drying processes varies, depending on temperature and other conditions. Water in solutions and in food freezes below 0°C.

The number of hydrogen bonds is twice the number of water molecules, when surface water molecules are ignored. The energy required to separate water molecules from the solid is the enthalpy of sublimation (55.71 J mol^{-1}). Half of this value, 26 kJ mol^{-1}, is the energy to separate the H- -O linkages, and it translates into 0.26 eV, per H- -O bond. These values are close to those obtained by other means (25, 26, 28–30). Several factors contribute to this linkage, and the hydrogen-bond energy is less than 0.26 eV.

B. Properties of Liquid Water

The macroscopic physical properties of this common but eccentric fluid at 298 K (25°C) are given in Table 12.6. Water has unusually high melting and boiling points for a substance of molar mass of only 18 daltons. Strong hydrogen bonds and high polarity account for this.

The heat of formation is the energy released when a mole of hydrogen and half a mole of oxygen at 298 K and 1.00 atm react to give one mole of water at 298 K. This value differs from that for ice in Table 12.4 due to both temperature and phase differences. As temperature increases, the average kinetic energy of molecules increases, and this affects water's physical properties. For example, surface tension of water decreases, whereas the thermal conductance increases as the temperature increases. Heat capacity at constant pressure (C_p), vapor pressure, viscosity, thermal conductance, dielectric constant, and surface tension in the temperature range 273–373 K (0–100°C) are given in Table 12.7.

Liquid water has the largest heat capacity per unit mass of all substances. Large quantities of energy are absorbed or released when its temperature changes. The large heat capacity makes water an excellent reservoir and transporter of energy. A large body of water moderates climate. The heat capacity C_p of water varies between 4.1 to

More detailed data can be found in the CRC Handbook of Chemistry and Physics (1).

4.2 J g^{-1} K^{-1} (74 to 76 J mol^{-1} K^{-1}) even at temperature above 100°C and high pressure. The enthalpy of vaporization for water is also very large (55.71 kJ mol^{-1} at 298 K). Thus, energy consumption is high for food processing when water is involved.

Water and aqueous solutions containing only low molar-mass solutes are typical Newtonian fluids for which the **shear stress** is proportional to **shear strain rate**. Viscosity is the ratio of shear stress to shear strain rate. On the other hand, viscosity of solutions containing high molar-mass substances depends on shear strain rate. For pure water, the viscosity decreases from 1.793 to 0.282 mPa s (millipascal seconds; identical to centipoise (cp)) as temperature increases from 0 to 100°C. Thus, the flow rate through pipes increases as water or solution temperature increases.

The dielectric constant of water is very large, and this enables water to separate ions of electrolytes, because it reduces the electrostatic attraction between positive and negative ions. Many salts dissolve in water. When an electric field is applied to water, its dipole molecules orient themselves to decrease the field strength. Thus, its dielectric constant is very large. The dielectric constant decreases as temperature increases, because the percentage of molecules involved in hydrogen bonding and the degree of order decrease (28, 29). The measured dielectric constant also depends on the frequency of the applied electric field used in the measurement, but the variation is small when the frequency of the electric field is less than 100 MHz. The dielectric behavior of water allows water vapor pressure to be sensed by capacitance changes when moisture is absorbed by a substance that lies between the plates of a capacitor. These sensors have been developed for water activity measurement (31).

The light absorption coefficients are high in the infrared and ultraviolet regions, but very low in the visible region. Thus, water is transparent to human vision.

The variation of vapor pressure as a function of temperature is the bases for defining **water activities** of food. Liquid water exists between the triple-point and the critical-point temperatures (0–373.98°C) at pressures above the vapor pressures in this range.

As with ice, the vapor pressure of liquid water increases as the temperature increases. Vapor pressures of water (in kPa instead of Pa for ice in Table 12.5) between the triple and critical points, at 10°C interval, are given in Table 12.8. When the vapor pressure is 1.00 atm (101.32 kPa) the temperature is the boiling point (100°C). At slightly below 221°C, the vapor pressure is 2.00 atm. The critical pressure at the critical temperature, 373.98°C, is 217.67 atm (22,055 kPa). Above this temperature, water cannot be liquefied, and the phase is called **supercritical water**.

The partial pressure of H_2O in the air at any temperature is the **absolute humidity**. When the air is saturated with water vapor, the **relative humidity** is 100%. The unsaturated vapor pressure divided by the vapor pressure of water as given in Table 12.8 at the temperature of the air is the **relative humidity**. The temperature at which the vapor pressure in the air becomes saturated is the **dew point**, at which dew begins to form. However, when the dew point is below 273 K or 0°C, ice crystals (frost) begin to form. Thus, the relative humidity can be measured by finding the dew point. Dividing the vapor pressure at the dew point by the vapor pressure of water at the temperature of the air gives the relative humidity. The transformations between solid, liquid, and gaseous water play important roles in hydrology and in the transformation of the environment on Earth. Phase transitions of water combined with the energy from the sun make the weather.

Density is a collective property, and it varies with temperature, isotopic composition, purity, etc. The International Union of Pure and Applied Chemistry (IUPAC) has adopted the density of pure water from the ocean as the density standard. The isotopic composition of ordinary water is constant, and the density of pure water between 0 and 39°C extracted from (32) is given in Table 12.9.

The density of cage-like ice I_h, due to 100% of its molecules involved in hydrogen-bonded is only 9% lower than that of water. This indicates that water has a high percentage of molecules involved in the transient and dynamic hydrogen bonding. The percentage of hydrogen-bonded water molecules in water decreases as temperature increases, causing water density to increase. As temperature increases, the thermal expansion causes its density to decreases. The two effects cause water density to increase from 0 to 3.98°C, reaching its maximum of 1.0000 g mL^{-1} and then decrease as temperature increases.

Incidentally, at 8°C, the density of water is about the same as that at 0°C. At 25°C, the density decreases 0.3% with respect to its maximum density, whereas at 100°C, it decreases by 4%. Dense water sinks, and convection takes place when temperature fluctuates at the surface of lakes and ponds, bringing dissolved air and nutrients to various depths of waters for the organism living in them. On the other hand, the pattern of density dependence on temperature of water makes temperatures at the bottoms of lakes and oceans vary little if the water is undisturbed. When water freezes, ice begins to form at the surface, leaving the water at some depth undisturbed. Water at the bottom remains at 4°C, preserving various creatures living in water.

When hydrogen bonded to tissues and cells or in food, water has a unique order and structure, and the vapor pressure and density differ from those of pure water. Yet, the collective behavior of water molecules sheds some light regarding their properties in food, cells, tissues, and solutions.

V. CHEMICAL PROPERTIES OF WATER

Water is a chemical as is any substance, despite the confusion and distrust of the public regarding the term "chemical." Thus, water has lots of interesting chemical properties. It interacts intimately with components of food particularly as a solvent, due to its dipole moment and its tendency to form a hydrogen bond. These interactions affect the chemical properties of nutrients, including their tendency to undergo oxidation or reduction, to act as acids or bases, and to ionize.

A. Water as a Universal Solvent

Water is dubbed a universal solvent because it dissolves many substances due to strong interactions between water molecules and those of other substances. Entropy is another driving force for a liquid to dissolve or mix with other substances. Mixing increases disorder or entropy.

1. Hydrophobic Effect and Hydrophilic Effect

Because of its large dielectric constant, high dipole moment and ability to donate and accept protons for hydrogen bonding, water is an excellent solvent for polar substances and electrolytes, which consist of ions. Molecules strongly interact with water-loving molecules are **hydrophilic**, due to hydrogen bonding, polar-ionic or polar-polar attractions. Nonpolar molecules that do not mix with water are **hydrophobic** or **lipophilic**, because they tend to dissolve in oil. Large molecules such as proteins and fatty acids that have hydrophilic and hydrophobic portions are **amphipathic** or **amphiphilic**. Water molecules strongly intermingle with hydrophilic portions by means of dipole-dipole interaction or hydrogen bonding.

The lack of strong interactions between water molecules and lipophilic molecules or the nonpolar portions of amphipathic molecules is called the **hydrophobic effect**, a term coined by Charles Tanford (33). Instead of a direct interaction with such solutes, water molecules tend to form hydrogen-bonded cages around small nonpolar molecules when the latter are dispersed into water. Hydrogen-bonded water molecules form cages, called **hydrates** or **clathrates**. For example, the clathrate of methane forms stable crystals at low temperatures (34).

Nonpolar chains in proteins prefer to stay together as they avoid contact with water molecules. Hydrophilic and hydrophobic effects play important roles in the stability and state of large molecules such as enzymes, proteins, and lipids. Hydrophobic portions of these molecules stay together, forming pockets in globular proteins. Hydrophilic and hydrophobic effects cause nonpolar portions of phospholipids, proteins, and cholesterol to assemble into bilayers or biological membranes (34).

2. Hydration of Ions

Due to its high dielectric constant, water reduces the attractions among positive and negative ions of electrolytes and dissolves them. The polar water molecules coordinate around ions forming hydrated ions such as $Na(H_2O)_6^+$, $Ca(H_2O)_8^{2+}$, $Al(H_2O)_6^{3+}$, etc. Six to eight water molecules form the first sphere of hydration around these ions. Figure 12.8 is a sketch of the interactions of water molecules with ions. The water molecules point the negative ends of their dipoles towards positive ions, and their positive ends towards negative ions. Molecules in the hydration sphere constantly and dynamically exchange with those around them. The number of hydrated-water molecules and their lifetimes have been studied by various methods. These studies reveal that the hydration sphere is one-layer deep, and the lifetimes of these hydrated-water molecules are in the order of picoseconds (10^{-12} s). The larger negative ions also interact with the polar water molecules, not as strong as those of cations. The presence of ions in the solution changes the ordering of molecules even if they are not in the first hydration sphere (9).

The hydration of ions releases energy, but breaking up ions from a solid requires energy. The amount of energy depends on the substance, and for this reason, some are more soluble than others. Natural waters in the ocean, streams, rivers and lakes are in contact with minerals and salts. The concentrations of various ions depend on the solubility of salts (35) and the contact time.

Drinking water includes all waters used in growth, processing, and manufacturing of food. J. De Zuane divides ions in natural water into four types in The Handbook on Drinking Water Quality (5).

Type A includes arsenic, barium, cadmium, chromium, copper, fluoride, mercury, nitrate, nitrite, and selenium ions. They are highly toxic, yet abundant.

Type B includes aluminum, nickel, sodium, cyanide, silver, zinc, molybdenum, and sulfate ions. Their concentrations are also high, but they are not very toxic.

Type C consists of calcium, carbonate, chloride, iron, lithium, magnesium, manganese, oxygen, phosphate, potassium, silica, bromine, chlorine, iodine, and ozone. They are usually present at reasonable levels.

Type D ions are present usually at low levels: antimony, beryllium, cobalt, tin, thorium, vanadium, and thallium.

Most metals are usually present in water as cations, with a few as anions. However, some chemical analyses may not distinguish their state in water. The most common anions are chloride, sulfate, carbonate, bicarbonate, phosphate, bromide, iodide, etc. Toxicity is a concern for ions in water, but some of these ions are essential for humans.

Pure water has a very low electric conductivity, but ions in solutions move in an electric field making electrolyte solutions highly conductive. The conductivity is related to total dissolved solids (TDS), salts of carbonate, bicarbonate, chloride, sulfate, and nitrate. Sodium, potassium, calcium, and magnesium ions are often present in natural waters because their soluble salts are common minerals in the environment. The solubilities of clay (alumina), silicates, and most common minerals in the Earth's crust, are low.

3. Hard Waters and Their Treatments

Waters containing plenty of dissolved CO_2 (H_2CO_3) are acidic and they dissolve $CaCO_3$ and $MgCO_3$. Waters with dissolved Ca^{2+}, Mg^{2+}, HCO_3^-, and CO_3^{2-} are called **temporary hard waters** as the hardness can be removed by boiling, which reduces the solubility of CO_2. When CO_2 is driven off, the solution becomes less acidic due to

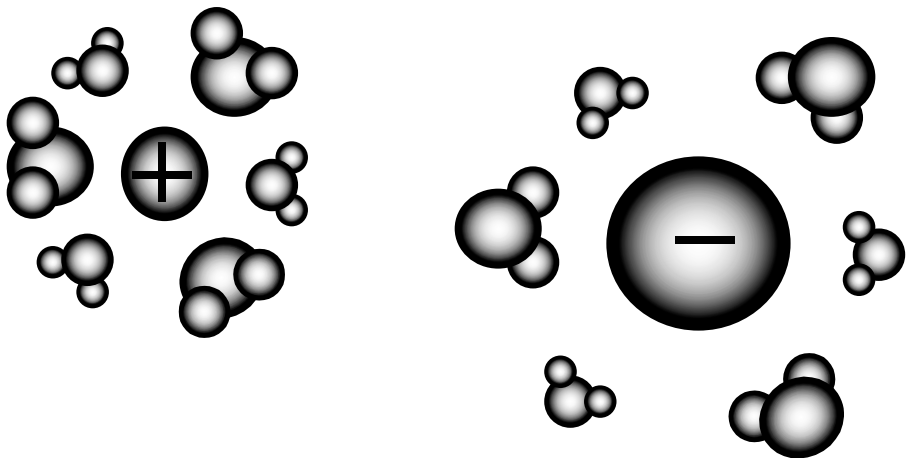

FIGURE 12.8 The first hydration sphere of most cations $M(H_2O)_6^+$, and anions $X(H_2O)_6^{-1}$. Small water molecules are below the plane containing the ions, and large water molecules are above the plane.

the following equilibria (the double arrows, ⇆, indicate reversible reactions):

$$H^+ (aq) + HCO_3^- (aq) \leftrightarrows H_2CO_3 (aq) \leftrightarrows H_2O + CO_2 (g)$$

$$HCO_3^- (aq) \leftrightarrows H^+ (aq) + CO_3^{2-} (aq)$$

Reducing the acidity increases the concentration of CO_3^{2-} and solids $CaCO_3$ and $MgCO_3$ precipitate:

$$Ca^{2+} (aq) + CO_3^{2-} (aq) \leftrightarrows CaCO_3 (s)$$

$$Mg^{2+} (aq) + CO_3^{2-} (aq) \leftrightarrows MgCO_3 (s)$$

Water containing less than 50 mg L^{-1} of these substances is considered soft; 50–150 mg L^{-1} moderately hard; 150–300 mg L^{-1} hard; and more than 300 mg L^{-1} very hard.

For the **lime treatment**, we determine the amount of dissolved Ca^{2+} and Mg^{2+} first and then add an equal number of moles of lime, $Ca(OH)_2$, to remove them by these reactions:

$$Mg^{2+} + Ca(OH)_2(s) \rightarrow Mg(OH)_2(s) + Ca^{2+}$$

$$Ca^{2+} + 2\,HCO_3^- + Ca(OH)_2(s) \rightarrow 2\,CaCO_3(s) + 2\,H_2O$$

Permanent hard waters contain sulfate (SO_4^{2-}) ions with Ca^{2+} and Mg^{2+}. Calcium ions, Ca^{2+}, of the sulfate solution can be removed by adding sodium carbonate:

$$Ca^{2+} + Na_2CO_3 \rightarrow CaCO_3\,(s) + 2\,Na^+$$

Hard waters cause scales or deposits to build up in boilers and pipes, and they are usually softened by ion exchange with resins or zeolites. In these processes, the calcium and magnesium ions are taken up by the zeolite or resin that releases sodium or hydrogen ions into the water. Reverse osmosis has also been used to soften hard water.

However, water softening replaces desirable calcium and other ions by sodium ions. Thus, soft waters are not suitable drinking waters. Incidentally, bakers use hard water because the calcium ions strengthen the gluten proteins in dough mixing. Some calcium salts are added to dough to enhance bread quality.

4. Properties of Aqueous Solutions

Waters containing dissolved substances are aqueous solutions; their physical properties differ from those of pure water. For example, at the same temperature, the H_2O vapor pressures of solutions are lower than those of pure water, resulting in **boiling point elevation** (higher), **freezing point depression** (lower), and osmotic pressure.

Concentrations can be expressed in several ways: part per million (ppm), percent, moles per liter, mole fraction, etc. The mole fraction of water is the fraction of water molecules among all molecules and ions in the system. The vapor pressure of an ideal solution, P_{solution}, is the vapor pressure of water (at a given temperature), P°_{water}, modified by the mole fraction X_{water}.

$$P_{\text{solution}} = X_{\text{water}}\, P^\circ_{\text{water}}\ (X_{\text{water}} < 1)$$

If the solute has a significant vapor pressure, P_{solute} is also modified by its mole fraction,

$$P_{\text{solute}} = X_{\text{solute}}\, P^\circ_{\text{solute}}$$

For non-ideal solutions, in which water and solute strongly interact, the formulas require modifications. A practical method is to use an **effective mole fraction** X defined by:

$$P_{\text{solution}} / P^\circ_{\text{water}} = X$$

In any case, the vapor pressures of solutions containing nonvolatile electrolytes are lower than those of pure water at their corresponding temperature.

Phase transitions take place when the vapor pressures of the two phases are the same. Because vapor pressures of solutions are lower, their melting points are lower but their boiling points are higher. The difference in temperature, ΔT, is proportional to the concentrations of all solutes, $m_{\text{all-solute}}$ (molality),

$$\Delta T = K\, m_{\text{all-solute}}$$

where K is either the molar boiling point elevation constant, K_b, or the molar freezing point depression constant K_f. For water, $K_f = 1.86$ K L kg^{-1}, and $K_b = 0.52$ K L kg^{-1}. Due to ionization of electrolytes, positive and negative ions should be treated as separate species and all species should be included in $m_{\text{all-solute}}$.

The tendency of water molecules from a dilute solution to diffuse into a more concentrated solution, through semipermeable membranes, has a measurable quantity called **osmotic pressure**, π, which is proportional to the concentration (mol per kg of water) of all dissolved species, $m_{\text{all-solute}}$ in mol kg^{-1} and temperature T in K,

$$\pi = -\, m_{\text{all-solute}}\, R\, T$$

where R is the gas constant 8.3145 J mol^{-1} K^{-1}. Water molecules diffuse from pure water ($\pi = 0$) into the solution, and the osmotic pressure is therefore given as a negative value here. Theoretically, a solution with $m_{\text{all-solute}} =$ 1.0 mol kg^{-1} of water, $\pi = -$ 2477 J kg or -2.477 kJ kg at 298 K. Note $m_{\text{all-solute}} = \Sigma m_i$ (m_i being the concentration of ion or molecule i) in the van't Hoff equation, which is often used in other literature.

Solutions having the identical osmotic pressure are isotonic. Applying more pressure to a solution to compensate for the osmotic pressure causes water molecules to diffuse through membranes, generating pure or fresh

waters. This process is called **reverse osmosis**, and it has been used to soften water or desalinate seawater, converting it to fresh water.

The lowering of vapor pressure and the osmotic pressure of solutions play important roles in hydration and dehydration of food and in living cells. Solutions containing proper concentrations of nutrients and electrolyte have been used to medically treat dehydrated patients. J.R. Cade and his coworkers applied these principles to formulate drinks for athletes; he and his coworkers were credited as the inventors of the sports drink Gaterade (36). The concept of a balanced solution for hydration became a great business decade after its invention.

B. Acidity and Alkalinity of Water

Acidity and alkalinity are also important characteristics of water due to its dynamic self-ionization equilibrium

$$H_2O\ (l) \leftrightarrows H^+ + OH^-,$$

$$K_w = [H^+][OH^-] = 1 \times 10^{-14} \text{ at 298 K and 1 atm}$$

where $[H^+]$ and $[OH^-]$ represent the molar concentrations of H^+ (or H_3O^+) and OH^- ions, respectively, and K_w is called the **ion product of water** (see tables in Refs. 1 and 36). Values of K_w under various conditions have been evaluated theoretically (37, 38). Solutions in which $[H^+] = [OH^-]$ are said to be neutral. At 298 K, for a neutral solution,

$$pH = -\log [H^+] = pOH = -\log [OH^-] = 7 \text{ (at 298 K)}$$

The H^+ ions or protons dynamically exchange with protons in other water molecules. The self-ionization and equilibrium are present in all aqueous solutions, including acid and base solutions, as well as in pure water. Water is both an acid and a base.

Strong acids such as $HClO_4$, $HClO_3$, HCl, HNO_3, and H_2SO_4 ionize completely in their solutions to give H^+ (H_3O^+) ions and anions: ClO_4^-, ClO_3^-, Cl^-, NO_3^-, and HSO_4^-, respectively. Strong bases such as NaOH, KOH, and $Ca(OH)_2$ also ionize completely giving OH^- ions and Na^+, K^+, and Ca^{2+} ions, respectively. In an acidic solution, $[H^+]$ is greater than $[OH^-]$. In a 1.0 mol L^{-1} HCl solution, $[H^+] = 1.0$ mol L^{-1}, pH = 0.

Weak acids such as formic acid HCOOH, acetic acid (CH_3COOH), ascorbic acid ($C_6H_8O_6$), oxalic acid ($H_2C_2O_4$), carbonic acid (H_2CO_3), benzoic acid (C_6H_5-COOH), malic acid ($C_4H_6O_5$), lactic acid H_3CCH-(OH)COOH, and phosphoric acid (H_3PO_4) also ionize in their aqueous solutions, but not completely. The ionization of acetic acid is represented by the equilibrium

$$CH_3COOH\ (aq) \leftrightarrows H^+\ (aq) + CH_3COO^-\ (aq),$$

$$K_a = 1.75 \times 10^{-5} \text{ at 298 K}$$

where K_a is the **acid dissociation constant**.

The solubility of CO_2 in water increases with its (CO_2 partial) pressure, according to Henry's law, and the chemical equilibria for the dissolution are

$$H_2O + CO_2\ (g) \leftrightarrows H_2CO_3\ (aq)$$

Of course, H_2CO_3 dynamically exchanges H^+ and H_2O with other water molecules, and this weak diprotic acid ionizes in two stages with their acid constants, K_{a1} and K_{a2}.

$$H_2O + CO_2\ (aq) \leftrightarrows H^+\ (aq) + HCO_3^-\ (aq),$$

$$K_{a1} = 4.30 \times 10^{-7} \qquad \text{(at 298 K)}$$

$$HCO_3^-\ (aq) \leftrightarrows H^+\ (aq) + CO_3^{2-}\ (aq),$$

$$K_{a2} = 5.61 \times 10^{-11}$$

Constants K_{a1} and K_{a2} increase with temperature. At 298 K, the pH of a solution containing 0.1 mol L^{-1} H_2CO_3 is 3.7. Acidophilic organisms may grow, but most pathogenic organisms are neutrophiles and they cease growing. Soft drinks contain other acids – citric, malic, phosphoric, ascorbic acids, etc. – which lower the pH further.

Ammonia and many nitrogen-containing compounds are weak bases. The ionization equilibrium of NH_3 in water and the **base dissociation constant** K_b are

$$NH_3 + H_2O \leftrightarrows NH_4^+\ (aq) + OH^-$$

$$K_b = 1.70 \text{ x } 10^{-5} \qquad \text{at 298 K.}$$

Other weak bases react with H_2O similarly.

The ionization or dissociation constants of inorganic and organic acids and bases are extensive, and they have been tabulated in various books (39–41).

Amino acids and proteins contain acidic and basic groups. At some specific pH called the **isoelectric point**, they carry no charge, but exist as zwitterions. For example, the isoelectric point for glycine is pH = 6.00 and it exists as the zwitterion $H_2C(NH_3^+)COO^-$.

C. Oxidation-Reduction Reactions in Water

Oxidation of hydrogen by oxygen not only produces water, but also releases energy. At the standard conditions, the electrochemical half reaction equations are:

$$H_2 = 2\ H^+ + 2\ e^- \qquad E° = 0.000 \text{ V (defined)}$$

$$O_2 + 4\ H^+ + 4\ e^- = 2\ H_2O \qquad E° = 1.229 \text{ V}$$

The cell reaction and the cell potential at the standard condition for it are:

$$2\ H_2 + O_2 = 2\ H_2O \qquad \Delta E° = 1.229 \text{ V}$$

Proper setups for harvesting this energy are the goals of hydrogen-fuel-cell technology. The cell potential ΔE for non-standard conditions depends on pH and temperature. Its value is related to the energy released in the reaction. A plot of ΔE versus pH yields a Pourbaix diagram, which is useful to evaluate the stability of various species in water. Water can be a reducing or oxidizing reagent, because it offers protons or electrons. Applying a voltage to pass electrons through a chemical cell decomposes water by electrolysis.

Waters containing dissolved oxygen cause additional reactions, for example:

$$2\ H_2O + 2\ e^- = H_2 + 2\ OH^- \qquad E° = -0.828\ V$$

$$O_2 + 2\ H^+ + 2\ e^- = H_2O_2 \qquad E° = 0.682\ V$$

$$O_2 + H_2O + 2\ e^- = HO_2^- + OH^- \qquad E° = 0.076\ V$$

$$O_2 + 2\ H_2O + 2\ e^- = 4\ OH^- \qquad E° = 0.401\ V$$

At the proper conditions, a suitable chemical reaction driven by the potential takes place.

Oxidation-reduction reactions involving water usually are due to proton or electron transfer. These oxidation-reduction reactions occur for the growth, production, manufacture, digestion, and metabolism of food.

Water participates in oxidation-reduction reactions in many steps of photosynthesis, resulting in the fixation of CO_2 into biomolecules, releasing oxygen atoms of water as O_2. Engineering a new generation of plants with greater photosynthetic capacity facing lack of waters challenges geneticists (42) and botanists. We now understand photosynthesis in great detail from the studies by many scientists. Photosynthetic reactions are related to food production, but they are so complex that we can only mention them here (43).

The oxidation-reduction reactions of water cause corrosion on metal surfaces. Not only is deterioration of facilities very costly for the food industry, corrosion of pipes results in having toxic metal ions Cu^{2+} and Pb^{2+} in drinking water. The concern about lead ions in drinking water led the Environmental Protection Agency to ban the use of high-lead solders for water pipes. These reactions are electrochemical processes. Galvanic effects, high acidity, high flow rate, high water temperature, and the presence of suspended solids accelerate corrosion, as do lack of Ca^{2+} and Mg^{2+} ions in purified waters. The formation of scales protects the metal surface. However, balancing the clogging against surface protection of pipes is a complicated problem, requiring scientific testing and engineering techniques for a satisfactory solution.

D. The Hydrogen Bond and Chemical Reactions

Enzymes are mostly large protein molecules, and they are selective and specific catalysts responsible for most reactions in biological bodies. Folding of the long protein provides specific 3-dimensional selective pockets for their substrates. The pockets not only fix the substrates in position, they also weaken certain bonds to facilitate specific reactions. This is the mechanism by which enzymes select their substrates and facilitate their specific reactions.

Hydrogen bond strength is stronger in nonaqueous media than in aqueous solutions as the charge densities on the donor and acceptor atoms increase (44). Hydrogen bonds between the enzyme and its substrate can be stronger than those in an aqueous environment, thus speeding up the reaction rate even further.

The hydrolysis of peptide linkage is the reaction of a protein with water:

$$\text{R-C(=O)-NH-R}' + H_2O \rightarrow \text{R-C(=O)OH} + H_2N\text{-R}'$$

This type of reaction can be catalyzed by acids, bases, and enzymes.

VI. WATER ACTIVITY

Water is a nutrient and a component in food groups: grains, meat, dairy, fruits and vegetables. Furthermore, major nutrients such as carbohydrates, proteins, water-soluble vitamins, and minerals are hydrophilic. Even parts of fat or lipid molecules are hydrophilic, but the alkyl chains of fats and proteins experience the hydrophobic effect in an aqueous environment (45).

Foodstuffs interact with water by means of polar, hydrogen-bonding, and hydrophobic interactions. The results of these interactions change the chemical potential (properties) of water. Foodstuffs dissolve in or absorb water. Thus, water within food may be divided into bound water, affected water, and free water in the order of their interaction strength. The bound water molecules are similar to those in the first hydration sphere of ions, and those close to the first sphere are affected water molecules. Further away from the interface are free water molecules. The structure and properties of the first two types change. Interaction of water with dietary fiber is an example (46). Thus, properties of water in food are different from those of pure water.

Water molecules in both liquid and vapor phases can participate in hydration reactions. At equilibrium in a system with two or more phases, their vapor pressure or chemical potential, μ, must be equal. The chemical potential, μ, of a solution or water-containing foodstuff must be equal at a given temperature T, and

$$\mu = \mu_w + R\,T \ln (p/p_w),$$

where R is the gas constant (8.3145 J mol^{-1} K^{-1}), p is the vapor pressure of the solution or of water in foodstuff, and p_w is the vapor pressure of pure water at the same temperature. The ratio p/p_w is called the **water activity**

a_w (= p/p_w), which is related to the water chemical potential of water in solutions or in the foodstuff. For ideal solutions and for most moist foods, a_w is less than unity, $a_w < 1.0$ (31).

Both water activity and relative humidity are fractions of the vapor pressure of pure water. Methods for their measurements are the same. We have mentioned the measurement by changes in capacitance earlier. Water contents have a sigmoidal relationship with water activities, $a_w = 1.0$ for infinitely dilute solutions, $a_w > 0.7$ for dilute solutions and moist foods, and $a_w < 0.6$ for dry foods. Of course, the precise relationship depends on the material in question. In general, if the water vapor of the atmosphere surrounding the food is greater than the activity of the food, water is absorbed. Otherwise, dehydration takes place. The water activity reflects the combined effects of water-solute, water-surface, capillary, hydrophilic, and hydrophobic interactions. The water activity of a foodstuff is a vital parameter, because it affects its texture, taste, safety, shelf life, and appearance.

Furthermore, controlling water activity rather than water content is important. When $a_w < 0.9$, most molds are inhibited. Growth of yeasts and bacteria also depends on a_w. Microorganisms cease growing if $a_w < 0.6$.

VII. WATER POTENTIAL

Similar to water activity in food, **water potential** is a term used in plant, soil, and crop sciences. Water potential, represented by Ψ (psi) or Ψw, is a measure of the free energy of water in a system: soil, material, seeds, plants, roots, leaves, or an organism. Water potential is the difference between the chemical potential of pure water and water in the system at the same temperature. Pure water has the highest free energy: $\Psi = 0$ for pure water by convention, and $\Psi < 0$ for solutions. Water diffuses from high potential to low potential. Physiological processes decrease as the water potential decreases.

In general, water potential, Ψw, is a combined effect of osmotic (Ψs), matrix (interface and water binding Ψm), turgor (Ψt) pressures, and gravity (Ψg).

$$\Psi w = \Psi s + \Psi m + \Psi t + \Psi g$$

Osmotic pressure, Ψs, is always present due to solutes in the fluids. The metric pressure, Ψm, is related to bound-, affected-, and free-waters in the system. The outwardly directed pressure extended by the swelling protoplast against the wall is called **turgor pressure**, Ψt. Usually, this term is insignificant until the cell is full, and at such point, Ψt increases rapidly and stops when Ψw = Ψt. Otherwise, the cell ruptures. The mechanical rigidity of succulent plant parts, the opening of stomata and the blossom are usually the results of turgor pressure. In systems such as tall plants and soil science, pressure due to the gravitational pull of water, Ψg, is also included in the water potential.

For example, the water potential of potato tissues can be measured by incubating them in a series of solutions of known osmotic pressures. The potato will neither lose nor gain water if the osmotic pressure of the solution equals the water potential of potato tissues. The osmotic pressure ($\pi = -m\,R\,T$) may be evaluated from a known concentration m, using the equation given earlier. Instead of energy units, water potential is often expressed in units of pressure (megapascal, MPa), which is derived by dividing the energy by the molar volume (0.018 L mol^{-1} for H_2O) of water (47).

There are many other methods for water potential measurements depending on the system: soil, leaf, stem, organism, etc. The soil water potential is related to the water available for the plants growing on the soil. Water potential of a plant or leaf indicates its health or state with respect to water. Thus, water potential is a better indicator for plant, agriculture, irrigation, and environmental management than water content. Water moves through plants because

$$\Psi_{water} = 0 > \Psi_{soil} > \Psi_{root} > \Psi_{stem} > \Psi_{leaf}$$

Thus, the concept of water potential and water activity are very useful in growth, manufacture, handling, storage, and management of food.

VIII. LIVING ORGANISMS IN WATER

The closer we look, the more we see. Living organisms on Earth are so complicated that their classification and phylogeny are still being studied and revised. New relationships are proposed to modify the five kingdoms proposed by Robert Whittaker in 1969. Nevertheless, most of the earliest unicellular living organisms in the Monera and Protista kingdoms are still living in water. Both the numbers of species and individuals are staggering. For example, photosynthesis by algae in oceans consumes more CO_2 than that by all plants on land. Algae were probably present on Earth before other organisms. Many phyla (divisions) of fungi, plantae, and animalia kingdoms also make water their home. Both numbers and species of organisms living in water are probably more than those on land. The subject of living organisms in water is fascinating, but we can only mention some fundamentals about their relationships to water here. Certainly, every aspect of living organisms in water is related to food, because Homo sapiens is part of the food chain, if not at the top of it.

All life requires energy or food. Some living organisms receive their energy from the sun whereas others get their energy from chemical reactions in the aquatic media. Chemical reactions are vital during their lives. For example, some bacteria derive energy by catalyzing the oxidation of iron sulfide, FeS_2, to produce iron ions $Fe(H_2O)_6^{2+}$ and elemental sulfur. Water is the oxidant, which in turn reduces oxygen (48). Chemical reactions provide energy for bacteria to sustain their lives and to reproduce. Factors

affecting life in water are minerals, solubility of the mineral, electrochemical potentials of the material, acidity (pH), sunlight, dissolved oxygen level, presence of ions, chemical equilibria, etc. Properties of water influence life in general, and in the aquatic system in particular. As the population grows, aquaculture probably will be seen as a more efficient way of supplying protein for the ever-increasing population.

Regarding drinking water, we are concerned with aquatic organisms invisible to the naked eye. Pathogenic organisms present in drinking water cause intestinal infections, dysentery, hepatitis, typhoid fever, cholera, and other illnesses. Pathogens are usually present in waters contaminated with human and animal wastes that enter the water system via discharge, run offs, flood, and accidents at sewage treatment facilities. Insects, rodents, and animals can also bring bacteria to the water system (49, 50). Testing for all pathogenic organisms is impossible, but some organisms share common living conditions with some pathogenic bacteria. Thus, water testing can use these harmless bacteria as indicators for drinking water safety.

IX. WATER RESOURCE, SUPPLY, TREATMENT, AND USAGE

About 70% of the Earth's surface is covered with water, but only about 2% is covered by fresh water. Ocean waters are salty; only a small percentage is fresh water resources (lakes, rivers, and underground). Fresh water is needed for drinking, food, farming, washing, and manufacturing.

When salty water freezes, the ice so formed contains very little salt, if any. Thus, nearly all ice, including the massive ice at the polar cap, is fresh water. In fact, the ice cap in the Antarctic contains a lot of fresh water ice, but that cannot be considered a water resource.

Hydrologists, environmentalists, and scientists, engineers, sociologists, economists, and politicians are all concerned with problems associated with water resources. Solutions to these problems require experts and social consensus.

X. SUBCRITICAL AND SUPERCRITICAL WATERS

Waters at temperatures between the normal boiling and critical points (0 to 373.98°C) are called **subcritical waters**, whereas the phase above the critical point is **supercritical water**. In the 17th century, Denis Papin (a physicist) generated high-pressure steam using a closed boiler, and thereafter pressure canners were used to preserve food. Pressure cookers were popular during the 20th century. Analytical chemists have used subcritical waters to extract chemicals from solids for analysis since 1994 (51).

Water vapor pressures up to its critical point are given in Table 12.8, but data on polarity, dielectric constant, surface tension, density, and viscosity above 100°C are scarce. In general, these properties decrease as the temperature increases. In fact, some drop dramatically for supercritical water. On the other hand, some of them increase with pressure. Thus, properties of sub- and supercritical waters can be manipulated by adjusting temperature and pressure to attain desirable properties.

As the polarity and dielectric constant decrease, water becomes an excellent solvent for non-polar substances such as those for flavor and fragrance. However, foodstuffs may degrade at high temperatures. Applications of sub- and super-critical water are relatively recent events, but applications of supercritical CO_2 (critical temperature 32°C) for chemical analyses started in the 1980s, and investigations of supercritical water followed. However, research and development have been intensified in recent years (52). Scientists and engineers explore the usage of supercritical water for waste treatment, polymer degradation, pharmaceutical manufacturing, chromatographic analysis, nuclear reactor cooling, etc. Significant advances have also been made in material processing, ranging from fine particle manufacture to the creation of porous materials.

Water has been called a green solvent compared to the polluting organic solvents. Sub- and super-critical waters have been explored replacements of organic solvents in many applications including the food industry (53). However, supercritical water is very reactive, and it is corrosive for stainless steels that are inert to ordinary water. Nevertheless the application of sub- and super-critical waters remains a wide-open field.

XI. POSTSCRIPT

Water, ice, and vapor are collections of H_2O molecules, whose characteristics determine the properties of all phases of water. Together and in concert, water molecules shape the landscape, nurture lives, fascinate poets, and captivate scientists. Human efforts to understand water have accumulated a wealth of science applicable in almost all disciplines, while some people take it for granted.

Water molecules are everywhere, including outer space. They not only intertwine with our history and lives, they are parts of us. How blessed we are to be able to associate and correlate the phenomena we see or experience to the science of water.

An article has a beginning and an end, but in the science of water, no one has the last word, as research and exploration on water continue, including its presence in outer space (54). Writing this chapter provoked my fascination on this subject, and for this reason, I am grateful to Professors Wai-kit Nip, Lewis Brubacher, and Peter F. Bernath for their helpful discussions and encouragement.

13 Bioactive Amines

Maria Beatriz Abreu Glória
Departamento de Alimentos, Universidade Federal de Minas Gerais

CONTENTS

I. DEFINITION, CLASSIFICATION, AND PHYSICO-CHEMICAL CHARACTERISTICS

It has long been known that certain amines fulfill a number of important metabolic and physiologic functions in living organisms. They are formed during normal metabolic processes and are, therefore, present in foods.

Bioactive or biologically active amines (Figure 13.1) are aliphatic, cyclic, and heterocyclic organic bases of low molecular weight (74, 102, 165). They are derivatives of ammonia in which the hydrogen atoms are replaced by one, two, or three alkyl moieties to give, respectively, primary, secondary, or tertiary amines. Many different structures of varying complexity are found (166).

Most of the amines have been named after their precursor amino acids, e.g., histamine originates from histidine, tyramine from tyrosine, tryptamine from tryptophan, and so on. However, the names cadaverine and putrescine are associated with decomposition and putrefaction, and spermine and spermidine with seminal fluids where they were found for the first time (59, 102).

Bioactive amines can be classified on the basis of the number of amine groups, chemical structure, biosynthesis, or physiological functions (9, 160, 165). According to the number of amine groups, they can be monoamines (tyramine, phenylethylamine), diamines (histamine, serotonin, tryptamine, putrescine, cadaverine), or polyamines (spermine, spermidine, agmatine). Based on the chemical structure, amines can be aliphatic (putrescine, cadaverine, spermine, spermidine, agmatine), aromatic (tyramine, phenylethylamine), or heterocyclic (histamine, tryptamine, serotonin). They can also be classified as indolamines (serotonin) and imidazolamines (histamine). According to the biosynthetic pathway, amines can be natural or biogenic. Natural amines – spermine, spermidine, putrescine and histamine – are formed during *de novo* biosynthesis, e.g., *in situ* as required from their precursors (9, 74). Biogenic amines are formed by bacterial decarboxylation of free amino acids. Histamine can be either natural (stored in mast cells or basophils) or biogenic. Based on the physiological functions, amines are classified as polyamines and biogenic amines. Polyamines play an important role in growth while biogenic amines are neuro- or vasoactive (9). This is the most widely used classification and will be the one considered throughout this chapter.

The common and chemical names, the molecular formulas and weights, and the physico-chemical characteristics of some bioactive amines are summarized in Table 13.1. The molecular weights are usually low, varying from 88.15 (putrescine) to 202.34 (spermine). The amines behave as

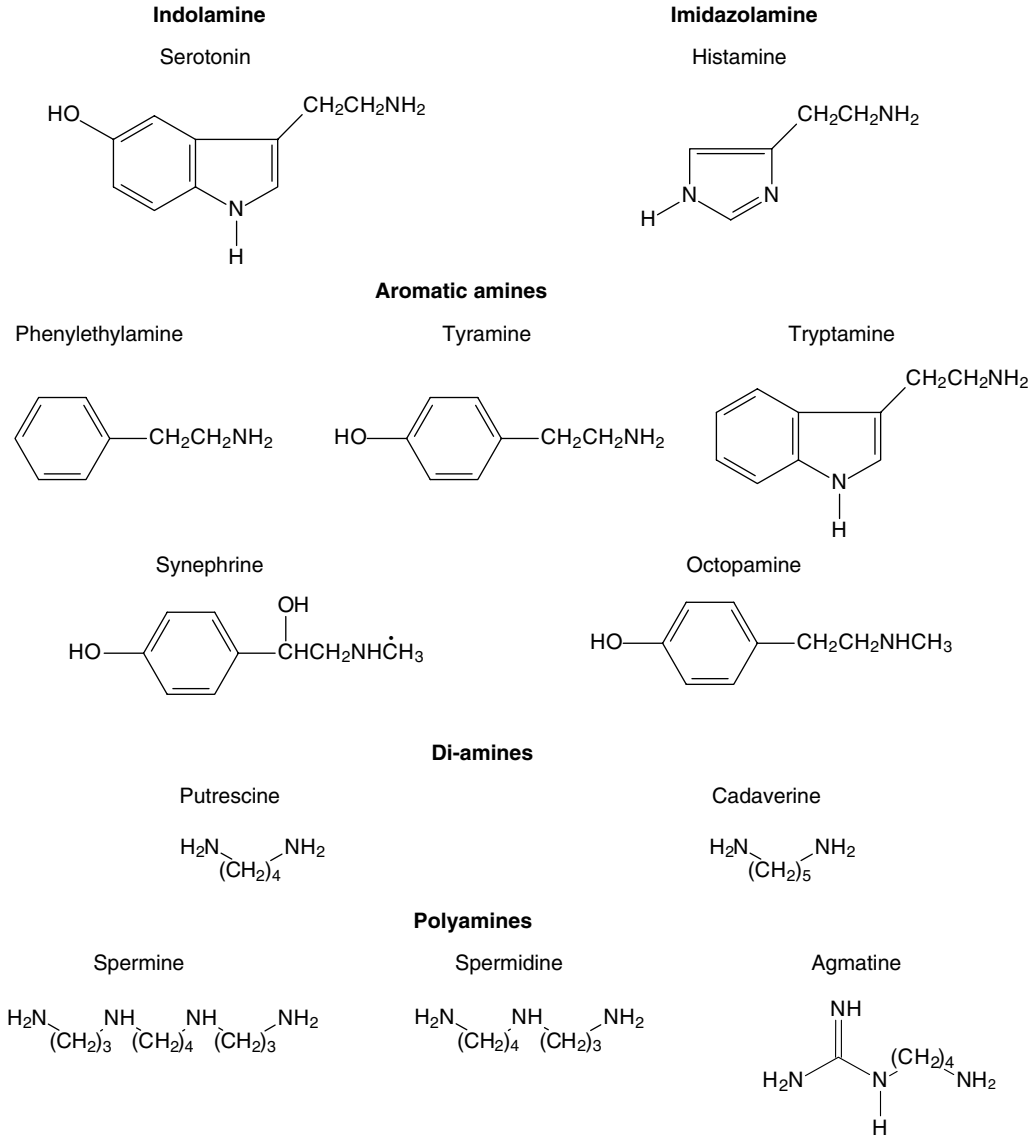

FIGURE 13.1 Classification and chemical structures of some bioactive amines.

cations, being protonated at physiological pH values (123). The pK_a for amines lies between 6 and 11 (41, 101, 166).

At room temperature, the free amines are either liquid, syrupy liquid, crystal, or needle. The boiling points vary from 128 to 210 °C, and the melting points from 9 to 231 °C. The solubility varies widely depending on the amine and on its form – salt or free base (101, 213). At high pH values, dissociation of amine salts into free amines may occur. The refractive index has been reported by Lide (101) for putrescine (1.4969), cadaverine (1.463), and phenylethylamine (1.5290). Density of cadaverine is 0.873 g/mL. Maximum UV absorptions for tryptamine are 222, 282, and 290 nm in ethanol; 224 and 278 nm in acetonitrile:water, 20:80; and 225 and 278 nm in methanol: water, 15:85. Maximum UV absorptions for tyramine and histamine are, respectively, 226 and 275 nm and 225 nm in acetonitrile:water, 20:80; and 228 and 275 nm and 228 nm in methanol:water, 15:85 (34). For synephrine and octopamine, maximum UV absorption values are 231 and 272 nm, and for tyramine 231 and 275 in acetate buffer (pH 4,9):acetonitrile, 9:91 (200, 213). The stability varies with the amines. Some amines can absorb CO_2. Synephrine is stable to light and air. Serotonin hydrochloride is sensitive to light and aqueous solutions are stable at pH 2.0 to 6.4. Decomposition of octopamine hydrochloride can occur at 170 °C (213).

Few sensory data on amines are available. This represents an area that deserves further attention. However, a few amine-based compounds can be used by the flavor compounder. For example, phenylethylamine, is recognized by the Flavor Extract Manufacturers' Association as FEMA # 3220, and has a fishy odor (108).

TABLE 13.1
Common and Chemical Names, Molecular Formulas and Weights, and Physico-Chemical Characteristics of some Bioactive Amines

Amine	Chemical Name	Molecular Formula	M W[1]	Melting Point °C	Boiling Point °C	pK_a	Solubility[2]
AGMATINE	4-(aminobutyl) guanidine; 1-amino-4-guanidobutane	$C_5H_{14}N_4$	130.19	231 ($C_5H_{14}N_4.H_2SO_4$)	—	—	1 – ethanol ($C_5H_{14}N_4{\cdot}H_2SO_4$) 2 – H_2O ($C_5H_{14}N_4{\cdot}H_2SO_4$)
PUTRESCINE	1,4-butane-diamine; tetramethylenediamine	$C_4H_{12}N_2$	88.15	23–24 280	158–160	pK_{a1} = 9.35 pK_{a2} = 10.80 (20 °C) ($C_4H_{12}N_2{\cdot}2HCl$)	1 – benzene; diethyl ether 3 – H_2O 4 – H_2O ($C_4H_{12}N_2{\cdot}2HCl$ & $C_4H_{12}N_2{\cdot}2HCl$); ethanol
SPERMIDINE	*N*-(3-aminopro-pyl)-1,4-butane-diamine; N-(γ-amino-propyl)	$C_7H_{19}N_3$	145.24	256–258 ($C_7H_{19}N_3.3HCl$)	128–130	pK_{a1} = 8.15 pK_{a2} = 9.74 pK_{a3} = 10.24	3 – H_2O; ethanol; diethyl ether
SPERMINE (gerontine, musculamine, neuridine)	*N,N′*-bis(3-aminopropyl)-1,4-butane-diamine; N,N´-bis(3-aminopropyl) tetramethylenediamine	$C_{10}H_{19}N_3$	202.34	55–60	141–142	pK_{a1} = 7.91 pK_{a2} = 8.68 pK_{a3} = 10.21 pK_{a4} = 10.56	1 – benzene; petroleum ether; diethyl ether 3 – H_2O; lower alcohols; chloroform
CADAVERINE (animal coniine)	1,5-pentanediamine; pentamethylenediamine	$C_5H_{14}N_2$	102.18	9 225–230 ($C_5H_{14}N_2.2HCl$)	178–180	pK_{a1} = 10.05 pK_{a2} = 10.93 (25 °C)	1 – absolute alcohol ($C_5H_{14}N_2{\cdot}2HCl$) 2 – diethyl ether 3 – H_2O; etanol; H_2O ($C_5H_{14}N_2{\cdot}2HCl$)
PHENYLETHYL-AMINE	benzene ethanoamine	$C_8H_{11}N$	121.18	—	197.5	pK_{a1} = 9.84 (25 °C)	3 – H_2O; CCl4 4 – diethyl ether
HISTAMINE	1H-imidazole-4-ethanamine; 2-(4-imidazolyl)-ethylamine	$C_5H_9N_3$	111.15	83–84 244–246 ($C_5H_9N_3.2HCl$)	209–210	pK_{a1} = 6.04; pK_{a2} = 9.75 (25 °C)	2 – diethyl ether 3 – H_2O; ethanol; chloroform 4 – H_2O ($C_5H_9N_3{\cdot}2HCl$) methanol
OCTOPAMINE (norsympatol, norsynephrine)	α-(aminomethyl)-4-hydroxy-benzene-methanol; α-(aminomethyl)-p-hydroxybenzyl alcohol	$C_8H_{11}NO_2$	153.18	160	—	—	4 – H_2O ($C_8H_{11}NO_2{\cdot}HCl$)
SEROTONIN	5-hydroxy-tryptamine; 5-hydroxi-3-(β-amino-ethyl) indol	$C_{10}H_{12}N_2O$	176.21	167–168 ($C_{10}H_{12}N_2O.HCl$)	—	pK_{a1} = 9.8 pK_{a2} = 11.1 (25 °C)	1 – 100% ethanol; acetone; pyridine; chloroform; ethyl acetate; diethyl ether; benzene 2 – metanol; 95% ethanol 3 – H_2O ($C_{10}H_{12}N_2O{\cdot}HCl$)
SYNEPHRINE (analeptin, ethaphene, oxedrine, p-sympatol, simpalon)	4-hydroxy-α[(methylamino)methyl]-benzene-methanol; 1-(4-hydroxiphenyl)-2-methylamino-ethanol	$C_9H_{13}NO_2$	167.2	184–185 151–152 ($C_9H_{13}NO_2.HCl$)	—	—	3 – ethanol 4 – H_2O ($C_9H_{13}NO_2{\cdot}HCl$ & $C_9H_{13}NO_2{\cdot}$tartrate)
TRYPTAMINE	1H-indole-3-ethanamine; 3-(2-aminoethyl) indol	$C_{10}H_{12}N_2$	160.21	118 ($C_{10}H_{12}N_2.HCl$)		pK_{a1} = 10.2 (25 °C)	1 – H_2O; diethyl ether; benzene; chloroform 3 – etanol, acetone
TYRAMINE	4-(2-aminoethyl)phenol; 2-*p*-hydroxy phenyl-ethyl amine	$C_8H_{11}NO$	137.18	164–165 269 ($C_8H_{11}NO.HCl$)	205–207	pK_{a1} = 9.74 pK_{a2} = 10.52 (25 °C)	2 – H_2O; benzene; xylene 3 – boiling ethanol

Wang et al. (206) investigated the odor threshold of polyamines. They reported that free polyamines have an unpleasant, almost putrid, ammoniacal odor. In food, because of their basic groups, polyamines normally bind with the acidic groups of other food components, notably those in nucleic acids or lipids. However, at high pH, free polyamines could result. The determination of odor thresholds for putrescine, spermidine, and spermine by an informal panel of nine people provided odor descriptions which varied widely from sodium hypochlorite bleach, dusty, and musty, to putrid, amine, and ammoniacal. Using a formal panel of 15 members, the odor threshold of the polyamines, e.g., polyamine concentration at which 50% of the panelists gave a positive response, was determined. Spermine and putrescine had odor thresholds in water of the same magnitude (2.4 and 2.2 mg/100 g, respectively), while those of cadaverine (19.0 mg/100 g) and spermidine (12.9 mg/100 g) were approximately six to nine times higher. However, when 2% soybean flour was added, odor thresholds increased significantly, from five to ten times greater than those in water, reaching values of 10.9 g for putrescine and 102.5 mg/100 g for spermidine.

II. PHYSIOLOGICAL IMPORTANCE

Bioactive amines participate in important metabolic and physiological functions in living organisms. Biogenic amines are generally either psychoactive, neuroactive, or vasoactive. Psychoactive amines, such as histamine and serotonin, affect the nervous system by acting on neural transmitters in the central nervous system. Vasoactive amines act directly or indirectly on the vascular system. Pressor amines – tyramine, tryptamine, and phenylethylamine – cause a rise in blood pressure by constricting the vascular system and increasing the heart rate and force of contraction of the heart. However, tyramine does it indirectly by causing the release of noradrenaline from the sympathetic nervous system (158, 165). Serotonin and histamine are also strongly vasoactive (139).

Histamine is a powerful biologically active chemical that can exert many responses within the body. Although mast cells and blood basophiles contain large amounts of histamine stored in special granules, the effect of histamine does not appear unless special reactions (i.e., an allergic reaction) release it into the bloodstream. Histamine exerts its effects by binding to receptors on cellular membranes which are found in the cardiovascular system and in various secretory glands (87). Histamine is a strong capillary dilator and can produce hypotensive effects. It can directly stimulate the heart, cause contraction or relaxation of extravascular smooth muscle (excite the smooth muscle of the uterus, intestine and respiratory tract), stimulate both sensory and motor neurons, and control gastric acid secretion. It also mediates primary and immediate symptoms in allergic responses (139, 158, 165, 173, 177).

Serotonin is a vaso- and bronco-constrictor, reduces the volume and acidity of the gastric juice, has anti-diuretic effect, stimulates smooth muscle, and affects carbohydrate metabolism (63). When introduced into the afferent circulation, serotonin causes a release of prostaglandin and other vasoactive substances. Serotonin is a neurotransmitter, particularly in the central nervous system. It is involved in the regulation of a number of important functions, including sleep, thirst, hunger, mood, and sexual activity (42).

Tyramine is taken up into adrenergic nerves and causes a massive release of noradrenaline. It has a marked effect on the release of the putative neurotransmitter amines dopamine, noradrenaline, and serotonin from nerve terminals (42).

Phenylethylamine and tryptamine are endogenous constituents of many tissues, including brain. Both can cross the blood-brain barrier with ease. It is conceivable that large amounts of phenylethylamine and tryptamine from foodstuffs may enter the central nervous system and lead to side-effects of psychiatric nature. It has been reported that phenylethylamine and tryptamine can inhibit uptake and stimulate release of catecholamines and serotonin from a variety of preparations of brain and heart tissues. It has also been demonstrated that phenylethylamine can affect binding of serotonin to its receptor sites in the human and rat brain. Introduction of tryptamine into the afferent circulation can cause a release of prostaglandin and other vasoactive substances into the systemic circulation (42).

There is evidence, particularly with respect to the invertebrate nervous system, suggesting that octopamine may be a neurotransmitter. Less is known about synephrine, although it has been shown to be a constituent of various tissues and body fluids. Synephrine is used pharmacologically as a stimulant, decongestant, and in the treatment of hypotension in oral form (42, 165).

Polyamines are indispensable components of all living cells, where they play essential roles in cell metabolism, growth, and differentiation (11). During normal and adaptive growth, polyamines are involved in a variety of growth-related processes which reflect their multifunctional character. Polyamines have various electrostatic interactions with macromolecules especially DNA, RNA, and protein and are involved in the regulation and stimulation of their synthesis (104).

Diverse effects of the polyamines on cell replication have been identified, such as the control and initiation of translation and regulation of its fidelity, stimulation of ribosome subunit association, enhancement of RNA and DNA synthesis, and reduction in the rate of RNA degradation. Polyamines stabilize the structure of tRNA and help condense DNA and covalently modify proteins (9, 10). Polyamines stimulate the rate of transcription, the amino acid activation, and the rate of translation during the course of protein synthesis (148). Polyamines also stimulate cell differentiation and interact and module various intracellular

messenger systems (104). The most important function of polyamines, one in which they cannot be replaced by any other positively charged molecule, is to act as second messengers, thereby mediating the action of all known hormones and growth factors (9).

Polyamines interact with different components of the cell membrane thus modulating its functions. They are, therefore, important in the permeability and stability of cellular membranes (9, 48, 104, 160). During the period that follows birth, antigenic macromolecules can penetrate the small intestinal mucosal membranes in quantities that may be of immunologic importance. Polyamines reduce mucosal permeability to macromolecules and prevent food allergies by decreasing mucosal permeability to allergenic proteins (27, 147).

According to Drolet et al. (48) and to Bardocz (9), spermine and spermidine, as well as the diamines putrescine and cadaverine, are efficient free radical scavengers in a number of chemical and *in vitro* enzyme systems. They could inhibit lipid peroxidation and prevent senescence. Levels of superoxide radical formed either enzymatically with xanthine oxidase or chemically from riboflavin or pyrogallol were significantly inhibited. The more reactive hydroxyl radical generated by the Fenton reaction was also effectively scavenged by spermine and spermidine. The efficacy of polyamine scavenging appears to be correlated with the number of amino groups (48, 168).

Polyamines are essential for the maintenance of the high metabolic activity of the normally functioning and healthy gut. They are involved in the repair of gut damage caused by the deleterious components of the food and/or bacteria (11, 104). The development of gastrointestinal tract in ruminants and non-ruminants is dependent upon the increases in ornithine decarboxylase (ODC) activity and in polyamines content in the mucosa (123). Studies performed with rats indicated that during the third postnatal week, rapid intestinal maturation occurs and this period is characterized by an increase in epithelial cell proliferation and differentiation, resulting in histological and enzymatic maturation of the small bowel epithelium, marked increase in mucosal thickness, and increase in mature mucosal enzyme activities. Prior to this process of epithelial maturation, a ten- to twenty-fold increase in mucosal ODC activity and a concomitant increase in *S*-adenosyl-L-methionine decarboxylase (SAMDC) activity as well as putrescine, spermidine, and spermine content were found (104, 123). Simultaneous administration of α-difluoromethyl ornithine (DFMO), a potent irreversible ODC inhibitor, to the nursing mother or directly to the newborn rat pups, resulted in a marked attenuation of the increase in mucosal ODC and polyamine content which was followed by a significant delay in biochemical and histological maturation of the intestinal epithelium (123).

According to Löser (104), polyamines in milk exert various direct and indirect trophic effects on the immature intestine and play an important role as luminal growth factors for intestinal maturation and growth. The protective effect of milk against a newborn's allergies could be explained by its high levels of polyamines. They bring about a decrease in protein permeability, diminishing the amount of allergens reaching the intestinal submucosa, and thus allow a better maturation of the immune system in susceptible newborn (106, 147).

Because of the diversity of the roles of polyamines in cellular metabolism and growth, they are important in health and disease. The requirement for polyamines is particularly high in rapidly growing tissues, e.g., in the young during periods of intense growth and in the mucosa of the gastrointestinal tract. Similarly, during periods of wound healing, post-surgery recovery, liver regeneration, and compensatory growth of the lung, requirements are also high. In healthy adults, however, requirements should not be as high because polyamines are only needed to replace cells and mediate the action of hormones and growth factors (9, 123). Studies are needed to determine the daily requirements.

Three sources of polyamines have been identified: biosynthesis *in situ* from amino acids, direct ingestion from the diet and synthesis, and release by the bacterial flora resident in the gastrointestinal tract of the individual. It is now clear that the diet is an important source of polyamines and it is likely to supply at least a part of the polyamines required to sustain normal metabolism (9).

III. SYNTHESIS

The synthesis of the biogenic amines histamine, tyramine, tryptamine, phenylethylamine, and cadaverine occur through decarboxylation of the precursor amino acids histidine, tyrosine, tryptophan, phenylalanine, and lysine, respectively. In the synthesis of serotonin, tryptophan is transformed by tryptophan hydrolase in 5-hydroxitryptophan, which is decarboxylated by aromatic amino acid decarboxylase in 5-hydroxytryptamine or serotonin. Tyrosine is the precursor of the phenolic amines octopamine and synephrine in citrus (165).

The generalized reaction for amino acid decarboxylation is indicated in Figure 13.2. Aldehyde amination can be another route of synthesis, carried out by aldehyde transaminases (166).

Prerequisites for the formation of amines in foods are the availability of free amino acids, high processing temperatures, or the presence of decarboxylase-positive microorganisms and favorable conditions for microbial growth and decarboxylase activity. Free amino acids occur as such in foods, but may also be released from proteins as a result of proteolytic activity or thermal degradation. The formation of amines by high processing temperatures has been demonstrated by Cirilo et al. (38) during coffee roasting. Longer roasting time (12 compared to 6 minutes) at

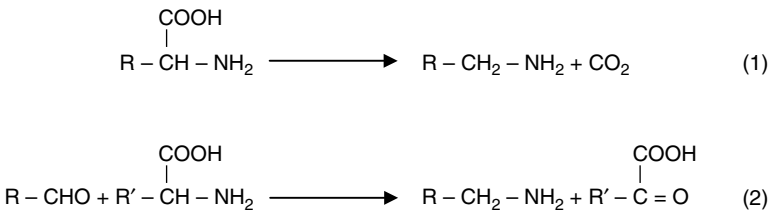

FIGURE 13.2 Formation of amines by amino acid decarboxylation (1) and by aldehyde amination (2).

300 °C in a Probat roaster caused significant increase in spermidine and serotonin levels and formation of agmatine. Decarboxylase-positive microorganisms may constitute part of the associated population of the food or may be introduced by contamination before, during, and after processing (74, 108).

Two mechanisms of action for amino acid decarboxylation have been identified: a pyridoxal phosphate dependent and a non-pyridoxal phosphate dependent reaction. Pyridoxal phosphate joined in a Schiff base linkage to the amino group of a lysil residue forms the active site of the enzymes. The carbonyl group of pyridoxal phosphate reacts readily with the amino acid to form Schiff base intermediates, which are then decarboxylated with the elimination of water to yield the corresponding amines and the original pyridoxal phosphate moiety. Non-pyridoxal phosphate-catalyzed decarboxylation involves a pyruvoyl residue instead. The pyruvoyl group is covalently bound to the amino group of a phenylalanine residue of the enzyme and is derived from a serine residue. The pyruvoyl residue acts in a manner similar to pyridoxal phosphate in the decarboxylation reaction (158)

Regarding the formation of amines by microorganism decarboxylase activity, several studies have been performed to investigate the production of amines by species isolated from fish, cheese, meat products, vegetables, and alcoholic beverages. These studies indicated that many species of *Escherichia*, *Enterobacter*, *Salmonella*, *Shigella*, and *Proteus* are active biogenic amines formers. Certain species of *Achromobacter*, *Lactobacillus*, *Leuconostoc*, *Pseudomonas*, *Pediococcus*, *Streptococcus*, *Micrococcus*, and *Propionibacterium* are also capable of amine production (16, 23, 51, 82, 149, 195).

In fermented foods, the applied starter cultures may also affect amine production. Straub et al. (174) investigated the production of putrescine, cadaverine, histamine, tyramine, and phenylethylamine by 523 strains of 35 species of food fermentation microorganisms. These authors observed that some strains of carnobacteria, *Lactobacillus buchneri*, *L. curvatus*, *L. reuteri*, and *Staphylococcus carnosus* were proficuous amine producers. However, some strains of *L. alimentarius*, *L. brevis*, *L. bavaricus*, *L. delbrueckii* ssp. *Lactis* and *Micrococcus* spp. were capable of producing amines at smaller quantities. The importance of selecting starter cultures based on their potential for amine production is emphasized.

The amino acid decarboxylating activity of some food microorganisms is indicated in Table 13.2. The production of amines by bacteria is affected by pH, temperature, oxygen tension, presence of vitamins and cofactors, and availability of free amino acids and of fermentable sugars. In pH values of 2.5 to 6.5, the production of amines by the bacteria is stimulated as a protection against the acidic environment (201). The activity of decarboxylases is dependent on the microorganism's growth phase, being higher at the stationary phase. With regard to the temperature, decarboxylases are more active at temperatures lower than 30 °C and without action at temperatures above 40 °C. However, at temperatures between 0 and 10 °C, the activity will depend on the microorganisms present (7, 74).

Polyamine synthesis is a more complex process, although the first few steps also include decarboxylation reactions. There are several proven biosynthetic pathways responsible for polyamine production (Figure 13.3). Putrescine is an obligate intermediate in polyamine synthesis. In animals the first step is decarboxylation of ornithine by ODC (EC 4.1.1.17). In plants and some microorganisms, an alternative pathway exists to produce putrescine from arginine via agmatine by arginine decarboxylase (ADC; EC 4.1.1.19). An additional path for the formation of putrescine is via citrulline (9, 59, 168, 202).

Both ODC and ADC are dependent on pyridoxal phosphate. Agmatinase is the enzyme that converts agmatine to putrescine. Agmatine is metabolized to putrescine in a two-step conversion. Agmatine iminohydrolase (AIH) catalyzes the formation of N-carbamoylputrescine, which is converted to putrescine by N-carbamoylputrescine amido hydrolase (NCPAH). N-carbamoylputrescine can also be formed from citrulline by citrulline decarboxylase (CDC). The arginine pool can be increased through protein degradation. Ornithine and urea formation from arginine allows recovery of nitrogen and carbon (59).

Spermidine and spermine are formed by the subsequent addition of an aminopropyl moiety to putrescine and spermidine, respectively. These reactions are catalyzed by the aminopropyltransferase enzymes spermidine synthase (SpdS, EC 2.5.1.16) and spermine synthase (SpmS, EC 2.5.1.22). The aminopropyl group is derived from methionine via *S*-adenosyl-L-methionine (SAM) in a reation

TRYPTAMINE (Tryptophane decarboxylase)	*Lactobacillus bulgaricus*	33

catalyzed by the enzyme SAMDC (AdoMetDC; EC 4.1.1.50). The 5′-methyltioadenosine, resulting from the liberation of the aminopropyl group by SAM is converted in methyltioribose and in methionine, recycling the $–SCH_3$ group which warrants the synthesis of polyamines (59, 168, 202).

The rate-limiting enzymes for polyamines synthesis are ODC and SAMDC. DFMO is an irreversible inhibitor of ODC (26). A similar difluoromethyl analog of arginine (DFMA) can also inhibit putrescine formation from arginine. Both inhibitors are highly specific and in most cases DFMA can also be partially metabolized to urea and DFMO, thereby indirectly inhibiting ODC. Methylglyoxal bis-guanylhydrazone (MGBG) is the most common inhibitor of SAMDC, which catalyzes the step committing SAM to the synthesis of polyamines (59).

The regulation of polyamine biosynthesis is complex and precise control prevents overproduction and deficiency of polyamines in animals (130). Several regulatory mechanisms contribute to the regulation of intracellular polyamine homeostasis. Intracellular polyamine concentrations are primarily regulated by intracellular polyamine *de novo* synthesis, conversion and degradation as well as uptake of extracellular polyamines. Preliminary regulatory mechanisms are intracellular *de novo* synthesis via ODC, reconversion of polyamines via interconversion pathway (spermine/spermidine N-1-acetyltransferase and polyamine oxidase) and oxidative degradation of polyamines (46, 104).

Uptake of extracellular polyamines from the gut lumen was found to be a further important regulatory mechanism of polyamine metabolism. It is well established that the

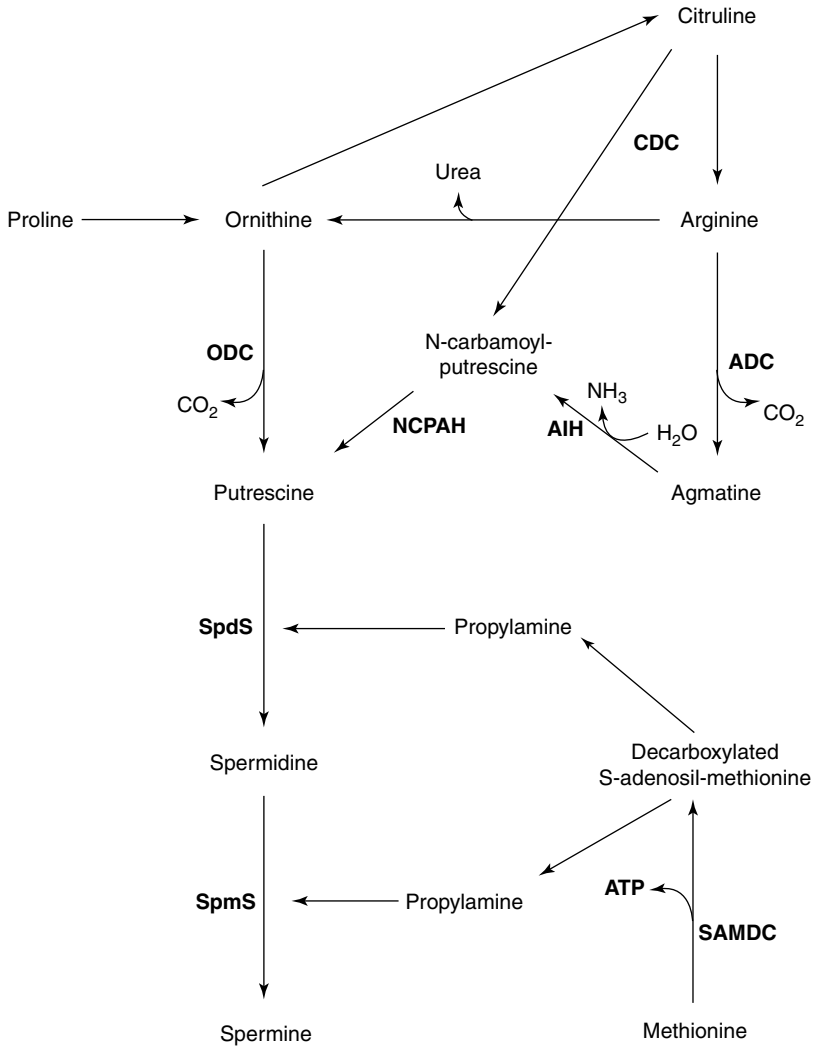

FIGURE 13.3 Pathways for the synthesis of polyamines.

alimentary tract is an important source of polyamines and that dietary as well as to some extent gut bacterial-derived polyamines significantly contribute to the total polyamine body pool. These findings stress the importance of a rapid uptake of dietary, luminal (brush-border membrane) polyamines by the intestinal mucosa upon demand with a consecutive passage through the blood stream (basolateral membrane) to the body (104).

IV. CATABOLISM OF BIOACTIVE AMINES

Healthy individuals can metabolize amines present in foods by acetylation and oxidation (9, 165). Biogenic amines are oxidized by monoaminoxidases (MAO; EC 1.4.3.4) and diaminoxidases (DAO; EC 1.4.3.6). Polyamines are usually acetylated first, then oxidized by polyaminoxidases (PAO; EC 1.5.3.11).

The general equation for the oxidation of amines by amine oxidases (166) is shown in Figure 13.4 and results

$$RCH_2NH_2 + O_2 + H_2O \rightarrow H_2O_2 + RCHO + NH_3 \quad (1)$$

$$R\text{-}CH_2\overset{+}{N}RR'R'' + \tfrac{1}{2}O_2 \rightarrow RCHO + \overset{+}{N}H_2R'R'' \quad (2)$$

FIGURE 13.4 Equations for the oxidation of amines by amine oxidases in the (1) absence and (2) presence of catalase.

in aldehydes, ammonia, and hydrogen peroxide (H_2O_2). According to Marley and Blackwell (113), it is the ionized form of the amine, i.e., the form that is not readily absorbed from the gut, that reacts with the enzyme. Amines that are not ionized to any extent are not oxidized. The overall reaction in the presence of catalase is also shown in Figure 13.4. The aldehyde formed may be oxidized further to the corresponding carboxylic acid.

Amine oxidases belong to a large class of deaminating oxidases (amine:oxygen oxidoreductases) widely distributed among all living organisms. This class of enzymes is

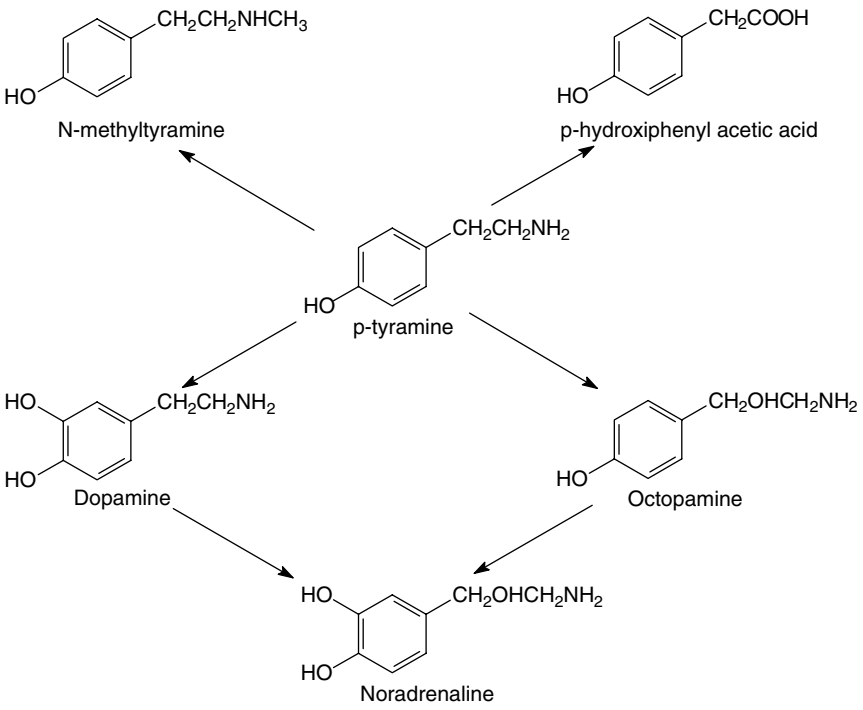

FIGURE 13.5 Tyramine metabolism in man.

divided into two subclasses: copper- and FAD-containing amino oxidases. The copper containing are active on primary amino groups and the FAD-dependent cleave secondary amino groups (134). The amine oxidases contain copper and are sensitive to carbonyl groups. Enzyme activity is usually inhibited by carbonyl reagents and metal chelators (166). Many aliphatic amines of the series $CH_3(CH_2)_nNH_2$ are substrates for the enzyme. The rate of oxidation and affinity vary with the number of carbon atoms in the carbon chain. With increasing length of chain, the rate of oxidation increases, a maximum being reached with 5 or 6 carbon atoms (113). Any substrate of amine oxidase, because it has affinity for the enzyme, may interfere with the oxidation of another substrate.

Tyramine may undergo one of several different catabolic reactions (Figure 13.5). According to Bieck & Karl-Heinz (17), tyramine is extensively metabolized in the gastrointestinal mucosa and liver. The major route is the oxidative deamination to p-hydroxyphenylacetic acid. It is catalyzed by MAO. Other pathways are oxidation to octopamine by dopamine-β-hydroxylase and methylation to N-methyltyramine by N-methyltransferase. Conjugation with either sulphate or acetate groups is also possible. Sulfate conjugation to the o-sulfate accounts for 10–15% of the total dose in urine after oral tyramine administration (17, 60, 87, 115, 139).

Serotonin is oxidized by MAO in man to 5-hydroxyindolacetic acid (5-HIAA). Deamination of tryptamine by monoamine oxidase has also been demonstrated. These amines compete with tyramine as substrate for the enzyme. Such substrate competition could be relevant with a food that contains a number of amines deaminated by amine oxidase (113).

Histamine can also be catabolized by several different catabolic reactions (Figure 13.6). The two main routes are oxidation to imidazole-acetaldehyde and methylation to 1,4-methylhistamine. Indeed, in mammals, 60 to 80% of the metabolites of histamine are derived from oxidative deamination. Amine oxidases are involved in both routes. They convert 1,4-methylhistamine to the corresponding aldehyde and play a minor role in the conversion of histamine to imidazole-acetaldehyde. Inhibitors of monoamine oxidase could therefore interfere with either of these stages, although the metabolism of 1,4-methylhistamine is the one most likely to be affected since diamine oxidase is primarily involved in the conversion of histamine to imidazole-acetaldehyde (113). Percentage recovery of histamine and its metabolites in the urine 12 hours after intradermal ^{14}C-histamine administration in human males indicated that the majority of the radioactivity was recovered as N-methylimidazole acetic acid (42–47%), followed by imidazole acetic acid conjugated with ribose (16–23%), as imidazole acetic acid (9–11%), as N-methylhistamine (4–8%), and as histamine (2–3%) (211).

DAO is a non-selective enzyme and also oxidizes putrescine and cadaverine. In fact, histamine is not the

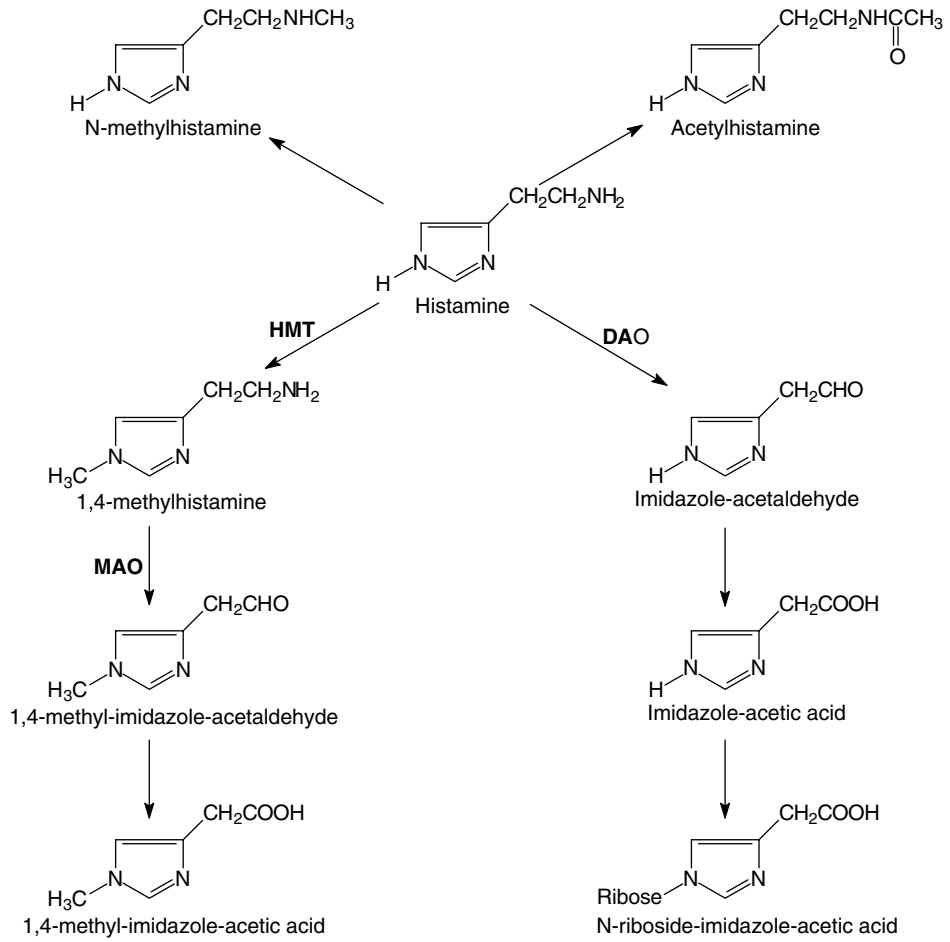

FIGURE 13.6 Histamine metabolism in man.

favored substrate of DAO, being deaminated at about one-third the rate of putrescine and cadaverine. Histamine N-methyl transferase (HMT) is very selective for histamine and requires S-adenosylmethionine as a methyl donor (183).

Several studies were undertaken to assess the potential inhibitory effect of various chemicals on histamine metabolizing enzymes. Taylor and Lieber (181) investigated 37 chemicals and observed that seven strongly inhibited rat jejunal mucosa HMT, while eight inhibited DAO. The most potent inhibitors of HMT activity were tyramine (99%), phenylethylamine (99%), tryptamine (98%), octopamine (94%), agmatine (87%), aminoguanidine (81%), and nicotine (78%), whereas cadaverine, indole, tartrazine, theophylline, thiamin, and trimethylamine gave intermediate levels of inhibition. The most potent inhibitors of DAO activity were aminoguanidine (100%), anserine (100%), carnosine (100%), histamine (99%), agmatine (97%), thiamin (92%), cadaverine (87%), and tyramine (77%). Caffeine, hypoxanthin, indole, 1-methylhistidine, phenylethylamine, piperazine, spermidine, spermine, synephrine, theobromine, theophylline, tryptamine, and xanthine gave intermediate levels of DAO inhibition.

Acidic but not basic drugs are rapidly absorbed from the stomach. This is because the gastric mucosa is selectively permeable to undissociated forms of drugs. Consequently, basic substances such as histamine, serotonin, or tyramine present in foods would be ionized at the acid pH of the stomach and therefore not absorbed whereas in the duodenum and distal gut the alkaline pH would convert them to the un-ionized form which is lipid soluble and more easily absorbed. Once the amines have crossed the intestinal wall, they are carried in the portal blood to the liver and then to the lungs before having access to the systemic circuit (113).

Putrescine and cadaverine are oxidatively deaminated by the reaction of DAO (EC 1.4.3.6). DAO converts putrescine yielding 4-aminobutyraldehyde after cyclization to form Δ^1-pyrroline, with the release of ammonia and hydrogen peroxide (Figure 13.7). Cadaverine is converted via oxidation and cyclization to the 6-membered piperidine ring of anabasine and other alkaloids (62).

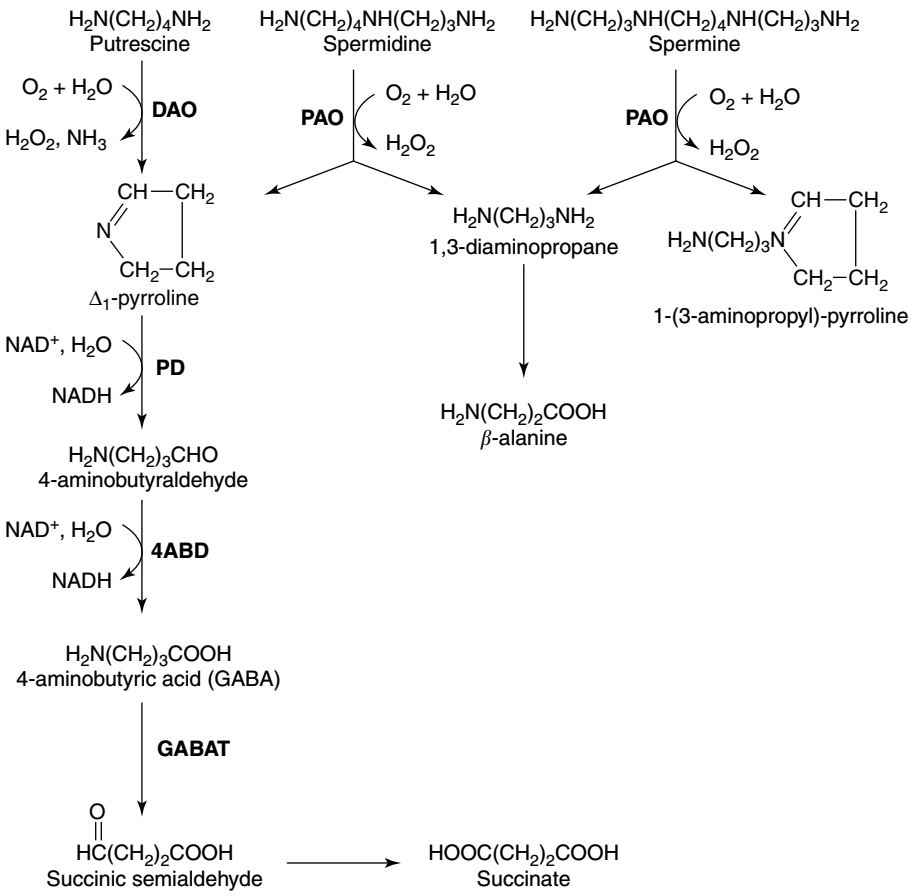

FIGURE 13.7 Putrescine, spermidine, and spermine metabolism in man.

The polyamine oxidases (PAO) are specific for polyamines, and they have FAD as a cofactor (59). Polyamine oxidases degrade spermidine and spermine via the oxidative cleavage at the secondary amino group (153). Degradation of spermidine by PAO yields Δ^1-pyrroline, 1,3-diaminopropane, and hydrogen peroxide, while spermine oxidation yields 1,3-aminopropylpyrroline along with diaminopropane and hydrogen peroxide. Diaminopropane can originate β-alanine (62, 168, 202).

The 4-aminobutyraldehyde formed by the oxidation of putrescine and spermidine can be further oxidized to 4-aminobutyric acid (GABA) by a NAD-dependent pyrroline dehydrogenase (4-aminobutyraldehyde dehydrogenase, 4ABD). This enzyme has been found where DAO or PAO activity is present. The product of this reaction, GABA, can be transaminated and the resulting succinic acid incorporated into the Krebs cycle (Figure 13.7). This metabolic sequence can account for the complete recycling of the carbon and nitrogen from di/polyamines. It may also explain the fact that, in at least some cases, di- and polyamines can be used as organic nitrogen sources by some cells (59, 202).

It has been demonstrated that there is a conversion of spermine and spermidine back into putrescine. The enzymatic reaction of such a reversal pathway has been established; it involves two enzymes acting sequentially, spermidine/spermine N-1-acetyltransferase (SAT; EC 2.3.1.57) and polyamine oxidase (PAO, EC 1.5.3.11) (57).

The amounts of polyamines reaching the body are different for individual polyamines. One hour after rats were intubated with ^{14}C-labeled putrescine, only 29–39% of the label was found as polyamines, with 11–15% remaining as putrescine. Spermidine and spermine were better conserved: 79% of spermidine and 72–74% of spermine were recovered in the original form. If conversion to the other two natural polyamines is also taken into account, 87–96% of the radioactive spermidine and 79–82% of spermine was conserved in polyamine form (10). Since spermidine and spermine are better preserved for further utilization in the body, they are considered the right polyamines to be absorbed from foods.

Catabolism of histamine or tyramine can also be achieved by bacteria. Tyramine oxidase from *Sarcina lutea* was observed to oxidatively deaminate tyramine in the presence of oxygen and to form p-hydroxyphenylacetaldehyde, ammonia, and hydrogen peroxide. *Aspergillus niger* and *Trichosporon* sp. possess amine oxidases that oxidize a wide range of primary amines. Numerous bacteria possess diamine oxidase and are able to degrade histamine, including *Pseudomonas aeruginosa*,

E. coli, *Proteus vulgaris*, *Serratia flava*, and *Clostridium feseri*. In the intestine of man, *E. coli* and *E. aerogenes* are capable of acetylating histamine (124, 139).

V. TOXICOLOGICAL ASPECTS

Amines in foods do not usually represent any health hazard to individuals unless excessive amounts are ingested or the natural mechanism for their catabolism is genetically deficient or impaired by diseases or pharmacological agents (45, 139). Individuals with respiratory and coronary problems, hypertension, or vitamin B_{12} deficiency are at risk because they are sensitive to lower amounts of amines. Men with gastrointestinal problems (gastritis, irritable bowel syndrome, Crohn's disease, stomach, and colonic ulcers) are also at risk since the activity of oxidases in their intestines is usually lower than that in healthy individuals. Patients taking medication that are inhibitors of MAO, DAO, and PAO activity can also be affected, as such drugs prevent amine catabolism. These MAO and DAO inhibitors are used for the treatment of stress, depression, Alzheimer's and Parkinson's diseases, pulmonary tuberculosis, malaria, panic syndrome, and social phobia (60, 61).

Bioactive amines have been implicated as the causative agents in a number of food poisoning episodes (Table 13.3), particularly histamine and tyramine toxicity (158, 177). Tryptamine and phenylethylamine are associated with migraine (87). Furthermore, the importance of polyamines in tumor growth is widely recognized (9, 137).

The most frequent food-borne intoxication caused by amines involves histamine**.** Histamine intoxication is also referred to as "scombroid poisoning" due to its association with the consumption of scombroid fish; however, non-scombroid fish, cheese, and other foods have also been implicated in some cases (173). The disease manifests several minutes to a few hours after ingestion of the histamine containing food (79). At first, a flushing of the face and neck is usually observed, accompanied by a feeling of heat and general discomfort. Often it is followed by an intense throbbing headache. Other symptoms may be cardiac palpitations, dizziness, faintness, thirst, swelling of the lips, urticaria, rapid and weak pulse, and gastrointestinal complaints (abdominal cramps, nausea, diarrhea). However, the most common symptoms are rash, diarrhea, sweating, and headache. In severe cases, bronchospasms, suffocation and severe respiratory distress are reported. Recovery is usually complete within 8 h (12, 139, 158, 165).

TABLE 13.3
Toxic Effects of Bioactive Amines

Toxic Effects	Amines Involved	Food Associated	Symptoms
Histamine intoxication or scombroid poisoning	Histamine (toxic effect is potentiated by putrescine, cadaverine, spermine, tryptamine, tyramine, phenylethylamine, ethanol)	Scombroid fish: tuna, bonito, mackerel, skipjack, herring Other fish: sardines, anchovy, mahi-mahi Cheese: Swiss, Gouda, Cheddar, Gruyere, Cheshire; Sauerkraut; sausage; wine	**Gastrointestinal:** nausea, vomiting, diarrhea, abdominal cramps **Neurological:** throbbing headache, palpitation, flushing, burning throat, itching, rapid and weak pulse, dizziness, faintness, tingling **Hemodynamic:** hypotension, capillary dillatation **Cutaneous:** rash, urticaria, edema, localized inflamation **Severe cases:** bronchospasms, suffocation, severe respiratory distress
Tyramine intoxication	Tyramine	Cheese Beer Wine	Headache, fever, increased blood pressure, vomiting, perspiration, pupils and palpebral tissue dilatation, salivation, lacrimation, increased respiration, palpitation, dyspnea
Cheese reaction[1] or hypertensive crisis (associated with patients under MAOI drugs)	Tyramine 2-phenylethylamine	Cheese: Gouda, Swiss, Gruyere, Cheddar Beer, wine, yeast extract, Chocolate, pickled herring, Dry sausage, broad beans	Hypertensive crisis, severe headache, cerebral hemorrhage, neuronal sequel, cardiac failure, pulmonary edema, visual alterations, palpitation, nausea, sweat, vomit, muscle contractions, excitation, mental confusion, high blood pressure, fever, perspiration
Migraine	Tyramine 2-phenylethylamine tryptamine serotonin	Cheese Chocolate Beer Wine	Throbbing headache, migraine attack
Increased growth hyperplasia	Spermine spermidine	Meat	Increased growth of tumors

Cases of histamine intoxication have been reported in the United States, Japan and United Kingdom. A few incidents have also been reported in several other countries as indicated in Table 13.4. However, outbreaks and cases of histamine poisoning are often not reported since it is relatively mild, has short duration and many patients do not seek medical attention. Furthermore, many physicians remain unaware of histamine poisoning and do not consider it as a possible diagnosis. Even when medical attention is sought and a correct diagnosis is made, only a few countries keep official records of incidents (177). Therefore, it would be safe to assume that the true incidence of histamine poisoning is unknown.

Fish incriminated in outbreaks of histamine poisoning included scombroid (tuna, bonito, mackerel, skipjack, albacore, bluefin tuna, herring and saury) and non-scombroid fish (mahi-mahi, sardines, pilchards, herring, bluefish, jack mackerel, anchovies, kahawai, black and striped marlin), which contained high histamine levels (12, 139). Misidentification of the fish involved in outbreaks may occur on occasion due to different common names used in different places. The type of fish consumed, the method of harvesting, and the consumption patterns are important factors in determining the likelihood of histamine poisoning (177).

Cases of cheese-related histamine poisoning were also reported. The first case was reported in the Netherlands in 1967 and was associated with Gouda cheese. Since then, several cases have been reported after consumption of Gouda, Swiss, Gruyere, Cheddar, and Cheshire cheeses (158, 173, 177, 180). Other foods have also been implicated in incidents of histamine poisoning, among them chicken, sauerkraut, and ham. Fermented foods and proteinaceous foods subject to spoilage are particularly likely to contain large amounts of histamine. Sauerkraut, yeast extract, wine, and fermented, dry sausages can, on occasion, have sufficient histamine levels to cause a toxic response if enough quantities are consumed (66, 139, 177).

Outbreaks of histamine poisoning have also been observed in patients on antituberculosis therapy. Such outbreaks were associated with interaction of fish or cheese

containing high histamine levels with isoniazid and other nicotinamide derivatives (154, 179).

Marley and Blackwell (113) reported that following intravenous injection of 0.1 mg of histamine phosphate, facial flushing, pulse quickening, fall in the blood pressure and rise in cerebrospinal fluid pressure occurs within 20 seconds and the onset of histamine headache occurs 1 min after injection. They also reported that less than 225 mg of histamine taken orally usually does not produce symptoms, although susceptible subjects (allergy, asthma, or peptic ulcers) might be adversely affected by smaller quantities. According to Taylor (177), some mild effects of histamine poisoning were observed in humans by orally administrating 100 to 180 mg of histamine in combination with good quality tuna. The paradox between the lack of toxicity of pure histamine and the apparent toxicity of smaller doses in fish or cheese could explain the existence of potentiators of histamine toxicity. These compounds would act to decrease the threshold dose of histamine needed to provoke an adverse reaction. They would enable absorption of amounts of histamine larger than could be achieved in their absence.

Two hypotheses have been used to justify the effect of potentiators on histamine poisoning: barrier disruption and inhibition of histamine metabolizing enzymes (179). In the first hypothesis, potentiators would interfere with the protective actions of intestinal mucin, which binds to histamine and prevents its passage across the intestinal wall. According to Chu and Bjeldanes (37) and Shalaby (158), such compounds are spermine, spermidine, cadaverine, and putrescine.

In the case of inhibition of histamine metabolizing enzymes, potentiators would inhibit DAO or HMT. DAO is not selective towards histamine but also oxidizes other diamines. Inhibitors of DAO include agmatine, cadaverine, tyramine, putrescine, phenylethylamine, anserine, carnosine, thiamin, semicarbazide, carbonyl reagents, imidazole derivatives, and the pharmacological agents: aminoguanidine and isoniazid (79, 139, 154, 183). Many antihistaminic drugs are DAO inhibitors. Some inhibitors of MAO are also somewhat effective as DAO inhibitors (177). The inhibitors of HMT include agmatine, tyramine, cadaverine, putrescine, tryptamine, and phenylethylamine (183). This enzyme is also inhibited by antimalarial drugs, among them, quinacrine, chloroquin, and amodiaquin (79, 173, 177). According to Hui and Taylor (79), amines were less potent inhibitors of DAO and HMT, compared to pharmacological compounds.

The toxic effect of histamine can also be potentiated by the presence of ethanol**,** which potentiates the effect of amines by directly or indirectly inhibiting amine oxidase (69, 138).

The threshold toxic dose for histamine in foods is not precisely known since the existence of potentiators could dramatically influence it. Based on experience acquired in the investigation of hundreds of histamine poisoning incidents, the U.S. Food and Drug Administration established 10 mg/100 g as the hazard action level for histamine in tuna (56).

Tyramine is the second type of amine involved in intoxication. When foods containing high tyramine levels are ingested, large amounts of non-metabolized tyramine can reach the blood stream. This causes release of noradrenaline from the sympathetic nervous system, leading to a variety of physiological reactions (Table 13.3). There is an increase in blood pressure by peripheral vasoconstriction and by increasing the cardiac output (87, 158). Tyramine can also dilate the pupils and the palpebral tissue, cause lacrimation, salivation, fever, vomit, and headache, and increase respiration and blood sugar (51, 60, 87, 113, 115). When consuming foods rich in tyramine, about 30% of individuals with classical migraine can have headaches. These tyramine-sensitive patients appear to suffer from a deficiency of the enzyme responsible for the formation of the sulfate conjugate of tyramine (42).

Ingestion of foods rich in tyramine by individuals under MAOI treatment results in a dangerous illness known as "cheese reaction." Such a name was given since most of the cases involved cheese. However, it is not the only type of food incriminated, since cases have also been reported with yeast extracts (marmite), pickled herring, dry sausage, alcoholic beverages, broad beans, chicken liver, beer, among others (60, 68, 87, 113). Cheese reaction consists in a hypertensive crisis, usually accompanied by severe headache. The attacks last from 10 minutes to 6 hours, during which hypertension and headache fluctuate. There can be visual alterations, nausea, vomit, muscle contraction, mental confusion, or excitation. Neck stiffness and photophobia can occur. Chest pain simulating angina pectoria, acute heart failure, pulmonary edema, neuronal sequel, and cerebral hemorrhage have also been described. Fatal incidents have been reported in the literature (60, 61, 87, 113, 158).

MAOI drugs have been widely used due to their efficacy in the treatment of malaria, tuberculosis, depression, atypical depression, social phobia, panic and anxiety syndromes, bulimia, Parkinson's and Alzheimer's (60, 94, 139). They include antidepressants, antihypertensive, antimicrobial, and antineoplastic drugs, among them isoniazid, tranylcypromine, isocarboxazid, pargyline, phenelzine, procarbazine, furazolidone, moclobemide, and ipronazide (87, 113, 115, 165). In order to prevent hypertensive attacks when prescribing these drugs, it is necessary to warn patients to avoid foods containing tyramine (42, 60, 139, 165). Foods that require absolute restriction on an MAOI regimen include aged cheese, smoked or pickled fish, cured or spoiled meat, yeast extract, marmite, sauerkraut, and broad beans. Foods that should be avoided unless tyramine contents are known are red wine, meat extracts, soy sauce, dry sausage, and draft beer (60, 64, 115).

In man, 20–80 mg of tyramine injected intravenously or subcutaneously causes a marked elevation of blood pressure. In individuals on MAOI, as little as 6 mg taken orally within a 4 h period can be deleterious (139, 176).

Tryptamine has pharmacological action similar to tyramine. High levels of tryptamine can exert direct effect on smooth muscles, cause headache, and increase blood pressure by constriction of the vascular system (87, 139, 165).

Phenylethylamine, like tyramine, causes an increase in blood pressure by liberating noradrenaline from tissue stores. Phenylethylamine may be the precipitant of migraine headache (87, 139, 165). Levels of 3 mg of phenylethylamine cause migraine headaches in susceptible individuals. Migraine has been observed about 12 h after ingestion of chocolate which contained phenylethylamine. Chocolate has also been implicated in a well-documented hypertensive attack in a patient taking the MAOI pargyline (139).

Even though putrescine and cadaverine have less pharmacological activity than the aromatic amines, after ingestion of very large amounts of these compounds, toxic effects can be observed. Intoxication symptoms reported are hypotension, bradycardia, dyspnea, lockjaw, and paresis of the extremities. However, the most important consequence of these compounds in food is probably the potentiation effect of the toxicity of other amines (66, 87).

Serotonin has been widely discussed as a possible cause of migraine headache, but the evidence is not clear. High levels in foods have been responsible for intestinal discomfort and fibrosis of the myocardium. Serotonin is a powerful vasoconstrictor and vasopressor when 1 mg is injected, but an oral dose of 20 mg has no effect. Although there are no definite reports of intoxication due to serotonin, elevated levels of its metabolites are biochemical signals of pheochromocytoma and malignant carcinoid. Therefore, plant products rich in serotonin like banana, pineapple, fig, walnut, and tomato should be excluded from the diet before attempting to diagnose carcinoid tumor (139, 165).

High spermine levels can cause kidney toxicity, and can affect blood coagulation and pressure, heart beat, and respiration (108).

Due to the diversity of the roles of polyamines in cellular metabolism and growth, rapidly growing tissues require very large amounts of polyamines. Accordingly, the importance of putrescine, spermine, and spermidine in tumor growth is widely recognized, and the inhibition of polyamine biosynthesis in tumor-bearing individuals is a major target of cancer therapy research (9, 11, 137). The capacity of tumor cells to synthesize polyamines by the decarboxylation of ornithine is higher than that of non-transformed tissues (10). Polyamines also have an effect on the non-specific immune system specialized in tumor killing, on the plasma concentration of interleukin-1 and -6, and on the tumor necrosis factor concentration (54). Polyamines absorbed from exogenous sources, mainly food, and the gastrointestinal tract, also play an important role in tumor growth (10).

In order to stop the formation of polyamines, the enzyme ODC can be inhibited. Although DFMO is an efficient and irreversible blocker of ODC, it does not completely stop growth as polyamines are also formed by alternative routes. A polyamine deprivation regimen in combination with polyamine oxidase and antibiotics suitable for the partial decontamination of the gastrointestinal tract, have been shown to reduce growth of tumor and to enhance the efficacy of chemotherapy (10, 54, 137).

Some amines can be nitrosated, or act as precursors for compounds capable of forming nitrosamines, some of which are carcinogenic to several species of animals. Putrescine and cadaverine, upon heating, can be converted to pyrrolidine and piperidine, respectively, from which N-nitrosopyrrolidine and N-nitrosopiperidine are formed upon heating and reaction with nitrite or nitric oxide (158). Spermidine, spermine, and agmatine can also react with nitrite to form nitrosamines in foods or *in vivo* in the gastrointestinal tract over a wide range of biological and environmental conditions (68, 74). A reaction product of tyramine and nitrite, 3-diazotyramine, induced oral cavity cancer in rats (47).

The determination of the exact toxicity threshold of amines is extremely difficult. The toxic dose is dependent on the efficiency of the detoxification mechanism of different individuals. Upper limits of 10 mg of histamine, 10 mg of tyramine, and 3 mg of 2-phenylethylamine in 100 g of foods have been suggested (74). In the case of alcoholic beverages the proposed limits are 2 to 8 mg of histamine and 8 mg tyramine per liter. However, ingestion of foods containing 6 mg of tyramine can cause migraine and 10 to 25 mg can cause hypertensive crisis in individuals taking MAOI drugs (35, 60).

Til et al. (186) investigated the acute and subacute toxicity of five amines in Wistar rats. The approximate LD_{50} values observed were as follows. Tyramine and cadaverine showed the lowest acute toxicity of more than 2000 mg/kg body weight. The approximate LD_{50} of putrescine was 2000 mg/kg, while spermidine and spermine showed the highest acute toxicity, namely 600 mg/kg body weight. The no-observed-adverse-effect level (NOAEL) was 2000 ppm (180 mg/kg body weight/day) for tyramine, cadaverine, and putrescine, 1000 ppm (83 mg/kg body weight/day) for spermidine, and 200 ppm (19 mg/kg body weight/day) for spermine.

VI. OCCURRENCE OF AMINES IN FOODS

Bioactive amines are inherent to living organisms and, therefore, are present in plants, meat, and dairy products. The amount and type of amines in foods depend on the nature and origin of the commodity. However, they can change during production, processing, fermentation, and storage. It can also be affected by hygienic conditions.

Amines are resistant to heat treatment employed in food processing. Based on these findings, amines have been considered good indicators of the freshness, spoilage, and of the degree of quality of fresh and processed food products, reflecting the quality of the raw material used and of hygienic conditions prevalent during processing.

It is evident that all types of food, whether originated from plants or animals, contain putrescine, spermine, and spermidine. In addition to these most common compounds, other amines may also occur naturally. During fermentation or spoilage, spermine content can decrease, because it can be used as a nitrogen source by some microorganisms. There is also formation and accumulation of different types of biogenic amines.

Much still remains unknown about the concentration of amines in food products. Most data available relate to specific amines, mainly histamine and tyramine in fish, cheese, meat, and alcoholic beverages. Comprehensive studies on the levels of all amines are useful from the toxicological, sensorial, and technological points of view. Recent work has focused on the role of polyamines in plant physiology and also on animal health and growth. However, bioactive amines is obviously an area deserving further detailed investigation.

A. Fruits and Vegetables

The polyamines spermidine and spermine occur ubiquitously in the plant kingdom, together with their diamine precursor putrescine. Polyamines are required for normal development and can be used as organic nitrogen sources. Work on higher plants suggests that polyamines play a critical role in several processes, among them, root growth, somatic embryogenesis, control of intracellular pH, flower and fruit development, and response to abiotic stress, such as potassium deficiency, osmotic shock, drought, and pathogen infection. They are also important in the synthesis of secondary metabolites of biological interest, for example, nicotine and alkaloids (59, 129, 168, 202).

A relation has been found between the synthesis of polyamines and the inhibition of ethylene biosynthesis. This has been interpreted as a result of metabolic competition by the same precursor, i.e., *S*-adenosylmethionine. Furthermore, polyamines can scavenge free radicals involved in the conversion of 1-aminocyclopropane-1-carboxylic acid to ethylene. Therefore, exogenous application of polyamines to delay fruit ripening has been proposed and used with promising results (55, 95).

Polyamines are associated with cell walls and cell membranes. They modulate pectinesterase and bind to pectin, delaying fruit softening and senescence (93, 99). The firming effect of the polyamines is similar to that of calcium chloride, and may be due to its ability to bind to cell walls and membranes, stabilizing them, or by making cell walls less accessible to wall-softening enzymes (93, 135). Another hypothesis is that polyamines inhibit the action of enzymes involved in softening or wall degradation. For instance, Kramer et al. (93) found polyamines to have inhibitory effect on polygalacturonase extracted from apples that had been inoculated with fungus. Exogenous application of polyamines to microsomal membranes resulted in a reduction in fluidity at the membrane surface through association of the polyamines with membrane lipid. Polyamines can also delay membrane deterioration by interaction with anionic components of the membrane and stabilizing the bilayer surface. The radical scavenging properties of polyamines have also been suggested to be involved in protecting membranes from lipid peroxidation and other oxidative stresses (70).

In higher plants, polyamines occur in the free form, electrostatically bound to negatively charged molecules or conjugated to small molecules, such as cinnamic acids, e.g., p-coumaric, ferulic, and caffeic acids, resulting in hydroxycinnamic acid amides (HACCs). These compounds have been implicated in a variety of plant growth and developmental processes. More recently, HACCs have begun to attract renewed attention with several studies suggesting an important role in plant responses to pathogens (202).

Besides the polyamines spermidine, spermine, and putrescine, other amines are also naturally present in fruits and vegetables, among them phenylethylamine, serotonin, tryptamine, histamine, cadaverine, agmatine, adrenaline, noradrenaline, octopamine, synephrine, agmatine, and aliphatic amines. Some amines may have a protective role in deterring predators. Serotonin is one of the active principles that occurs in the stinging hairs of *Mucuna pruriens*, *Girardinia heterophylla*, and *Urtica* spp. (167). Histamine occurs in stings of *Jatropha urens* and *Urtica dioica* (166). Some amine conjugates are important as antifungal and antiviral agents. Some aliphatic amines simulate the smell of rotting meat, thereby attracting pollinating insects (165, 167). Some amines are quite important as precursors of compounds of biological significance. For instance, the plant hormones indol-3-yl-acetic acid (IAA) and phenylacetic acid are derived from tryptamine and phenylethylamine, respectively. The tryptamines are also precursors of the tricyclic beta-carboline alkaloids formed by condensation with one or two carbon moiety (42, 167).

Aliphatic volatile amines are widespread in food plants. In the late 1960s and early 1970s several studies were conducted to identify these compounds. Dimethylamine, ethylamine, propylamine, isopropylamine, and butylamine were found in most of the products analyzed, among them apple, banana, potato, cocoa, coffee, oat, soybean, and tea. Other amines detected included hexylamine in apple, isoamylamine in banana and cocoa, ethylmethylamine in coffee, trimethylamine in cocoa and tea, and triethylamine in cocoa (108, 165).

The occurrence of bioactive amines in different fruits and vegetables is indicated in Table 13.5. Tyramine has been

A=amylamine, ADR=adrenaline, AGM=agmatine, B=butylamine, CAD=cadaverine, DE=diethylamine, DM=dimethylamine, DOP=dopamine, E=ethylamine, EM=ethylmethylamine, GRA=gramine, HIM=histamine, HOR=hordenine, HX=hexilamine, IA=isoamylamine, IB=isobutylamine, IP=isopropylamine, NADR=noradrenaline, OCT=octopamine, P=propylamine, PHM=phenylethylamine, PR=propanolamine, PUT=putrescine, SPD=spermidine, SPN=spermine, SRT=serotonin, SYN=synephrine, TE=triethylamine, TM=trimethylamine, TRM=triptamine, TYM=tyramine.

detected in cabbage, lettuce, chicory, radish, tomato, potato, green onion, spinach, eggplant, elderberry, avocado, banana, plum, grapes, raspberry, pineapple, orange, lemon, and tangerine (40, 115, 188). Other phenolic amines such as octopamine and synephrine occur in citrus. Octopamine was also found in banana (165). Histamine has been found in cabbage, eggplant, tomato, beet, and spinach. Tryptamine was reported in tomato, eggplant, barley, orange, plum, and watermelon (59, 164, 188). Cadaverine is naturally found only in plants of the *Leguminosae* family (168, 172). Phenylethylamine was detected in beet, cabbage, cauliflower, rhubarb, carrots, radish, maize, and banana (165). Serotonin has been most frequently reported in banana, plantain, pineapple, plum, peach, avocado, tomato, apricot, eggplant, coffee, and walnut (40, 59, 188, 197). Due to the specific occurrence of bioactive amines in the plant kingdom, they have been used as a tool for taxonomic studies. However, some of them can also be formed by decarboxylases from contaminant microorganisms (59, 168, 172).

Most of the studies on polyamines in fruits and vegetables were performed recently, in the last decade. It is well known that spermidine is the prevalent amine followed by putrescine. Most fruits and vegetables contain only small amounts of polyamines; however soybean and chicory were found to contain the largest amounts (130).

As indicated in Table 13.6, very few studies investigated several amines simultaneously in fruits and vegetables. Therefore, information is still lacking on the levels of amines and on the influence of many factors including plant species and variety, type of tissue, conditions of growth, stage of development, degree of ripening, processing, and storage conditions (164, 188).

The tyramine content of fruits is generally low. Raspberries contain the highest reported levels, averaging 4.8 mg/100 g. Similar levels have been found in ripe banana pulp. Red plum, orange, and avocado contain between 0.6 and 2.3 mg/100 g, but most fruits contain 0.1 mg/100 g or less (42). With a few exceptions, fruits and vegetables contain very low levels of histamine. Histamine concentration in fresh tomatoes and maize is less than 0.4 mg/100 g, while levels in spinach and eggplant vary from 3 to 6 mg/100 g. Baking reduced histamine content in spinach and eggplant. Fresh fruits and vegetables generally contain less than 1 mg of phenylethylamine per 100 g. The highest level (4 mg/100 g) was found in swede. It was also reported in grapes (42, 125). The tryptamine content of plants has been reported to be less than 0.5 mg/100 g in several fruits and vegetables (42). Synephrine is most prevalent in citrus fruits. The juices of tangerines and Cleopatra mandarins contain 13 and 28 mg/100 mL, respectively, while orange and lemon juice contain 1.9 mg/100 g (42, 210). Generally, low quantities of octopamine have been detected in orange, lemon, tangerine (0.1 mg/100 g), mandarin (0.2 mg/100 g), and banana, with similar levels reported in their juices. Octopamine has been reported in bell pepper at levels of 23.4 mg/100 g (210). Serotonin has been detected in some fruits at levels of 0.1 to 0.2 mg/100 g in papaya, 0.1 to 0.4 mg/100 g in

passion fruit, 1.0–1.2 mg/100 g in avocado and fig, 1.2 to 7.8 mg/100 g in pineapple and banana. The serotonin content in plantain is substantially higher. Banana peel contains higher serotonin levels than the pulp (3, 165, 188). Serotonin has also been detected in green and roasted coffee. Green beans of *Coffea arabica* L. cv red catuaí contained 0.94 mg/100 g of serotonin, while American (300 °C/6 min) and French (300 °C/12 min) roasted beans contained 0.16 and 0.29 mg/100 g, respectively (38).

Spermidine levels are high in tissues undergoing growth and in seeds, which are responsible for the preservation of the specie (59, 168, 172). Studies by Starling (172) corroborated this distribution pattern of spermidine in vegetables of the *Solanaceae* family. Moreover, this investigator detected higher histamine levels in the peel of these vegetables, which reinforces their role as plants protectors.

Studies on the influence of polyamines during development of fruits such as avocado, mandarin, apple, tomato, pear, pepper, litchi, and olive, revealed peak levels of putrescine and spermidine and rapid cell proliferation during early stages of growth and, then, decreasing values as the fruits grow and become ripe (129, 141, 155, 187). However, different results were observed during eggplant development and ripening (141). The serotonin content in bananas is affected by the degree of ripening. As the fruit ripens, serotonin in the peel increases steadily while in the pulp it increases and then decreases (188, 197). However, the levels of serotonin and putrescine decreased as the fruit changed from ripe to over-ripe (3).

Changes in bioactive amine levels and profiles at preharvest stage have been reported in response to various kinds of stress, including those from water (39, 204), mineral deficiency (13, 168), acid, herbicide, ozone-caused damages (41), osmotic shock, temperature or altitude variation (165), and chilling injury (129, 203). These reports have demonstrated that most of the stress conditions resulted in an increase of polyamine levels, particularly putrescine.

In a variety of fruits and vegetables, chilling injury is manifested by significant increases in polyamine levels. Putrescine accumulated in different products exposed to chilling temperature, among them lemon (116, 190), broccoli (129), grapefruit, pepper (116), and zucchini squash (92, 156, 203). Chilling injury caused a decrease of spermidine and spermine levels in zucchini squash (92, 156), but an increase of spermidine in peaches (191). Pretreatment of zucchini squash with CO_2 alleviated chilling injury and caused a smaller increase in putrescine (156). Infiltration of zucchini squash with spermidine prior to storage at 2.5 °C was efficient in reducing chilling injury (92). Acording to Serrano et al. (156) polyamines can prevent chilling injury by protecting membrane lipids from peroxidation.

Many researchers studied the relationship between food freshness and amine levels. In this respect, bioactive amines may be indicators of the freshness and quality of fruits and vegetables. During storage at 5 °C for 6 days, total amine content increased in Chinese cabbage from 2.0 to 3.4 mg/100 g, in chicory from 1.5 to 2.1 mg/100 g, in iceberg lettuce from 1.4 to 2.4 mg/100 g, and in radishes from 1.9 to 2.6 mg/100 g fresh weight. Among the amines detected, only putrescine concentration markedly and continuously increased during storage. Putrescine levels increased 3- to 8-fold depending on the type of vegetable. Spermidine and tyramine contents varied randomly and probably resulted from endogenous plant cell metabolism. The total bacterial numbers reached a maximum of 4×10^7 CFU/g at the end of storage, with *Enterobacteriaceae* representing ca 90 to 99% of the total microbial population. A relationship was established between *Enterobacteriaceae* population and putrescine concentration (164). Storage temperature affected markedly putrescine and spermidine contents of broccoli buds packed in polyethylene pouches. Spermidine levels decreased with storage time; however, at 2 °C the rate was slower compared to 23 °C. At 2 °C there was a significant increase in putrescine levels, whereas at 23 °C the levels decreased (129).

There is evidence that direct application of polyamines can have beneficial effects on the shelf life of fruits. During controlled atmosphere storage of apples, reduced rates of softening correlated with increased levels of endogenous polyamines (93). Pressure infiltration of polyamines caused an immediate increase in apple firmness and a decrease in softening rate at 0 °C. In addition, vacuum infiltration of polyamines in tomatoes resulted in firmer fruits than water-infiltrated ones (135).

The exogenous application of putrescine was shown to increase fruit firmness and to retard softening during storage (135, 205). However, vacuum-infiltrated spermine and spermidine (10 mM or 100 mM) significantly increased firmness of strawberry slices, whereas putrescine was not as effective. The greater ability of spermidine and spermine to bind isolated polysaccharides may explain why putrescine was less effective at increasing firmness of strawberry slices than spermidine and spermine at the same concentrations (93, 135).

Processed vegetables usually contain higher biogenic amine levels compared to the fresh product (90). During processing, the incorporation of ingredients can alter amine profile and levels. Furthermore, microorganisms with amino acid decarboxylase activity can be introduced either by addition of starter cultures or by contamination (74). Cocoa beans contain relatively low quantities of phenylethylamine and tyramine. During fermentation there was an increase in the levels of these amines, while roasting increased phenylethylamine levels substantially (42, 86). During coffee roasting there was a significant change in amine profile with total loss of putrescine and spermine, and decrease of spermidine and serotonin levels (38).

During germination of legume grains, protein is synthesized rapidly and increased levels of polyamines are

expected. Furthermore, there is development of biogenic amines due to physiological changes in the tissues during sprouting and/or the activity of bacterial decarboxylase enzymes. The warm and moist environment is conducive to the rapid proliferation of microorganisms including *Enterobacteriaceae* and *Pseudomonas* spp., known to produce amino acid decarboxylases. During germination of *Phaseolus mungo*, putrescine content sharply increased, spermine levels decreased, and spermidine fluctuated, resulting in an overall increase in polyamines. The increase of putrescine levels was also observed in the germination of pea and maize, in bean and soybean seedlings, and in lentil sprouts (157, 162).

B. Fermented Beverages

Bioactive amines are among the major factors determining the quality of fermented beverages such as wine and beer (151). High amine levels can make the product unfit for consumption due to toxicological aspects. Furthermore, amines can also be significant in terms of aroma and flavor. In general, a weakening of the flavor impression is attributed to amines, whereby an unpleasant, bitter aftertaste has been noted and described as off-taste in wine and mousy in beer (45). Although tyramine and histamine are the major amines investigated in fermented products, several different amines have been detected. The types and concentrations of amines in fermented beverages vary widely (Table 13.7).

The origin of bioactive amines in wines is still a matter of controversy. Some amines are normal constituents of grapes with amounts varying with variety, soil type and composition, fertilization and climatic conditions during growth, and degree of maturation. Putrescine and spermidine are usually abundant in grapes, whereas agmatine, cadaverine, spermine, histamine, tyramine, and phenylethylamine have been found in small amounts (69, 73, 131, 151, 198). Lower amine levels in grapes were observed to be formed in cooler and rainier seasons (151). The degree of maturity of grapes is important since nitrogen content in the pulp is two to five times higher in ripened grapes (216).

Several amines can be formed and accumulate during wine making, among them putrescine, tyramine, histamine, and phenylethylamine, while spermidine levels decrease (73, 151). Reports are contradictory on the origin of biogenic amine during wine making. According to Vidal-Carou et al. (198), there was a slight formation of tyramine and no histamine formation during alcoholic fermentation of Spanish wines. On the contrary, Buteau et al. (25) found histamine production during alcoholic fermentation. However, in these studies there was no control of the microbial population present in the must; therefore, the formation of amines could not be attributed solely to the yeast.

Most researchers attribute the formation of biogenic amines, especially tyramine and histamine, to the action of bacteria involved in malolactic fermentation (25, 170, 198). The rates of formation and the levels of amines accumulated vary widely according to the type of microorganisms and vinification practices. One evidence of amine formation during malolactic fermentation was reported by Soufleros et al. (170). During malolactic fermentation carried out by indigenous lactic acid bacteria, amino acid concentrations decreased significantly while biogenic amines increased. Another evidence was the negative correlation with malic and citric acids content (146). Delfini (44) compared the ability of several strains of *Leuconostoc* spp., *Lactobacillus* spp., and *Pediococcus* spp. to produce histamine, and observed that *Pediococcus damnosus* (*P. cerevisiae*) could produce significant amounts of histamine while *Leuconostoc oenos* (*O. oeni*) strains were poor producers of biogenic amines. Lafon-Lafoucade (96) suggested that histamine build-up occurred mainly as a result of bacteria growth in poor media. Lonvaud-Funel & Joyeux (105) showed that histamine production by *O. oeni* was stimulated in media without glucose or malic acid and depended particularly on the histidine concentration. Under those conditions, histidine decarboxylation contributed an additional energy source for the bacteria as already demonstrated for other microorganisms (120). Moreno-Arribas et al. (122) isolated *Lactobacillus brevis* and *L. hilgardii* capable of tyramine and phenylethylamine formation from wines containing high amine levels. They observed that the factors affecting tyramine formation were tyrosine levels in the must and also the presence of sugars, mainly glucose. However, malolatic fermentation does not necessarily result in the formation of biogenic amines (198).

Biogenic amines can also be formed in wine by the action of contaminant microorganisms, e.g., enteric bacteria. In this case, formation of amines has been related to the lack of hygiene during wine making. Based on this assumption, histamine alone or together with other amines can be an indicator of the quality of raw materials employed or unsanitary conditions prevailing during wine production (25, 170, 198).

Other factors during the vinification process can affect amine formation, among them must treatment, length of fermentation in the presence of pulp and skin, alcohol content, sulfur dioxide concentration, added nutrients, pH, temperature, use of proteolytic enzymes, length of maturation or aging step, and quantity and type of finings and clarification agents (6, 25, 69, 73, 98, 102, 151, 169, 171, 194, 198, 216).

According to Battaglia and Frolich (14), concentrations of 5 mg/L of histamine may provoke headache after the consumption of 0.5 L of wine. Therefore, the content of bioactive amines in wines may be regulated in the future following the implemented regulations by FDA for fish (56). Moreover, some countries have established limits for histamine in wines. Switzerland recommends 10 mg/L as maximum level, Germany 2 mg/L, Belgium 5 mg/L, and France 8 mg/L (97).

Source: Refs. 68, 69, 83, 171, and 216.

The types and levels of amines detected in beers are indicated in Table 13.7. Agmatine and putrescine were often detected in beer, being the prevalent amines. Spermidine, spermine, cadaverine, histamine, tryptamine, and phenylethylamine occurred sporadically (68, 83). Kriek and spontaneous fermentation beers showed the highest histamine and tyramine levels (83). Amine levels in beers varied widely, being affected mainly by raw materials, brewing techniques, and microbial contamination during brewing (45, 85, 215).

Some amines at low levels are normal constituents of the raw materials for beer production, such as putrescine, agmatine, and spermidine. Malt can contribute significantly to amine contents in wort and beer. High levels of putrescine, agmatine, spermine, and spermidine and low levels of histamine, phenylethylamine, tryptamine, and cadaverine are usually found in malt. Tyramine, putrescine, spermine, spermidine, and agmatine have been detected in barley. Relatively high levels of tyramine, phenylethylamine, putrescine, spermine, spermidine, and agmatine have been detected in hops; however, its contribution to amine levels in the beer is not significant since the amount used is very small. The use of judicious choice of adjuncts (corn syrup, corn, wheat, barley, or rice) could result in lower amine levels. Rice was observed to be useful in reducing biogenic amines levels in worts and beers (68, 84, 89, 166, 215).

During beer production and storage several amines can be formed and accumulate. The formation of amines during brewing occurs principally during main fermentation (89). High amine production has also been observed during malting (84). During mashing and wort boiling, some amines such as tyramine and agmatine can accumulate. Their formation is attributed to thermal amino acid decarboxylation and possibly to enzymatic activity in the malt (45, 84). Acidified compared to original wort showed increased amine levels (45). During fermentation, *Saccharomyces uvarum*, a top or ale yeast, and *Saccharomyces cereviase* var. *uvarum*, a bottom or lager yeast, did not produce histamine or tyramine (85, 215). *Saccharomyces cereviase* var. *uvarum* recycling with phosphoric acid treatment did not influence biogenic amine formation (82).

During fermentation, wort contamination by amino acid decarboxylase bacteria such as lactic acid bacteria, might occur, leading to the formation of biogenic amines, mainly histamine, tyramine, tryptamine, phenylethylamine, and cadaverine (45, 83, 215). Therefore, biogenic amines could be associated with hygienic conditions during brewing (32, 45, 68, 82, 215). *Lactobacillus brevis* was responsible for tyramine and putrescine production in wort

fermented with a top-fermenting yeast (215). *Pediococcus* spp. produced tyramine during beer fermentation and the amount produced depended on the contaminants counts (84). Experiments with beer spoilage microorganisms showed that *Lactobacillus frigidus*, *L. brevissimilis*, *L. brevis*, and *L. casei* produced higher amine levels compared to *L. plantarum*, *L. lindneri*, and *Pediococcus damnosus*. Moreover, commercial samples with *lactobacillus* contamination, had higher levels and different amine profiles (45). Wort contamination with *Enterobacter agglomerans*, *E. cloacae*, *E. intermedium*, and *Serratia marcescens* produced increased levels of putrescine and cadaverine. Wort contaminated with *Serratia marcescens* incubated at 27 °C produced higher amine levels compared to 6 °C (65). Therefore, biogenic amines could be used as indicators of microbial contamination.

C. Milk and Dairy Products

The types and levels of bioactive amines found in milk and dairy products are indicated in Table 13.8. In general, amine content in milk and dairy products is quite low, except for cheeses which can contain very high levels. Polyamines are naturally present in cow's milk. Spermine is the prevalent amine (34%), followed by putrescine (17%), spermidine (15%), and agmatine (3%) (11, 150). Serotonin and phenylethylamine were also detected in fresh milk corresponding to 16 and 15% of total amine levels, respectively (150). In reconstituted powdered milk (149), UHT milk (4), and yogurt (128) the amine profile changed, keeping similar total levels. There was loss of spermine and putrescine. Cadaverine, which is not inherent to milk, was also detected. Its presence could be correlated with *Enterobacteriaceae* counts, suggesting contamination of the product during processing (112).

A variety of amines has been found in different types of cheese (Table 13.8). In general, spermine and spermidine are present at low levels. The levels of other types of amines vary widely, depending on the cheese, ripening time or aging, and type of microorganisms present. However, high histamine and tyramine levels have been reported in several types of cheese (81, 173, 189).

Cheeses represent an ideal environment for biogenic amine production. Whether or not amines accumulate and

persist in cheese depends on a number of factors. Biogenic amine formation can be affected by the availability of free amino acids and the presence of microorganisms, both added or contaminant, capable of amino acids decarboxylation. Conditions favorable for microbial growth and decarboxylase activity are also important, e.g., pH, salt concentration, temperature, water activity, ripening temperature and time, storage temperature, presence of suitable cofactors, and amine catabolism by means of mono- and diaminoxidase (51, 58, 72, 143, 173, 189).

Cheese is a protein-rich food, and amino acid is mainly brought about by the action of proteolytic enzymes from the starter and the rennet which contribute to the breakdown of casein (87). Amino acid decarboxylating enzymes show optimum activity at acid pH as a mechanism of environment neutralization against an excessive pH decrease which is incompatible with the bacteria's growth. The pH of cheese, 5.0–6.5, is the optimum range for most decarboxylase activity (5, 51, 143). The production of histamine and other biogenic amines is accelerated by high temperatures during production and manufacture of cheese (51, 87, 173). The increase in the concentration of salt can decrease amine formation, but salt-tolerant, amine-producing bacteria need to be controlled (51, 87, 143, 173, 175). The cofactor piridoxal phosphate, necessary for decarboxylase activity mainly over tyrosine, lysine, and ornithine, is present in milk and cheese at levels of 42 to 215 μg/100 g, which is sufficient to saturate the decarboxylases required for amine production (51, 143). However, there can be a decrease in biogenic amine levels due to catabolic activity of some microorganisms. Bacteria capable of metabolizing histamine (*Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus vulgaris*, *Serratia flava*, *Clostridium feseri*) and tyramine (*Sarcina lutea*, *Aspergillus niger*, *Trichosporum* spp.) have been reported in the literature (139, 143).

Numerous bacteria, both intentional (starter cultures) and adventitious, have been reported as being capable of amine production at levels depending on bacterial densities and synergistic effects between microorganisms (81). The decarboxylase-positive microorganisms can be part of the natural population of the milk, or can be introduced as starter culture or by contamination, before and during cheese making and after processing. According to Joosten and Northold (88), it is necessary to have densities of 10^7 to 10^9 CFU/g in order to produce high concentrations of amines.

The hygienic quality of milk is very important in the formation of biogenic amines in cheese (143, 173). Cheese made with milk of poor microbial quality contains higher amine levels than cheese made with high quality milk (5, 87, 133). Among contaminating microorganisms, *Enterococcus* ssp. are notorious tyramine formers. *Enterococcus faecalis* was associated with considerable production of biogenic amines including phenylethylamine (126). *Enterobacteriaceae* species, even at low densities, have been observed to produce and accumulate histamine, tyramine, putrescine, cadaverine, and phenylethylamine (51, 88, 112, 126, 173). *Clostridium* can produce histamine, tryptamine, and tyramine (51). Gram-negative microorganisms can increase the concentrations of putrescine and cadaverine in cheese (87, 112, 133).

According to Fernández-García et al. (58) and Greif et al. (72), lactic starter cultures used in the production of cheese can be an important critical point in the production of biogenic amines. The production of acid is the first manifestation of their growth. A second major change is the alteration of proteins. Starter cultures hydrolyze proteins and increase free amino acids levels which can be used for their growth (143). Several starter cultures have been observed to possess amino acid decarboxylase activity (87, 173). According to Straub et al. (174), several fermentation organisms failed to produce amines in phosphate buffer. However, in milk, *Lactobacillus* ssp. play a major role in histamine, tyramine, and putrescine accumulation. Various species of *Lactobacillus* produce histamine, e.g., *L. bulgaricus*, *L. casei*, *L. acidophilus* (51, 133, 173). *Lactococcus lactis* was observed to produce histamine, tyramine, and tryptamine (33). Wild lactococcal and leuconostoc strains were capable of tyramine formation (71). According to González de Llano et al. (71), Halász et al. (74), and Straub et al. (174), the amine forming ability should be taken into account when selecting starter cultures.

The influence of temperature, rennet, and NaCl on bioactive amines formation in milk by a commercial starter culture containing *Lactococcus lactis* ssp. *cremoris* and *L. lactis* ssp. *lactis* was investigated by Santos et al. (149). Sterilized reconstituted dry milk was inoculated with 1% culture in the presence or not of rennet and NaCl and incubated at 20 and 32 °C/24 h. There was a change in the levels of amines natural to milk. Histamine, serotonin, phenylethylamine, and tryptamine were also formed. Tyramine was only formed at 32 °C. Addition of rennet favored the formation of putrescine, tyramine, and tryptamine. Incorporation of NaCl in the milk for cheese manufacture decreased agmatine, spermidine, putrescine, histamine, and tyramine levels. By decreasing incubation temperature and adding NaCl, it was possible to minimize bioactive amine formation.

Pasteurization of milk can affect amine formation in cheese. In cheeses made from pasteurized milk, decarboxylase-positive bacteria usually remain at low levels, with reduced risk of biogenic amine formation even if the substrate is enriched in free amino acids by proteolytic enzymes. However, in cheeses made from raw milk, where a considerable population of decarboxylase-positive lactic acid bacteria is more likely to occur, formation of biogenic amines was enhanced by the higher levels of free amino acids (58). Pasteurization can be alternatively

achieved by high pressure treatment of milk. Besides destroying pathogenic flora of milk, cheese made with high-pressure-treated milk ripens faster as it promotes higher proteolysis, without increasing levels of biogenic amines (128).

Another factor that may affect amine formation during cheese manufacture is the aging process. Tyramine concentration increased in Gouda cheese from milk with added tyrosine or with proteolysis faster than normal (87). Indeed, incorporation of proteinases to accelerate the ripening process of raw milk Hispanico cheese resulted in higher tyramine concentration, which increased with cheese age. However, it did not affect histamine formation (58). The longer the aging process, the higher the content of some biogenic amines as indicated for Montasio cheese (Table 13.8).

Although it is very difficult to elaborate cheese free of biogenic amines, efforts should be made to elucidate amine formation in cheese in order to optimize technology and secure low amine levels, mainly of the most dangerous ones (143). Use of raw material of good hygienic quality, pasteurization of cheese milk, use of hygienic practices during manufacture, prevention of temperature abuse throughout production, and selection of starters with low decarboxylase activity are measures to avoid the accumulation of these undesirable compounds (126, 127, 189).

D. Fish

Small amounts of bioactive amines occur naturally in fish (Table 13.9). Under normal physiological conditions, fish muscle contains high levels of spermine and spermidine and low levels of histamine and putrescine (9, 68, 118).

Several factors have been observed to affect amine levels in fish. Fish-to-fish and seasonal variations are observed due to genetics, environment, sex, physiological stage, and tissue sampled (1, 43, 53, 117, 195). Scombroid fish, such as tuna, bonito, mackerel, yellowfin, and bluefin, are particularly susceptible to histamine formation as they contain large amounts of free histidine (7, 31, 177). However, fish from other families (Scomberesocidae, Pomatomidae, Coryhaenidae, Carangidae, Clupeidae, and Engraulidae) are also susceptible. Data are contradictory with respect to both histidine and histamine levels in light and dark muscles (7, 68, 208). However, no significant difference in biogenic amines levels was found between samples from different parts along the light muscle of *Thunnus thynnus* and upper and lower loin light muscles of *T. alalunga*, respectively (68, 195).

The microbial flora of the fish also plays an important role in the formation of amines. However, it may be transient, varying with the environment, diet and hygienic conditions during capture, handling, processing, and storage (29). Several species, either natural or contaminant, are capable of producing histamine, such as *Morganella morganii, Klebsiella pneumonia, K. oxytoca, Hafnia alvei, Clostridium perfringens, Lactobacillus delbrueckii, Escherichia coli, Citrobacter freundii, Enterobacter cloacae, E. aerogenes, E. agglomerans, Proteus mirabilis, P. vulgaris, Serratia liquefaciens, Acinetobacter lwoffi, Pseudomonas putrefaciens, P. putida, P. fluorescens, Vibrio alginolyticus,* and *Aeromonas hydrophyla* (1, 7, 23, 103, 117, 142, 195, 214). However, *Morganella morganii*, *Hafnia alvei,* and *Klebsiella pneumoniae* are the main histamine-producing bacteria which have been isolated from fish implicated in histamine poisoning outbreaks (177).

Other factors that influence the levels of amines in fish include place of capture, air, water and fish temperature, post-capture handling practices, chilling and freezing systems and rates, and storage conditions (7, 56, 68, 136). Several handling techniques have been used in commercial fishery. According to Dawood et al. (43) and Hardy and Smith (75), eviscerated fish contained lower concentrations of amines than whole samples. However, Price et al. (136) did not find significant differences in the quality and histamine levels of round, bled, or dressed albacore. Several investigations have demonstrated that storage temperature is a critical factor influencing histamine and other amine formation in fish muscle (49, 67, 182, 195). According to Ababouch et al. (1), freshly caught sardines contained high levels of bacteria located on the skin and the gills. These bacteria invaded and grew rapidly in sardine muscle, reaching 5×10^8 and 6×10^8 cfu/g, respectively, after 24 h at room temperature and 8 days in ice. Histamine, cadaverine, and putrescine accumulated to levels of 235, 105, and 30 mg/100 g, respectively, after 24 h storage at room temperature and after 8 days storage in ice. The requirement for rapid and uninterrupted refrigeration after catch can never be over-emphasized. The United States Food and Drug Administration (FDA) established a guidance level for histamine in fish at the dock or before processing of 5 mg/100g. The FDA also states that rapid chilling of fish immediately after catch is the most important strategy to limit histamine formation. The internal temperature of the fish should be brought to 10 °C or below within 6 hours of death. Chilling from 10 to 4.4 °C or less should not take longer than 18 hours. Any time above 4 °C significantly reduces the expected safe shelf life (56).

Studies have indicated that the levels of spermine and spermidine decrease and those of putrescine and histamine increase during storage and deterioration of fish such as tuna, rainbow trout, salmon, sardine and some fresh water fish, e.g., snapper, carp, catfish, "tambaqui," "lambari," and "tilápia" (23, 43, 67, 118). There is also formation and accumulation of cadaverine, tyramine, tryptamine, and phenylethylamine. The rates of change, however, are affected by storage temperature, pH, oxygen, nutrients presents, incorporation of additives, and packaging system (1, 23, 117, 118, 142, 195, 207). Studies on the influence of temperature on histamine formation by *Morganella morganii* and *Hafnia alvei*, prolific histamine

formers, indicated that at 1 °C, no histamine was formed, whereas at 19 and 30 °C, the highest levels were found (7). Veciana-Nogués et al. (195) investigated the influence of temperature on bioactive amine formation in tuna and observed similar evolution profile at the three temperatures, although the highest amounts were achieved in samples stored at the higher temperature. There was a great increase in histamine followed by cadaverine. Formation of histamine, tyramine, and cadaverine were related to mesophilic microorganisms, *Enterobacteriaceae*, and coliforms. According to Du et al. (49), as histamine levels exceeded 5 mg/100 g in tuna fillets stored at 4, 10, and 22 °C, the total bacterial counts reached 10^7 cfu/g and the histamine producers reached 10^2 to 10^3 cfu/g. Histamine production by *Klebsiella pneumonia* was reduced as the concentration of NaCl increased, with marked inhibition occurring at 5.5% NaCl (184). Use of antimicrobial agents may provide an additional impediment to bacterial histamine production. Potassium sorbate at a concentration of 0.5% inhibited growth and histamine production by selected strains of *Morganella morganii* and *K. pneumonia* (182). Sodium chloride at 1% stimulated amine formation; however, levels above 3% or 2% combined with 0.5% clove completely inhibited growth and amine production by *Enterobacter aerogenes* in mackerel broth (209). Vacuum packaging did not show any beneficial effect in controlling bacterial growth and histamine production on tuna samples (207). Canning of fish does not affect significantly histamine levels. However, significant losses are observed for spermine, putrescine, and tyramine and accumulation for phenylethylamine (68, 80).

Based on the changes observed in bioactive amines, Mietz and Karmas (118) proposed a chemical index to evaluate the quality of tuna. It is calculated by the sum of the levels of putrescine, histamine, and cadaverine divided by the sum of spermine and spermidine added by 1. Nominal cutoff values were 0 to 1 for good quality, 1 to 10 for borderline, and higher than 10 for decomposed tuna fish. This index compared favorably to sensory and authentic pack value scores. It was considered adequate to evaluate the quality or freshness of tuna and other types of fish and seafood, among them salmon, rockfish, snapper, lobster, and shrimp (119). In some species of fish, the presence of tyramine can also be detected during storage and deterioration. Based on these findings, Veciana-Nogués et al. (195) proposed for the quality assessment of tuna the use of an index calculated from the sum of the contents of histamine, tyramine, cadaverine, and putrescine. According to these authors, it showed

good correlation with both storage time and organoleptic assessment and the level of 5 mg/100 g could be a guiding limit value for tuna and anchovy acceptance.

A maximum average histamine content of 10 mg/100 g has been established by several countries and communities (European Community and Mercosur) for acceptance of canned tuna and other fish belonging to the Scombridae and Scomberesocidae families (56). Because of the potentiating effect of other amines on the toxic effect of histamine, European regulation recommends the use of HPLC technique for the determination of the amines (107).

E. Meat and Meat Products

Spermine, spermidine, and putrescine occur naturally in meat. Meat is very susceptible to chemical and physical changes during storage of fresh meat or during processing of meat products. It is also susceptible to proteolysis by microorganisms and endogenous or microbial enzymes, which can liberate amino acids. The biogenic amines histamine, putrescine, tyramine, tryptamine, 2-phenylethylamine, and cadaverine can, then, be formed (76, 102, 196). Since biogenic amines are metabolites of microbial activity and are resistant to heat treatment (67, 102), they have been considered to be a useful index of quality of fresh and processed meat, reflecting the quality of the raw material used and the hygienic conditions prevalent during its processing. Amine levels in different types of fresh and stored meat are indicated in Table 13.10.

Immediately after slaughter, high levels of spermine and spermidine and traces of putrescine and cadaverine have been detected in red and white chicken meat. Spermine is the prevalent amine contributing with 70% of total amine levels. Low levels of histamine are also detected in thighs. During storage at 4 ± 1 °C, there was a decrease in spermine, spermidine levels remained constant, and putrescine, cadaverine, histamine, and tyramine were formed. At 15 days, higher levels of amines were found in breast compared to thigh. An index based on the ratio of the polyamines spermidine/spermine levels was considered appropriate for the evaluation of chicken meat quality (161).

Amine types and levels detected in chicken-based products, mortadella, frankfurters, sausage, meatballs, hamburger, and nuggets varied widely, indicating that ingredients added and processing affected amine profiles. Nuggets were the only products with an amine profile similar to that of fresh chicken meat. There was prevalence of spermidine over spermine for most of the products, suggesting the incorporation of significant amounts of vegetable protein in the formulations. Significantly higher biogenic amine levels were observed in sausages, which could indicate the use of low quality raw material or of contamination during processing and storage (161).

In fresh pork meat, spermine was the prevalent amine followed by low levels of spermidine and agmatine. No significant difference was observed between loin and leg tissues. During storage of pork loin at 5 ± 1 °C, mean spermine and spermidine levels remained constant, and putrescine, cadaverine, and histamine were formed. Cadaverine was detected on the 4th day of storage when mesophilic and psychrotrophic counts reached 4.9×10^5 and 7.9×10^5 cfu/g, respectively. Putrescine and histamine were detected only on the 12th day, with counts of 1.3×10^6 and 1.9×10^8 cfu/g for mesophilic and psychrotrophic microorganisms, respectively (193). Small changes in spermine and spermidine levels and formation and accumulation of putrescine, cadaverine, histamine, and tyramine were also observed by Hernández-Jover et al. (78). They suggested that the sum of these four biogenic amines could be a useful index to evaluate meat freshness, with values below 5 mg/kg indicating high hygienic quality meat.

Spermine was also the prevalent amine in fresh beef, followed by spermidine. Low levels of histamine were also detected in some samples (30, 76). At 4 °C, vacuum-packed beef had three times the shelf life of the unpacked product and lower levels of histamine, putrescine, and cadaverine (91).

Cooked meat products such as ham and mortadella showed prevalence of spermine over spermidine as observed for fresh meat; however, levels were lower compared to fresh products due to dilution of meat with fat and other ingredients used in the manufacturing process. The levels of biogenic amines varied widely (76, 78).

Much higher amounts of biogenic amines have been reported in dry fermented sausages. Tyramine was the prevalent amine, followed by putrescine, but their contents fluctuated widely. The presence of tryptamine and phenylethylamine was found to be common in the majority of the ripened products, although at low levels (28, 52, 76). Although the contents reported for certain amines are occasionally higher than those reported for fish products, there is still a lack of information on the incidence of histamine and tyramine intoxication with these products. However, sausages have been incriminated in migraine headaches and in hypertensive crisis episodes (60, 76).

Production of dry sausages offers favorable conditions for the formation of biogenic amines. There is growth of microorganisms for several days, and a certain degree of proteolysis takes place giving rise to the presence of free amino acids, which favors amino acid decarboxylase activity. Furthermore, raw material quality, thawing conditions, ripening temperature, and addition of a properly selected starter culture can affect formation and accumulation of biogenic amines. Therefore, these are important critical control points in amine formation (18, 111).

Good quality raw material only contributes with spermine and spermidine to the sausage. However, high

amounts of biogenic amines in sausages can be related to the use of low hygienic quality meat (76, 77, 132). The choice of good quality raw materials helps minimize the number of amine-producing bacteria. Furthermore, biogenic amine formation may be affected by the thawing time and storage temperature of raw material (110). Fresh lean meat stored for 5 days at −20 °C maintained hygienic quality and low tyramine, cadaverine, and putrescine content. However, when stored for 5 days at 4 °C, sausages formed amines earlier and accumulated up to 50-fold higher amounts. Storage temperatures of 15 °C, compared to 4 °C, favored proteolytic and decarboxylase reactions, resulting in increased amine concentration (20). Isolates obtained from raw sausages showed histamine-forming activity, most of them belonging to the *Enterobacteriaceae* family, *Klebsiella oxytoca*, *Enterobacter aerogenes*, and *E. cloacae* (144).

Intense proteolysis takes place during the dry curing process, mainly due to muscle proteinases (76). Proteolysis during fermentation is favored by the denaturation of proteins as a consequence of acidity, dehydration, and action of sodium chloride. The activity of endogenous but also microbial proteases modifies the composition of the non-protein nitrogen fraction, including the production of free amino acids (18).

Dry sausages can be spontaneously fermented by wild microbial flora. However, tyramine and putrescine are usually produced and accumulated. The use and selection of starter cultures can reduce the production of these and other amines (77, 110). Starter culture shortens the fermentation process and also reduces the growth of deleterious microorganisms (76). They usually consist of one or several strains of lactic acid bacteria and the group of catalase-positive cocci, including micrococci and staphylococci, or a combination of both (18). Lactic acid production by lactic acid bacteria has a preservative effect, and facilitates the drying process, the development of the typical curing color, and the cohesion of the sausages. However, the production of biogenic amines in meat and meat products has often been related to lactic acid bacteria, *Enterobacteriaceae* and *Pseudomonas*. Micrococci and staphylococci also contribute to sausage ripening by enhancing the development of the characteristic flavor and color. Catalase production protects against color changes and rancidity, while nitrate and nitrite reductase aid reddening and reduce residual nitrite content (21).

Several reports on the effect of different combinations of starter cultures on biogenic amines formation and accumulation *in vitro* and in sausage are available. *Staphylococcus carnosus* and *S. xylosus* were considered safe starter cultures according to their tyramine production *in vitro* (114). However, *S. carnosus* was observed to have a remarkable potential to form biogenic amines, but not *S. xylosus* (174). Indeed, *S. carnosus* did not prevent the formation of tyramine and phenylethylamine by contaminant lactic acid bacteria during sausage ripening (110). Sausages made with *S. carnosus* and *S. xylosus* showed strong proteolysis but had lower amounts of tyramine compared to naturally fermented sausages (18).

The use of *Lactobacillus sake*, *Pediococcus pentosaceus*, *Staphylococcus carnosus*, and *S. xylosus* inhibited formation of putrescine but not tyramine during ripening of Turkish "soudjoucks" (8). *L. sakei* and *Staphylococcus* spp. drastically reduced tyramine, cadaverine, and putrescine accumulation (21, 22). *L. curvatus* only attenuated tyramine content compared to *L. sakei*; however, both were able to limit production of putrescine and cadaverine and to prevent tryptamine and phenylethylamine formation by the wild flora (22). Mixtures of *Pediococcus cereviseae* and *L. plantarum* were unable to produce significant levels of histamine and tyramine (140). Histamine production was lower in sausage fermented by mixed starter cultures of *Lactobacillus plantarum*, *Pediococcus acidolactici*, and *Micrococcus roseus* compared to those fermented by natural microflora (16). Some strains of *Enterococcus*, *L. curvatus*, or *S. carnosus* produced tyramine and phenylethylamine (121).

The technological conditions used to produce sausages can also affect amine formation since they affect the growth and activity of the microorganisms present. The largest diameter contained higher amines levels than thinner sausages. Histamine levels in "sobrasada" and tyramine, histamine, putrescine, and cadaverine levels in sausages were higher in the central part compared to the edges (19, 196). The choice of optimal processing temperature for the amine-negative starter culture is an important critical control point in the formation and levels of biogenic amines (111). Addition of glucono-delta-lactone (GLD) to sausage causes a faster decrease in pH, stabilizes the color, simplifies production, and suppresses microorganisms which cause spoilage (streptococci, coliforms, and total plate counts), thereby decreasing significantly the levels of histamine and putrescine (109). However, sausages produced with 0.3% GLD contained higher histamine and tyramine levels and less acceptable organoleptic evaluation (24). Moreover, tyramine degradation by microorganisms with tyramine oxidase activity, such as *Micrococci* during ripening, can be used (100).

A recommended upper limit of 10 to 20 mg/100 g for histamine in meat products has been proposed by the Netherlands Institute of Dairy Research and by the Czech Republic (121, 185). A recommendation should be extended for tyramine in meat products. Furthermore, the addition of selected starter culture, the use of proper technological conditions favoring starter development, and the utilization of raw materials with good hygienic quality make it possible to produce fermented sausages nearly free of biogenic amines (21).

14 Pigments in Plant Foods

JaeHwan Lee
Department of Food Science and Technology, Seoul National University of Technology

Steven J. Schwartz
Department of Food Science and Technology, The Ohio State University

CONTENTS

I. INTRODUCTION

The appearance of foods, especially color, is one of the major contributors to consumers' food choices. Color level also influences the sweetness and flavor of foods (1–3). Pigments in plants are responsible for the coloration of fruits and vegetables. Naturally occurring pigments from plants are generally considered safe due to their presence in edible plant materials and are exempt from the toxicological testing that synthetic dyes must undergo. Consumers' preferences are shifting from synthetic food dyes to natural food colorants due to a perceived health concern and potential health benefit of some pigments: β-carotene is a nutrient precursor of vitamin A, chlorophyll

derivatives are potential chemo preventatives, lycopene is associated with decreasing the risk of several types of cancer, and phenolic anthocyanins in wines have been implicated in reducing heart disease (4, 5).

Color perception of food is the result of the pigments' ability to reflect or emit the electromagnetic spectrum of light energy and stimulate the retina in eye. The majority four pigments from plant foods can be classified into four groups depending on their structures: chlorophylls (tetrapyrroles), carotenoids (tetraterpenoids), anthocyanins (*O*-heterocyclic), and betalains (*N*-heterocyclic) (4, 6). Generally, chlorophylls and carotenoids are lipid-soluble pigments and flavonoids and betalains are water-soluble pigments (2). Chlorophylls are green pigments ubiquitously found in photosynthetic tissues of higher plants. Carotenoids are a large group of compounds that provide yellow to red coloration in plants. Flavonoids, especially anthocyanins, provide red, blue, and violet colors of many fruits and vegetables. Betalains are responsible for the red and yellow colors in beef root and amaranth (4, 7).

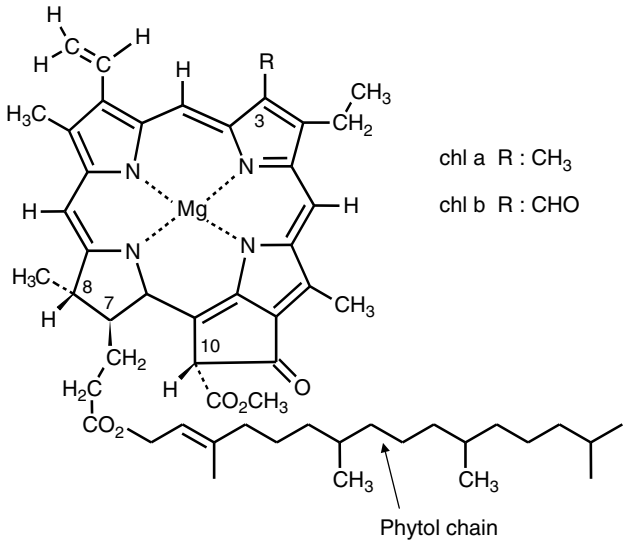

FIGURE 14.1 The structure of chlorophyll *a* and *b*.

II. CHLOROPHYLL

Chlorophylls are present in green plants capable of photosynthesis. Chlorophylls are the most abundant pigments among biologically produced pigments (8, 9). In foods, chlorophylls are widely distributed in green leafy edible plants and vegetables.

A. Structures of Pigment and Its Derivatives

Chlorophylls are derived from porphyrin complexed with magnesium. The porphyrin ring is a fully unsaturated and conjugated macrocyclic structure with tetrapyrrole units in which the pyrrole rings are joined by methylene bridges. Several chlorophylls are found in plants. Chlorophyll *a* (blue-green) and *b* (yellow-green) are present in green plants in the ratio of 3:1 (Figure 14.1). The magnesium in chlorophylls can be removed easily by acids and chlorophyll *a* and *b* form pheophytins *a* and *b* (olive-brown color), respectively. Hydrolysis of the phytol side chain forms the water-soluble chlorophyllide derivative. Both the removal of phytol group and magnesium can generate pheophorbide, which is also water soluble (Figure 14.2) (4, 7, 10). The C10 carbomethoxy groups (CO_2CH_3) of pheophytins and pheophorbide can be removed by thermal processing and pyropheophytin and pyropheophorbide are formed, respectively (Figure 14.2).

B. Chemical Properties

1. Thermal Processing

Thermal processing can isomerize the C10 carbomethoxy groups (CO_2CH_3) of chlorophyll *a* and *b*, and produce chlorophyll *a′* and *b′*, respectively (11). The colors of epimers are the same as that of parent chlorophylls due to their identical spectral properties. Thermal processing enhances removal of Mg in the tetrapyrrole center in weakly acidic conditions forming the olive-brown colored pheophytins. Chlorophyll *b* is more stable to thermal processing than chlorophyll *a* due to the electron withdrawing effects of its C3 formyl group. Thermal degradation of chlorophylls in vegetable tissue is affected by pH. In alkaline condition (pH 9.0), chlorophyll is stable to

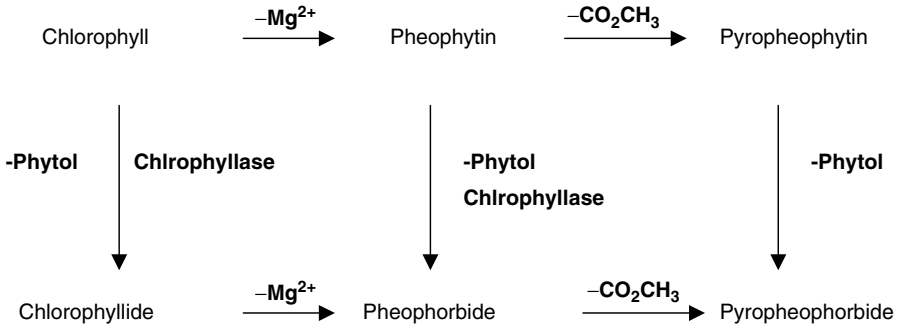

FIGURE 14.2 Reaction of chlorophylls and derivatives.

heat treatment while it is unstable in acidic condition (pH 3.0). Thermal processing for chlorophylls is sequential: Chlorophyll changes to pheophytin by first removing Mg and finally to pyropheophytin by loss of the C10 carbomethoxy groups (12). Canned products of vegetables contain mainly pheophytin and pyropheophytin, which are responsible for the olive-brown color in many canned vegetables (11, 12).

2. Allomerization

Chlorophylls in alcohol or other solvents exposed to oxygen can be oxidized and produce blue-green color compounds, which is called allomerization. The major allomerization products are 10-hydroxychlorophyll and 10-methoxylactones. The main allomerization product of chlorophyll *b* is 10-methoxylactones (8, 13).

3. Photodegradation

Chlorophylls in plant tissue are protected from degradation during photosynthesis when located within the plant matrix. However, when exposed to light chlorophylls in solution are light sensitive and degrade into colorless chlorophyll derivatives. It is believed that photodegradation of chlorophylls is due to the opening of tetrapyrrole rings and fragmentations of chlorophylls into small molecules (14). Chlorophylls are well-known photosensitizers, which can be excited by light absorption and generate many reactive oxygen species, including hydroxyl radicals and singlet oxygen. Singlet oxygen and hydroxyl radicals can react with the tetrapyrrole ring of chlorophylls and produce peroxides and more free radicals, which eventually degrade chlorophylls into colorless photodegradation products (7, 15).

4. Enzymatic Decomposition

Chlorophyllase is an esterase and can catalyze the removal of the phytol group from chlorophylls and pheophytins to form chlorophyllides and pheophorbies, respectively (Figure 14.2). Chlorophyllase can be active only on porphyrins with a C10 carbomethoxy group (CO_2CH_3) and hydrogens at the C7 and C8 positions (16). The activity of chlorophyllase is optimum at the temperature between 40°C and 82°C (7, 17) and some mild heat treatment can activate the chlorophyllase enzyme (18). Chlorophyllase in vegetable tissue loses its activity when vegetables are heated over 100°C.

C. Physical Properties

Chlorophyll is located in chloroplasts of green plants. Approximate chlorophyll contents of selected green vegetables are shown in Table 14.1. Due to the biological variability and differences among varieties, chlorophyll content in Table 14.1 should be used as a general guide (18). Chlorophylls can absorb visible light between 600 and 700 nm (red region) and between 400 and 500 nm (blue region). Depending on the presence of the metal atom in the tetrapyrrole center, the color of chlorophylls can change. Replacement of magnesium with Sn^{2+} and Fe^{3+} give a grayish-brown color while copper and zinc ions retain a green color (10). The stability of chlorophylls can be increased by substituting magnesium with copper. Copper chlorophyll complexes have better stability to oxygen, light, and alkaline conditions. Chlorophylls in leaves are broken down during senescence. Chlorophylls in fruits are often present in an unripe state such as in tomatoes and gradually disappear during ripening (19). In

TABLE 14.1
Approximate Chlorophyll Content in Selected Vegetables

		Chlorophyll Content (μg/g plant tissue)		
Vegetables		***a***	***b***	**Total**
Spinach	Fresh tissue	1380	440	1576
	Dry tissue	6980	2490	
	Canned-dry tissue	830 (Phe *a*) 4000 (Pyro *a*)		
Peas	Fresh tissue	106	12	
	Dry tissue	34 (Phe *a*) 33 (Pyro *a*)	13 (Phe *b*) 12 (Pyro *b*)	
Lettuce	Fresh tissue	334	62	
Kale	Fresh tissue	1370	464	1870
Celery	Leaves-fresh tissue	1143	225	
	Stalk—fresh tissue	29	7	
Asparagus	Fresh tissue	139	74	180–300
	Dry tissue	180 (Phe *a*) 110 (Pyro *a*)	51 (Phe *b*) 30 (Pyro *b*)	
Beans	Fresh tissue	54	17	
	Dry tissue		230–870	
	Canned-Dry tissue	340 (Phe *a*) 260 (Pyro *a*)	180 (Phe *b*) 95 (Pyro *b*)	

Chl = Chlorophyll, Phe = Pheophytin, Pyro = Pyropheophytin.
Adapted from Ferruzzi and Schwartz (18).

Europe, copper chlorophyll derivatives have been used as colorants in sugar confectionary, ice cream, dessert mixes, and cheeses with a combination of other colorants while in the U.S. the use of the derivatives is limited toothpaste and tooth powder (9).

III. CAROTENOIDS

Carotenoids are the most widely distributed pigments in nature with over 700 carotenoids identified. Carotenoids are located in the chloroplasts of plants and often masked by more dominant chlorophyll pigments. In humans, some carotenoids can act as precursors of vitamin A and have been associated with biological activities to inhibit specific chronic diseases (7, 20).

A. Structures of Pigment and Its Derivatives

Carotenoids are a group of tetraterpenoids. The basic carotenoid structural backbone consists of isoprenoid units formed either by head-to-tail or by tail-to-tail biosynthesis. There are primarily two classes of carotenoids: carotenes and xanthophylls. Carotenes are hydrocarbon carotenoids and xanthophylls contain oxygen in the form of hydroxyl, methoxyl, carboxyl, keto, or epoxy groups. Lutein in green leaves and zeaxanthin in corn are typical xanthophylls. The structures of carotenoids are acyclic, monocyclic, or bicyclic. For example, lycopene is acyclic, γ-carotene is monocyclic, and α- and β-carotenes are bicyclic carotenoids (4). Double bonds in carotenoids are conjugated forms and usually the all *trans* forms of carotenoids are found in plant tissues (Figure 14.3).

Carotenoids are distributed in a wide range of fruits and vegetables containing chlorophyll pigments. The most common carotenoid in plant tissue is β-carotene, which exhibits a yellow color. Tomatoes (lycopene), carrots (α- and β-carotenes), pumpkin (β-carotenes), corn (lutein and zeaxanthin), and sweet potatoes (β-carotenes) are other typical examples. Annatto, which is the seed of the tropical bush *Bixa orellana*, is in the class of carotenoids and has a yellow to orange color. The major coloring annatto pigment is *cis*-bixin used in dairy products such as cheese (7) (Figure 14.3).

B. Chemical Properties

1. Thermal Processing

Carotenoids are relatively stable during typical thermal processing. However, severe heat treatment can induce isomerization of carotenoids and even fragmentation of carotenoids into volatile compounds. Isomerization of carotenoids can be induced by heat, acid, or light.

2. Oxidation

Carotenoids are easily oxidized due to the presence of conjugated double bonds in molecules. In the case of β-carotene, epoxides and carbonyl compounds are first formed. Further oxidation results in the formation of short-chain mono- and deoxygenated compounds including epoxy-β-ionone. Extensive oxidation causes the loss of color in carotenoids (4, 7).

3. Enzyme Effects

Lipoxygenase indirectly accelerates the oxidation of carotenoids and loss of pigments. Lipoxygenase first catalyzes the formation of peroxides of unsaturated double bonds in fatty acids and the generated peroxides of fatty acids react with carotenoids. The coupled reactions are efficient enough to be used for measuring the activity of lipoxygenase in plant tissue (21).

C. Physical Properties

Red, yellow, and orange fruits, root crops, and vegetables are rich in carotenoids. The color of carotenoids ranges from yellow to red depending on the number of conjugated double bonds. Carotenoids show three distinct maxima in the visible spectrum (Table 14.2) (10). The absorption of light of carotenoids is between 430 and 480 nm. A minimum of 7 conjugated double bonds is needed to produce the characteristic yellow color. Currently β-carotene, β-apo-8′-carotenal, and canthaxanthin have been synthesized and used in food industry. Carotenoids from plant extracts and/or individual compounds have been used to impart a color to foods products, including margarine, ice cream, cheese products, beverages, and bakery products (22).

D. Nutritional and Functional Properties

1. Nutritional Effects

Carotenoids can serve as precursors of provitamin A. Provitamin A activity requires that the carotenoids possess a retinoid structure (β-ionone ring). β-Carotene possesses the highest provitamin A activity due to the two β-ionone rings in the structures (Figure 14.4). *Cis* forms of carotenoids have been reported to decrease provitamin A activity (23).

2. Antioxidant Effects

Carotenoids are known to serve as efficient singlet oxygen quenchers and free radical scavengers due to the many double bonds in the molecule. As the number of double bonds increases in carotenoids, the singlet oxygen quenching ability increases (20, 24). However, some carotenoids, such as β-carotene, may act as either an antioxidant or prooxidant depending on the conditions, especially oxygen concentration (20).

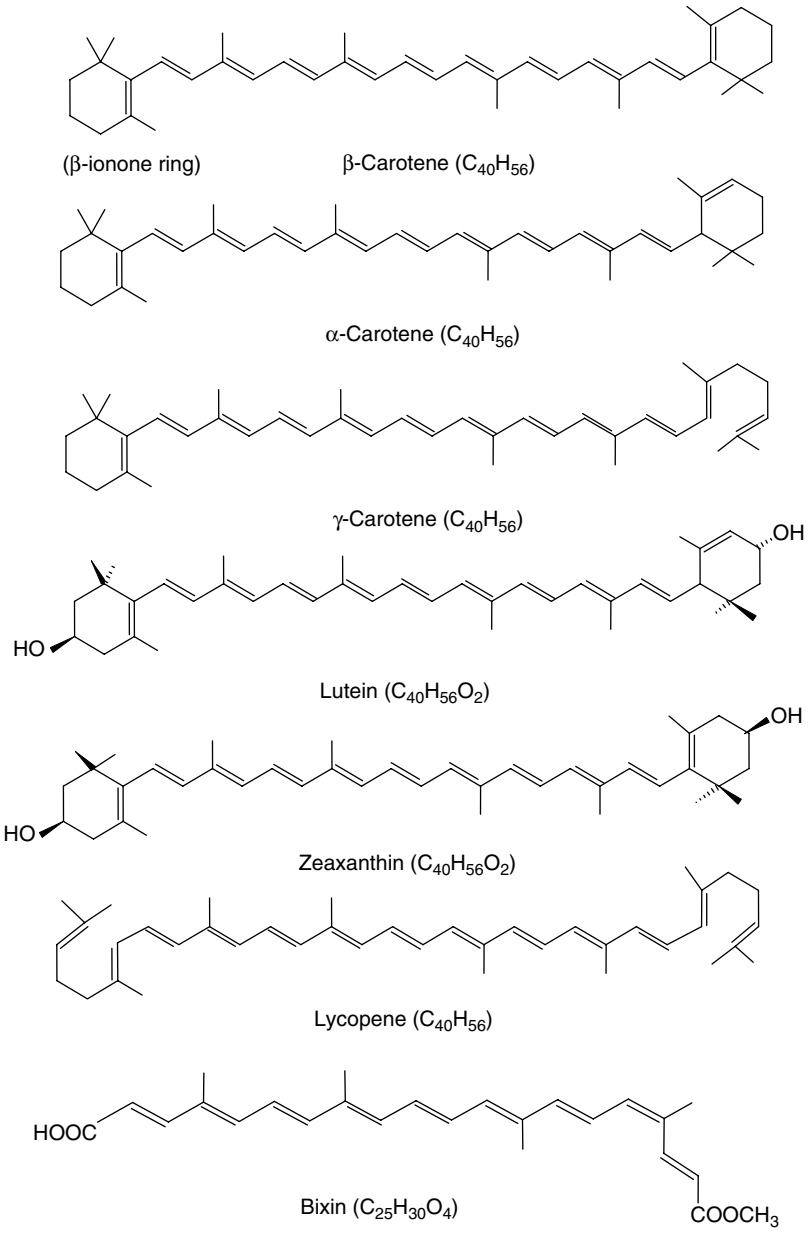

FIGURE 14.3 Structures of carotenoids.

TABLE 14.2
Absorption Wavelength Maxima for some Carotenoids

Compounds	Conjugated Double Bonds	Wavelength, nm (in petroleum ether)		
A. Effects of the number of conjugated double bonds

B. Effects of the ring structure				
γ-Carotene	11	431	462	495
β-Carotene	11	425	451	483

IV. FLAVONOIDS

The red and blue colors in flowers and fruits are due to the presence of flavonoid pigments especially anthocyanins. Other groups of flavonoids are responsible for the yellow or white color of flowers. Some brown or black colors in nature arise from either oxidation of flavonoids or chelation with metals (25). Flavonoids are polyphenolic compounds. Approximately 5,000 flavonoid compounds are reported in the literature (26).

A. ANTHOCYANINS

Anthocyanins are generally located in petal epidermal cells in the plant vacuoles (27). Anthocyanins give a wide

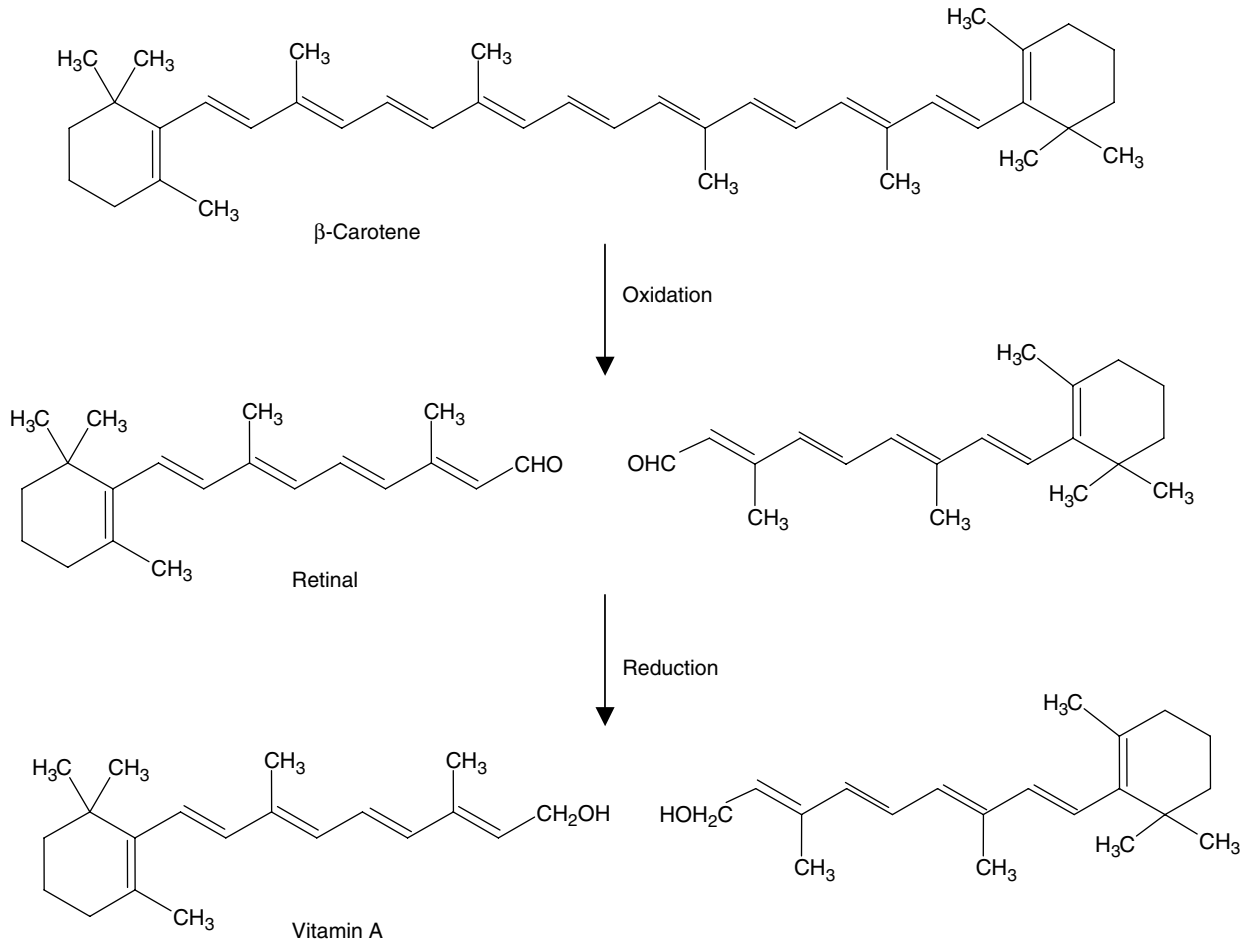

FIGURE 14.4 Formation of retinal and vitamin A from β-carotene.

range of colors with red, blue, purple, violet, magenta, and orange in many fruits and vegetables. The word anthocyanin comes from two Greek words: *anthos*, flower, and *kyanos*, blue. More than 300 anthocyanin pigments have been identified in nature (7, 26, 28).

1. Structures of Pigment and Its Derivatives

The chemical structures of anthocyanins and flavonoids are *O*-heterocyclic compounds (Figure 14.5). The basic carbon skeleton structure of anthocyanins is $C_6C_3C_6$. Anthocyanins are present in polyhydroxy and/or polymethoxy derivatives of salts. The types of anthocyanins differ depending on the number of hydroxy or methoxy groups, the type, number, and sites of bound glycosidic sugars, and the type and number of aliphatic or aromatic acids attached to the sugars (Figure 14.6). Some anthocyanins exist complexed with metals, such as Fe, Al, and Mg (28, 29).

Anthocyanins always exist as glycosides in nature. The aglycone of anthocyanin, a sugar free form, is known as anthocyanidins. Anthocyanidins are very unstable. Glycosidic substitution of anthocyanins increases the stability and water solubility of these pigments. Common glycosidic sugars in anthocyanins are one or two molecules of glucose, galactose, arabinose, xylose, and rhamnose. The sugar moiety is usually attached to the C3-position of the hydroxyl group. Increasing the number of sugar residues within the anthocyanin molecule tends to increase the stability. Acylation of the sugar residues in anthocyanins can also increase the stability of these pigments (26, 30). Acylated anthocyanins are highly colored above pH 4.0, while conventional anthocyanins are colorless above pH 4.0 (26). Acids found in acylated anthocyanins are cinnamic (*p*-coumaric, caffeic, ferulic) and aliphatic (malic, succinic, and acetic) acids. Only 6 anthocyanins are commonly found in foods out of known 22 aglycones, including pelargonidin, cyanidin, delphinidin, peonidin, petunidin, and malvidin (Figure 14.6) (26). As the number of hydroxyl groups of anthocyanins increases, the blue color of anthocyanins increases (pelargonidin → cyanidin → delphinidin). As the number of methoxyl group or glycoside linkages within anthocyanins increases, the red color of anthocyanins increases (cyaniding → peonidin; pelargonidin → pelargonidin-3-glucoside) (10).

2. Chemical Properties

Anthocyanin pigments are relatively unstable and influenced mainly by pH and temperature. Other factors

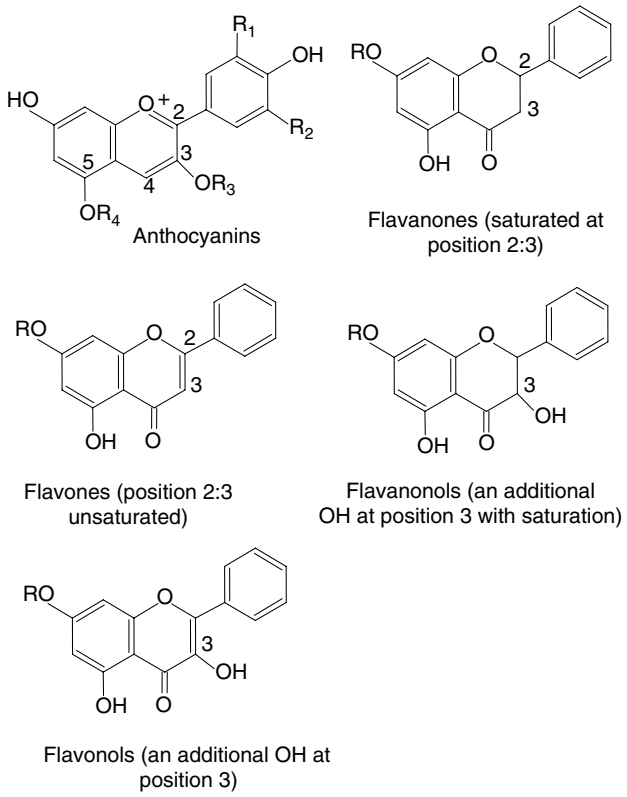

FIGURE 14.5 The chemical structures of flavonoids and anthocyanins. R_1 and R_2 = −H, -OH, or $–OCH_3$, R_3 = − glycosyl, R_4 = −glycosyl or –H.

influencing the stability of anthocyanin pigments are enzymes, oxygen concentration, ascorbic acid, sulfur dioxide, metal ions, and sugars.

The color stability of anthocyanins also depends on the substituents. Increased hydroxylation decreases stability, while methylation tends to increase pigment stability, which is due to the blocking of reactive hydroxyl groups.

a. pH effects

Color and structures of anthocyanin pigments in an aqueous medium changes depending on pH: the blue quinonoidal base, the red flavylium cation (R^+), the colorless carbinol base, and the colorless chalcone (Figure 14.7). Two compounds, red flavylium cation and colorless carbinol base, are important during pH changes from 1 to 6. At low pH, red flavylium cation dominates while at pH 4–6, the colorless carbinol base prevails. As the pH increases, the carbinol base increases and the color becomes weaker. The loss of color is due to a pH-dependent hydration at the C2 position of red flavylium cation.

$$R^+ + H_2O \leftrightarrows ROH + H^+$$

In alkali solutions (pH 8–10), highly colored ionized anhydro bases are formed. At pH 12, the fully ionized chalcones are the predominant pigments of anthocyanins. The major limitation of anthocyanin pigments as food colorants is the reduction of color intensity, changes in hue, and instability at upper pH (31, 32). However, anthocyanins in plants have vivid color and are quite stable within the plant matrix. The color of anthocyanins in plants may be stabilized through the self association of cationic forms, copigmentation with other flavonoids, formation of metal complexes with Fe, Al or Mg, and/or intramolecular interactions between acyl groups and phenolic groups (31).

b. Thermal processing

Thermal processing may easily degrade anthocyanin pigments. Thermal processing can change the equilibrium of the four types of anthocyanins toward a colorless chalcone derivative because all the reactions are heat sensitive (31).

Quinonoid ⇆ Flavylium ⇆ Carbinol base ⇆ Chalcone

c. Enzyme effects

Glycosidases and polyphenol oxidases can cause the loss of color from anthocyanin pigments. Glycosidases hydrolyze glycosidic linkages and produce sugars and aglycone. Anthocyanidins are less water soluble than their corresponding anthocyanins and can transform to colorless products. Polyphenol oxidase oxidizes anthocyanins in the presence of oxygen and *o*-diphenols. The enzyme first oxidizes *o*-diphenols into *o*-benzoquinone, which reacts with anthocyanins to form oxidized anthocyanins and degradation products (7, 29).

d. Other factors affecting stability of anthocyanin

Oxygen can react with double bonds of anthocyanin pigments resulting in loss of color. The color stability of anthocyanins in many fruit products, such as grape and cranberry juices, can be increased by removing oxygen using vacuum processing or adding nitrogen headspace (7, 32). It has been known that ascorbic acid and anthocyanin pigments disappear simultaneously in fruit juice. Oxidation of ascorbic acid produces hydrogen peroxide, which cleaves the pyrylium ring and produces colorless esters and coumarin derivatives (29).

Generally, light accelerates the decomposition of anthocyanin pigments especially in fruit juices and red wines. Anthocyanins with C5 hydroxyl groups are more susceptible to photodegradation than without C5 hydroxyl groups. In red wine, acylated and methylted diglycosides are more stable than nonacylated diglycosides, which are more stable than monoglycosides (26, 33, 34).

High concentrations of sugar can stabilize the anthocyanin pigments, which may be due to the lowering of water activity in the system. Water can react with flavylium cation at the C2 position and form colorless carbinol base. At low concentration of sugars, not only water but sugar itself can accelerate the degradation of anthocyanins. Brown pigments in fruit juices can be formed from anthocyanins and furfural or hydroxylmethylfurfural, which are Maillard browning reaction products (29).

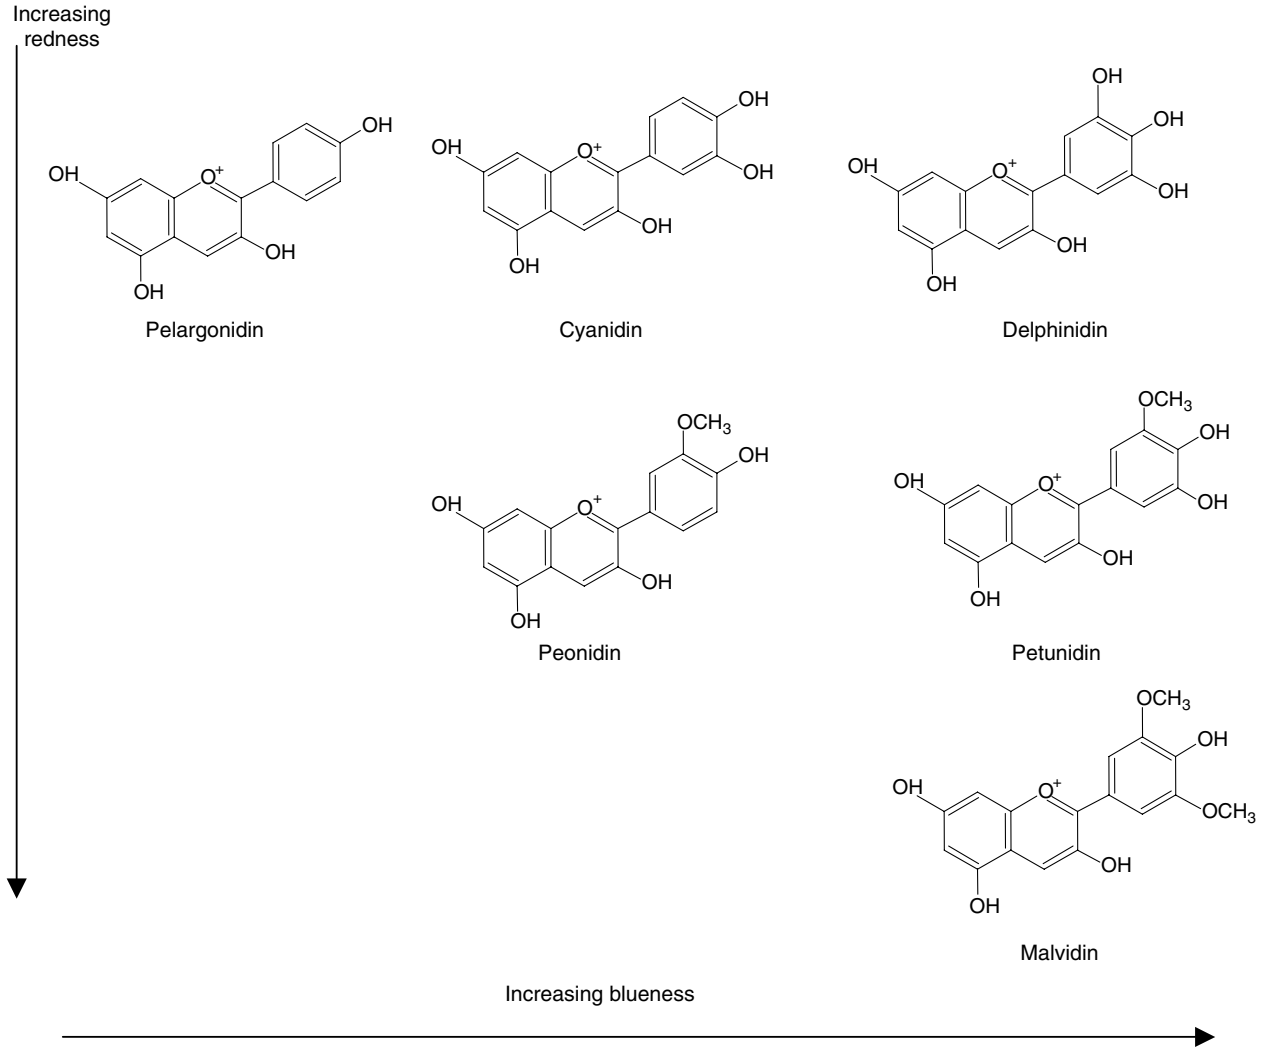

FIGURE 14.6 The most common anthocyanins in foods.

Metal complexes of anthocyanins are common and stabilize the color of anthocyanin-containing foods. Metals, including Ca, Fe, Al, and Sn, have protective effects on the anthocyanin stability in cranberry juices (29). However, a fruit discoloration, or "pinking" in pears and peaches, is believed to come from a metal anthocyanin complex.

Sulfur dioxide (SO_2), an antimicrobial agent in some fruit products, can react with anthocyanins at the C4 position and produce colorless pigments. This bleaching process can be reversible by desulfuring using thorough washing procedures before further processing.

The more concentrated anthocyanins show higher stability than less concentrated pigments (26). Copigmentation of anthocyanins with other polyphenolic compounds and metal ions can improve the stability and intensity of the color (29, 35).

3. Physical Properties

The color of anthocyanins and anthocyanidins arises from the excitation of many double bonds through absorbing light energy. Anthocyanidins have two absorption maxima: one in the visible light spectrum at 500–550 nm and a second in the ultraviolet spectrum at 280 nm. Anthocyanins in selected fruits, vegetables, and food products are shown in Table 14.3.

Currently, grapes and red cabbage are commercially available major anthocyanin sources (26). Fruit juices, vegetable juices, jellies, jams, ice cream, yogurts, canned candies, and bakery fillings are the main food products where anthocyanin pigments are applied. Europe, Asia, and South America use anthocyanin pigments to a less limited extent compared to the U.S. (28).

B. Other Flavonoids

Flavonoids include flavones, flavonols, flavanones, flavanonols, and anthocyanins, which are all based on a common structure (Figure 14.5). The flavones have a double bond between C2–C3, while flavanones are saturated at C2–C3. Flavonols possess an additional hydroxyl group at the C3 position and flavanonols are

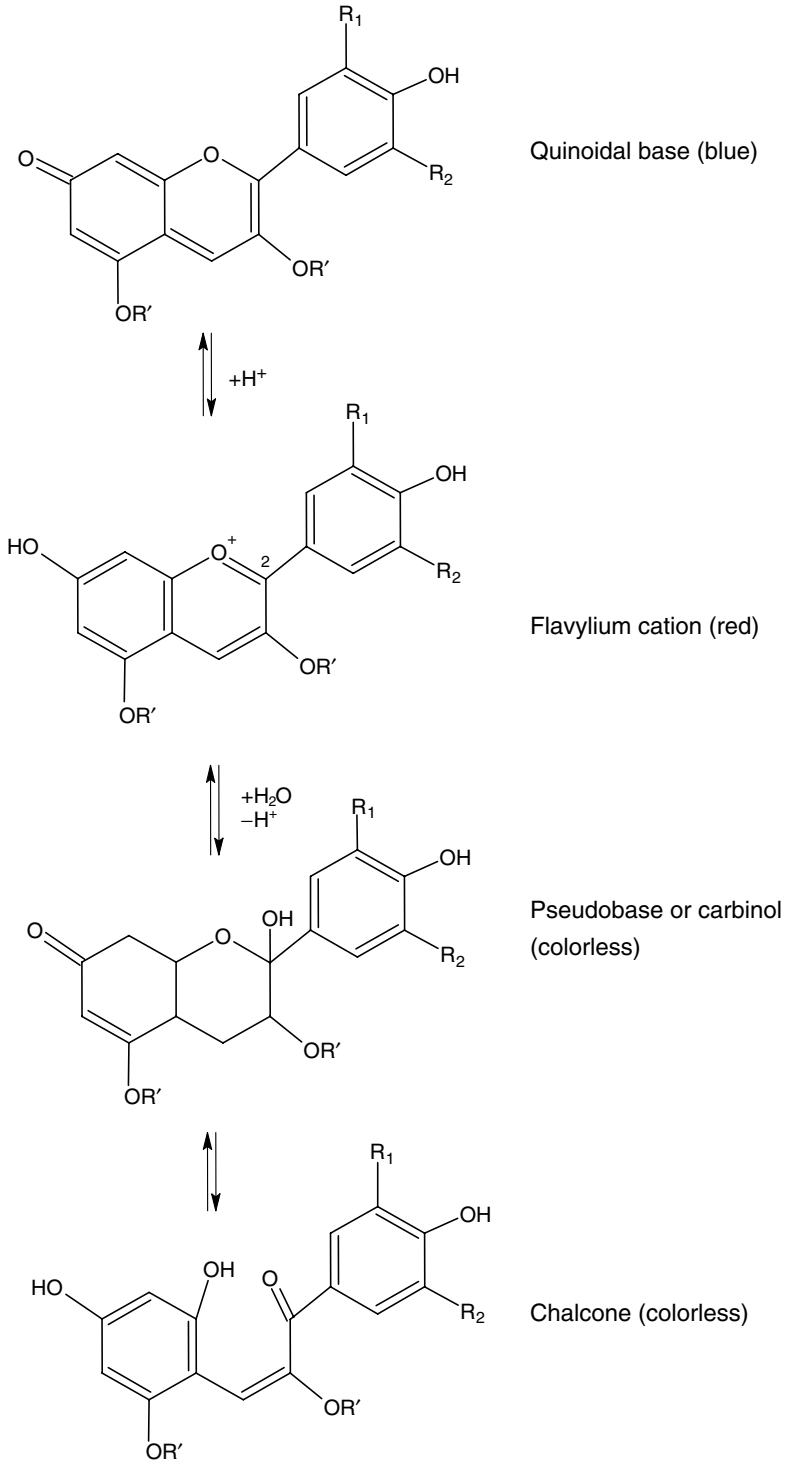

FIGURE 14.7 Structure changes of anthocyanins at 25°C with pH. R = sugar moiety.

saturated between C2 and C3 with hydroxyl group at the C3 position. Each flavonoid group is different depending on the number of hydroxyl, methoxyl, and other substituents on the two benzene rings. The most ubiquitous flavonoid is quercetin, 3, 5, 7, 3′, 4′-pentahydroxy flavone (4).

The spectral absorption of flavonoids occurs between 280 and 390 nm depending on the substituents and chelation with metals. Metals such as iron and aluminum increase the yellow color of flavonoids. Flavonoids play important roles in the formation of color in processed foods through metal chelation and copigmentation with other pigments (35).

Tannins are water-soluble polyphenolic compounds that can react with protein and other polymers such as polysaccharides. The color of tannins ranges from

yellowish-white to light brown, and tannin contributes to the astringency in foods. Proanthocyanidins, condensed tannins, are colorless compounds and can convert to colored compounds during food processing. Proanthocyanidins are present in cocoa beans, apples, pears, and other fruits (36).

V. BETALAINS

Betalains are found in beetroot and amaranth, and provide red and yellow colors to these plants. The red betalains are known as betacyanins and the yellow betalains are betaxanthins. Betalains are water-soluble and located in the vacuoles of plant cells (37, 38).

A. Structures of Pigment and its Derivatives

General structures of betalains, *N*-heterocyclic compounds, are the condensation of a primary or secondary amine with betalamic acid (Figure 14.8). Betacyanin pigments contain 1, 2, 4, 7, 7 pentasubstituted 1, 7-diazaheptamethin system and exhibit a light absorption maximum at 540 nm. Betaxanthins do not have 1, 2, 4, 7, 7 pentasubstituted 1, 7-diazaheptamethin system and the light absorption maximum is approximately 480 nm. Depending on the substituents, various betacyanins can be present such as betanidin, betanin, amaranthin, isobetanidin, isobetanin, and isoamaranthin. Isobetanidin, isobetanin, and isoamaranthin are the epimers of betanidin, betanin, amaranthin, respectively, at C15 positions (Figure 14.8). Betanin from red beet and amaranthin from amaranth are major sources of betalain pigments. Betaxanthins possess an amino acid substituents rather than the indole nucleus found in betacyanins (Figure 14.8). Indicaxanthin, vulgaxanthin-I, and vulgaxanthin-II are betaxanthins with proline, glutamine, and glutamic acid, respectively, as the amino acid substituent. Betacyanins can be converted into betaxanthins in the presence of excessive amino acids, which indicates that betacyanins and betaxanthins are structurally related.

B. Chemical Properties

1. Thermal Processing

Betanin, the major pigment found in beetroot, degrades to betalamic acid and cyclopa-5-*O*-glucoside either under mild alkaline condition, heating of alkaline solutions, or during thermal processing (Figure 14.9). This reaction requires water, indicating that water activity affects the stability of betanin in food products. Low water activity helps to retain their pigments. This reaction is reversible during thermal processing and betanin can be regenerated through Schiff-base condensation between the aldehyde group of betalamic acid and amine of cyclopa-5-*O*-glucoside. Heat treatment increases the isomerization of betanin into isobetanin (38).

2. Other Factors Affecting Betalain Stability

Betalain can be oxidized in the presence of oxygen and degrades the color of its pigments. Light exposure also accelerates the oxidation of betalain. The presence of antioxidants, such as ascorbic acid and isoascorbic acid, can improve stability (38).

C. Physical Properties

Betalain solutions show a maximum light absorbance at 537–538 nm between pH 3.5 and 7.0. Below pH 3.5,

maximum absorption of betalain shifts towards shorter wavelengths (535 nm at pH 2.0), while above 7.0, the maximum absorption shifts to longer wavelengths (544 nm at pH 9.0). The antioxidant effects of betalain on lipid peroxidation have been reported (39). Extracts of beetroot containing these pigments are used in foods, particularly confectionary products (29, 38).

15 Carbonated Beverages

Daniel W. Bena
PepsiCo International

CONTENTS

I. BACKGROUND INFORMATION

A. History of Soft Drinks

The first carbonated beverage, of sorts, was provided by nature, and dates back to antiquity, when the first carbonated natural mineral waters were discovered—although they weren't usually used for drinking. Instead, they were used for bathing by the ancient Greeks and Romans, owing to their purported therapeutic properties. It wasn't until thousands of years later, in 1767, that the British chemist, Joseph Priestley, was credited with noticing that the carbon dioxide he introduced into water gave a "pleasant and acidulated taste to the water in which it was dissolved" (1). The history of carbonated soft drinks (CSDs) is somewhat sparse during its early evolution, but most agree that development of CSDs is due, in large part, to pharmacists.

Today, carbonated beverages are primarily recognized for their refreshing and thirst-quenching properties. In the early to middle 1800s, however, it was these pharmacists who experimented with adding "gas carbonium," or carbon dioxide, to water, and supplementing its palatability with everything from birch bark to dandelions in the hopes of enhancing the curative properties of these carbonated beverages (2). "Soft drinks," a more colloquial yet very common name for carbonated beverages, distinguish themselves from "hard drinks," since they do not contain alcohol in their ingredient listing (3). This is in clear contrast to other beverages, such as distilled spirits, beer, or wine. These non-alcoholic, carbonated beverages are also called "pop" in some areas of the world, due to the characteristic noise made when the gaseous pressure within the bottle is released upon opening of the package (4). Figure 15.1 provides a brief illustration of the major milestones in the history of American soft drinks.

CSDs, "pop," soda—whatever the moniker given to these beverages, one thing is clear: they have been an important part of our popular culture for decades, and will continue to be for many years to come.

B. Soft Drink Facts and Figures

Few people consciously consider how something as ostensibly simple as "soda pop" can markedly affect the economy on several fronts. The National Soft Drink Association (NSDA), founded in 1919 as the American Bottlers of Carbonated Beverages (ABCB), today represents hundreds of beverage manufacturers, distributors, franchise

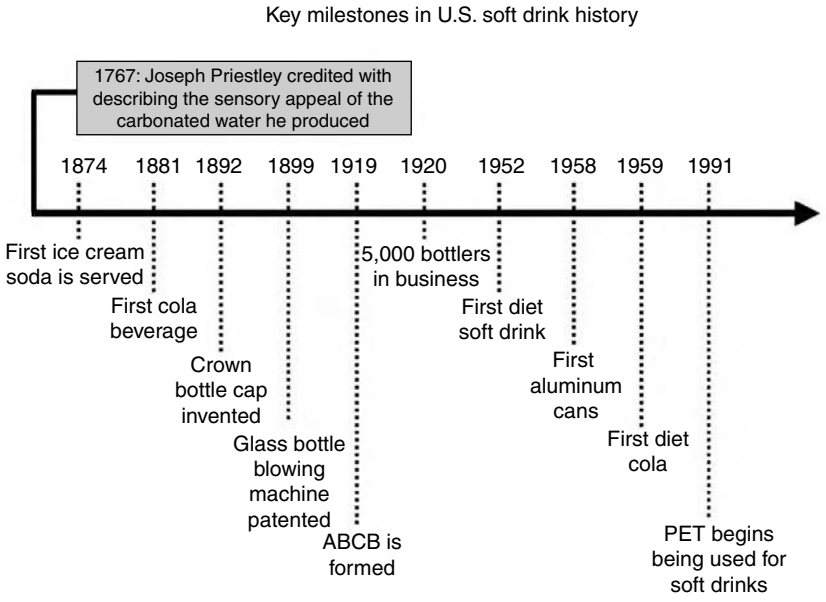

FIGURE 15.1 Key milestones in the U.S. beverage industry.

companies and support industries in the United States. According to the NSDA, Americans consumed nearly 53 gallons of carbonated soft drinks per person in 2002, and this translated into retail sales in excess of $61 billion. Nearly 500 bottlers operate across the United States, and provide more than 450 different soft drink varieties, at a production speed of up to 2,000 cans per minute on each operating line! Figure 15.2 summarizes the apportionment of total soft drink production in the year 2000.

Finally, as an industry, soft drink companies employ more than 183,000 people nationwide, pay more than $18 billion in state and local taxes annually, and contribute more than $230 million to charities each year. Few could argue that the soft drink industry has earned its place in the history of the American (and global) economy!

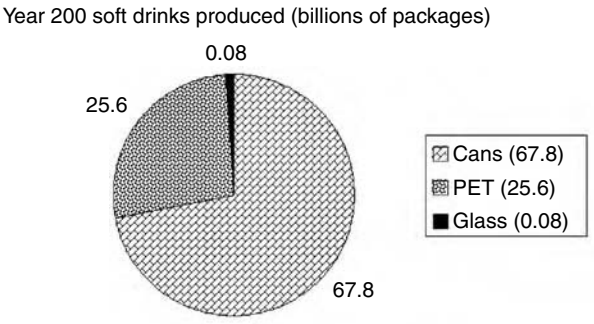

FIGURE 15.2 Distribution of cans, PET, and glass CSD packages.

C. Carbonation Science

Before discussing the process of manufacturing carbonated soft drinks, it is important to establish some fundamental chemical/physical concepts with regard to the carbonation process itself. Simply put, in the beverage industry, "carbonation" is the introduction of carbon dioxide gas into water, as depicted in Figure 15.3.

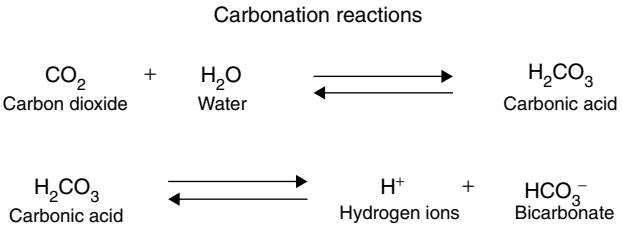

FIGURE 15.3 Carbonation reactions.

The favorable results of this simple combination are many: (1) the carbonation provides the characteristic "refreshing" quality for which carbonated beverages are most popular; (2) the dissolved carbon dioxide acts as both a bacteristat and a bactericide; and (3) the carbon dioxide dissociates in aqueous medium to form carbonic acid, which depresses the pH of the solution, thereby making the product even more protected from microbial harm (5). All in all, from a microbiologic perspective, carbonated soft drinks are innately very safe beverages.

Once the carbon dioxide is introduced into the water, which will ultimately join with flavors and sweeteners to form the complete beverage, the beverage technologist must understand how to measure and express the level of carbonation. The accepted convention in the beverage industry is *not* to measure carbon dioxide as a true concentration,

expressed in parts per million, or milligrams per liter. Instead, carbonation is expressed in units called "volumes." The concept is ultimately based on the physical gas laws of Henry, Boyle, and Charles, wherein pressure, temperature, and volume are closely interdependent. The colder the liquid, the more gas can be dissolved within it. Even within the industry, however, there is some confusion over what the exact definition of a "volume" is (6), usually arising from the temperature included in the definition. For our purposes, we will define one "volume" based on the Bunsen coefficient, described by Loomis as, "The volume of gas (reduced to 0°C and 760 mm) which, at the temperature of the experiment, is dissolved in one volume of the solvent when the partial pressure of the gas is 760 mm" (7). More informally, and to put this concept in perspective, consider a 10-ounce bottle of carbonated beverage, representing roughly 300 ml of liquid. If this carbonated beverage is prepared at one "gas volume," the package would contain approximately 300 cc of carbon dioxide. We would consider this very low carbonation from a sensory perspective, and would have a barely noticeable "fizz" upon removal of the closure. Imagine, however, for the same 300 ml of liquid, we carbonate to four gas volumes (a level typical of many products on the market today). This means that roughly 1200 cc of carbon dioxide has been introduced into the same 300 ml volume of liquid. More gas, into the same amount of liquid, and the same vessel size—imagine the increase in pressure contained within the bottle. This example explains why the characteristic "pop" of soda pop is heard when a bottle is uncapped, or a can is opened!

For the purposes of this text, the discussion of carbonation has been somewhat oversimplified, in order to make the concept more easily understood. As with any industry, the more one investigates any given topic, the more complicated and scientifically intense the subject usually becomes. Carbonation, for example, can be affected by a variety of factors, including other solids present in the liquid being carbonated, temperatures of the gas and the liquid, atmospheric pressure/altitude, and how far carbon dioxide varies from ideal gas behavior (8). These are cited merely for consideration, but are outside the scope of this chapter.

D. Process Overview

The process of manufacturing carbonated beverages has remained fundamentally the same for the last several decades. Certainly, new equipment has allowed faster filling speeds, more accurate and consistent fill heights, more efficient gas transfer during carbonation, and other improvements, but the process remains one of cooling water, carbonating it, adding flavor and sweeteners, and packaging it in a sealed container. Figure 15.4 illustrates the overall process in somewhat more detail, as we continue to build upon the basic foundation we will be discussing throughout this chapter. As we proceed, the figures depicted will become more complete, as each critical process to carbonated beverage manufacture is explained.

Carbonated beverage production begins with careful measurement of the formula quantities of each component into the syrup blending tank. Critical components include the concentrate, which contains the bulk of the flavor system; the sweetener, which typically includes the nutritive sweeteners high-fructose syrup or sucrose (in the case of

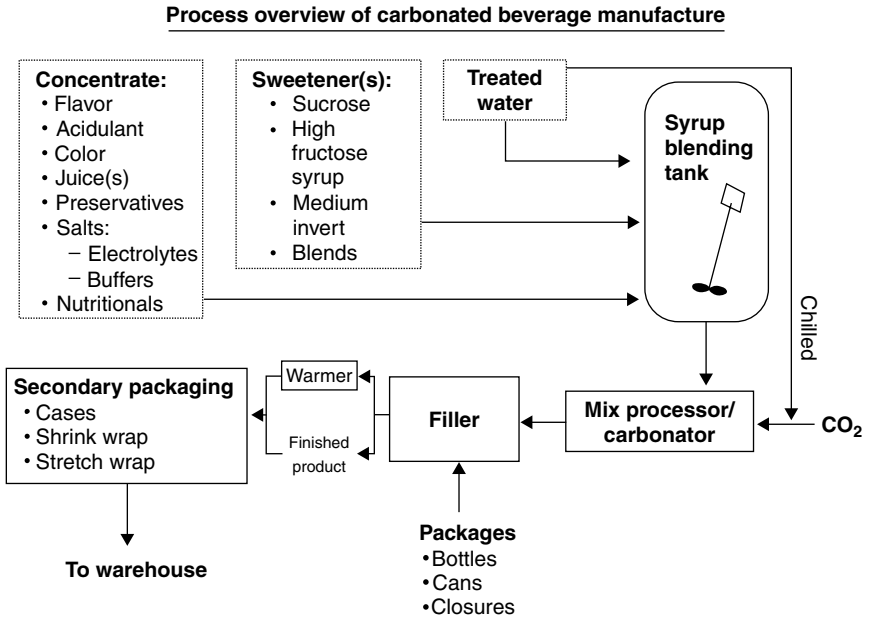

FIGURE 15.4 Process overview of carbonated beverage manufacture.

diet beverages, these are replaced with one of the high-potency sweeteners available); and water, which generally begins as municipal drinking water, and is further purified within the beverage plant. These are then blended to ensure homogeneity of the batch according to carefully prescribed standard operating procedures.

Once blending in the syrup tank is complete, the "finished syrup" is tested for correct assembly, then pumped to the mix processor, where the syrup is diluted to finished beverage level with chilled, carbonated, treated water (often a 1:6 dilution of syrup:treated water, although this varies by product). After this, the now carbonated beverage-level solution proceeds to the filler, where it is fed (usually volumetrically, by gravity) into bottles or cans, then sealed (capped in the case of bottles, seamed in the case of cans). Then, the finished product is either passed through a warmer, in order to avoid excessive condensation from forming (depending on the type of secondary packaging used), or sent directly to secondary packaging. This can include plastic or cardboard cases, shrink wrap, stretch wrap, or even more innovative devices. After packaging, the product is palletized, and stored in the warehouse until it is ready for distribution.

II. RAW MATERIALS PREPARATION

A. Concentrate

In the carbonated soft drink industry, "concentrate" is the name given to a mixture of many different categories of ingredients, illustrated in Figure 15.5.

The most notable of these, and, indeed, the topic of many urban legends surrounding its utter secrecy, is the flavor component. This is where the proprietary formulations of essential oils are found, which combine to form the characteristic flavor of the trademark beverage. Flavor components can include a single, "primary" component, or be distributed in various ways among multiple components—for example, a high-potency sweetener supplied as a dry salt as part of a secondary flavor component. In general, the majority of flavor systems include primary flavor components, and these fall into three broad categories: (1) simple mixtures, (2) extracts, or (3) emulsions.

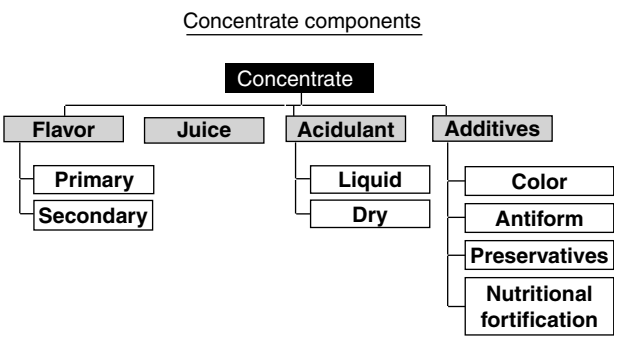

FIGURE 15.5 Concentrate components.

Simple mixtures. These are perhaps the simplest of the flavor categories to understand, but they also represent the minority of those in existence. Here, a combination of miscible liquids, or easily soluble solids, are blended together to form a homogenous aqueous mixture. Because so many essential flavor oils are not readily water soluble, the beverage technologist must abandon the idea of the simple mixture for one of the other, more flexible categories of flavors.

Extracts. As the name implies, this category of flavors involves extracting the desired flavor constituents from essential oils. Simply put, the extraction solvent—usually ethanol (although sometimes propylene glycol is used)—is used to partition those flavor constituents which are soluble in the solvent, but not freely soluble in the water directly. In this way, these flavor compounds become fully dissolved in the ethanol first. Then, this ethanolic "extract" (which is, in effect, an ethanolic solution of the flavor compounds) is added to water. Since ethanol is freely miscible with water, it acts as a carrier vehicle to help dissolve or disperse the otherwise water-insoluble flavor constituents (9). Today, equipment for both batch and continuous liquid extraction of flavor oils is available, and more novel approaches have also been developed (for example, gas extraction, super-critical fluid extraction, and other patented processes).

Emulsions. This third category is likely the largest, encompassing the bulk of the flavor systems available today. In the carbonated beverage industry, oil-in-water (or o/w) emulsions are the standard. This model involves an oil (lipophilic) internal phase, and an aqueous (hydrophilic) external phase, being made "compatible" by the use of a surfactant, or emulsifier. Surfactants are compounds that are amphiphilic; that is, there are both hydrophilic and lipophilic portions of the same molecule! This facilitates a decrease in the surface tension when oil and water are mixed together, and also allows the lipophilic portion to align with the oil, and the hydrophilic portion to align with the water (10). In so doing, the emulsifier forms a bridge, of sorts, between the two phases, and allows them to be dispersed, without gross separation, for the desired length of time (generally at least as long as the technical shelf life of the beverage).

Since carbonated beverages are of low pH, owing in part to the carbonic acid from the dissolved carbon dioxide, but also from the acid components of the formulae, acid hydrolysis is one of the major concerns to the beverage flavor developer. By positioning itself between the oil and water phases, the emulsifier protects the sensitive flavor oils from chemical degradation in this acidic environment. In addition, the emulsifier protects the flavors oils from oxidation from the naturally dissolved oxygen in the water which constitutes the aqueous phase. So, a well-designed

and prepared emulsion can dramatically extend the sensory shelf-life of the flavor system, and the overall physical stability of the beverage.

In addition to the flavors, Figure 15.5 also depicts a variety of other components which may be part of the concentrate. These include juices, which must be handled and stored carefully in order to preserve their quality, acidulants (both liquid and dry), and a host of other additives, depending on their desired function (for example, antifoam, preservative, nutrients, etc.).

B. WATER

Water is the major component in carbonated beverages, and represents anywhere from 85 to near 100% of the finished product. Interestingly, it is unlike any other ingredient, since we rarely have the number of options for water supply that we have with other raw materials! Obviously, then, particular diligence must be employed when selecting a water supply. Beverage plants use water from ground supplies, surface supplies, or both. Ground supplies include springs, deep and shallow wells, and artesian aquifers. Surface supplies include rivers, lakes, streams, and reservoirs. Within these sources, there is wide variation in type and content of inorganic (for example, metals, minerals, sulfate, chloride, nitrate), organic (for example, volatile organics, natural organic matter), microbiologic (bacteria, viruses, protozoa), and radiologics (radionuclides, alpha- and beta-activity). Table 15.1 provides a relative comparison of some characteristics of ground and surface supplies (11).

One critical point of which to be aware is that municipal treatment plants should not normally be depended upon to consistently supply water suitable for the needs of most carbonated beverage manufacturers. While the municipality treats the water so that it is safe to drink, and aesthetically pleasing to the consumer (potable and palatable), they cannot afford to consider the needs of all industrial end users, so they may not consistently supply a water of the high quality needed for producing our finished product and ensuring the beverage a long shelf life. There is also the possibility of contamination of the city water as it passes through the distribution system from the municipal treating plant to the beverage plant. This is particularly true with respect to organic matter and metal content, such as iron. The quality of the water used for carbonated soft drinks must be considered from several perspectives:

(1) *Regulatory Compliance*: The water used must be in compliance with all presiding local and national laws and guidelines. This jurisdiction is generally clear in the United States, between the Environmental Protection Agency and the Food and Drug Administration. However, as you consider the international beverage locations, the regulatory picture sometimes becomes more cloudy.

(2) *Beverage Stability*: Intuitively, as the major ingredient in carbonated soft drinks, the constituents in water can have a profound impact on the overall quality and shelf life of our beverage products. For example, if alkalinity is not

TABLE 15.1
Comparison of Ground and Surface Water Supplies

Parameter	Ground Water	Surface Water
Total dissolved solids	Higher	Lower
Suspended solids	Lower	Higher
Turbidity and color	Lower	Higher
Alkalinity	Higher	Lower
Total organic carbon	Lower	Higher
Microbiology		
Protection from bacteria and viruses	Highly protected	Highly susceptible
Protection from protozoa	Almost completely protected	Highly susceptible
Presence of iron and/or manganese bacteria	Common	Rare
Hydrogen sulfide gas	Common	Uncommon
Aeration/dissolved oxygen	Lower	Higher
Temperature	More consistent	More variable
Flow rate	Very slow (1 m/day)	Very fast (1 m/sec)
Flow pattern	Laminar	Turbulent
Susceptibility to pollution through surface run-off	Low	High
Time for a contaminant plume to resolve	Very long—often decades, potentially centuries	Usually short—days/months; sometimes years

Source: Bena, D. 2003. Water Use in the Beverage Industry, in Food Plant Sanitation (YH Hui, ed.). Marcel Dekker, New York.

controlled, the acidic profile of the beverage formulae will be compromised, making the beverage more susceptible to microbial growth and spoilage.

(3) *Sensory*: Many contaminants, even at levels within drinking water standards, may adversely affect the finished beverage. For example, some algae produce compounds (geosmin and methyl isoborneol) which are sensory active at levels as low as nanograms per liter (12). These can result in "dirty, musty" flavor and aroma in finished products.

(4) *Plant Operations*: Water for non-product (auxiliary) uses must also meet the performance standards of the carbonated soft drink producer. These standards and guidelines are usually enacted to prevent corrosion (for example, from high chloride content in heat exchangers) and scaling (for example, from hardness salts in boilers), which may result in premature equipment failure and/or loss of operational efficiency.

Whether the beverage plant has its own well, or the water supply comes from a modern municipal treatment plant, each individual water supply presents its own particular problems. In most, if not all cases, the incoming raw water which supplies a beverage plant already meets the applicable standards for potability of drinking water. The beverage producer then further purifies the water to meet the quality necessary for its products. This treatment can take many forms, but the three largest categories of in-plant beverage water treatment are (1) conventional lime treatment systems (CLTS), (2) membrane systems (including reverse osmosis, nanofiltration, and ultrafiltration), and (3) ion-exchange. Volumes have been written about each treatment modality, and a detailed discussion is beyond the focus of this chapter. However, a brief summary of each treatment category is provided below (13).

(1) Conventional lime treatment systems (CLTS). This treatment chain represents the majority of most beverage treatment armadas worldwide, although the balance is quickly shifting in favor of membrane technologies. CLTS involves the addition of a coagulant (as an iron or aluminum salt), hydrated lime (for pH control), and chlorine (for oxidation and disinfection) to a reaction tank. The agitation is gently controlled over the course of a two-hour retention time, during which a floc begins to form, grow, and settle, bringing contaminants with it to the bottom of the tank, where they await discharge. Figure 15.6 illustrates what happens in this reaction vessel.

Historically, and as little as twenty-five years ago, conventional lime treatment was regarded as the "ideal" treatment for raw water of virtually any quality. Indeed, this system, coupled with the required support technology—fine sand filtration, granular activated carbon, polishing filtration, and ultraviolet irradiation—does address a broad range of water contaminants. The advantages and

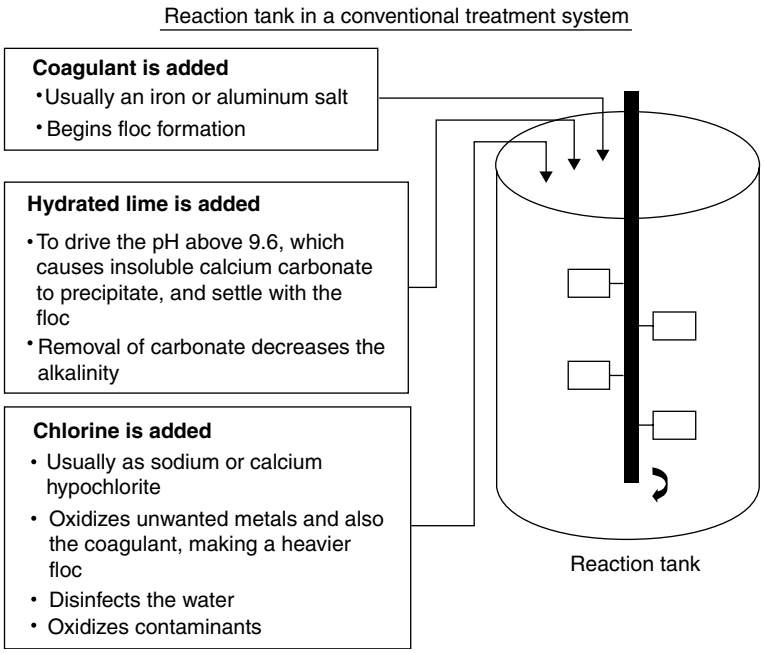

FIGURE 15.6 Reaction tank in a conventional lime treatment system.

disadvantages of conventional lime treatment are summarized in Table 15.2.

(2) Membrane technology. Clearly, this has seen the most growth in recent years with the advent of more resistant membrane materials of construction and more flexible rejection characteristics. Included in this category is the prototype of the cross-flow, polymeric membrane filtration systems—reverse osmosis, along with nanofiltration and ultrafiltration (both polymeric and ceramic). By carefully controlling the membrane pore size during manufacture, and the applied pressure during operation, reverse osmosis membranes can effectively remove in excess of 99% of many dissolved species—down to the ionic level (for example, dissolved calcium or sulfate). Table 15.3 illustrates the relative capabilities of the three major membrane processes with regard to a variety of constituents possible in the incoming water (14).

Since reverse osmosis is often the cited "membrane standard" against which the performance of others are judged, the advantages and disadvantages of reverse osmosis are listed in Table 15.4.

Also worth mentioning, though not discussed, among this group are the "hybrid" technologies, which include novel membrane and ion-exchange utilization. Examples are electrodialysis technology for removal of ionic species in water, and continuous electrodeionization.

(3) Ion-exchange. This technology is routinely utilized for partial or complete demineralization of the water supply, softening, or dealkalization, or it can be customized for selective removal of a specific contaminant (for example, denitratization). In simplest terms, ion-exchange involves using a selective resin to exchange a less desirable ion with a more desirable ion. Of course, a great deal of chemical research goes into the development of these selective resin materials, but the functional outcome remains

TABLE 15.2
Advantages and Disadvantages of CLTS

Advantages	Disadvantages
Removes alkalinity and hardness	Does not effectively reduce nitrate, sulfate, or chloride concentration
Removes organic debris, particulates, and natural organic matter (NOM)	Sludge formation and disposal requirements
Reduces metal concentrations (iron, manganese, arsenic, others) and some radionuclides	May promote the formation of disinfection by-products (trihalomethanes) under certain conditions
Reduces some color compounds (tannins), off-tastes, and off-odors	Often difficult to operate consistently in waters with very low dissolved solids
Reduces bacteria, virus, and protozoan populations	Relatively large space requirements on plant floor ("footprint")

TABLE 15.4
Advantages and Disadvantages of Reverse Osmosis

Advantages	Disadvantages
Removes nearly all suspended material, and greater than 99% of dissolved salts in full-flow operation	Pretreatment must be carefully considered, and typically involves operating costs for chemicals (acid, antiscalant, chlorine removal)
Significantly reduces microbial load (viruses, bacteria, and protozoans)	Does not produce a commercially sterile water
Removes nearly all natural organic matter (NOM)	Membranes still represent a substantial portion of the capital cost, and may typically last 3–5 years
May be designed as a fully automated system with little maintenance	Low solids water may be aggressive toward piping and equipment, so this must be considered for downstream operations
Relatively small space requirements on the plant floor ("footprint")	High pressure inlet pump is required

Source: Bena, D. 2003. Water Use in the Beverage Industry, in Food Plant Sanitation (YH Hui, ed.). Marcel Dekker, New York.

straightforward. For example, softening resins are often employed to remove hardness (calcium and magnesium) from the water entering boilers and heat exchangers. In this application, the hardness ions are not wanted. The softening resin (for example, a sodium zeolite clay) is charged with active and replaceable sodium ions. When the "hard" water passes across the softening bed, the resin has a selectivity for calcium and magnesium, so it replaces them for sodium. The result is that the water exiting the softener is virtually free of calcium and magnesium (since they were replaced by sodium), and is safe to use in boilers and other equipment, since it will no longer have the tendency to form scale.

To supplement the major treatment systems mentioned above, the carbonated beverage producer often utilizes a host of other "support technologies," including activated carbon filtration (to remove organic contaminants and chlorine), sand filtration (to remove particulates), and primary and secondary disinfection (using chlorine, ozone, ultraviolet, heat, or a combination). By the time the treated water is finished, it is microbially and chemically safe, clear, colorless, and ready to be used for syrup and beverage production.

C. Sweeteners

The two major categories of sweetener types are nutritive (that is, they provide some caloric value) and "high potency" (that is, the type used in diet beverages, since they are many times sweeter than sucrose, and generally non-caloric). There are several high potency sweeteners available to the worldwide beverage developer (aspartame, acesulfame potassium, and others), and they are almost exclusively, if not always, included as part of the "concentrate" flavor system as a dry substance package. As such, their quality can be more easily controlled by the vendor, as with any of the other concentrate ingredients, and minimal intervention is needed at the carbonated soft drink manufacturing facility. These high potency sweeteners, therefore, will not be addressed in this chapter. A concise treatise on the topic, however, is provided by the International Society of Beverage Technologists (15).

Next to water, however, the nutritive sweeteners represent the second most prevalent ingredient in the finished beverage. The most common nutritive sweeteners used in the carbonated soft drink industry are sucrose and high fructose syrups, with sucrose (from cane or beet) being the most common internationally. Within the United States, nearly all of the nutritive sweetener used in carbonated beverages is high fructose corn syrup (HFCS, either 42 or 55%). In 1996, the U.S. corn refining industry produced over 21 billion pounds of high fructose corn syrups, representing only about 12% of the total corn crop (16).

Although high fructose syrups may be obtained from other starting materials, like wheat or tapioca starch, corn remains the most prevalent starting material. A starch slurry is first digested by the addition of alpha-amylase enzyme, which results in gelatinization and ultimate dextrinization of the starting starch. Then, glucoamylase enzyme is added to result in an enriched glucose syrup (95% glucose). After this the glucose syrup is purified via particle filtration, activated carbon adsorption, and both cation and anion exchange. Then, evaporation brings the solids content within range for effective passage through the isomerization column containing the glucose isomerase enzyme. This enzyme converts much of the 95% glucose syrup to fructose, which is again purified as before and evaporated. The result is HFCS-55 of high quality. In some formulae and/or markets, HFCS-42 is used, which is simply a blend of the HFCS-55 with the 95% glucose stream to result in a product which is 42% fructose. The generic process by which corn starch is transformed to high fructose corn syrup is illustrated in Figure 15.7 (17).

In general, HFCS-55 (55% fructose) is a highly pure ingredient, due, in large part, to the activated carbon, cation, and anion exchange steps required of the process. However, the most recent research highlights the occurrence of potent sensory-active compounds which could form via chemical or microbial pathways in HFCS,

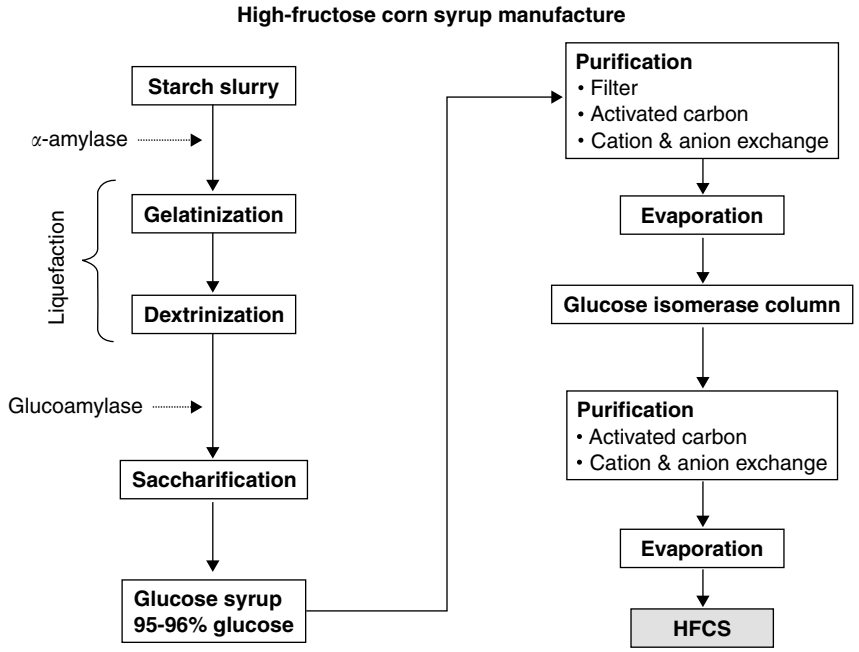

FIGURE 15.7 High fructose corn syrup manufacture.

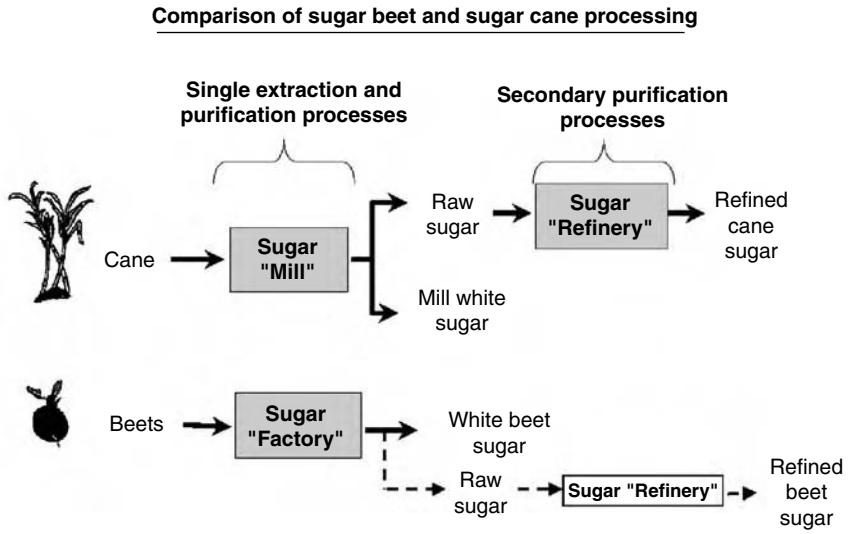

FIGURE 15.8 Cane vs. beet sugar process flow.

including isovaleraldehyde, 2-amino acetophenone, and maltol (18). When properly produced and stored, no additional treatment is necessary at the beverage plant.

Sucrose, though the clear exception in the North American beverage industry, continues to be the mainstay for international beverage markets. It may be obtained from sugar cane or sugar beet, following two distinct separation and purification schemes, as depicted in Figure 15.8 (19).

The three indicators of sucrose quality generally recognized by the sugar industry are color, ash, and turbidity. Internationally, depending on the quality of the available sucrose, it is not uncommon to subject the incoming granular or liquid sucrose to additional treatment at the beverage plant. Ash, or residual inorganic minerals, remains difficult to adequately treat at the carbonated soft drink plant, so great effort is made to source sucrose with an acceptable ash content (as defined by the individual company specifications). Turbidity is easily remedied at the beverage plant via an in-line filtration step, often incorporating diatomaceous earth as a filter aid. Color, considered by some as the primary indicator of sucrose quality, is also able to be treated at the beverage plant, but typically

requires hot treatment through activated carbon. This removes color and many sensory-active compounds, and also serves to render the sucrose free of most viable microorganisms. Figure 15.9 (19) briefly summarizes the handling and treatment of sucrose at the carbonated soft drink facility.

Liquid sucrose, usually commercially available at 67 Brix concentration (67 Brix is equivalent to 67% sucrose, by weight), is sometimes used for the production of carbonated soft drinks. Two distinct disadvantages of using liquid sucrose instead of granulated sucrose include the following: (1) the end user ultimately pays for shipping 33% water, since the ingredient is only 67% sucrose solids, as compared to granulated sucrose, which is 100% sucrose solids, and (2) this water also means that the liquid has a higher water activity than granulated sucrose, making it much more susceptible to microbial spoilage. With liquid sucrose operations, absolutely diligent transport and handling procedures are imperative.

The last, less common type of nutritive sweetener used in this industry is medium invert sugar. Chemically, this product has similarities to both sucrose and high fructose corn syrup. With medium invert sugar, or MIS, the starting material is liquid sucrose, which is then treated with one of three processes: (1) heat and acid, (2) ion-exchange, or (3) invertase enzyme. The end result of any of these processes is that roughly 50% of the starting sucrose is transformed into "invert sugar," an equimolar mixture of glucose and fructose. At this point, the inversion process is stopped, and the final commercial product contains 50% sucrose, 25% glucose, and 25% fructose. This gained favor over liquid sucrose in the beverage industry for two main reasons: (1) the finished material is 76 Brix, vs. 67 Brix for liquid sucrose, so less water is shipped, and (2) MIS has a much lower water activity, and is, therefore, much more microbiologically stable.

In summary, the producers of carbonated soft drinks have several options at their disposal for providing the sweetness to the consumer, which is so characteristic of these products. Internationally, sucrose is the major sweetener used, while in the United States, high fructose corn syrup is preferred. Irrespective of the type of sweetener, the beverage industry has treatment methods at its disposal to ensure that this ingredient consistently meets the high standards of chemical and microbial quality necessary to be used in the production of syrup and beverage.

D. Carbon Dioxide

At normal temperatures and pressures, carbon dioxide is a colorless gas, with a slightly pungent odor at high concentrations. When compressed and cooled to the proper temperature, the gas turns into a liquid. The liquid in turn can be converted into solid dry ice. The dry ice, on absorbing heat, returns to its natural gaseous state.

We learned a little of the history of carbonation earlier in this chapter, since the concept is so critical to the production of carbonated soft drinks. Just as critical is the

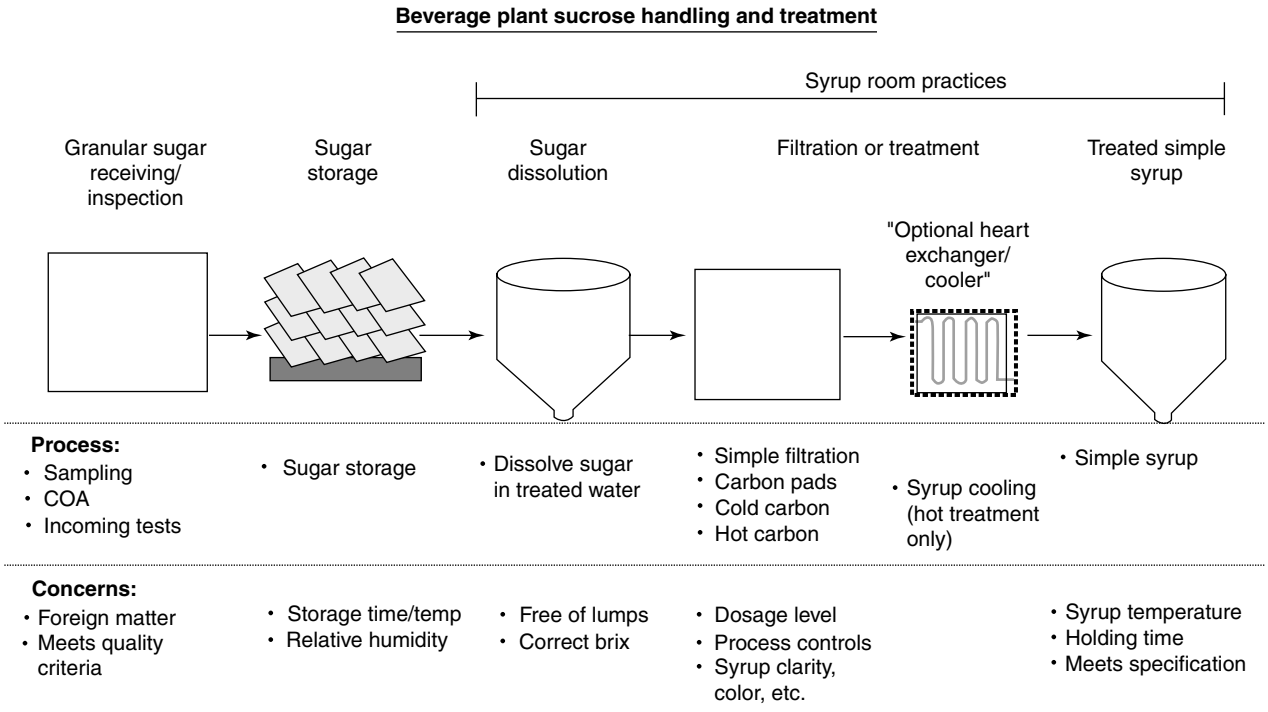

FIGURE 15.9 Sucrose handling and treatment at the beverage plant.

quality of the carbon dioxide used in this application. For many years, the quality of carbon dioxide was minimized, largely because there were no uniformly available methods with which to test the gas, as an ingredient. Those procedures that were available required special expertise to properly sample and handle this cryogenic gas. The standards of quality of the carbon dioxide used in beverages were traditionally relegated to the U.S. Compressed Gas Association (CGA), whose "quality verification levels" were incorporated into the beverage company's specification system. Then, in 1999, the International Society of Beverage Technologists (ISBT) developed the Quality Guidelines and Analytical Procedure Bibliography for Bottlers' Carbon Dioxide (20). This was a cross-corporate effort by carbon dioxide suppliers, end-users, testing labs, and allied businesses to completely update the obsolescent guidelines which had been recognized for decades. The guidelines are only available for purchase through ISBT (www.bevtech.org); they include parameters related to health/safety, sensory, and good manufacturing practices at the supplier.

Carbon dioxide may be obtained and purified from a number of different "feed gas" sources, the majority of which are listed in Table 15.5.

There are other more "exotic" sources which are often the result of carbon dioxide being generated as a by-product during an organic chemical synthesis. In addition to commercial supplies, some carbonated beverage plants produce and purify their own carbon dioxide. The most common feed gas sources for these applications are combustion (where the flue gas is recovered, concentrated, then purified) and breweries (where the CO_2 generated from microbial metabolism is recovered and purified). Whether supplied commercially or in-house, the carbon dioxide used in carbonated soft drinks is of high quality (greater than 99.9% CO_2); in most cases, it even exceeds that of medical grade gas.

The liquid carbon dioxide which is delivered to beverage plants is generally stored in large "bulk receivers," which are vertically or horizontally oriented steel tanks with urethane foam or vacuum insulation. In the most common arrangement, carbon dioxide is withdrawn from the liquid phase at the bottom of the tank, and vaporized by one of several methods. Due to this withdrawal, the equilibrium between vapor and liquid in the tank remains dynamic. The air gases (oxygen, nitrogen) partition into the vapor phase of the vessel, and are routinely purged to maintain the purity of the carbon dioxide within the bulk receiver. Similarly, some components preferentially partition, in trace amounts, into the liquid phase of the carbon dioxide (liquid CO_2 is an excellent solvent). Many beverage plants choose to subject the freshly vaporized carbon dioxide to one final step of purification just prior to the point of use. This is usually a simple filtration through activated carbon alone, or through a mixed adsorbent bed of carbon (to remove organic contaminants); a silica-based desiccant (to remove moisture); and a molecular sieve (to remove sulfur compounds and some oxygenates).

In addition to the quality considerations already discussed, carbon dioxide safety is a key consideration for beverage industry technologists. Carbon dioxide is not usually considered to be a toxic gas in the generally accepted sense of the term (that is, poisonous) and is normally present in the atmosphere at a concentration of approximately 0.03% (300 ppm). Under normal circumstances, carbon dioxide acts upon vital functions in a number of ways, including respiratory stimulation, regulation of blood circulation, and acidity of body fluids. The concentration of carbon dioxide in the air affects all of these. High concentrations are dangerous upon extended exposure, due to increased breathing and heart rates and a change in the body acidity. OSHA (Occupational Safety and Health Administration) establishes regulations governing the maximum concentration of CO_2 and the time-weighted average for exposure to CO_2. These regulations should be reviewed before installation of any CO_2 equipment, and the requirements fully met during operation and maintenance.

Since carbon dioxide is heavier than air, it may accumulate in low or confined areas. Adequate ventilation must be provided when carbon dioxide is discharged into the air. At lower levels where carbon dioxide may be concentrated, self-contained breathing apparatus or supplied-air respirators must be used. Filter type masks should not be used. Appropriate warning signs should be affixed outside those areas where high concentrations of carbon dioxide gas may accumulate, and lock-out/tag-out procedures should be followed, as appropriate (21).

III. SYRUP PREPARATION

Most carbonated beverage formulae begin with a "simple syrup," which is usually a simple combination of the nutritive sweetener (sucrose, HFCS, MIS) and treated water. In some cases, it may also contain some of the salts outlined in the specific beverage document, depending on the order of addition which is required. Once the sweetener is completely dissolved, and the simple syrup is a

homogenous batch, then the flavor and remaining components are added to form the "finished syrup." All simple syrup should be filtered before being pumped to the finished syrup blending/storage tanks.

Using Granulated Sucrose. Accurate weighing of granulated sugar is important. Granulated sugar is normally received in bulk form or in bags. Internationally, receipt in 50- or 100-pound jute or paper bags is not uncommon. It is extremely important that the sugar received by either means should be dry and free of lumps. Moist sugar creates two immediate and serious problems: (1) moist sugar can have high microbial counts, much of which will be yeast. Yeast is a serious problem for carbonated beverages, since it can lead to fermentation and eventual spoilage of the finished product. (2) Moist sugar makes accurate measuring difficult, since the moisture content is being weighed, in addition to the sucrose solids. This makes final control of the batch difficult and inconsistent.

Sugar in lumps will create difficulties in making simple syrup and will take longer to dissolve. Lump sugar is usually an indication that the sugar was not fully dried during refinery production or was stored improperly (22). Never use bulk sugar systems when faced with wet or even slightly moist sugar. It will cause "bridging" (flow restriction) in silo storage and make effective handling impossible. It is critical that any bulk sugar supply is consistently dry and that the storage environment can be controlled to ensure constant low humidity. Even the most modern silo can "bridge" when faced with a moisture problem.

Granulated sugar should always be added slowly into the treated water already measured into the tank. While sugar is being added, the tank agitator should be in constant operation. The agitation should continue until the sugar is completely dissolved. After the sugar has been completely dissolved, and the simple syrup has been filtered into the blending/storage tank, the syrup is checked for sugar content (Brix). Table 15.6 outlines intuitive, but useful, reasons for off-target Brix readings.

Using Liquid Sugars. There are three main types of liquid sugars that are used for syrup production, as discussed earlier: liquid sucrose, medium invert sugar, and high fructose syrups. Making simple syrup from liquid sucrose is similar to the procedure employed when using granulated sugar. The first step is to check the Brix of the liquid sucrose to find out how much water must be added to the batch to bring the Brix of the simple syrup to the level required by the formula. Most companies beverage documents include a table that specifies how much of the liquid sucrose and additional treated water should be added to the batch based on Brix. When liquid sucrose supplies are received at the plant, they should be accompanied by an analysis sheet comparing the tank load against the company standards.

TABLE 15.6
Possible Brix Errors during Simple Syrup Production

High Brix	Low Brix
Weighing error - excess sugar	Weighing error - short sugar
Faulty scale	Faulty scale
Instrument error	Not weighing sugar bags
Too little water	Too much water
	Instrument error
	Moist sugar

Source: Delonge, H. 1994. Pepsi-Cola Production Manual, Volume 2, Sugar and Sugar Handling.

Medium Invert Sugar is resistant to microbial spoilage when being transported from supplier to plant, and while in storage. However, good sanitation procedures are still required, as well as special precautions to prohibit secondary infection. When liquid invert shipments are received at the plant, they should be accompanied by an analysis sheet comparing the tank load against standards. The formula document should include a table that specifies how much of the sweetener and additional treated water should be added to the batch based on Brix and the percent inversion. When testing for Brix in MIS samples, a correction factor must be used on refractometer readings to compensate for the non-sucrose solids as a result of inversion.

Using High Fructose Syrups. For liquid sugars, in general, a sample should be taken before the sugar is accepted, and the analysis should confirm that the material is within standards. The installation, including receiving station, pumps, air blower/ultraviolet lamp, tanks and piping/fittings, should be of approved materials (stainless steel) and in accordance with the individual beverage company's design guidelines. High fructose syrup is subject to crystallization, so storage temperatures should be controlled (generally maintained between 75°F/24°C and 85°F/29°C), by the use of indirect heating. The receiving station is a critical point and should be fully cleaned and hot sanitized before every delivery. As with MIS, when testing for Brix in HFS samples, a correction factor must be used on refractometer readings to correct to true Brix and compensate for the non-sucrose solids.

No matter what type of nutritive sweetener is used, once the simple syrup has been correctly prepared in the mixing tank, it should be pumped through the syrup filter into the storage tank so that the other concentrate components may be added. Most simple syrups will be in Brix range between 60–65, which makes them extremely susceptible to microbial spoilage, again, with yeast the most likely culprit. Be sure to recognize and respect any time constraints included in the syrup preparation instructions. For example, a general "rule of thumb" is that simple syrup should not be kept longer than four hours before converting it to finished syrup. If hot sugar processing is used, remember to atemperate the simple syrup to

ambient temperature prior to the addition of concentrate. This will help minimize thermal degradation of the flavor oils. Also, it is very important to add the individual components in the specific order detailed in the syrup preparation instructions. Incorrect order of addition can lead to a variety of problems, including changes in viscosity, flavor degradation, nutrient breakdown, and precipitation of insoluble materials in the syrup tank.

IV. CARBONATION

Earlier in this chapter, we discussed the history, theory, and principle of introducing carbon dioxide gas into water to produce a carbonated beverage. We also addressed the importance of the quality of this carbon dioxide, as well as of the treated water used to dissolve it. In this section, we will discuss the practical aspects of carbonation control.

"Mix processing" refers to the process of combining the finished syrup, treated water, and carbon dioxide in the correct proportions to meet beverage specifications. In addition to the proportioning function, mix processing will usually incorporate deaeration, mixing, carbonating, and cooling, depending on the manufacturer's design and the type of products being handled. The design of mix processing systems will vary from one manufacturer to another, incorporating the features that the manufacturer feels are advantageous to controlling production.

The primary function of the carbonating unit or the carbonator is to add carbon dioxide to the product. It must be carbonated to the level that, after filling and closing, results in a product within the standards for beverage carbonation. Some carbonating units incorporate cooling in the same tank or unit. The product can be slightly pre-carbonated with CO_2 injection and then exposed to a CO_2 atmosphere directly where cooling is in progress. Other systems separate the carbonating and cooling steps. The three most common forms of carbonating technology incorporate one or a combination of the following: (1) conventional (atmospheric exposure) introduction, (2) CO_2 injection, or (3) CO_2 eduction.

The ability of water, or beverage, to absorb carbon dioxide gas, is largely dependent on the efficiency of the carbonating unit (23). Other factors that influence CO_2 absorption include (1) product type, (2) product temperature, (3) CO_2 pressure, (4) time and contact surface area, and (5) air content. If the water temperature rises, the gas pressure must be increased if the same absorption of CO_2 is to be maintained. Conversely, if the temperature of the water or beverage entering the carbonating unit drops, the CO_2 becomes more soluble, and the pressure must be decreased to keep the volumes of carbonation within standards. Automatic CO_2 controls compensate for fluctuations in temperature, pressure, and flow. This allows the carbonating unit to produce a constant CO_2 gas absorption. Such controls are standard in modern processing units, which are available as basic units, or with computer interfaces to track the variation in product temperature, pressure, flow, and final CO_2 gas volumes absorbed during operating hours.

In many ways, this is a gross oversimplification of a process which, to this day, sometimes eludes strict control. Certainly, equipment has dramatically improved over the years, but loss of carbon dioxide remains a significant issue in terms of overall plant productivity. New membrane carbonation systems hold great promise for continuing this evolution, by helping to carbonate, at least in theory, more precisely and accurately than ever before. It is yet to be seen if these systems will endure the economic challenges, industry acceptance, and rigors of time.

V. FILLING, SEALING, AND PACKING

In the most fundamental terms, this section will address the introduction of the now freshly prepared and carbonated finished beverage into the package, and sealing it in a manner so as to preserve its integrity: simple in theory, sometimes challenging in application. The bottle filling unit includes bottle handling/transfer components, a filling machine, and a capper/crowner.

The purpose of the filler is to fill returnable and nonreturnable bottles to a predetermined level. It should do this efficiently while minimizing foaming and deliver the bottle to a crowner or closure machine to be sealed, or, in the case of cans, to the lid seamer. A discussion of the design and engineering of filling machines is beyond the scope of this chapter, and is normally relegated to the specific operating manuals supplied by the respective equipment vendor.

Carbonated beverage fillers, to prevent the loss of carbon dioxide from the freshly carbonated beverage, must be counter-pressured. The advantage in using CO_2 gas for counterpressure purposes at the filler bowl is to reduce product air content. With can fillers, this is possible because the counterpressure gas is normally purged from the can to the atmosphere as part of the filling process. Most bottle fillers presently in use vacate the counterpressure gas back into the filler bowl as the bottle is being filled. The empty bottle moving into the sealing position (at the filling valve) already contains air. Even if the counterpressure gas is CO_2, vacating this mixture (air and CO_2) back into the filler bowl assures that the bowl will contain (predominantly) air. This can negate the advantage of CO_2 as a counterpressure gas, and actually be wasting CO_2 to the point of an economic disadvantage. In place of carbon dioxide, air or nitrogen is sometimes used as the counterpressure gases.

Imagine what happens when a carbonated beverage is agitated, and then quickly uncapped. Sometimes, this same type of foaming that results can occur during filling. Foaming at the filler, even in small amounts, can cause a number of problems. Some of these deal with product

TABLE 15.7
Problems Resulting from Foaming at the Filler

Quality	Economics/Operations
✓ Underfilled package	✓ Impact on filling speed
✓ Product residue on bottle	✓ Loss of CO_2 and product
✓ Incorrect CO_2 level	✓ Increased BOD (biochemical oxygen demand) to the drain (sewer surcharge)
	✓ Increased cost of clean-up

Source: Delonge, H. 1994. Pepsi-Cola Production Manual, Volume 2. Carbonation.

quality, others with economics or plant operation, and are summarized in Table 15.7 (24).

The cause(s) of foaming in a filling operation can range from a simple problem, that can be corrected quickly, to one requiring extensive trial and error testing. Many times, the troubleshooting exercise requires a combination of technical skill, creativity, and experience. Some causes of foaming at the filler are summarized in Figure 15.10.

When the problem is a single valve, or occurs for a short period of time, it is usually easy to troubleshoot and correct. On-going foaming problems can be extremely difficult to correct. Manuals supplied by the manufacturer of the filler/mix processor usually address troubleshooting foaming problems in detail, and should be consulted. If the problem persists, contact the filler manufacturer.

One of the problems which can result from excessive foaming at the filler, aside from the poor aesthetics of "sticky" packages, is the formation of mold colonies on the external walls of the package. This might also be evident in the thread areas of bottles when the cap is removed. Proper sealing of the newly filled package is a critical step in the processing of carbonated soft drinks. The closure can be a variety of different types, including crimp-on metal crowns on glass bottles, screw-on metal or plastic caps on plastic bottles, or a seamed lid onto a can body. Each of these applications requires different equipment, but the over-riding objectives are the same: (1) withstand the pressure from the carbon dioxide in this closed system, (2) provide the consumer with a safely sealed product, and one with tamper evidence, (3) prevent leakage of product out of the package, and (4) help contribute to the visual appeal of the overall package.

After proper application of the closure or lid, some beverage manufacturing plants pass the bottles and cans through a warmer, which is a tunnel of water sprays of carefully controlled temperature. The purpose is to bring the temperature of the filled packages (still cold from the

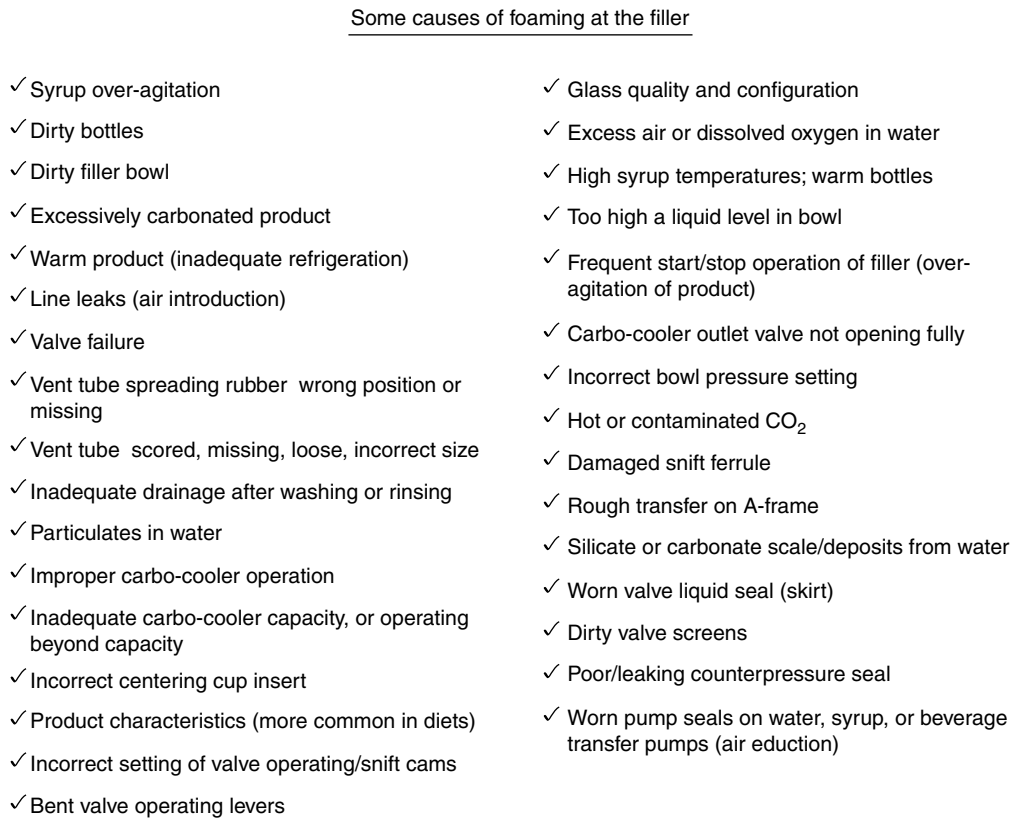

FIGURE 15.10 Some causes of foaming at the filler. Source: Bena (25).

chilled carbonated water introduced at the mix processor) up to close to ambient. The main reason for this is to prevent excessive condensation, which can lead to problems, depending on the secondary and tertiary packaging that are used.

For example, in the U.S. and in many countries internationally, it is common to place bottles of carbonated beverage into rigid plastic crates for transport to a retail outlet. In these instances, warming is not usually needed, since the plastic crates are essentially inert, and allow for adequate air flow and ventilation of the product. Some products, however, perhaps because of a particular marketing promotion, will shrink wrap multiple bottles together, then place them in a cardboard case box, and then stack them on a pallet which is stretch-wrapped for structural stacking integrity. In the second example, if the bottles were not warmed after filling, there is a high probability that the excess condensation would be trapped (by the shrink wrap), absorbed by the cardboard (presenting a mold risk), and then subjected to a "green house effect" from the poor ventilation of the stretch wrap. It becomes quickly evident that a beverage producer's job is not complete simply because the product makes it safely to a sealed container!

VI. QUALITY CONTROL AND ASSURANCE

In this section, we will distinguish quality "control" from quality "assurance" by having control refer to testing typically performed by the beverage plant, either immediately on-site or at a local contract lab. "Assurance" will refer to the subject of a broader, usually centrally managed program (for example, frequent testing of the product from the trade by a central corporate laboratory). Typically, the bulk of testing performed in a carbonated beverage facility falls under the category of quality control. Each company prescribes its own specific testing protocol, including the parameters to test, analytic test methods to apply, and frequency. In addition, a rigorous quality program would clearly outline the actions to be taken (and by whom) in the event that this testing demonstrates an out-of-specification situation.

Since there is no single protocol for all plants to follow, Figure 15.11 summarizes the major categories of testing to consider when evaluating a beverage plant's quality monitoring scheme. This list is by no means exhaustive, but it does provide an idea of how rigorous the monitoring and control in a beverage plant should be.

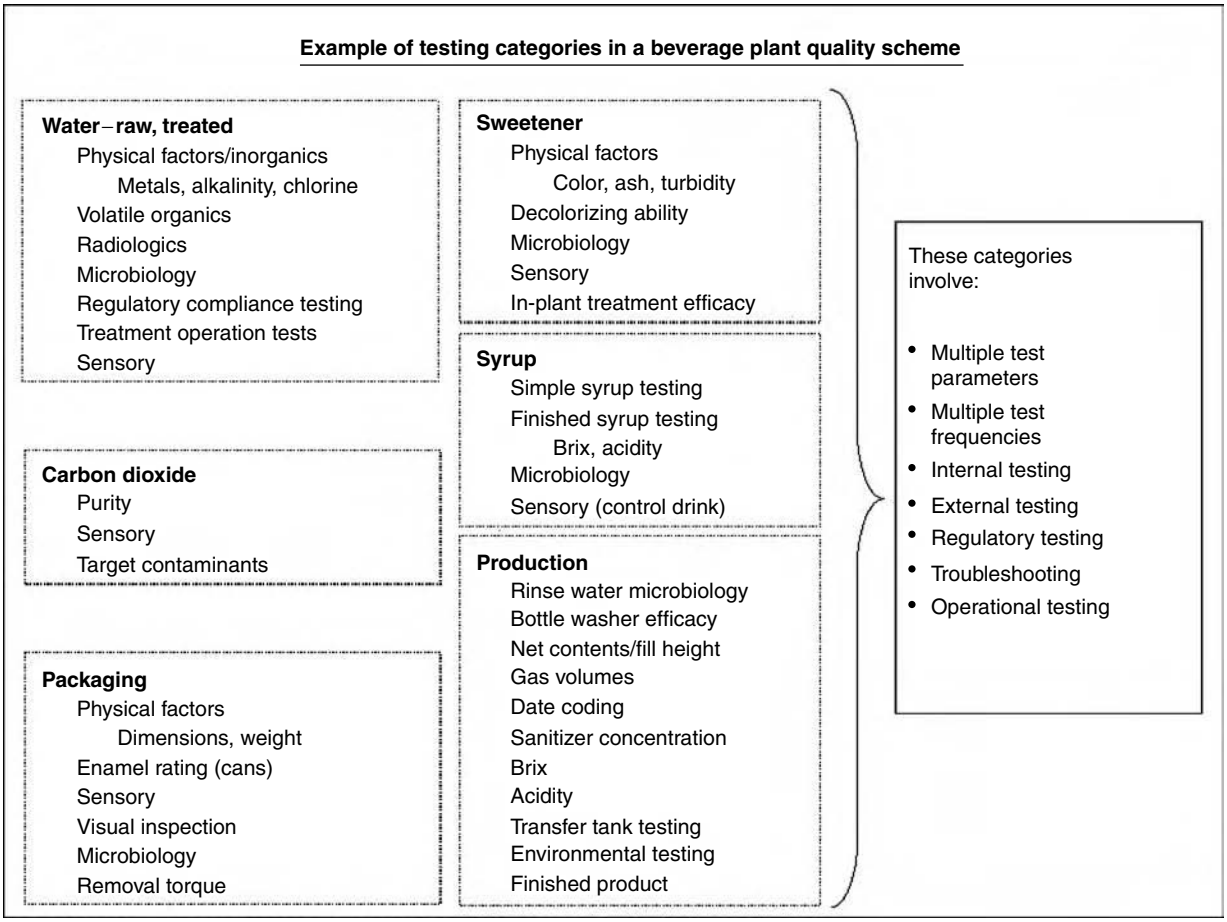

FIGURE 15.11 Example of testing categories in a beverage plant quality scheme.

In addition to this quality control scheme, most larger beverage companies have developed formalized quality assurance schemes, which are usually under a centralized corporate management. The programs generally include some auditing function to visit the production plants for compliance to standards and guidelines, and sampling of finished products from the trade. These programs vary in terms of their focus and rigor, but trade sampling provides perhaps the best representation of what the consumers in a particular market are receiving. From this perspective, the data obtained are of extreme value, and must be reviewed in concert with in-plant and external data, in order to provide the best overall picture of quality performance.

VII. FINISHED PRODUCT

Low pH, high acidity, carbonation, and often ingredients that provide some natural antimicrobial activity (for example, d-limonene in citrus oils) all combine to make carbonated soft drinks a robust category of beverages. Of course, "robust" is a relative term, so as not to imply that carbonated beverages are completely immune to problems in finished product. The formulae, however, go a long way in providing a margin of "designed" product safety.

In fact, for non-fruit-juice-containing carbonated beverages, the types of problems which are typically encountered in the trade are relatively few, and rarely, if ever, present a health or safety threat to the consumer. Microbiologically, we have already mentioned the possibility of having mold form where the overall moisture in the environment is not controlled. For example, remember the scenario of freshly filled bottles, moist with condensation, then shrink wrapped, palletized, and stretch wrapped. The resulting "green house" effect could easily provide the necessary conditions in which mold could grow. In finished product, however, these beverages might contain a variety of organisms, but they will not remain viable under the conditions of the beverage. Only aciduric organisms can multiply, and these include some molds, yeasts, lactic acid bacteria, and acetic acid bacteria (26). Of these, the clear majority of microbial problems are caused by spoilage yeast. This "spoilage" normally refers to any condition which affects the design appearance, flavor, or aroma of the product, and is usually a problem of aesthetics where carbonated soft drinks are concerned.

In addition, as with any packaged products, the packaging materials can be the source of finished product problems. For example, misapplication of closures may occur, where removal torque is so high that consumers have difficulty opening the bottles. In areas of the world where returnable bottles are used, depending on their handling, they can become badly scuffed, presenting an unappealing look to the consumer.

Many problems with finished product can be—and are—averted before the product ever leaves the beverage facility. This is due, in large part, to the diligent monitoring of the soft drink manufacturing process from beginning to end. We have already learned that the raw materials are held to high standards of quality upon receipt, and some—like water, sucrose, and carbon dioxide—are often further purified within the beverage plant itself. Then, these raw materials are combined into a finished syrup, and it is checked against standards of assembly and quality. This finished syrup is then diluted and carbonated, filled, then sealed to form the final beverage. The final product is tested chemically, microbially, and sensorially, to ensure that it meets the highest standards of its trademarked brand.

This said, the summary above represents only a small portion of the quality systems that overarch most finished products, and which are clearly beyond the scope of this chapter. Suffice to say that many beverage companies begin to control quality as far back in the supply chain as possible, so far, that some companies own their own citrus groves in order to strictly control the quality of the orange juice used in their orange-juice containing carbonated beverages! In addition, as the principles of HACCP (Hazard Analysis and Critical Control Points) become more commonplace in the beverage industry, many bottlers and canners are voluntarily formulating their own HACCP plans to formalize the monitoring and control of their processes. All of this is done with a single, predominant end-goal in mind, to provide the consumer with consistently high-quality, great tasting, refreshing beverages.

16 Muffins

Nanna Cross
Consultant, Chicago, IL

CONTENTS

I. BACKGROUND INFORMATION

A. History of Muffins

English muffins originating in London were made from yeast dough in contrast to quick-bread muffins served in early America. Muffins are described as a quick bread since "quick-acting" chemical leavening agents are used instead of yeast, a "longer-acting" biological leavening agent. Muffins have become increasingly popular as a hot bread served with meals or eaten as a snack. Freshly baked muffins are served in restaurants and bakeries and consumers can buy packaged ready-to-eat muffins from grocery stores and vending machines. It is possible for restaurants and small bakeries to serve a muffin of a consistent high quality with the availability of dry mixes, frozen muffin batter, and pre-deposited frozen muffins available on the wholesale market.

B. Health Concerns

The economic burden of chronic disease is a worldwide problem. Chronic diseases contributed to 60% of the deaths worldwide in 2001 (55). The increasing rate of obesity and the ageing of the population are expected to impact the burden of chronic disease. Those with obesity are at greater risk and have an earlier onset of the chronic diseases of diabetes, cardiovascular diseases, cancer, and stroke. Ageing increases the risk for all chronic diseases. Nearly one-quarter of the population in developed countries is made up of those above 60 years of age, with expectations for the numbers to increase to one-third of the population by 2025 (55).

The problems of overweight and obesity are growing rapidly around the world and co-exist with malnutrition in developing countries (55). Surveys of U.S. adults done in 1999–2000 showed that 64% of adults were overweight and 30% were obese (21). The percentage of children and adolescents in the U.S. who are overweight has tripled in the past 30 years with 15% of 6–19 year olds being overweight in 1999–2000 (41).

Obesity rates have increased threefold or more in some parts of North America, Eastern Europe, the Middle East, the Pacific Islands, Australasia, and China since 1980 (54). The prevalence rates of overweight and obesity are growing rapidly in children and adults in such countries as Brazil and Mexico where malnutrition and obesity co-exist in the same household (9). Countries with the highest percentage (5% to 10%) of overweight preschool children are from the Middle East (Qatar), North Africa (Algeria, Eqypt, and Morocco), and Latin America, and the Caribbean (Argentina, Chile, Bolivia, Peru, Uruguay, Costa Rica, and Jamaica) (10).

Globalization of food and the availability of energy-dense snack and "fast foods" have had a significant impact on dietary patterns and the incidence of chronic disease in both developing and developed countries (27). For example, Coca-cola and Pepsi soft drinks and McDonald's, Pizza Hut, and Kentucky Fried Chicken fast foods are now available worldwide (27). Changes in dietary patterns combined with a sedentary lifestyle have increased the rates of obesity and chronic disease. Dietary factors related to chronic disease are excessive intakes of calories, fat—especially saturated fat—and sodium, and low intakes of fruits and vegetables and whole-grain breads and cereals (52).

National dietary guidelines recommend limiting intakes of total fat, saturated fat, trans fat, cholesterol, free sugars, and sodium, and promote dietary fiber from whole grain breads and cereals and fruits and vegetables (56). In 2002, consumers in the U.S. reported making food choices in an effort to avoid fat, sugar, calories, and sodium, and to increase fiber intake (39). Consumers chose fat free foods or foods low in fat 74% to 80% of the time and selected low calorie foods and low sodium foods 76% and 67% of the time, respectively. High fiber foods were chosen 75% of the time and 40% reported using organic foods (39).

The food industry has responded to concerns of consumers and public health officials by developing "healthy" food products, lower in saturated fat, trans fat, cholesterol, sodium, sugar, and calories. New ingredients have been developed by food scientists in government and industry to use as fat replacers and sugar replacers to use in preparing baked products that are lower in calories and saturated and trans fat (Table 16.1, Table 16.2). The newest category of ingredients is concentrated bioactive compounds with specific health benefits (Table 16.3) (43). These ingredients are added to formulations during food processing to enhance the health benefits of specific food products or to develop "functional foods." Individual foods, such as apples, blueberries, oats, tomatoes, and soybeans, are being marketed as functional foods because of the health benefits of components of these foods. For example, diets that include oat fiber and soy protein lower serum cholesterol, and lycopene in tomatoes reduces the risk of prostrate cancer. Apples and blueberries contain unique antioxidants shown to reduce the risk for cancer (42). Examples of bioactive ingredients available to the baking industry are OatVantage™ (Nature Inc., Devon, PA) a concentrated source of soluble fiber, and FenuPure™ (Schouter USA, Minneapolis, MN), a concentrated source of antioxidants from fruits and vegetables.

C. Food Labeling and Health Claims

The Nutrition Labeling and Education Act (NLEA) issued by the Food and Drug Administration (FDA) in the U.S. in 1990 required food labels to include nutrition content on all packaged foods to be effective in 1994 (11). Information required on the Nutrition Facts portion of the food label are the serving size and the amount per serving

TABLE 16.1
Ingredients Used as Fat Replacers in Baked Products

Brand Name	Composition	Supplier
Carbohydrate Based		
Beta-Trim™	Beta-glucan and oat amylodextrin	Rhodia USA, Cranbury, NJ
Fruitrim®	Dried plum and apple puree	Advanced Ingredients Capitola, CA
Just Like Shorten™	Prune and apple puree	PlumLife division of TreeTop, Selah, WA
Lighter Bake™	Fruit juice, dextrins	Sunsweet, Yuma City, CA
Oatrim®	Oat maltodextrin	Quaker Oats, Chicago, IL
Paselli FP	Potato maltodextrin	AVEBE America, Inc., Princeton, NJ
Z-Trim	Multiple grain fibers	U.S. Department of Agriculture
Low and Noncaloric Lipid Based		
Enova™	Diglycerides	Archer Daniels Midland/Kao LLC, Decatur, IL
Benefat®	Triglycerides modified by substituting short or medium chain fatty acids	Danisco Culter, New Century, KS
Salatrim/Caprenin		Proctor & Gamble, Cincinnati, OH
Olestra/Olean®	Sucrose polyester	Proctor & Gamble, Cincinnati, OH

TABLE 16.2
Ingredients Used as Sugar Replacements in Baked Products

Sweetener	Brand Name	Sweetness Compared to Sucrose	Supplier
Acesulfame-K	Sunett®	200% sweeter	Nutrnova, Somerset, NJ
Sucralose	Splenda®	600% sweeter	Splenda, Inc., Fort. Washington, PA

TABLE 16.3
Ingredients Marketed for Specific Health Benefits

Brand Name	Composition	Health Benefit	Supplier
Caromax™ Carob Fiber	Carob fruit fiber; soluble fiber, tannins, polyphenols, lignan	Lower serum cholesterol	National Starch & Chemical, Bridgewater, NJ
FenuPure™	Fenugreek seed concentrate; galactomannan	Regulate blood glucose; lower serum cholesterol	Schouten USA, Inc., Minneapolis, MN
Fibrex®	Sugar beet fiber; soluble fiber, lignan	Lower serum cholesterol; regulate blood glucose	Danisco Sugar Malmo, Sweden
MultOil	Diglycerides + phytosterols	Lower serum cholesterol	Enzymotec Migdal HaEmeq, Israel
Nextra™	Decholesterolized tallow and corn oil; free of trans fat	Reduce the risk for coronary heart disease	Source Food Technology, Durham, NC
Novelose 240	Corn fiber; high amylose, resistant fiber	Reduce risk for colon cancer	National Starch & Chemical, Bridgewater, NJ
Nutrifood®	Fruit and vegetable liquid concentrates; source of antioxidants–carotenoids, anthocyanins, polyphenols	Reduce risk for chronic diseases–cancer, diabetes, and cardiovascular disease	GNT USA, Inc., Tarrytown; NYGNT Germany, Aachen, Germany
OatVantage™	Beta-glucans, a soluble fiber	Lower serum cholesterol	Nurture, Inc., Devon, PA

of calories, protein, fat, saturated fat, cholesterol, carbohydrates, fiber, sodium, calcium, vitamins A and C, and iron. A 1993 amendment to the NLEA authorized food manufacturers to add health claims related to specific food components (11) (Table 16.4). However, many "functional foods" lack the scientific evidence to meet FDA criteria to make health claims (50). A 2003 amendment to NLEA requires that trans fatty acids be listed under saturated fat on the Food Facts label by January 1, 2006 (11).

The Codex Alimentarius Commission of the Food and Agriculture Organization of the United Nations World Health Organization (FAO/WHO) Codex Guidelines on Nutrition Labeling adopted in 1985 are similar to the

TABLE 16.4
Health Claims Approved for Food Labeling in the U.S.[1]

Food Component	Health Claim
Calcium	Osteoporosis
Dietary fat	Cancer
Dietary saturated fat and cholesterol	Coronary heart disease
Fiber-containing grain products, fruits and vegetables	Cancer
Sodium	Hypertension
Folate	Neural tube defects
Dietary sugar alcohol	Dental caries
Fruits, vegetables and grain products that contain fiber, particularly soluble fiber	Coronary heart disease
Soy protein	Coronary heart disease
Whole-grain foods	Heart disease and certain cancers
Plant sterols/stanol esters	Coronary heart disease
Potassium	High blood pressure and stroke

[1] FDA/CFSAN. 2002b. Food labeling and nutrition. Information for industry. A food labeling guide. Appendix C. Health claims. http://www.cfsan.fda.gov/~dma/flg-6C.html. Accessed on July 3, 2003.

NLEA implemented by the FDA in 1994 (13). The Codex Alimentarius Commission adopted the Codex Guidelines for the use of Nutrition Claims on food labels in 1997 (14). Codex standards are voluntary and each country within the United Nations is free to adopt food-labeling standards. The European Union that includes 15 member states in Europe also sets guidelines for nutrition labeling and nutrition claims, subject to requirements of individual member states.

The Food Standards Agency of the United Kingdom (U.K.) was established in 2000 as the regulatory agency to set policy for food labeling in Great Britain and Northern Ireland (23). The Food Standards Australia New Zealand (22) specifies the requirements for food labeling in these countries (22). Health Canada published new food labeling regulations January 1, 2003, making nutrition labeling mandatory for most foods and allowing diet-related health claims on food labels for the first time (26).

D. Food Labeling Standards for Organically Grown Foods

The Organic Foods Production Act of 1990 passed by the U.S. Congress required the U.S. Department of Agriculture to develop certification standards for organically produced agricultural products (2). Producers who meet the standards may specify the percentage of the product that is organic on the food label if 70% or more of the ingredients in the product are organically grown (2). The Codex Alimentarius Commission has also published standards for labeling organically grown foods (15). Organic fruits and vegetables are produced without using conventional pesticides, petroleum-based fertilizers, or sewage sludge-based fertilizers. Animal products identified as organic come from animals given organic feed without antibiotics or growth hormones. Food products that have been developed through genetic modification cannot be labeled as organically grown foods (2,15).

E. Ingredient Labeling for Possible Allergens

The Codex Alimentarius Commission of FAO/WHO and FDA/CFSAN require that food labels list all ingredients known to cause adverse responses in those with food allergies or sensitivities (11,20). The FDA requires listing ingredients from eight foods that account for ~90% of all food allergies. These foods are peanuts, soybeans, milk, eggs, fish, shellfish, tree nuts, and wheat (20). Codex standards require listing ingredients from these same eight foods plus all cereals that contain gluten—rye, barley, oats, and spelt—lactose, and sulphite in concentrations of 10 mg/kg or more (11). Gluten, lactose, and sulphite are listed on food labels because these substances cause distress for some, even though these substances are not considered allergens. Individuals with celiac disease or gluten intolerance eliminate all sources of gluten from the diet. A small percentage of individuals lack lactase, the enzyme needed to digest lactose, and avoid dairy products and all other foods with lactose additives.

Food processing plants are required to follow Good Manufacturing Practices (GMP) to avoid possible cross-contamination with trace amounts of allergens during processing. An example of possible cross-contamination is using the same plant equipment to prepare "nut free" muffins after the equipment was used to prepare muffins with nuts (49). An example of GMP is dedicating food-processing plants to the production of allergenic free foods (49).

Small bakeries, defined by the number of employees or annual gross sales, and restaurants are exempt from the FDA food labeling requirements. Food labeling to identify foods that have been genetically modified through bioengineering (GM) is voluntary (16). However, because of consumer concerns about GM foods, managers of bakeries may choose to include a statement on the ingredient label such as "we do not use ingredients produced by biotechnology" (16,17). Consumers with food allergies have learned to read the list of ingredients on the food label to identify any possible sources of allergens. Managers of small bakeries that use nuts or soy flour in their operation, but unable to follow GMP because of the added cost, may choose to alert consumers with a statement on the ingredient label, such as "this product was made on equipment that also makes products containing

tree nuts." Making a decision to sell bakery products made with organic ingredients requires assessing the market for these products, the availability of organic ingredients, and the expected income from the operation.

II. RAW MATERIALS PREPARATION

A. Selection and Scaling of Ingredients

Muffins made by large commercial bakeries are cake type muffins while those made in the home or small institutions are bread muffins. The differences between cake and bread muffins are that cake muffins are higher in fat and sugar and use soft wheat flours. A common problem encountered in bread type muffins is tunnel formation resulting from overdevelopment of gluten. However, this problem is avoided in cake muffins since sugar, fat, and soft wheat flours interfere with gluten development and prevent tunnel formation. Bread muffins contain 12% of both fat and sugar compared to 18% to 40% fat and 50% to 70% sugar in cake muffins (5).

Formulas for a standard cake muffin and bran muffin are shown in Table 16.5. Ingredient formulas used by commercial bakeries are based on the weight of flour at 100% (25). The amounts of other ingredients are a percentage of flour weight (Baker's percent). For example,

$$\frac{\text{total weight of muffin ingredient}}{\text{total weight of flour}} \times 100\% = \% \text{ of the ingredient}$$

If the weight of another ingredient is the same weight as flour, the percent for that ingredient is also 100%. The advantage of using Baker's percent is that batch sizes can be easily increased or decreased by multiplying the percent for each ingredient by the same factor. Weighing all ingredients, including liquids, is faster and more accurate than using measurements, especially in large commercial bakeries.

1. Flour

Flour is the primary ingredient in baked products. Flour represents 30% to 40% of the total batter weight in most cake muffins (5). Most muffin formulas contain a blend of cake or pastry flour and a high protein flour such as bread flour, or all bread flour (51). The protein in flour is needed to provide structure in quick breads made with limited amounts of sugar. Flour contains starch and the proteins, glutenin, and gliadin, which hold other ingredients together to provide structure to the final baked product. Hydration and heat promote gelatinization of starch, a process that breaks hydrogen bonds, resulting in swelling of the starch granule, which gives the batter a more rigid structure (27).

Substituting whole-wheat flour, wheat germ, rolled oats, or bran for part of the flour is an excellent way to increase fiber. Other flours used in muffins include cornmeal, soy, oat, potato, and peanut. An acceptable product is possible when cowpea or peanut flours are substituted for 25% or when whole-wheat flour or corn meal is substituted for 50% of all-purpose flour (29). Acceptable muffins have been prepared when soy protein flour was substituted for 10% to 20% (47) or 100% of all-purpose flour (6). None of these flours contains glutenin or gliadin except whole wheat, and large pieces of bran in whole-wheat flour cut and weaken gluten strands. Thus, there is minimal gluten development when these flours are used; however, the muffins tend to be crumbly and compact unless other modifications are made in the formula.

2. Sugar

Amounts of sugar in muffins range from 50% to 70% based on flour at 100% (5). Sugar contributes tenderness, crust color, and moisture retention in addition to a sweet taste. Sucrose promotes tenderness by inhibiting hydration of flour proteins and starch gelatinization. Sugar is hygroscopic (attracts water) and maintains freshness. Corn syrup, molasses, maple sugar, fruit juice concentrates, and honey are used as sweeteners for flavor variety. Honey or molasses is often used as a sweetener in whole wheat or bran muffins to cover the bitter flavor of the bran (51). The quantity of liquid will need to be decreased if these sweeteners are used instead of sucrose because of the high water content in these syrups.

Chemical changes in sugars during baking contribute characteristic flavors and browning. Carmelization of sugar is responsible for the brown crust of muffins. Carmelization involves dehydration and polymerization (condensation) of sucrose (35). Reducing sugars such as dextrose, corn syrup, or high fructose corn syrup are often added to muffins at levels of 1% to 3% to increase crust color (51). Reducing sugars react with amino acids in flour, milk, and eggs to form a complex responsible for the flavor and brown crust of muffins.

The reaction between the aldehyde or ketone group in reducing sugars and the amino acids in protein is described as the Maillard reaction (37). This Maillard reaction together with carmelization contributes to the characteristic flavor and color of the crust of a baked muffin. Crust temperatures reach 100°C and above, which lower water activity. Both the high temperature and low water activity are necessary for the Maillard reaction to occur (38).

Sugar replacers such as acesulfame-K and sucralose (Table 16.2) can be substituted for all or part of the sugar. Sugar replacers, however, do not contribute to tenderness, browning, or moisture retention, thus other formula modifications are necessary for an acceptable product. For example, adding a small amount of molasses or cocoa for

TABLE 16.5
Muffin Formulas Listed by Baker's Percent and Weight[1,2]

Ingredient	Basic Cake Muffin Baker's %	Weight gm	Bran Muffin Baker's %	Weight gm
Flour	100.00	990	–	–
Bread flour	–	–	50.0	4545
Cake flour	–	–	18.75	1704

Total	303.75	27616	316.70	32790

Mixer: Hobart N-50 with 5 quart bowl and paddle agitator.
Directions for basic cake muffin formula:
Blend dry ingredients together by mixing for 1 minute at low speed.
Add shortening and eggs and mix for 1 minute at low speed.
Add water and mix for 1 minute at low speed.
Scaling Weight: 2.5 ounces batter.
Yield: 2–1/2 dozen muffins.
Bake: at 205°C for 19–21 minutes in a gas-fired reel oven.
Directions for bran muffin formula:
Blend dry ingredients and mix for 1 minute at low speed.
Add shortening, eggs, honey, molasses, and 50% (4.5 kg) of the water and mix for 1 minute at medium low speed.
Add the remaining water and mix for 1 minute at low speed.
Add raisins and mix at low speed for 3 minutes or until raisins are dispersed.
Scaling Weight: 3 ounces batter.
Yield: 3 dozen muffins.
Bake: at 193°C for 20–25 minutes in a gas-fired reel oven.

color to substitute for color from carmelization of sucrose. The shelf life of muffins prepared without sugar would be very limited.

3. Fat

Muffins contain 18% to 40% fat based on flour at 100% (5). Fat contributes to the eating qualities of tenderness, flavor, texture, and a characteristic mouthfeel. Fat keeps the crumb and crust soft and helps retain moisture, and thus contributes to keeping qualities or shelf life (36). Fat enhances the flavor of baked products since flavor components dissolve in fat. Both shortening and vegetable oils are used in muffins.

To meet the demands of the consumer, muffin formulas are being modified to reduce total, saturated fat, trans fat, and calories, and to increase the amount of monounsaturated and polyunsaturated fat. Canola oil and flaxseed meal are being added to muffins to increase the proportion of monounsaturated fat. Muffins made with reduced fat and polyunsaturated fatty acids (13% safflower oil) were comparable in sensory and physical characteristics to the standard muffin made with shortening at 20% (8). Low fat and fat free muffins are available ready to eat and as frozen batters or dry mixes for bakeoff.

Various fat replacers have been classified by their macronutrient base (Table 16.1). Carbohydrate- and lipid-based fat replacers can be used to prepare muffins acceptable to the consumer. Lipid-based fat replacers that have the same chemical and physical characteristics of triglycerides are described as fat substitutes (1). These products

provide the same characteristics as fat but with fewer calories. Monoglycerides, diglycerides, and modified triglycerides are examples of fat substitutes that replicate the mouthfeel and sensory qualities of baked products made with shortening.

Enova™ (Archer Daniels Midland KAO LLC, Decatur, IL) is an example of a diglyceride that is lower in calories than other oils and being marketed as beneficial in weight management (45). Benefat® (Danisco Culter, New Century, KS) and Caprenin (Proctor & Gamble, Cincinnati, OH) are examples of triglycerides modified by substituting shorter chain fatty acids (1). Sucrose polyesters of six to eight fatty acids are marketed as Olean® (Procter & Gamble, Cincinnati, OH), a fat substitute with the same physical qualities as shortening without the calories since sucrose polyesters are not digested or absorbed in the human intestinal tract.

A commercial shortening product (Nextra™) (Source Food Technology, Durham, NC) made from decholesterolized tallow and corn oil is being marketed to the baking industry as a trans-free fat to replace shortening (44). Other methods used by the food industry to decrease the amount of trans fat are 1) blending hydrogenated fat high in stearic acid with unhydrogenated oils, and 2) interesterifying (rearranging) unhydrogenated oils with saturated-fat-based oils (30).

Carbohydrate-based fat replacers are described as fat mimetics. These include cellulose, corn syrup, dextrins, fiber, gum, maltodextrins, polydextrose, starches, and fruit based purees. Z-trim, developed by a U.S. Department of Agriculture scientist, is a mixture of plant fibers (31). Fat mimetics replicate the mouthfeel and texture of fat in baked products and extend the shelf life by binding water and trapping air (3). Acceptable low fat cake muffins (5% fat) used 2% pregelatinized dull waxy starch and corn syrup (3.6%) to replace fat (28).

Fruit purees or pastes of one or more fruits—apples, dates, figs, grapes, plums, prunes, and raisins—are being promoted as fat replacers. Just Like Shorten™ is a mixture of dried prunes and apples. The fruit purees have humectant properties, promote tenderness and moistness, increase shelf life, and can replace some of the sugar and/or fat in muffins and cakes.

Formulas will need to be developed based on adjustments in ingredients when fat replacers are substituted for all or part of the fat in the formula. New formulas need to be prepared and the muffins evaluated using the muffin scorecard (Table 16.6) as well as evaluating the shelf life. Several formula adjustments may be necessary before an acceptable muffin is developed.

4. Leavening Agents

The amount of baking powder used in muffins varies between 2% and 6% based on flour at 100% with lower amounts in muffins with ingredients that increase acid (5). Gases released by a leavening agent influence volume and cell structure. During baking, heat increases gas volume and pressure to expand cell size until proteins are coagulated (35). Stretching of the cell walls during baking improves texture and promotes tenderness (35).

The quantity of leavening used in a baked product depends on the choice of leavening agent as well as other ingredients. Formulation of baking powders considers the amount of leavening acids needed to neutralize baking soda or sodium bicarbonate, an alkaline salt. Double-acting baking powder (most commonly used in muffins) contains both slow- and fast-acting acids (37). Fast-acting acids are readily soluble at room temperature while slow-acting acids are less soluble and require heat over extended time to release carbon dioxide. Formulations of slow- and fast-acting acid leavening agents control the reaction time and optimize volume (7). An example of a formulation to neutralize sodium bicarbonate is a mixture of slow- and fast-acting acids—monocalcium phosphate monohydrate (a fast-acting acid) combined with sodium aluminum sulfate (a slow-acting acid). Development of baking powder requires consideration of the unique neutralizing value (NV) and the rate of reaction (ROR) or the percent of carbon dioxide released during the reaction of sodium bicarbonate with a leavening acid during the first eight minutes of baking (4,7).

Baking soda is used in addition to double-acting baking powder when muffins contain acidic ingredients such as sour cream, yogurt, buttermilk, light sour cream, molasses, and some fruits and fruit juices (37). Baking soda in the amount of 2% to 3% in addition to baking powder is added to acidic batters (5).

Sodium carbonate is a product of an incomplete reaction in formulas with excess sodium bicarbonate. Excess sodium carbonate results in a muffin with a soapy, bitter flavor, and a yellow color because of the effect of an alkaline medium on the anthoxanthin pigments of flour (38). Also, formulas with too much baking powder or soda results in a muffin with a coarse texture and low volume because of an overexpansion of gas, which causes the cell structure to weaken and collapse during baking. Inadequate amounts of baking powder will result in a compact muffin with low volume. Figures 16.1 and 16.2 show different chemical reactions for fast-acting and slow-acting baking powders (37).

5. Whole Eggs

Liquid eggs contribute 10% to 30% of muffin batter based on flour at 100% and dried eggs contribute 5% to 10% (5). Eggs provide flavor, color, and a source of liquid. Upon baking, the protein in egg white coagulates to provide structure. Adding egg whites to muffin batter provides structure to the finished product and a muffin that is

TABLE 16.6
Scorecard for Muffins[1]

Evaluator	Product	Date
External Qualities		
1a. Volume	Score	
Specific Volume: $\pi r^2 \times$ height = weight in grams (cm) 1=low volume, compact cells; 5=light with moderate cells; 7=large volume, large cells and/or tunnels		
1b. Contour of the surface		
1=absolutely flat; 3=somewhat rounded; 5=pleasingly rounded; 7=somewhat pointed; 9=very pointed		
1c. Crust color		
1=much too pale; 3=somewhat pale; 5=pleasingly golden brown; 7=somewhat too brown; 9=much too brown		
Internal Qualities		
1d. Interior color		
1=much too white; 3=somewhat white; 5=pleasingly creamy; 7=somewhat too yellow; 9=much too yellow		
1e. Cell uniformity and size		
1=much too small; 3=somewhat thick; 5=moderate; 7=somewhat too large; 9=numerous large tunnels		
1f. Thickness of cell walls		
1=extremely thick; 3=somewhat thick; 5=normal thickness; 7=somewhat too thin; 9=much too thin		
1g. Texture		
1=extremely crumbly; 3=somewhat crumbly; 5=easily broken, 7=slightly crumbly; 9=tough, little tendency to crumble		
1h. Flavor		
1=absolutely not sweet enough; 3=not nearly sweet enough; 5=pleasingly sweet; 7=somewhat too sweet; 9=much too sweet		
1i. Aftertaste		
1=extremely distinct; 3=somewhat distinct; 5=none		
1j. Aroma		
1=lack of aroma; 5=sweet and fresh aroma; 9=sharp, bitter, or foreign aroma		
1k. Mouthfeel		
1=gummy, cohesive; 3=somewhat gummy; 5=tender, light and moist; 7=somewhat dry and tough; 9=tough and hard to chew		
Overall Acceptability		
1=very unacceptable; 3=somewhat acceptable; 5=very acceptable		

[1] Modified from McWilliams M. 2001. Chapter 3: Sensory evaluation. In: Foods: Experimental Perspectives. 4th ed. Upper Saddle River, NJ: Prentice Hall. pp. 33–57.

easily broken without excessive crumbling (48). Substituting egg whites for whole eggs, however, will result in a dry, tough muffin unless the formula is adjusted to increase the amount of fat (48). Fat in the yolk acts as an emulsifier and contributes to mouthfeel and keeping qualities.

6. Nonfat Dry Milk Powder

Milk powder represents 5% to 12% of the muffin batter based on flour at 100% (5). Milk powder is added to dry ingredients and water or fruit juice is used for liquid in muffin formulas. Milk powder binds flour protein to provide strength, body, and resilience—qualities helpful in reducing damage during packing and shipping (51). In addition, milk powder adds flavor and retains moisture. The aldehyde group from lactose in milk combines with the amino group from protein upon heating, contributing to Maillard browning.

7. Sodium Chloride

The amount of salt in muffins is 1.5% to 2% based on flour at 100% (5). The function of sodium chloride is to enhance the flavor of other ingredients. Sodium chloride may be omitted from the formula without compromising flavor, if other ingredients such as dried fruit or spices are added for flavor.

$$3CaH_4(PO_4)_2 + 8NaHCO_3 \rightarrow Ca_3(PO_4)_2 + 4Na_2HPO_4 + 8CO_2 + 8H_2O$$

8. Liquids

Liquids perform several functions in baked products (5). These include dissolving dry ingredients and gelatinization of starch and providing moistness in the final baked product. Insufficient liquid results in incomplete gelatinization of the starch and a muffin with insufficient structure to support expansion of air volume. The muffins will have non-uniform cell structure, overly crumbly texture, low volume, and a dip in the top.

9. Additional Ingredients

Other ingredients are often added to muffins for variety in flavor, texture, and color, and to increase the specific nutrients or health components such as fiber, vitamins and minerals, or antioxidants from fruit and vegetable extracts. Part of the flour may be replaced with cornmeal, bran, whole-wheat, oat, or other flours to increase the fiber content. Adjustments in the amount of water in the formula are necessary when whole-wheat flour, bran, or other concentrated sources of fiber are added because fiber absorbs a great deal of water (51). An example of a concentrated source of fiber is Caromax™ (National Starch & Chemical, Bridgewater, NJ)(42). Nutrifood® (GNT USA, Tarrytown, NY), a liquid concentrate marketed as a blend of the antioxidants carotenoids, anthocyanins, and polyphenols is an example of a bioactive ingredient (43).

Other ingredients can be substituted for part of the liquid. For example, applesauce, bananas, shredded carrots, or zucchini. Variations in texture are achieved by adding fresh fruit such as apples or blueberries or dried fruit such as dates, raisins, or apricots. Nuts and poppy seeds complement the flavor of sweet muffins while grated cheese, whole-kernel corn, green peppers, chopped ham, and bacon add interest to corn muffins. Added flavorings include cinnamon, nutmeg, allspice, cloves, and orange or lemon zest. Topping mixtures such as chopped nuts, cinnamon, and sugar are added to the batter after depositing.

III. PROCESSING STAGE 1

A. Mixing

There are two primary methods for mixing muffins—the cake method and the muffin method. The cake method involves creaming sugar and shortening together, followed by adding liquid ingredients with the final addition of dry ingredients. The muffin method of mixing involves two to three steps. First, dry ingredients are mixed together; second, shortening or oil and other liquids are mixed together; and third, the liquids are added to the dry ingredients and mixed until the dry ingredients are moistened. Additional ingredients are added at the end of the mixing cycle or after depositing the muffin batter. Institutional or commercial bakeries use a mixer on slow speed for three to five minutes. Inadequate mixing results in a muffin with a low volume, since some of the baking powder will be too dry to react completely.

IV. PROCESSING STAGE 2

A. Depositing

The traditional size of muffins is two ounces although today muffins are marketed in a wide range of sizes from one-half ounce mini-muffins to muffins five ounces or larger in size (51). For institutions or bakeries, small batter depositors are available that will deposit four muffins at a time. Also available are large piston type depositors that maintain accurate flow of the batter (5).

V. PROCESSING STAGE 3

A. Baking

Many physical and chemical changes occur in the presence of heat to transform a liquid batter into a final baked muffin. Solubilization and activation of the leavening agent generates carbon dioxide that expands to increase the volume of the muffin. Gelatinization of starch and

coagulation of proteins provide permanent cell structure and crumb development. Carmelization of sugars and Maillard Browning of proteins and reducing sugars promote browning of the crust. Reduced water activity facilitates Maillard Browning as well as crust hardening (38).

The choice of oven, baking pans, and baking temperature influence the final baked product (5). A good flow of heat onto the bottom of the pan is necessary to produce a good product. Muffin tins are usually placed directly on the shelf or baking surface. The appropriate oven temperature is related to scaling and the type of oven. Standard two-ounce muffins are baked at 204°C or slightly higher in a deck oven. Deck ovens may be stacked and are often used in small retail bakeries since these are less expensive and easier to maintain than reel or rotary ovens. Reel ovens consist of an insulated cubic compartment six or seven feet high. A Ferris wheel type mechanism inside the chamber moves four to eight shelves in a circle, allowing each shelf to be brought to the door for adding or removing muffin tins from the shelves (32). Retail bakers often prefer the reel oven since several hundred to several thousand pounds of batter can be baked each day. Rack ovens may be stationary or the racks may be rotated during baking.

VI. PROCESSING STAGE 4

A. Cooling

Products should be cooled prior to wrapping. This allows the structure to "set" and reduces the formation of moisture condensation within the package. Condensed moisture creates an undesirable medium that promotes yeast, mold, bacterial growth, and spoilage.

VII. PROCESSING STAGE 5

A. Packaging

Muffins may be wrapped individually, in the tray in which they are baked, or transferred into plastic form trays for merchandizing (5). The shelf life of muffins is three to five days for wrapped muffins, and four to seven days for those packaged wrapped in foil or plastic wrap. The storage life of muffins is significantly influenced by exposure to oxygen and moisture (46). Cake muffins have a longer shelf life than bread muffins because of the high sugar content and lower water activity (51). Added ingredients such as cheese, ham, and dried fruits, high in sodium or sugar content, reduce water activity and increase the shelf life.

VIII. FINISHED PRODUCT

A muffin fresh out of the oven will vary in appearance based on the formula, whether the formula is for a cake or bread muffin; the size of the muffin, mini-muffin or mega-muffin; and the desired shape from flat or mushroom shaped tops to the traditional bell-shaped muffin (51). In general, a desirable muffin product has a symmetrical shape, a rounded top golden brown in color, cells that are uniform and moderate in size, a sweet flavor and pleasant aroma, is tender and moist, is easily broken apart, and is easy to chew with a pleasant aftertaste.

A. Muffin Evaluation

Bakers can use the Table 16.6 Scorecard for Muffins to evaluate muffins in the process of developing or modifying muffin formulas. Large commercial bakeries may use more sophisticated methods to evaluate bakery products, such as gas chromatography to evaluate flavor components.

1. Volume

Compact muffins with small cells or large muffins with peaked tops and tunnels are undesirable in all types of muffins. Diameter is a more important criterion than volume for evaluating mushroom and flat topped muffins. For bell shaped muffins, volume can be evaluated objectively by measuring the height and width of the muffin ($\pi r^2 \times$ height). The volume can be determined indirectly by measuring the circumference of a cross section of the muffin in cubic centimeters and dividing by the weight in grams. This can be done by measuring the height of the muffin at the highest point, then slicing off the top of the muffin and measuring the diameter of the muffin.

2. Contour of the Surface

The muffin should be rounded with a pebbled surface.

3. Color of Crust

Crust color should be a pleasing golden brown, not pale or burnt.

4. Interior Color

Crumb color should be a pleasant creamy color, not white and not too yellow. Crumb color will be darker with whole grain flour or added ingredients such as nuts or dried fruits, or spices.

5. Cell Uniformity and Size

Cell structure can be evaluated by making a vertical cut in the muffin to form two equal halves and then making an ink print or photocopy (34). A desirable muffin should have a uniform cell structure without tunnels.

6. Thickness of Cell Walls

Uniform thick-walled cells are desirable. Coarseness, thin-cell walls, uneven cell size, and tunnels indicate poor grain.

7. Texture

Texture depends on the physical condition of the crumb and is influenced by the grain. A desirable muffin should be easily broken, and slightly crumbly. Extreme crumbling, or toughness with lack of crumbling, are undesirable characteristics.

8. Flavor

An acceptable muffin should have a pleasingly sweet flavor. Flat, foreign, salty, soda, sour, or bitter tastes are undesirable.

9. Aftertaste

An acceptable muffin should have a pleasant, sweet aftertaste, not bitter or foreign.

10. Aroma

Aroma is recognized by the sense of smell. The aroma may be sweet, rich, musty, or flat. The ideal aroma should be pleasant, fresh, sweet, and natural. Sharp, bitter, or foreign aromas are undesirable.

11. Mouthfeel

Mouthfeel refers to the textural qualities perceived in the mouth. Characteristics can be described as gritty, hard, tough, tender, light, and moist. A desirable muffin is tender, light, and moist, and requires minimal chewing.

17 Cereals–Biology, Pre- and Post-Harvest Management

Yizhong Cai and Harold Corke
Cereal Science Laboratory, Department of Botany, The University of Hong Kong

CONTENTS

I. INTRODUCTION

Cereals are the most important crops in the world. They dominate world agricultural production since they directly or indirectly provide a large proportion of the human sustenance. About half of the plowed land in the world is used for growing the principal cereals. Cereal grains commonly contain 60–70% starch and 7–14% protein. They are the most important source of carbohydrates for humans and domestic animals, and also provide a substantial proportion of protein. Cereals are the staple foods for many people everywhere on the globe, particularly in the developing countries, because they are a relatively cheap source of calories and protein compared to meat.

Grain is a collective term applied to cereals. The main cereal grains include wheat, rice, maize, barley, sorghum, rye, oats, and millets. The majority of the world population subsists mostly on wheat, rice, and maize. These three cereals account for more than 80% of total cereal grain yield in the world. Other cereals belong to minor cereal crops called coarse grains. Most cereals can be used as staple grains for humans, but maize, barley, oats, and grain sorghum can also be used as feed grains for livestock, particularly in developed countries.

Cereals are members of the grass family Gramineae, being monocotyledonous angiosperms. They show great genetic diversity and are ubiquitous, ranging in adaptation from the semi-arid and humid tropics to both wet and dry temperate zones, and even to very cold climates (e.g., rye and oats). Typical characteristics include fibrous root systems, an upright stalk with nodes and internodal spacing and a pithy stalk, and narrow long blade leaves with parallel veins. Cereal grains are single-seed fruits called caryopses. The seed consists of seed coat, embryo (germ) and endosperm. Cereal grains contain starch, protein, lipid, fiber, vitamins, and minerals.

Cereals are comparatively easy to grow and harvest, to store, and to process into versatile and popular foods. The chemical, physical, and biological properties of cereal grains determine their suitability for a specific market. Grain yield and quality are genetically controlled and climatically influenced, and also are dependent on field, pre- and post-harvest management during the growing, harvesting, drying and storage periods. Cereal grain losses occur throughout production, harvesting, threshing, drying, storage, marketing, and distribution. These losses are estimated to be nearly 20–30% of grain yield. Therefore, it is important for proper field, pre- and post-harvest managements to reduce or eliminate losses of cereal grains and provide high quality product to market.

II. BIOLOGICAL CHARACTERISTICS

Cereals are usually referred to their common names, such as durum wheat and common wheat. In botanical classification, cereals are monocotyledonous plants belonging to the Gramineae family. Each cereal has a genus, and the genus contains more than one species or subspecies. Each species of cereals has different varieties. Table 17.1 shows the genus, species, and common names of major cereal crops. Figure 17.1 shows the morphology of major cereal plants (1). General biological traits of different parts in cereal plants are described in the following sections.

TABLE 17.1
Scientific and Common Names of Major Cereals in the Grass Family (Gramineae)

Common Name	Scientific Name (genus and species name)
Common wheat	*Triticum aestivum*
Durum wheat	*Triticum durum*
Rice	*Oryza sativa*
Maize (corn)	*Zea mays*
Barley	*Hordeum vulgare*
Grain sorghum	*Sorghum vulgare*
Common oats	*Avena sativa*
Rye	*Secale cereale*
Foxtail millet	*Setaria italica*
Pearl millet	*Pennisetum glaucum*

A. ROOTS

Cereal plants have seminal or primary roots and coronal roots. Seminal roots produce when the seed germinates. Wheat, barley, rye, and maize commonly develop 3, 5, or 7 seminal roots, whereas rice and sorghum produce only a single branched seminal root. Seminal roots may function until the plant matures. After the young cereal plant unfolds a few leaves, coronal roots arise from stem nodes underground and develop into an elaborate root system. Coronal roots normally grow below soil surface, but sometimes arise from the nodes above soil surface as aerial roots (e.g., maize and sorghum). The root systems are responsible for absorption of water, fertilizers and mineral nutrients, and also for anchor and support of the plants.

B. STEMS

Stems of cereals are divided into nodes and internodes, being cylindrical, or nearly so. The length of internodes varies with position and by species. The basal internodes generally remain short. In addition to main stem, branches called tillers may grow from subterranean nodes in most cereals. A number of tillers can be produced from the primary stem, and they in turn develop others. The number of tillers varies significantly among different species and varieties of cereals. Generally 5–40 tillers may arise from a single seed under favorable planting conditions. Most cereals (e.g., wheat, rice, barley, oats, rye, and finger millet) are thin-stemmed grassy plants, but maize, sorghum, and pearl millet have thick stems more similar to sugar cane than grass.

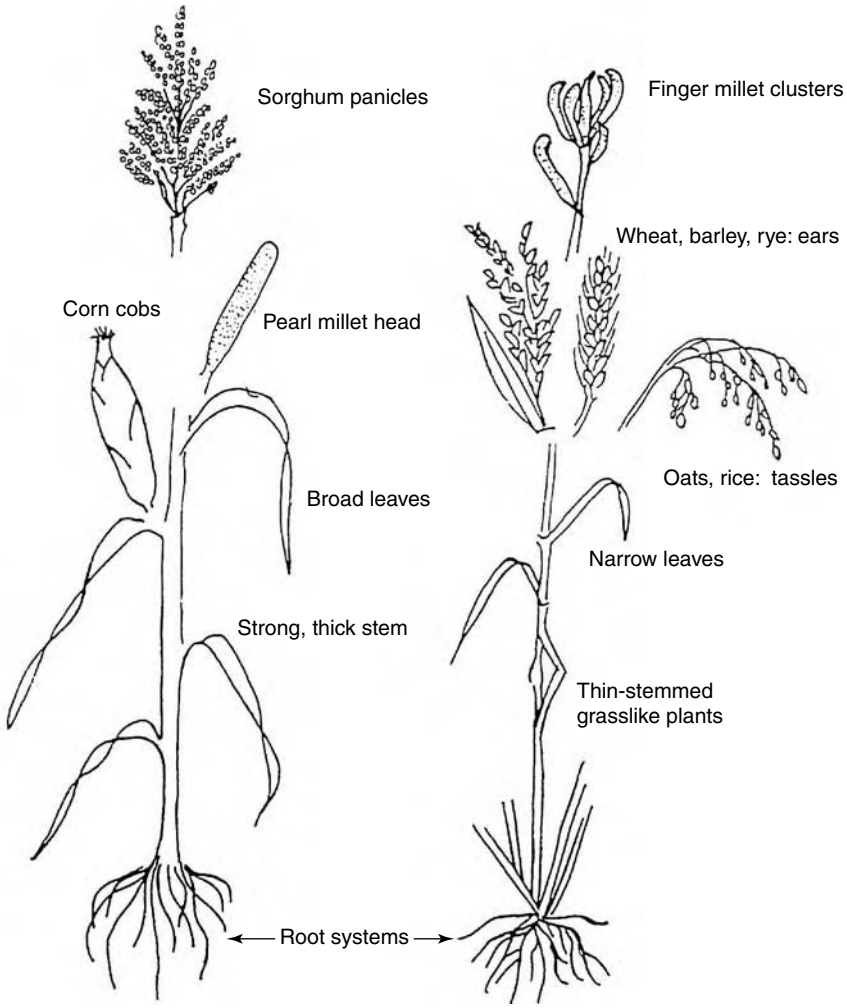

FIGURE 17.1 Morphology of major cereal plants. (Adapted from Ref. 1.)

The functions of stems are to support the plants and be responsible for transportation of water, fertilizers, and mineral nutrients. Resistance to lodging, the capacity of stems to withstand the adverse effects of rain, wind, and even diseases and pests, is an important characteristic of cereals because plant lodging usually results in serious loss of yield. Short, thick, heavy stems with thick walls are considered to be the best insurance against lodging. Excessive soil nitrogen may accelerate plant growth, which easily leads to increased lodging. A suitable balance of nitrogen, phosphorus, and potassium in the soil reduces lodging to a minimum (2).

C. Leaves

Leaves of cereals consist of sheath and blade (lamina), arising from buds that are lateral appendages of the stems. Cereal leaves are characterized by long, narrow, flat blades that taper to a point. The leaves of maize, sorghum, and pearl millet are broader and larger than those of other cereals. The leaf veins usually run parallel. At the junction of the sheath and blade is a thin membranous outgrowth called ligule that often is of taxonomic value. Lateral outgrowths called auricles occur above the ligule. Rice and barley have long clasping smooth auricles, while wheat has shorter hairy auricles, and rye has very short auricles. Oat sheath has no auricles. The sheaths of rye and oats and the leaf margins of oats have hairs (2). Furthermore, the shapes of the shieldlike ligule at the base of each leaf blade are also different. These leaf traits are very helpful to distinguish between cereal plants at the earlier developmental stages.

Leaves are mainly responsible for photosynthesis and transpiration. In photosynthesis, carbon dioxide and water react in the presence of light and chlorophyll in leaves and produce food and oxygen. In order for photosynthesis to take place, the stomata must be open, exposing the mesophyll tissues to carbon dioxide in the air. With the stomata open, the tissues are also exposed to the drying influence of air, resulting in evaporation. Evaporation of water through open stomata of leaves is called transpiration.

D. Inflorescences

Flowers of cereals are grouped on an axis of the inflorescence. The inflorescence of wheat, barley, and rye is a spike in which the sessile spikelets are attached along a rachis. Inflorescence of rice, oats, sorghum, and most of the millets is a branched panicle bearing spikelets on pedicels. A spikelet contains one or more florets subtended or enclosed by two bracts (lemma and palea) known as glumes. In the floret are the stamens, pistil, and lodicules. There are three stamens in each floret, except for rice which has six. Most cereals have perfect or bisexual flowers which contain both stamens and pistils. Maize and wild rice have separate staminate and pistillate flowers borne on the same plant. The staminate and pistillate flowers of maize are borne in separate inflorescences on the same plant. The staminate flowers are borne in the tassel at the top of the stalk, while the pistillate flowers are located in spikes which terminate lateral branches arising in the axils of lower leaves.

Cereals may be naturally self-pollinated (wheat, rice, barley, and oats), cross-pollinated (sorghum and proso millets), or naturally cross-pollinated (maize, rye, and pearl millet) (2, 3). Reproduction of cereal crops is by means of inflorescences which develop grains or seeds through pollination and fertilization.

E. Grains

The structure, chemical composition, and physical properties of cereal grains determine their suitability for a specific market. Knowledge of grain structure, composition, and physical properties is essential to drying, storage, milling, and even food processing of cereal grains.

1. Grain Structure

Cereal crops, like other members of the grass family, produce one-seeded fruit which is a caryopsis, but generally called a grain or kernel. Botanically, caryopsis contains a seed and a fruit coat (pericarp) which surrounds the seed and adheres tightly to a seed coat. The seed consists of a seed coat, an embryo (germ), and an endosperm. All cereal grains have these parts in approximately the same relationship to each other. The caryopsis of all cereals develops within floral envelopes which are actually modified leaves. These are called chaffy parts (glumes), and constitute the hulls or husks of cereal grains. In the threshing process, hulls are separated from the naked caryopsis, such as wheat, maize, sorghum, millets, rye, and naked barley, but not from rice, oats, and most cultivars of barley because their floral envelopes cover the caryopsis so closely and completely that they remain attached to the caryopsis after threshing. In addition, the kernels of wheat, rye, barley, and oats usually have a longitudinal crease (ventral furrow).

Cereal grains include pericarp, seed coat, endosperm, and embryo. The pericarp is composed of several layers and surrounds the entire seed. The starch-rich endosperm contains simple or compound starch granules, and it is the principal portion of the grains serving as food reserve for the embryo. The outermost layer of endosperm is called the aleurone layer, consisting of a single layer or more layers. Peripheral to the aleurone is a series of highly compressed remnant cell layers comprising the nucellus, seed coat, and pericarp. These, in combination with the aleurone layer, are usually referred to as the bran.

Grain size and proportions of the major parts of mature kernels from eight cereals are shown in Table 17.2 (4–6). Table 17.3 compares the major structural characteristics of

TABLE 17.2
Grain Size and Proportions of the Major Parts of Mature Cereal Kernels

Cereal	Germ (%)	Pericarp (%)	Aleurone (%)	Endosperm (%)
Wheat	2–3	12–15	—81–86—	
Rice	3.5	1.5	4–6	89–92
Maize	8.4–10	5.5–8		82–84
Barley	3.4	18.3	—79—	
Sorghum	7.8–12.1	—7.3–9.3—		80–85
Oats	3.7	—28.7–41.4—		54.9–67.6
Rye	3.5	12	—85—	
Pearl millet	17.4	—7.5—		75

the cereal grains of commerce (4, 7). Longitudinal cross sections of the kernels from the three major cereals (wheat, rice, and maize) are shown in Figures 17.2, 17.3, and 17.4 (4, 5, 8, 9).

a. Wheat

Wheat kernels are 5–8 mm in length, 2.5–4.5 mm in width, and 30–45 mg in weight. The kernel size and shape of the wheat vary significantly depending on cultivars and kernel position in the spike. Also, there is wide variation in endosperm texture (hardness) and color of the wheat kernels. Wheat pericarp comprises about 12–15% of the kernel weight, removed in the milling process along with the aleurone layer of endosperm. Wheat endosperm constitutes 81–86% of the kernel weight, being the major end product of a wheat flour mill, whereas germ accounts for only about 2–3%.

Wheat pericarp surrounds the whole seed and includes outer and inner layers. The seed coat has three layers, a thick outer cuticle, a thin inner cuticle, and a pigment layer (only for colored wheat). The aleurone layer is the outermost layer of endosperm, containing thick-walled cells. Wheat germ is composed of two major parts, embryonic axis (rudimentary root and shoot) and scutellum (cotyledon). The starchy endosperm of wheat contains starch granules embedded in or surrounded by an amorphous protein matrix. Three types of cells (peripheral, prismatic, and central) make up most of the wheat endosperm. Wheat endosperm usually varies in hardness (texture) and appearance (vitreousness) among different cultivars. Generally, high-protein hard wheat varieties

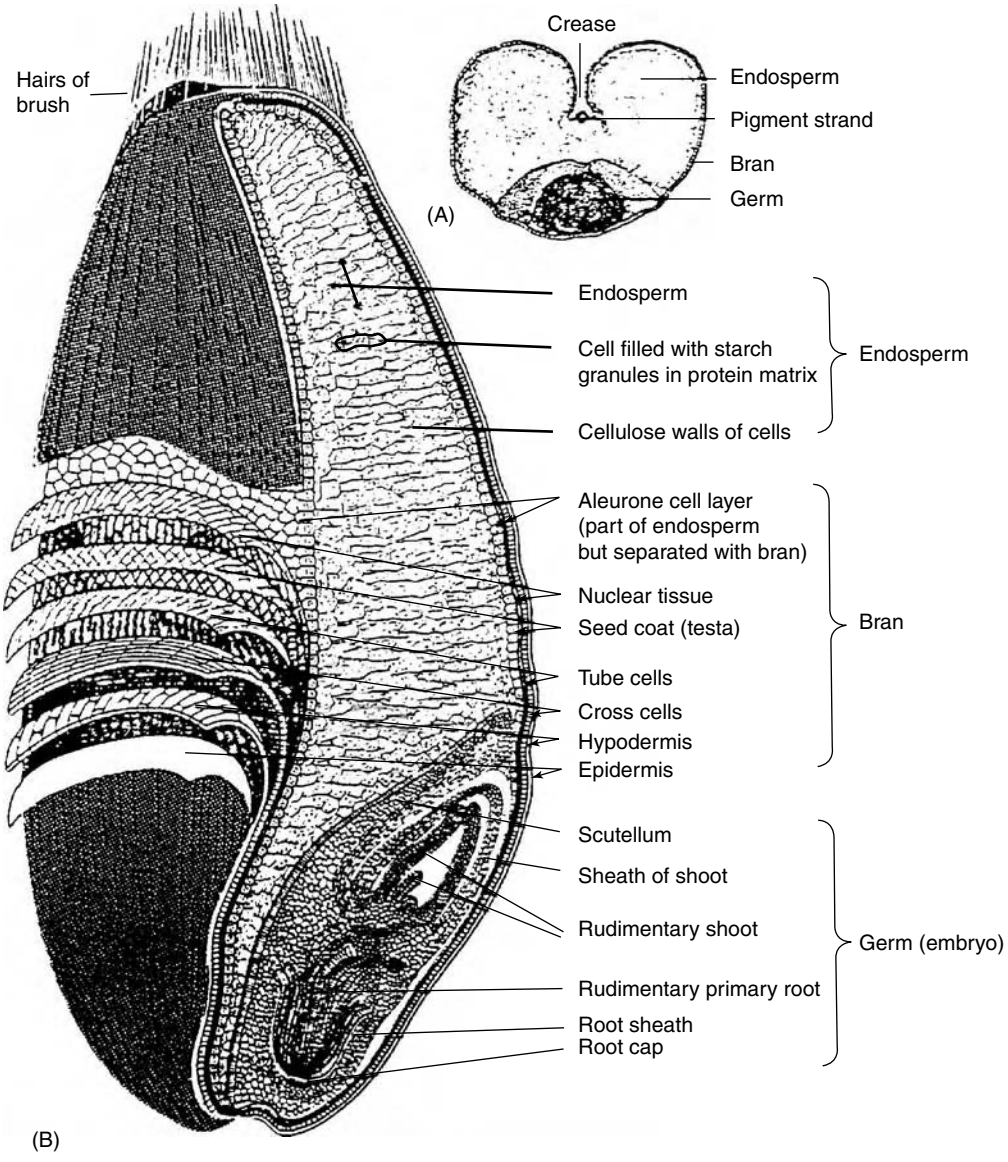

FIGURE 17.2 Diagram of a wheat kernel in (A) cross and (B) longitudinal sections. (From the Wheat Flour Institute, Washington, D.C.)

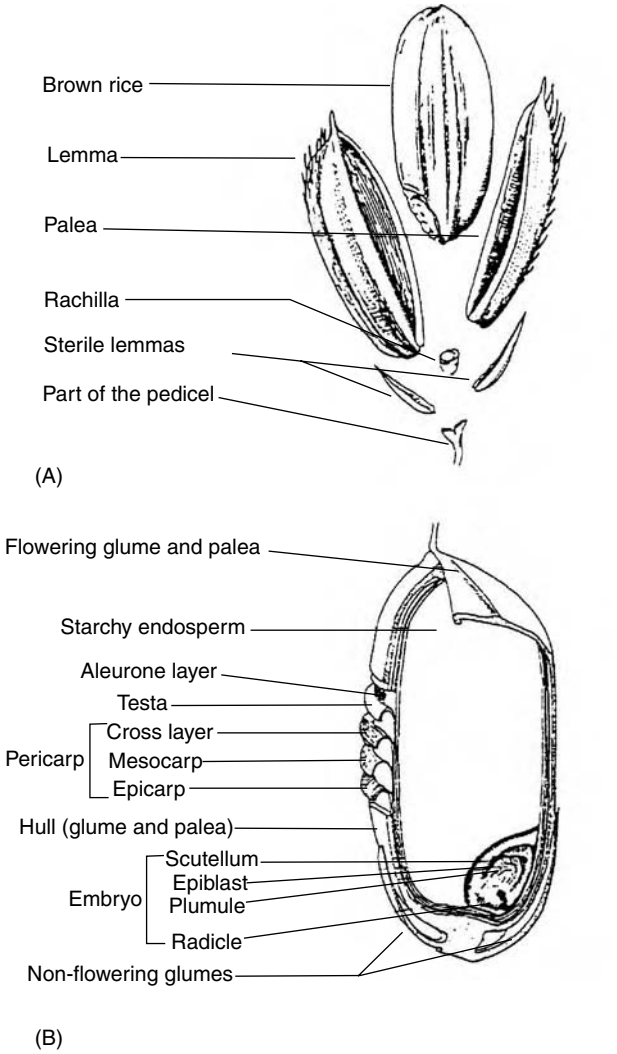

FIGURE 17.3 Structure of a (paddy) rice grain (A) and mid-longitudinal section (B). (Adapted from Ref. 9.)

tend to be vitreous, whereas low-protein soft wheat varieties tend to be opaque.

b. Rice

Rice grains are also called paddy or rough rice because of attached husks. Based on the length-to-width ratio, rice grains are divided into three grain types, long-grain, medium-grain, and short-grain. The grain is about 5–10 mm in length, 1.5–5.0 mm in width, and 20–35 mg in weight. A paddy rice grain consists of the husk (lemma and palea) (~20% in weight) and the brown rice kernel. Brown rice (rice after removing husk) contains pericarp (about 2%), seed coat and aleurone layer (about 5%), germ (3–4%), and endosperm (89–92%). After removing the pericarp during milling, brown rice produces white rice (milled rice). Rice endosperm is both hard and vitreous. Some rice cultivars have opaque areas called white belly, resulting from air spaces in the endosperm. The thin-walled endosperm cells are tightly packed, with polygonal compound starch granules and protein bodies. Protein bodies are more numerous in the cells just inside the aleurone layer than in cells near the center of endosperm. In addition to oats, rice is the only cereal with compound starch granules.

c. Maize

Compared to other cereal grains, maize has a unique shape and low specific gravity. Maize kernels are the largest cereal grains, weighing 250–300 mg each (wider variation 150–600 mg), 8–17 mm in length, and 5–15 mm in width. They are flat because of pressure during growth from adjacent kernels on the cob, have a blunt crown and a pointed conical tip cap. Maize kernel is composed of four parts, tip cap, pericarp, germ, and endosperm. The tip cap is often separated from the kernels along with the shelling process. Pericarp makes up about 5–7% of the kernel weight and germ constitutes about 8–11%. The endosperm comprises 82–84% of the kernel weight, being the major end product of maize flour mill.

There are seven major types of maize kernels, including dent, flint, flour, sweet, pop, waxy, and pod maizes (10). Their major differences are based on quality, quantity, and pattern of endosperm composition. Dent maize is characterized by the presence of corneous, horny endosperm at the sides and back of the kernels, whereas the central core is soft and floury. The indented crown is peculiar to dent types and is the basis for the term "dent corn." Flint maize has a thick, hard, vitreous endosperm layer surrounding a small, soft, granular center. The kernels are smooth and rounded. Popcorn is the most primitive race of maize, characterized by a very hard, corneous endosperm, essentially a small-kernelled flint. Flour corn is one of the oldest maizes, characterized by soft endosperm throughout the kernel. The endosperm of flour corn is almost floury, with little or no corneous endosperm. Sweet corn is believed to have originated from a mutation of a Peruvian race. The sugary gene of sweet corn retards normal conversion of sugar to starch, and the kernel accumulates a water-soluble polysaccharide, making up about 12% of the dry weight of sweet corn (but only 2–3% in other types). The kernel starch of waxy maize is almost amylopectin, a branched-chain α-D glucose polymer. Waxy maize is used to manufacture starch. Pod corn is an ornamental type with long glumes enclosing each kernel except husks covering the ear, but not grown commercially.

2. Grain Composition

High level of starch (starchy seeds) is the most important characteristic of all cereal grains. The starch contents of cereals usually account for 55~75% of total grain weight. Protein is another important component in cereal grains, consisting of 6~14%. Most cereal grains contain a low level of lipids, normally below 2–3%. Of all cereal grains, maize contains the highest level of oils; oil content of some varieties reaches about 6%. Additionally, moisture contents of cereal grains commonly range from 12 to 15%. Cereal fiber is an important source of human dietary fiber. Typical composition of three major cereals (wheat, rice, and maize)

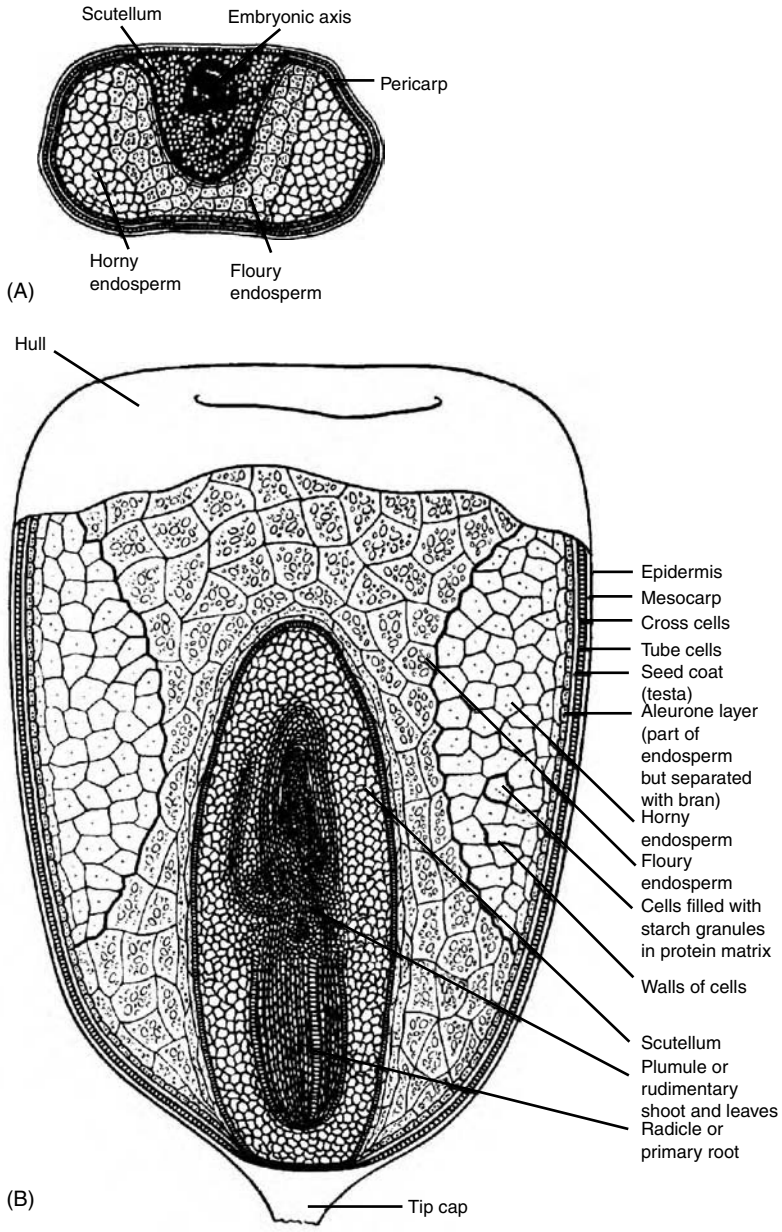

FIGURE 17.4 Diagram of a corn kernel in (A) cross and (B) longitudinal sections. (From the Corn Refiners Association.)

TABLE 17.4
Typical Composition of Three Major Cereal Grains[a]

Cereals	Starch (%)	Protein (%)	Fat (%)	Fiber (%)
Wheat	69.7	10.6	1.9	1.0
Rice (brown)	64.3	7.3	2.2	0.8
Maize	63.6	9.8	2.0	4.9

Source: Data from Refs. 5 and 11.

[a] At 14% moisture content.

is shown in Table 17.4 (5, 11). Other nutritional constituents of cereals have also been extensively investigated, including minerals and vitamins (10, 12, 13).

The chemical composition of the different parts in cereal grains varies widely, depending on position within the grain and also between grains of different species and varieties. Table 17.5 shows the composition distribution of endosperm, germ, and bran in wheat grain (14). Starch is mostly distributed in the endosperm. Protein and lipids normally occur in germ. Bran and germ contain more pentosans (cellulose) and minerals (14).

3. Physical Properties of Grains

Physical properties of cereal grains commonly include 1000-kernel weight, bulk density or test weight, repose angle,

TABLE 17.5
Composition Distribution of Endosperm, Germ, and Bran in Wheat Grain (%, dw)

Grain Parts	Total Weight (%)	Starch (%)	Protein (%)	Fat (%)	Pentosans (%)	Mineral (%)
Endosperm	82–85	70–85	8–13	1–1.6	0.5–3.0	0.3–0.8
Bran	15	0	7–8	1–5	30–40	3–10
Germ	3	20	35–40	15	20	5–6
Total Grain	100	60–70	10–14	1.5–2.5	5–8	1.6–2.0

Source: Adapted from Ref. 14.

porosity, thermal conductivity, grain hardness, etc. (4, 5). These properties are important in the design of handling equipment, drying and storage facilities, and influence drying and storage of cereal grains. Principal physical properties of the three major cereals are shown in Table 17.6 (5, 15).

The weight of grain is ordinarily given as the 1000-kernel weight. The 1000-kernel weight of maize is significantly higher than that of wheat and rice, which can translate to a lower drying rate for maize kernels. The weight of a given volume of grain including the voids is the bulk density, a widely used property which usually determines the bin volume required to store a certain mass of grain, and also affects the grain velocity in a continuous-flow grain dryer at a certain capacity. Wheat has the highest bulk density, while rice has the lowest. The void space in a mass of grain is expressed as a percentage of the total volume of the grain, and is called the porosity. The porosity of the three grains varies between 40% and 48%, typical of cereal grains. Resistance of bulk grain to airflow is, in part, a function of the porosity and the grain size.

When poured on a level surface, grain forms a pile whose outer edge makes an angle to that surface. The value of the angle is specific to the grain and is called the angle of repose which determines the maximum angle of a pile of the grain with the horizontal plane. It is important in the filling of a flat storage facility when grain is not piled at a uniform bed depth but rather is peaked. The slope of a pile of grain may be less than the angle of repose but not greater.

The specific heat expresses the energy required by a unit mass of grain to increase in temperature by 1°C. Of the three cereal grains, maize requires the most energy to reach the desired temperature at which the optimal evaporation rate of water occurs. Thermal conductivity is a determination of the resistance to the conduction of thermal energy within individual cereal grains. In grain with high conductivity, the thermal gradients in the kernels disappear faster during drying than in equal sized kernels of another grain with lower conductivity. The specific surface area refers to the kernel area per unit volume of cereals which exchanges energy and moisture with air during the drying process. For same volumes, there is more heat and mass transfer area for wheat and rice than for maize.

TABLE 17.6
Major Physical Properties of Wheat, Rice, and Maize (Typical Grains) at 12–16% Moisture Content (wb)

Physical Properties	Wheat	Rice	Corn
1000-kernel weight (g)	32	27	325
Bulk density (kg/m^3)	805	590	745
Test weight (kg/L)	77	58	72
Porosity (%)	41	48	40
Repose angle (°)	31	36	35
Specific heat (J/kg · °C)	1.67	1.51	2.01
Conductivity (W/m · °C)	0.137	0.106	0.159
Specific surface area (m^2/m^3)	1181	1132	784

III. GROWTH PROCESSES AND PRODUCTION

A. Growth Cycles and Habits

In general terms, the completed life cycle of plants refers to the stages that occur from the time a seed is planted until a new seed is produced, including seed sowing, germination, vegetative growth, reproductive growth, production of seeds, and death. Cereal plants pass through a typical vegetative growth and reproductive growth cycle (16). They grow primarily in a vegetative stage and then go into a reproductive stage. Stalks and leaves grow first and then start flowering and producing grains. Vegetative growth still continues during the reproductive stage, but at a much slower rate than prior to the start of reproduction.

Higher plants can be classified as annuals, winter annuals, biennials, or perennials (3). All cereals are normally annuals; that is, they complete the life cycle in one season. However, certain rice and sorghum species (e.g., wild rice) are able to live as perennials for several years in mild climates. Except in very cold climates, some cereals behave as winter annuals; that is, they live through the winter as small plants in the vegetative stage, and send up stalks and flower in the spring. There are spring and winter types of wheat, barley, oats, and rye. Winter varieties are planted in the fall, vernalized (require freezing temperature) during the fall and winter, and produce seeds and are harvested in the next summer. Spring varieties usually live in cold on mild climates, and are sown in the spring and harvested in the late summer and fall.

The length of the vegetative and reproductive period of any cereals or cereal varieties is greatly determined by temperature, photoperiod, plant nutrition, and growth

hormones, and also by genetic factors that affect reactions to these conditions. Each cereal species has an approximate minimum, optimum, and maximum temperature at which growth occurs, although varieties of a species may differ somewhat in their temperature reaction. When the mean temperature is 10°C below the optimum, the time required to grow a crop to maturity is about doubled. All cereal varieties with a winter growth habit, as well as some spring small-grain varieties, require cold for initiation of the flower primordia. Warmer temperatures favor rapid growth and flowering after the initial floral structure is formed.

Photoperiod is also an important factor affecting growth habits. When nights (daily dark periods) are short and days (photoperiods) are long, long-day cereals (wheat, barley, oats, and rye) can flower normally, otherwise their growth period will delay. Some can flower even under continuous light. However, when nights are long and days are short, short-day cereals (rice, maize, sorghum, oats, and millets) can flower normally, otherwise their growth period will postpone. They need a daily dark period for 3–5 weeks to initiate flowering. Additionally, soil rich in nitrogen will keep down the carbon-nitrogen ratio and delay flowering in wheat, barley, oats, and rye, known as nitronegative cereals, but favor early flowering in maize, sorghum, rice, and millets, called nitropositive cereals, unless the nitrogen supply is excessive. Therefore, wheat, barley, oats, and rye are cool-season, long-day, nitronegative, winter or spring habit plants, whereas rice, maize, sorghum, and millets are warm-season, short-day, nitropositive, spring habit plants.

B. Distribution and Production

Cereals grown in temperate climates are wheat, maize, barley, rye, grain sorghum, oats, and some millets. Important cereals grown in hot climates are rice, sorghum, pearl millet, and finger millet. Winter rye, wheat, barley, and oats can be suitable for cold climates. The world production of major cereals is shown in Table 17.7 (1). Wheat, rice, and maize are the three most important cereal crops, accounting for 70–80% of total area and total yield in the world. Major cereals are grown and distributed in about 170 countries and regions. The principal areas of cereal production are located in North America, China, Europe, India, Argentina, Australia, and Northern Africa (2, 17).

Wheat, the most important cereal crop in the world, is grown widely in the northern hemisphere in Europe and North America, but large quantities are also planted in China (the largest production of any country), Australia, India, Russia, and South America (Table 17.8) (14). About 95% of rice in the world is produced in Monsoon Asia, an area that extends across the southeastern part of Asia from India to Japan and includes most of the adjacent tropical and subtropical island countries. Maize is the highest yield cereal crop, distributing mainly in the United States, Canada, China, Brazil, Europe, and Africa.

C. Factors Affecting Grain Production and Quality before Harvest

In addition to climate (days of sunshine, temperature, and precipitation), many other factors influence grain production and quality of cereal crops, including varieties, cropping systems (e.g., rotation), soils, fertilizers, water, weeds, diseases, insect pests, and so on. Grain yield and quality are formed and determined during the growing season. Thus, varietal selection, suitable rotation arrangement, and favorable field management are essential to cereal production.

The great contribution of good varieties to profitability of cereal production and quality is well recognized. Good varietal selection and utilization is the most important strategy to increase yield and improve quality. Numerous breeders and farmers are devoting to the breeding and improvement of new cereal varieties. Many excellent varieties with high yield, good quality, and resistance to diseases and pests, have been selected and bred for

extensive production in many countries including some developing countries. Modern biotechnology will play a more important role in these aspects.

Principal field managements include seed sowing, cultivation, fertilizers and water management, weed control, and disease and insect control. In addition to varieties, the yield and quality of all cereal crops are strongly dependent on the availability of an adequate supply of soil mineral nutrients and water throughout the growing season. The higher the yield potential, the higher the nutrient demand is. Nitrogen (N), phosphorus (P), and potassium (K) are three major nutritional elements required by cereal crop growth, largely affecting both grain yield and quality. Crop nutrition demand is normally met through the application of inorganic fertilizers (N, P, and K), although in organic cereal systems additional nutrients can only be supplied from manures and other organic sources. During major fertilizer application, an adequate ratio of N, P, and K should be controlled, normally around 3:1:1 (various ratio for different crop species/varieties); otherwise it will cause abnormal growth and affect grain quality. Other essential trace elements include sulfur, calcium, magnesium, iron, zinc, boron, and so on, normally being supplied by the fertile soil (17).

Water is also essential to the life processes of cereal plants. Water shortage occurs at the vegetative growth stages, which frequently makes shorter plants and earlier maturity. Water shortage at flowering and maturity periods usually causes serious decrease of grain yield and produces many bad grains. For different cereals, irrigation and drainage in the field should be conducted at the adequate growth stages. For instance, rice needs more water during tillering stage and flowering period, and irrigation should be done. At late tillering stage it is required to drain water for controlling tillers, and at late maturity drainage should be done again for full maturity and drying field for harvest.

Additionally, the presence of weeds, diseases, and insect pests during growth obviously reduces cereal grain yield, and influences grain quality. Control of weeds, diseases, and pests is also an important field management measure to maintain and protect grain quantity and quality during the growing season. In addition to using varieties with strong resistance to diseases and pests, pesticides/fungicides and bio-insecticides are usually used. Herbicides are widely applied to kill or control weeds in the field. Appropriate cultivations and rotations not only reduce the loss and damage from diseases and pests, but also control weed growth and decrease weed competition on cereals.

IV. HARVESTING AND THRESHING

Harvesting, threshing, drying, and storage are the important steps of pre- and post-harvest management between producing cereal grains and becoming various cereal food products. Successful, suitable, and efficient harvesting and threshing of cereal crops is one of the key steps to keep grain quality and quantity. It is desirable to know when to harvest, to understand harvesting and threshing machines and their operation, and to minimize losses during harvesting and threshing.

A. Harvesting Time

Cereal grains normally stop growing and gaining in dry weight when they approximately reach the hard-dough stage, or when the moisture content drops below 20~40%. Further ripening is only a desiccated process of the kernels, not accompanied by transport of nutrients into the grains. Ripening is not entirely uniform among different heads or different grains within a head. Most cereals at the hard-dough stage have a moisture content of 25~35%, the heads are usually light yellow, and the kernels are too firm to be cut easily with the thumbnail. Grain quality normally starts to deteriorate in the field prior to harvest. Rainfall prior to and during the harvest period may induce ear diseases and premature sprouting, and high grain moisture contents may necessitate increased drying costs. Cereal grains should be harvested as near maturity as possible to avoid losses of prematurity and overmaturity (3, 18).

Premature harvest reduces yield and quality of cereal grains. Underdeveloped grains are low in test weight, starch content, and market value. Cereal crops are usually harvested 7 days or more before they are ripe and allowed to dry under cool humid conditions, or 3 to 4 days early under warm dry conditions, without appreciable loss in yield and quality (3). Wheat grain sometimes draws material from the straw after it is cut when nearly ripe. Considerably more growth has occurred when immature barley grains were left to dry in the head than when they were threshed immediately.

Delayed harvest also influences grain yield and quality. Losses from the delayed harvest are caused by shattering, crinkling, lodging, and leaching. For instance, delay in rice harvesting leads to lower yield because of lodging and shattering, and overmaturity may induce the formation of longitudinal and multiple transverse cracks in rice grains. Formation of such cracks leads to milling losses. Delaying wheat harvest may result in grains with high α-amylase content, lower specific weight and protein content, which seriously reduce grain quality for breadmaking. Cereal stems may crinkle down or break over soon after maturity, especially in damp weather. Oats are more susceptible than barley to crinkling, while barley is more susceptible than wheat or rye. Most tall-stalked grain sorghum varieties go down soon after maturity or after a frost. Weathered or sun-bleached grains are unattractive and often bring a lower grade and price on the market. Overmature grains exposed to wet and dry weathering for long periods in the field are

TABLE 17.9
Moisture Contents for Wheat, Rice, and Maize at Harvest and for Safe Storage (%, wb)

lowered in test weight because the grains swell when damp and do not shrink to their original volume after drying (3).

Moisture contents of wheat, rice and maize at harvest are shown in Table 17.9 (5). Grain moisture content at harvest is an important consideration, and usually varies with seasons and geographic regions. In wheat, grain moisture at harvest should be about 10~20%. Rice is harvested at a moisture content of 20~30%. Maize is harvested at considerably higher moisture levels than wheat, especially at higher latitudes. Maize is often harvested at 30~35% moisture in the northern Corn Belt of the United States, and at 35~45% in Eastern Europe (5). In Britain, cereal grain is often harvested at moisture contents of about 16~20%, whilst in exceptionally late seasons in northern regions grain may be harvested at around 25% (18).

Barley is commonly harvested at about 15% moisture, but sometimes producers started harvesting at 30~40% moisture, resulting in a higher yield because of reduced losses at harvest. The fresh barley grain is either artificially dried for food use or stored in silage-type bins for livestock feed. Oats should be at around 13~14% moisture for harvest; however, since oats shatter easily, it is common practice to cut and windrow them when the grain contains about 20% moisture. When it dries to a moisture content of 13~14%, the grain is combined. Sorghum should be harvested at 18~20% moisture if it is to be dried, but at around 13% moisture if it is to go directly to storage (19).

B. Methods and Machines of Harvesting and Threshing

Nowadays, all cereal crops can be harvested by modern machines that replace traditional harvesting tools, such as hand sickle, scythe, and cradle. Because of high working efficiency, machine harvesting and threshing saves time and labor, reduces cost, and is extensively used in developed countries (17). However, manual harvesting and threshing is still widely used in most developing countries. For example, rice harvesting is mostly done manually in Asia and Africa. The rice plants are cut near the ground with a sickle, allowed to dry in the field, collected, stacked, and threshed. In Asia and Africa, paddy rice is traditionally threshed by manually beating the straws against a slat or stone, or by trampling under feet of animals, bullock draw carts, tractor wheels, or tractor-drawn roller. However, the drum thresher is also widely used nowadays for rice threshing in Japan, China, India, and others.

There are many types of machines for crop harvesting and threshing, such as harvester-threshers, mowers, windrowers, strippers, pickers, choppers, balers, rakes, cubers, stackers, and conditioners (3, 17). The word combine is used to describe machines that combine several harvesting and threshing operations into one. Grain combine is usually adapted to each cereal crop by making small changes in the cutter bar, the reel, or the thresher (cylinder or similar mechanism). For example, for maize, the cutter bar-reel combination used for wheat is replaced by a header which strips the ear of maize off the stalk.

The most common combine is the harvester-thresher combination used to harvest most cereal crops. Bishop et al. (19) summarized the basic operation of the combine, including the following procedures: 1) the grain is cut and conveyed to a thresher; 2) the thresher removes the grain from the head, or stalk, or cob; 3) the grain is separated from the hulls, straw, cob, pods, leaves, or similar plant materials; 4) the grain is cleaned by removing the rest of the chaff, dirt, and remaining trash; and 5) the grain is transferred to a bin. Additionally, in operating a combine, the various parts must be properly adjusted. The reel and cutter bar should be adjusted to the correct height, and the correct cylinder speed in the thresher should be employed for different grains.

The harvest-thresher or combine is most extensively and the earliest used to harvest wheat and barley. Maize is commonly harvested with a combination picker-sheller or a combine with a special header. These two machines can remove ears of maize from the stalk. The ears are then shelled by the machine, the grain is sent to the bin, and the rest of the plant material is discarded back onto the field. Combine harvesters are also used for rice harvesting in some developed countries. Sorghum may be harvested with a simple combine. Sorghum grain is relatively soft, and speed of the cylinder that threshes the grain has to be reduced to prevent grain damage.

Conditions of cereal crops at harvest have a significant influence on combine performance, e.g., severely lodged cereals not only produce inferior quality grains, but also reduce combine speed and efficiency. The presence of weeds also interferes with harvesting and often leads to higher grain moisture contents and contamination with weed seeds which increase cleaning costs.

C. Harvesting and Threshing Losses

Losses in yield can be due to improper harvesting techniques or harvesting too early or too late. If harvest begins too early, plants have not reached full maturity, causing shrinkage of the grain. If harvested too late, plants can

lodge or stalks can break, grain can shatter or ears can drop, and quality will deteriorate.

Factors affecting harvester efficiency and yield losses include combine adjustments, field speed, kernel moisture levels, and lodging. Suitable adjustment and operation of harvest equipment helps minimize harvest losses, and losses should not exceed 3% from a properly adjusted and operated combine.

Threshing losses are caused by incomplete threshing, physical damage by beaters in the machine, or even by hand spillage and cleaning losses in the winnowing and screening processes, which immediately follow threshing. Incomplete stripping is common in areas of high labor cost, causing paddy losses up to 12%. When harvesting takes place in the rainy season, the paddy is wet and can easily choke cleaners on mechanical threshers and cause losses. Maize shelling losses are also caused by incomplete stripping of grain from cob, kernel breakage in the machine, and kernel scratching. Small-toothed shellers give low damage with 3% loss, and threshing machines and combine harvesters can give more than 5% broken grains (20).

V. DRYING AND STORAGE

Drying and storage are important post-harvest managements for achieving high quality grain to meet market requirements. After harvesting, it is necessary to clean, dry, and store cereal grains and protect their quality and quantity properly until cereals are processed into food products. To protect cereal grains appropriately after harvesting, producers need to know how to clean, dry, and store grains, to regulate storage conditions (temperature and moisture), and to control insects, microorganisms, and rodents.

A. Grain Cleaning

For drying and good storage, chaff, dust, straw particles and broken grains should be removed from harvested grains. Weeds and other impurities (e.g., mud, stone, and sand) must be also separated from grains. For good quality to market, the grain must be as near 100% as possible of one variety free from broken, discolored grains and shriveled, undersized grains of the same variety. A typical grain cleaner often consists of two parts, a shaking screen and a fan driven from the same motor. Straw and other large objects are removed by screening, and dust and other lightweight materials are blown out by aspiration. Machines used to remove unwanted grains include three types: slotted cylindrical grader, indented cylinder, and optical sorter (20). Bailey (21) also introduced grain cleaning methods and equipment. Three common cleaning and separating methods are used in elevators, those using air streams, perforated screens, and indents.

B. Principles of Drying and Storage

Moisture is one of the major factors contributing to the deterioration of cereal grain quality during storage. Moisture content of grains is defined as the amount of water that can be removed without alterations in chemical structure, which varies depending on the types of grains (e.g., covered husk, naked, or pearled kernels), moisture at harvest, harvesting method, chemical composition, relative humidity of atmosphere, and seasonal fluctuations. Safe storage moisture content of grains is commonly defined as the amount of water at which the rate of respiration is low enough to prevent generation of heat and consequent deterioration (22, 23). For safe storage, wheat, rice, and maize grains have to be dried to 14% moisture or lower (Table 17.9) (5). For long-term storage (over 1 year), lower moisture contents are recommended to prevent microbial growth and insect reproduction. For short-term storage (1–3 months), moisture can be slightly higher (above 15%).

Equilibrium moisture content (EMC) is also important to grain drying and storage. EMC is defined as the moisture content of material after exposed to a particular environment for an infinite period of time, usually depending on humidity and temperature of the environment (5). Moisture content of cereal grains tends to equilibrate with the moisture of surrounding air. Wet grains lose moisture to dry air, and dry grains absorb moisture from wet air. Also, the amount of water held by a volume of air depends on temperature. When drying with air of a specified temperature and humidity, grain can dry to no lower than the EMC. Once the grain has reached the EMC, no further moisture transfer will occur. Dry grain will absorb moisture when exposed to air leading to an EMC higher than current moisture content of the grain (23). As shown in Table 17.10, EMC values increase with increase of relative humidity and decrease slightly with increase of storage temperature (5, 23). Furthermore, EMC values usually vary with differences in grain structures and maturity of various cereal grain species/varieties.

Infestation of insects and microorganisms is affected by interaction of grain moisture, relative humidity, and storage temperature (21, 22). Insects attack grains at moisture content above 8% at all ranges of relative humidity, if the storage temperature is above 19°C. Molds harm grains at above 60~65% relative humidity and above 12% moisture, irrespective of temperature at 20–40°C. To control both insects and molds, grains should be stored at or below 19°C and 60~65% relative humidity. This basically coincides with 12~14% EMC in the grains. However, it may not be economically feasible to maintain storage temperature at or below 19°C. Thus, safe storage moisture of grains is usually based on EMC at 27°C and 70% relative humidity, particularly in developing countries (Table 17.11) (22–24). Drying cereal grains to safe moisture levels and storing in moisture-proof structures sufficiently

[a]This storage condition is particularly suitable for the developing countries.

resistant to insects, molds, and rodents would greatly reduce storage losses.

C. Drying Methods and Facilities

1. Sun Drying or Natural Air Drying

In ancient times, harvested grains were usually sun-dried or air-dried. This traditional drying method is still widely used by farmers in developing countries and some developed countries. The bulk of the grain is still dried by spreading the wet grain in thin layer on the ground in open air to be dried by the sun. Sun drying is a very simple and cheap method of drying cereal grains harvested in the warm part of the year, but is not suitable for large quantities of grains, and not under wet weather conditions.

2. Mechanical Drying

Since industrialized times, mechanical drying has gradually replaced traditional drying methods. Mechanical drying essentially involves forcing or sucking ambient or heated air through the mass of grains. The major features of mechanical drying methods are: 1) drying rate can be controlled by regulating air temperature ventilating through the grains; 2) grains can be dried irrespective of weather, and does not depend on natural resources like solar energy; 3) losses due to insects, birds, rodents, or rains are eliminated; 4) it requires little space for drying; 5) turnover is high; and 6) drying cost is much higher than sun drying (22).

a. Drying systems

Mechanical drying systems can be divided into on-farm drying and off-farm drying (5). On-farm driers have three categories: bin, non-bin, and combination driers. Bin driers are normally low-capacity and low-temperature systems, able to produce excellent quality grain. Non-bin driers, the most popular drier type in the United States, are high-capacity and high-temperature systems that frequently overheat and overdry the grain, thus easily causing grain quality deterioration. Combination drying uses the non-bin high-temperature drier to dry the grain from harvest moisture content to 16–20% and completes the drying process

with in-bin drying. Combination drying has the advantages of both systems (i.e., high capacity and good quality), but requires additional investment and is more complicated.

Off-farm or elevator grain driers also have three categories: crossflow, concurrent flow, and mixed flow, which are high-capacity and high-temperature units. Crossflow models dry grain nonuniformly, causing considerable stress cracking of the kernels. Mixed-flow driers dry the grain more uniformly; the dried grain is normally of higher quality than that dried in crossflow models. Concurrent-flow driers have counterflow coolers and produce the highest quality grain; their disadvantages are relatively high capital cost and complexity of the technology. A significant improvement in grain quality can be obtained with off-farm driers by optimizing the operating parameters and by installing automatic drier controllers.

Salunkhe et al. (22) summarized the two major types of mechanical drying systems advocated for either batch or bulk drying process in developing countries, i.e., low-temperature drying and medium-temperature drying systems. In low-temperature drying, there is an increase in airflow through the grains by means of a fan. The grains gradually reach a moisture level in equilibrium with the relative humidity of ambient air which must be below 70% for such drying. Various drying-cum-storage structures employed for such process are on-the-floor drying, in-bin drying, or tunnel drying. Medium-temperature drying is needed when air humidity is above 70%, initial grain moisture is too high, or ambient temperature is too low to effect drying before deterioration begins. Warm air is blown through a bed of grain of controlled depths, and the drying process ceases before EMC is reached. This can be applied for both batch and bulk drying. Medium-temperature driers have several types, such as tray drier, radial-flow drier, sack drier, and multi-duct ventilated flow drier.

Brook (23) comprehensively described the mechanical grain drying systems commonly used in the United States, including 1) Fans: two typical fans, axial-flow fan and centrifugal-flow fan, are used for forcing drying air through a mass of grain. 2) Low-temperature bin driers: drying with natural air or air with temperature increased by up to 5°C. Drying and storage occur in the same bin, called an in-bin drier which consists of high-capacity fans, grain unloading equipment, perforated drying floor, heater, spreader, and grain stirrer (Figure 17.5) (23). These are low initial investment and low-drying-capacity systems best for grains with low moisture levels at harvest and for drier geographical areas with low humidity. 3) High-temperature bin-batch driers: can dry batches of grains with heated air and remove moisture in a shorter time, with drying temperatures of 35–60°C. In these systems, drying and storage occur in separate bins. They require moderate initial investment and medium energy use, and often cost less per unit drying capacity but require more labor because of transfer of each batch to storage. Two typical high-temperature bin-batch

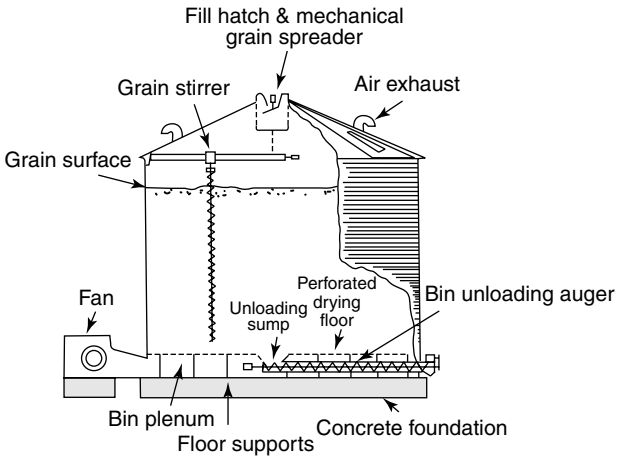

FIGURE 17.5 Low-temperature bin drier. (From Ref. 23.)

driers include on-floor bin-batch driers and roof bin-batch driers. 4) High-temperature column driers: characterized by multiple vertical columns that hold grains while the air is forced horizontally through grains, with airflows of 80–100 m^3/min·t and with drying temperatures up to 100°C. These are advanced driers which require moderate to high initial investment and high energy use. Three common types of high-temperature column driers are manual batch column driers, automatic batch driers, and continuous-crossflow column driers. 5) Continuous-flow bin driers: have a bin with a perforated drying floor, fan, heater, grain spreader, grain-unloading equipment, and an auger to transfer grain to storage. They unload hot and dried grains semicontinuously from the bottom of the drying bin to storage bins for cooling. Grain flow is automatically controlled to limit overdrying, with typical airflows of 10–25 m^3/min·t and with drying temperatures of less than 80°C. 6) Others: concurrent-flow driers, fluidized-bed driers, spouted bed driers, rotary drum driers, and so on. These belong to high-investment and high-drying-capacity drying systems. New drying technologies, such as differential grain-speed crossflow drying, multistage concurrent-flow drying, multistage mixed-flow drying, and cascading-rotary drying, have the potential to decrease energy consumption and grain deterioration by about 50%.

b. Cooling equipment

Cooling equipment is one part of the drying systems. Grains dried through any heated air driers should be cooled in time, otherwise causing quality deterioration. Delayed-cooling methods are usually used to decrease energy consumption during high-temperature drying, increase drier throughput, and reduce stress cracks and breakage susceptibility.

The three most commonly used delayed-cooling methods are in-bin cooling, dryeration, and combination high- and low-temperature drying (23). The in-bin/in-storage

cooling is the simplest delayed-cooling method suitable for any type of high-temperature driers. Dryeration is an energy-efficient method of delayed-cooling and drying completion, and can cut 15–30% off energy consumption of high-temperature drying while increasing drying capacity, although dryeration requires more management. With dryeration, hot grains are transferred to the cooling bin immediately after drying. Cooling is delayed at least 4 hours for steeping or tempering. After grains are cooled in the dryeration bin, they should be moved to storage. Combination high- and low-temperature drying is most suitable for crops harvested too wet for safe low-temperature bin drying, particularly wet maize (>22% moisture content). A combination system normally costs more than a single drying method, but can give high drying capacity, flexibility of high-temperature drying, and energy savings and superior grain quality of low-temperature drying.

3. Drying Losses

Drying losses are caused by underdrying or overdrying, from pre-harvest to post-storage. Two kinds of losses often occur. The first is actual removal of moisture from the grain system, and the second is damage to the grain during drying, leading to subsequent loss during milling (15).

Modern drying systems normally cause lower losses to most cereal grains. However, drying of rice or maize by mechanical driers requires more care to avoid losses in processing properties. In developing countries, threshed grains or harvested ears are usually spread on a hard surface in the farmyards for sun drying, which easily causes higher grain losses. Part of the grains may be eaten by birds and other animals, or may be blown away. If grains are rewetted in the drying yard by a sudden storm, they will be damaged.

D. Storage Methods and Facilities

Since ancient times, peasants have used traditional methods and containers to store cereal grains, such as small buildings, earthenware pots, small wooden containers, underground pits, outdoor piles, woven bags and baskets. Most traditional methods and containers are still employed in many developing countries. In recent centuries, advanced storage technologies and facilities have been developed to provide safe storage environments of grains and to maintain grain quality and quantity more efficiently.

Various types of storage facilities have been introduced (15, 21, 22), including piles of unprotected grain on the ground, underground pits or containers, piles of bagged grain, storage bins of many sizes, shapes, and types of construction. Major classifications are farm storage, bin sites, country elevators, and terminal elevators. Storage structures and facilities should meet the following major requirements: 1) provide maximum protection from moisture, insects, molds, and rodents; 2) have aeration design for regulation of storage temperature and relative humidity; 3) allow smooth in-and-out movement of grains; 4) be sufficiently airtight for fumigation; and 5) have capacity to protect grains from fire.

1. Farm Storage Facilities

Harvested cereal grains are often or temporarily stored at the farm in developing countries. Farm storage structures are constructed from locally available materials which are simple and cheap, and are based on the principle of hermetic storage with aeration facilities. Major structure types of farm storage in India include circular steel bin, plastic bin, pre-fabricated steel bin with hopper bottom, aluminum bin, reinforced cement concrete bin, cement masonry bin, welded wire-mesh bin, ferro-cement bin, and so on (22). In China, simple storage structures are built with local cheap materials, e.g., sticks, mud, stalk or straw, timber.

Modern farm silo is basically a large cylinder of corrugated galvanized steel, with means of access for cleaning, input, and extraction of grain and, sometimes, a built-in drier consisting of a fan with air heater and a means of distributing the warm air through the grain so that moisture can be removed (15). Since modern silo is with good storage conditions, and is durable and secure from attack by predators and even thieves, it has replaced other storage facilities for farm storage in developed countries.

2. Commercial Storage Facilities

Commercial storage systems involve storage of large quantities of cereal grains, with better storage structures and functions. In China, storage facilities of town-level and county-level, normally constructed of concrete, are the important commercial storage systems, with moisture- and rodent-proof structures, and with an arrangement for controlled aeration as well as fumigation.

Elevators are the most common, advanced commercial storage facilities in developed countries. In addition to storage, elevators have other functions such as sorting, cleaning, sizing, drying, and fumigation. They serve the marketing system by equating supply with demand, by providing convenient means for transferring title by endorsement of warehouse receipts, and by transferring grain from one transportation facility to another such as trucks to cars, cars to barges, and barges to ocean vessels.

Country elevators receive grains directly from producers. These storage facilities are usually constructed of wood, concrete, or steel. Their main function is to accumulate grains from nearby farms, to reload them into transportation facilities such as trucks, railroad cars, or barges, and to send them to market. Country elevators were originally intended to serve an area limited by horse and wagon delivery, and their storage capacity was very small. Truck transport from farms has broadened access areas, and elevator sizes have increased accordingly. The

largest elevators approach the size of terminal elevators and are often referred to as subterminals.

Terminal elevators are ordinarily constructed in transportation terminals and larger markets. Their storage capacity is very large, normally ranging in total storage space from 5,000 to 500,000 tons or more (200,000 to 20 million bushels). They receive grains from country elevators by truck or railroad and transfer them to storage or into other transportation equipment such as barges or other vessels. Terminal elevators also equip with high-capacity facilities for cleaning, drying, and conditioning of grains.

Flat bins are auxiliary bins of large capacity in connection with terminal elevators. The pressure of grain surpluses requiring safe storage for long periods leads to the construction of flat bins. These bins are built wider and lower than common silo storage bins to reduce costs and side-pressures, thus can provide ample storage space at the lowest possible cost. Floors are directly on the ground, handling equipment is kept at a minimum, and the roof tends to follow the slope of the pile of grains. Large bins may be directly attached to the elevator or may be built adjacent to it.

Additionally, the slip-form storage bins (silo-type bins) for construction of round concrete bins were developed in about 1900 and are still in commercial use. The slip-form consists of a concentric, double-ring form into which concrete is poured. Often two or more rows of round bins are built side by side to form a block of bins. The areas between the circles also become bins, and are called interstitial or star bins. Concrete silos may be as high as 40 m. Although other shapes such as oval or hexagonal have been tried with concrete, the round form gives the greatest strength with the least material.

In developed countries, grain is almost completely handled and stored in bulk, but in developing countries bag storage is still practical and common, since farms are often scattered and labor for filling and loading bags costs is low. Bag is made of plant fiber or woven polymer threads. Air can pass through this barrier, and moisture can migrate from or into the grain, but grain in bags can normally be accepted for storage at 1–2% higher moisture content than for bulk storage. Bags with grains are usually stored in a well-sealed and secure warehouse with regulating openings for controlled ventilation and complete building fumigation. Openings can be used for both natural air and fan-controlled aeration. Bags should be carefully stacked so that alternate layers are placed that can be covered with a tarpaulin for fumigation. A one-meter corridor is left between stacks for the operatives to pass when examining the storage state.

E. Aeration and Stored Grain Management

Dried grains should be aerated as soon as possible after they are put into storage. Frequent aeration during storage is necessary to control grain temperature, to avoid formation of hot spots due to insect and mold activity, to reduce the risk of grain damage or spoilage, and to maintain grain quality (22, 25).

1. Effects of Aeration

Aeration is the process of moving air at ambient temperature through stored grains in order to decrease or increase grain temperature to desired level (5). The major effect of aeration is to control and maintain a uniform temperature in stored grains and to keep that temperature as low as is practical. Also, aeration can equalize grain moisture and remove odors from stored grains. Use of fumigants with aeration systems can permit their distribution through the grain in deep bins and silos.

2. Aeration Systems

An aeration system mainly consists of fan and duct systems. The major considerations in the design of aeration systems are airflow rate, fan selection, and air distribution (25). The airflow rate recommended depends on purpose of aeration, type of stored grains, storage structures, and climate conditions. Fan selection is based on airflow rate and type and depth of stored grains. There are two common kinds of fans used for aeration, axial-flow fans which are suitable for horizontal storage structures, and centrifugal fans suitable for vertical storage structures. Other fans, such as radial-bladed fans, are suitable for vertical low-capacity bins. Occasionally, aeration fans are mounted on top of storage bins or silos. Some aeration systems are equipped with two fans, a pressure fan on the bottom and a suction fan on top. Airflow is usually downward in a suction system and upward in a pressure aeration system.

Duct systems are used for air distribution. Most aeration systems use perforated ducts to distribute the air and provide for air movement whether out of the duct into the grain in a pressure aeration system or into the duct from the grain in a suction system. Many farm bins are equipped with full-perforated false floors or partial perforated floors. In flat storages, large bins, and tanks, more than one ventilating duct is required, and the layout of the duct system is also important.

3. Operation and Management of Aeration Systems for Stored Grains

Foster and Tuite (25) described how to operate aeration systems, including seasonal aeration operating schedules, daily fan operation, and airflow direction regulation. Aeration practices depend on local climate, e.g., the mean temperature difference between the warmest month and coldest month is 28°C in the Corn Belt of the United States. The mean daily humidity of the air is usually below that in equilibrium with grain at safe storage

moisture content, except in winter. Under mean climatic conditions, grain can be aerated continuously without undesirable moisture increase.

Once grains are put into storage, they should be aerated immediately to remove harvest or dryer heat. The temperature should be uniformly reduced to 15–20°C for summer-harvested grains and to 10–15°C for fall-harvested grains. Grains are aerated in late fall and winter to cool them to below 5°C. Weather in late November and early December is usually suitable for cooling grains to near mean winter temperatures. Once this is completed, no further aeration is recommended until spring. In March or April, grains may be aerated to warm them to above 10°C. After spring aeration is started, it should continue until grains are uniformly warmed to near mean outdoor temperature. As the warming front moves through, moisture condenses on the cold grains, providing ideal conditions for rapid mold growth. Continued aeration keeps the condensation area moving and helps avoid serious spoilage.

Most seasonal aeration schedules described above are based on daily 24-hour fan operation. In much of the United States, mean humidity in the fall cooling and spring warming periods permits continuous fan operation without increasing moisture of cereal grains above the safe level (13–15%). However, in rainy seasons or regions with higher humidity, fan operation should be limited or even prohibited in high-humidity weather. For instance, in Central, Eastern, and Southern China, aeration is limited or prohibited in rainy weather of late spring and summer.

4. Losses during Storage

Insects, microorganisms, and rodents or birds cause major losses and deterioration of cereal grains during storage, especially in developing countries. Losses during storage may increase if condition of the received grains is unsatisfactory, if the storage sites and facilities are unsuitable for safe storage, or if there is poor management during storage or deterioration in storage environment. Transportation is temporary storage and may also cause losses under unsuitable environments, such as dirty and already infested railcar, or improper supervision (20).

Deterioration caused by insects, microorganisms, and rodents during storage is usually affected by the storage structures and environments. Higher storage temperature and grain moisture content may lead to multiplication and growth of insects and microorganisms. Poor storage management and unsuitable storage structures easily cause serious damage from rodents and birds. Additionally, cracked, broken, damp, and dirty grains with foreign materials (e.g., straw and trash) are more easily infested by insects and molds. Drying and cleaning of cereal grains before storage and appropriate storage management are important for reducing storage losses.

F. Control of Insects, Microorganisms, and Rodents during Storage

Principal measures for decreasing storage losses are to prevent and control insects, microorganisms, and rodents. When grain storage starts, destruction from insects, microorganisms, and rodents may begin, with the rate of grain losses depending on storage conditions. The growth rate of microorganisms usually depends on grain moisture content and storage temperature, and that of insects mainly on storage temperature.

1. Insects

Insects are the major cause of losses of stored grains. Beetles, moths, and certain mites are serious pests of stored grains. Table 17.12 lists the major insects of stored cereal grains and their optimum growth temperatures (15, 22, 26). There are two major groups of storage insect, external and internal infesters. Almost all are either beetles (*Coleoptera*) or moths (*Lepidoptera*) (15). The nature of insect damage is classified into three types: 1) grains are bored inside, leaving the outer coat practically intact; 2) only the germ of grains is damaged; 3) a part of the grains, including the outer coat, is eaten (22). Rice weevil, maize weevil, granary weevil, lesser grain borer, and Angoumois grain moth develop and feed inside kernels. Infestation remains hidden until the adults emerge from the kernels. Other beetles feed primarily on broken and whole kernels. Grain-infesting insects are very sensitive to temperature, but insensitive to moisture. Generally, they grow slowly or not at all below 16°C, and cannot survive in temperatures of 42°C or above, and appear to thrive best at about 29°C. Storage pests are well adapted to live in a very dry environment.

Insects not only consume large quantities of grains but also decrease the quality by the presence of insect fragments, feces, and unnatural odors. Insects consume nutritious components, encourage moisture uptake by the infested grains, and promote growth of microorganisms. When insect population reaches a certain level, temperature of stored grains will increase rapidly. If insects are at over-growth, temperature may increase up to 45°C. When microorganisms are associated, temperature may rise even up to 75°C, causing massive spoilage of grains. Thus overgrowth of insects usually results in serious losses of grain quality and quantity.

2. Microorganisms

Molds are also important damaging agents of stored grains. Under favorable moisture, temperature, and relative humidity, many molds can grow on grain surface. Common molds founds in grains belong to the genera *Aspergillus*, *Fusarium*, *Penicillium, Alternaria*, *Cladosporium*, and *Helminthosporium* (22).

TABLE 17.12
Insects of Stored Cereal Grains and Their Optimum Growth Temperature

Common Name	Scientific Name	Optimum Temp. (°C)	Minimum Temp. (°C)
Rice weevil	*Sitophilus oryzae* L.	27–31	17
Maize weevil	*Sitophilus zeamais* Motsch.	28	17
Grain weevil	*Sitophilus granaries* L.	26–30	15
Angoumois grain moth	*Sitotroga cerealella* Ol.	26–30	16
India meal moth	*Plodia interpunctella* Hub.	28–30	–
Almond moth	*Ephestia cautella* Walk	25	10
Rice moth	*Corcyra cephalonica* Staint	28–30	10
Lesser grain borer	*Rhizopertha dominica* F.	32–35	23
Larger grain borer	*Prostephanus truncatus*	–	–

Flour or grain mite	*Acarus siro* L.	21–27	7
Warehouse moths	*Ephestia* spp.	–	–

Source: Adapted from Refs. 15, 22, and 26.

The most dangerous and important fungi are from three genera: *Aspergillus*, *Fusarium*, and *Penicillium* (15). Most storage fungi cannot survive at grain moisture content below 17%. They can survive at 50°C and above 65% relative humidity, but are most destructive below 25°C and above 80–85% humidity. Fungal damage to stored grains includes losses of seed viability, nutritional and apparent quality, processing properties, and production of mycotoxins (e.g., aflatoxins and ochratoxin), heating, mustiness, and decay. *Aspergillus flavus*, *Furarium graminearum*, and *Penicillium verrucosum* produce alflatoxins, zearalenones, and citrinin/ochratoxins, respectively. These toxins are important from the point of health hazards. Aflatoxins are carcinogenic agents and ochratoxin can cause liver and kidney damage. Although mycotoxins-induced diseases are rare in developed countries, they commonly occur among rural populations in developing countries.

Bacteria are also found in stored grains, mainly belonging to the families Bacillaceae, Pseudomonadaceae, and Micrococcaceae. Activities of bacteria are normally affected by temperature and moisture content of the grains during storage. Bacteria require higher moisture content (>20%) and higher humidity (>90–95%) for their growth than fungi. Thermophilic bacteria can proliferate at 55°C and raise the temperature of infected grains to as high as 70–75°C. Bacterial damage to stored grains is similar to that of fungi, but occurs more rarely.

3. Rodents

Vertebrates (rodents and birds) cause extensive damage to grain in both field and store. Damage from rodents is a serious problem at farmer's and trader's level. Commensal rats and mice are the most destructive vertebrates on Earth. There are 21 common species of rodents that attack stored grains in different sites throughout the world (22). In addition to house mice, Norwegian rats and mice are conventional rodents.

Not only do rodents eat large quantities of grains, they also contaminate grains with urine, hairs, and excreta. Rodents are energetic creatures and eat about 10% of their body weight of food per diem. One rat will consume around 10 kg of grain each year and excrete 2–5 kg of droppings (15). Apart from consuming and contaminating grains, certain rodents can damage containers (e.g., bags and wooden, bamboo or mud bins, and make burrows in walls, warehouse floor, and cables) and spread diseases.

4. Control Methods and Measures

a. Control of storage temperature and moisture

An important measure of controlling insects and microorganisms is to keep a safe storage environment with cool temperature and low moisture. The recommended safe storage moisture contents of most cereal grains range from 13 to 15% (Table 17.11) (22–24). Lower temperatures increase shelf life of grains by decreasing respiratory

rate and inhibiting activities of insects and microorganisms. When grains are cooled below 15°C, most insects and fungi cannot grow. In developing countries, control of such low temperature will greatly increase storage costs. Generally, maintenance of temperature at about 27°C and relative humidity below 70% during storage are important. Frequent aeration during storage is necessary to avoid formation of hot spots due to activities of insects and microorganisms and to control uniform temperature throughout storage environments.

b. Cleanliness

Cleanliness is considered the most common means of reducing or eliminating pest infestation. It is important to thoroughly clean storage facilities before new grains are stored. Old infested grains, empty bags or sacks, chaff, webs, and other junk that may harbor insects must be cleaned out. The floor, walls, and roof structure should be brushed and sprayed with insecticide before storage. Cleaning of harvesting equipment and transportation tools is also required. Also, clean conditions around storage area and facilities can help keep rodent numbers down.

c. Use of fumigants and insecticides

Fumigants are quick-acting respiratory poisons which can be applied to static grains. Commonly used fumigants are methyl bromide, carbon disulfide, carbon tetrachloride, ethylene dichloride, ethylene dibromide, chloropicrin, hydrogen cyanide, and phosphine (3, 15). The effectiveness of each fumigant is dependent on species of insects, stage of development, temperature, humidity, application method, fumigant concentration, storage facilities, etc. Some recommendations for fumigation of stored grains are shown in Table 17.13 (15). Because chemical fumigants are also highly poisonous to man, precautions given on the labels of the chemical containers must be strictly followed. Great care is required in their application, and staff must be trained well. Gas masks should be worn during the use of fumigants. Storage bins and buildings that have been fumigated must be opened for ventilation for several hours or days before people can enter.

Insecticides that kill insects of stored grains belong to the contact type which can penetrate the insect cuticle and enter body tissue. Common contact insecticides include pyrethrum (pyrethrins), chlorinated hydrocarbon insecticides, organophosphorus insecticides, etc. (22). For example, pyrethrins can be used to kill insects on walls and floor of storage bins during cleaning, and can also be used as protecting agent by spraying on the grains.

d. Control measures of rodents

Rodents cause serious storage losses of cereal grains, particularly in developing countries. Relevant control measures include sanitation, removal of foods easily accessible to rodents, proofing, trapping, use of ultrasonic devices, biological control, single- or multi-dose poisons, tracking poisons, fumigations, and the use of chemosterilants, attractants, and repellants (22). The most common control measures are sanitation, use of anticoagulants, and fumigation of live burrows. Fumigation of live burrows with aluminum phosphide is a cheap and effective method with usually 100% killing after second fumigation. Anticoagulants were tested and also found to be effective in controlling rats.

e. Other control methods

Other promising control methods have been investigated, including modified atmosphere, irradiation, use of insect sex attractants, insect growth regulators, insect pathogens, parasites and predators, etc. (15, 22). As an alternative to fumigation, grain storage atmosphere can be made lethal or inhibitory to insects and microorganisms by reducing oxygen concentration, increasing carbon dioxide or nitrogen concentrations, or creating a partial vacuum (tight-air packaging). Radiation treatments usually cause mutation, sterilization, or death of insects and microorganisms, and are considered a control method for stored grains. The use of sex attractants produced by insects has been investigated to control stored-grain insects. Insect growth regulators can interfere with either morphogenesis or molting of insects. These compounds have intense biological activity, specificity, and little or no vertebrate toxicity. Because of economic factors or chemical toxicity, these promising control methods have, however, not yet been commonly used for stored grains.

TABLE 17.13
Some Recommended Fumigants and Used Dosages of Stored Cereal Grains[a]

Storage Structure or Situation	Application	Fumigants	Dosage (g/tonne)	Treatment Time (days)
Silos, deep bins	Admixture during filling	Phosphine	3–4	5
Flat bulk storage	Admixture by probe	Phosphine	3–4	5
Flat bulk storage	Surface application	Methyl bromide	34	1
Rail cars in transit	Gas jets at top of stack	Methyl bromide	58	1
Stacks under tarpaulins[b]	Gas jets at top of stack	Methyl bromide	28–54	1

Source: Adapted from Ref. 15.

[a] Fumigating is conducted at 20–25°C.

[b] Different cereals require various dosage: wheat, 34 g/tonne; rice, 28 g/tonne; maize, 36 g/tonne; and sorghum and millets, 54 g/tonne.

CONTENTS

I. INTRODUCTION

In terms of agricultural production, cereals are the most important source of human food and animal feeds but the legume family, Leguminosae, encompasses an extremely diverse group of herbs, vines, shrubs and trees (1). The subfamily Papilionoideae has 600 genera and 13,000 species of plants which have fruits enclosed in a specific pattern in elongated pods and whose roots form symbiotic relationships with nitrogen-fixing bacteria in nodules. Over 80 legume species are consumed world-wide and represent the second most important food source. About 20 legume species are cultivated on an appreciable hectareage. These legume crops are primarily herbaceous annuals that can be consumed directly as mature dry seeds, as immature green seeds, or as whole green pods.

The most important food legumes are listed in Table 18.1 with their botanical names, global distribution, and approximate annual production. Soybean and peanut are grown widely for extraction of refined vegetable oils and high protein meals, but also have important whole seed uses. About one-half of the world production of peanut is crushed for production of edible oil and meal for animal feeds; much of the large U.S. crop is processed into peanut butter or roasted for direct consumption. On the other hand, over 80% of the world soybean production is pressed for the edible oil and valuable soybean meal, and only about 15% is processed directly into food products.

The low alkaloid sweet lupin *(L.angustifolius*) is a protein supplement in ruminant feeds and, after removal of 25% hull, in pig and poultry rations in Australia (Table 18.1). *Lupinus albus*, with 12% lipid, is grown in other

TABLE 18.1
Scientific and Common Names and Annual Production of Important Food Legumes

Name	Scientific Name	Common Names	Distribution	Production (mt)
Proteinaceous Oilseeds				
Peanut	*Arachis hypogaea* L.	Groundnut, goober	India, China, USA	23
Soybean	*Glycine max* (L) Merr.	Soyabean, Japan pea	USA, Brazil, China	175
Lupin	*Lupinus albus, luteus* and *angustifolius* L.	Sweet lupin, tarwi	Australia, Russia, Mediterranean	1
Starchy Pulses				
Common bean	*Phaseolus vulgaris* L.	Haricot, dry bean	Brazil, India, China	20
Dry pea	*Pisum sativum* L.	Field pea, garden pea	Russia, China, France	10
Chickpea	*Cicer arietinum* L.	Bengal gram, chana	India, Turkey, Pakistan	8.5
Fababean	*Vicia faba* L.	Broad bean, horse bean	China, Ethiopia, Egypt	3.5
Lentil	*Lens culinaris* Medik.	Masur, red dhal	India, Turkey, North America	3
Pigeon pea	*Cajanus cajan* (L) Millsp.	Red gram, Congo pea	Asia, Africa, South America	3
Cowpea	*Vigna unguiculata* (L) Walp.	Black-eyed pea, kaffir bean	Africa, Asia, Nigeria	1
Mung bean	*Vigna aureus, mungo,* and *radiata* (L.) Wilczek	Green, black, and golden gram	India, China, Thailand	1
Lima bean	*Phaseolus lunatus* L.	Butter bean, sieva bean	USA, Central and South America	<1

parts of the world. In efforts to breed an oilseed crop, lines with 16% oil have been reported.

Pulses have limited industrial applications and are mainly consumed directly as whole or dehulled split seeds. Common beans and dry peas constitute about one-half of global pulse production of about 58 mt, and production is widely distributed among countries in the Americas, Indian sub-continent, Asia, and Europe (Table 18.1). However, about 90% of global pulse utilization is concentrated in developing countries. In these low-income food-deficit areas, pulses contribute about 10% of the daily protein and 5% of the energy intake of human diets.

Driven by increasing demand from West Asia, North Africa, Central and South America, and India, production and export of the principal pulses has expanded in North America, Australia, China, Turkey, and Argentina. With respect to world trade, common beans and dry peas are the major imported pulses while lentils, chickpeas, and broad beans are also purchased by low-income countries.

II. MORPHOLOGY AND MICROSTRUCTURES OF SEEDS

Compared to cereal grains, legume seeds are medium to large in size (0.3–2.5 cm diameter), rounded in shape, with relatively hard texture. Seeds vary from white to colored or mottled in appearance and surfaces can be smooth, textured, or wrinkled (1). The proportions of the three major seed components are 8–18% seedcoat, 80–90% cotyledons (Figure 18.1), and 1–2% embryonic axis (not shown) (2). The seedcoat or testa protects the embryonic structures from water absorption, microbial and insect invasion. In lentils, the seedcoat exhibits a pattern of conical papillae on the surface, about 3 μm at the base (Figure 18.2C). The outermost layer of the seedcoat is a thin waxy cuticle that serves as a hydrophobic barrier (Figures 18.1 and 18.2C). The major structure of the seedcoat is a single layer of vertical, elongated palisade cells. The thick walls of the palisade cells provide strength and rigidity to the seedcoat; the wall thickness and depth determine the proportions of 'hull' that is characteristic of each species. The thin layer of hourglass cells (5–6 μm thick) occurs, with interconnecting air spaces, below the palisade layer.

Between the hourglass cells and the cotyledon is a separate layer of flattened parenchyma cells (Figure 18.2C) that constitute the residue of the once prominent endosperm in the fertilized ovule (See Section IV.F, Dietary Fibre). When seeds are decorticated during processing, the endosperm layer separates with the seedcoat. The seed embryo consists of the embryonic axis and two cotyledons or seed leaves. The embryonic axis has a small plumule (foliage leaves) with shoot-tip, an embryonic stem (hypocotyl), and a radicle or root that are attached to, and enclosed by, the cotyledons.

There are two openings in the legume seedcoat (2). The small micropyle is the site where the pollen tube entered the valve, and is closed in some species. The large oval hilum is the scar where the seed was attached to the pod and is large enough to be a major factor in regulation of seed drying or rehydration (Figure 18.2A, B). Along the hilum length, but behind the opening, is the tracheid bar with numerous ducts that interconnect the pod and seed vascular systems. Although not an opening, there is a linear ridge on one end of the hilum, called the raphe, that arose from the fusion of the pod to the seedcoat during seed development (Figure 18.2A).

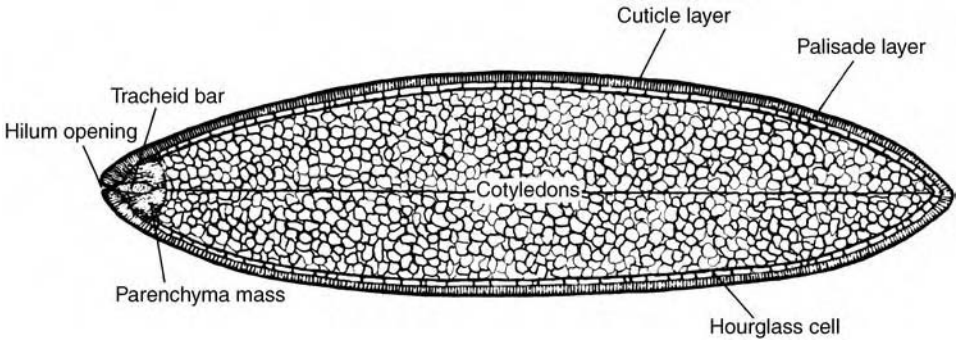

FIGURE 18.1 Schematic diagram of the structure of a cross section through a lentil seed. (From Ref. 2.)

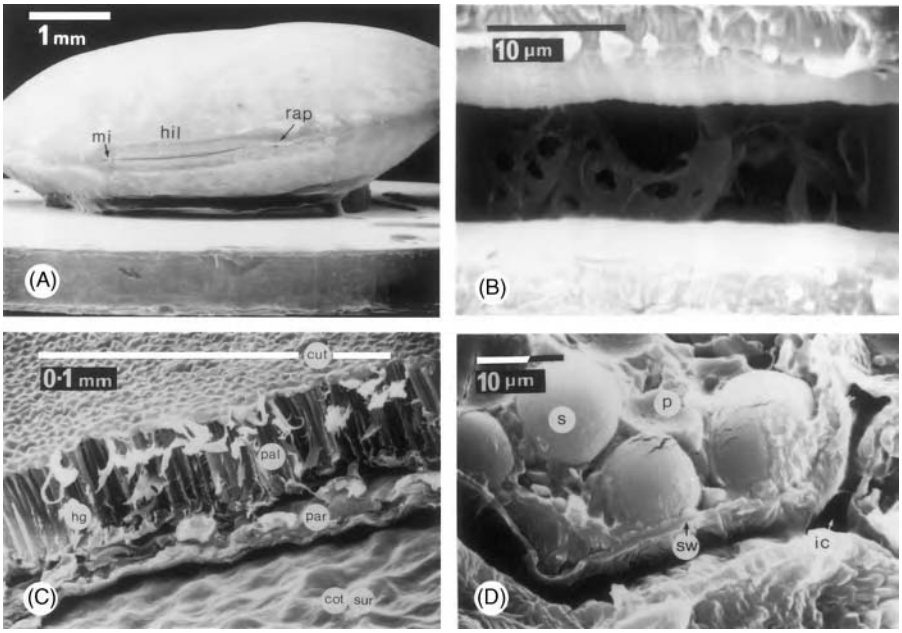

FIGURE 18.2 SEM micrographs of: (A) a gold-coated lentil seed illustrating the micropyle (mi), hilum (hil), and raphe (rap); (B) the hilum opening exposing the tracheid bar; (C) the lentil seedcoat showing the cuticle (cut) layer on the surface of the palisade (pal) cells, traces of hourglass (hg) cells in open spaces, parenchyma (par) layer, and the cotyledon surface (cot sur); (D) an exposed portion of the cotyledon with the storage cell wall (sw) enclosing several starch (s) granules in the protein matrix (p), and the intercellular spaces (ic). (From Ref. 2.)

The two large cotyledons contain nutrient reserves to support early shoot and root growth during germination (Figure 18.1) (2). Their large parenchyma cells (100–130 µm diameter) have thin tough cell walls (1–2 µm thick) that are cemented together by a layer of pectic substances called the middle lamella (Figure 18.2D). There are intercellular spaces between the cells, primarily at the junctures of three or more adjacent cells that facilitate water uptake and hydration. Each cotyledonary cell is packed with round or oval starch granules (10–30 µm dia) that have smooth surfaces, unlike the tightly packed angular granules in cereal endosperms. The legume starch granules are embedded in a thick protein matrix which also contains small protein granules.

III. THE HARD-TO-COOK PROBLEM

Most pulses are consumed directly as cooked whole or split (dehulled) seeds, and long cooking times are characteristically required to achieve the desired degree of softness, digestibility, and inactivation of heat-labile antinutrients. Slow water uptake by seeds has been associated with long cooking times, but dehulling and presoaking of seeds overnight can reduce cooking time, often by as much as 75%. Soybean and dry pea have only 5–8% hulls that are easily removed; other pulses contain 10–18% hulls that are removed by abrasive dehullers, or after soaking or boiling.

Tang et al. (3) found that the initial moisture contents of lentils markedly affected the route of moisture migration,

rate of water absorption, imbibition time, and proportion of hardshell lentils. At moisture contents of 16–24%, moisture diffused mainly through the large surface of the seedcoat. The permeability of lentil seedcoats decreased with decreasing moisture content because of reduced pore and fissure sizes in the cuticle and palisade layers. When lentil moisture content was at 12%, the hilum opening became the dominant route for moisture to enter the seed. The width of lentil hilum openings also decreased with moisture content, and some hila were closed at 12% moisture content. Impermeable seedcoat and concurrent closing of the hilum opening resulted in hardshell lentils. The complexity of the hardshell and hard-to-cook phenomena in other legumes has been reviewed by Swanson et al. (4) and Stanley (5).

IV. CHEMICAL AND NUTRITIONAL COMPOSITION

A. Energy

The metabolizable energy contents of legume oilseeds are proportional to their oil or lipid contents (Table 18.2). With over 50% lipid, peanuts average 2255 kJ/100 g while soybean, lupin, and chickpea have 1695, 1565, and 1530 kJ/100 g, respectively. The starchy pulses contain about 1440 kJ/100 g of metabolizable energy which is similar to those of whole grain cereals but 5–7% less than in milled cereal flours. The metabolizable energy in pulses arises from their high compositions of starch and protein, but is subject to the slow rates of digestion described below.

B. Lipids

Most pulses are low in lipid, only 1–2% (Table 18.2), of which one half are neutral lipids (mono-, di-, and triacylglycerides) and the remainder are metabolic polar lipids (phospholipids, glycolipids, sterols, sterol esters, and lipoproteins) (6). On the other hand, the proteinaceous oilseeds like peanut and soybean are rich in neutral lipids and are commercial sources of edible oils. These neutral lipids are stored in the cotyledons as oil bodies or spherosomes and contain primarily unsaturated and polyunsaturated fatty acids in the triacylglycerols which have important functional and nutritional attributes. Many legumes contain linolenic acid as a component in the lipids, as well as the bound enzyme lipoxygenase, so that oxidative rancidity and off-flavor development are a problem once seed contents are mixed by grinding.

C. Starch

While the oilseeds are nearly devoid of starch, it is the main component in pulses (Table 18.2). The large starch granules in the cotyledon cells are composed of a combination of two glucose polymers (7). Inside cell organelles these polymers are synthesized into interwoven strands to form the semicrystalline granules. Amylopectin, the larger polymer, is an α-1,4-linked glucose chain with α-1,6 branches, with molecular weights in the millions. Amylose is a smaller linear polymer composed of α-1,4-linked glucose units, and few branches. The number of glucose units in the amylose chain range from 1300 to 1900 among pulse species and the average molecular weight is 177,000. In pulses, the proportion of amylose to

* N × 5.7.

amylopectin by weight is about 33:67, but amylose contents can vary from 20–65%. Tuber starches contain up to 20% amylose. Genotypes of the major cereals vary from 0–85% amylose, but 25% is normal for corn and wheat starch. As a class, pulse starches are considered to be high in amylose content.

The shape and size of starch granules are also characteristic of the plant source, those of legumes being oval, round, spherical, or kidney shaped with smooth surfaces and no apparent fissures (7). The starch granules in pulses vary widely in width (10–55 μm) and length (8–70 μm). Most of the pulse starches are simple granules, the exception being wrinkled pea starch, which appears to be a mixture of simple and compound granules, the latter being composed of 3–10 subunits joined together.

D. Proteins

The proteinaceous oilseeds are rich sources of protein, and the defatted meals are major protein supplements for cereal-based animal feeds (Table 18.2). Similarly, the pulses at 18–30% protein are major sources of protein for human nutrition in low-income countries.

There are enzymatic, structural, and globular storage proteins in pulses. Storage proteins account for 70–80% of seed nitrogen and occur within the cell as matrix or discrete protein bodies (1). The major storage proteins are classified as either legumin or vicilin, their subunit compositions and molecular weights being characteristic of the species. These are reported elsewhere under the appropriate section, for the legume species. (see Chapters 5–7, 19.)

While pulses are considered to be good sources of protein for human nutrition, their utilization may be quite inefficient. The digestibilities of pulse proteins can vary between 65 and 88%, depending on the structure and composition of storage proteins (8). Most pulse proteins are rich in essential amino acids, especially lysine and threonine. However, they are deficient in sulphur-containing amino acids, methionine, and cystine. The biological value of legume proteins, as measured by protein efficiency ratio (PER), may vary from 0.2 to 2.0 where a balanced protein like casein has a PER = 2.5. By blending a low PER pulse with a source of cereal protein rich in sulphur amino acids, PER values in the range of 1.8–2.0 can be obtained.

The Kjeldahl method for determination of total organic nitrogen (N) is a widely accepted procedure. However, the selection of the appropriate nitrogen-to-protein conversion factor (N:P factor) for calculating total protein content has been a point of controversy, and practices are not consistent among laboratories. Based on amino acid composition, the true N:P factors for common bean and dry pea were found to be 5.4, and the mean N:P factor for 23 diverse food products was 5.7 ± 0.3 (9). The latter factor was recommended for all mixed or blended food diets instead of the common factor of 6.25 which exaggerates the true protein content.

E. Toxins and Antinutritive Factors

Food legume seeds may contain a wide range of constituents which have adverse effects on digestive enzyme activity, digestibility, nutrition, and health (10). Most commercial cultivars have been selected for reduced levels of these factors and heat processing inactivates the proteinaceous factors. Protease inhibitors in soybean, lima bean, common bean, and chickpea retard proteolytic enzyme activity (11). Lectins are polymeric proteins in soybean and common bean that bind to monosaccharides in glycoproteins of the cell membranes, causing lesions in the intestinal mucosa and reduced nutrient absorption. The presence of saponins in some cultivars of common bean and cowpea can reduce feed intake and cause growth depression, but the concentrations are usually too low for significant effects. Goitrogenic substances in soybean and peanut cause enlargement of the thyroid gland, an effect that is counteracted by administrating iodine. Certain cultivars of lima bean grown in some tropical countries contain a cyanogenic glycoside that is enzyme-hydrolyzed to release hydrogen cyanide during processing, causing outbreaks of cyanide poisoning. Lupin cultivars have been bred to eliminate alkaloids which are particularly poisonous but can be detected by their bitter taste. Vicine and convicine in fababean can cause a haemolytic anemia called favism in genetically susceptible individuals. Fortunately, the broad bean/fababean cultivars are consumed primarily as whole seeds and so can be readily avoided if one is susceptible.

F. Dietary Fiber

Recent definitions of dietary fiber include all components of plant material that are resistant to the digestive secretions of the human upper gastrointestinal tract. These components are predominantly non-starch polysaccharides and lignin associated with the structure of cell walls. In legumes the main dietary fiber constituents are cellulose, xyloglucans, galactomannans, pectic polyuronides, and glycoproteins. While peanut is relatively low in total dietary fiber, other legumes contain 13–23% (Table 18.2), and are viewed favorably in control of many diseases associated with Western diets.

The cell walls in legume cotyledons are relatively thick (2) and resist physical disruption during processing and cooking, and subsequently during their passage through the alimentary tract (12). The cell walls constitute a barrier to digestive enzymes and delay the rate of starch and protein digestion. Thus legumes are an important component of low calorie diets. A slow rate of glucose absorption has been recorded for beans and other pulses,

a favorable result for diabetics where high blood sugar levels are a problem. Beans and lentils in Western diets give relatively flat postprandial blood-glucose curves, often expressed numerically as the "glycaemic index." The slow digestion of legume starch has been attributed to the survival of intact cell walls after cooking, but evidence is presented in a later section on slow digestibility of starch granules as well (Section V.C).

Cell wall polysaccharides are also implicated in binding of essential minerals such as iron, zinc, and calcium when diets contain a high proportion of legumes (12). This adverse effect on mineral absorption in humans is exacerbated by the mineral binding effects of phytate (myo-inositol hexaphosphate) that is associated with legume cell walls. Mineral bioavailabilty can be greatly improved by commercial dephytinization procedures in the preparation of special dietary foods that are rich in fiber.

Most pulses are not rich sources of soluble fiber such as gums, pectins, and β-glucans which have an important role in controlling gastrointestinal and metabolic diseases. Legumes with fully developed endosperms as the storage organ, and reduced cotyledons in the seeds, have galactomannans as the reserve carbohydrates. Guar and locust bean contain water soluble gums with unique thickening properties that have many uses in ice cream, cheese, sauces, salad dressings and, industrially, in paper making, drilling muds, etc.

G. Sugars

Food legumes in general contain significant concentrations of free sugars (4–12%) (Table 18.2), which are composed of about 40% disaccharides (sucrose mainly) and 60% α-galactosides (raffinose, stachyose, and verbascose) (13). The latter group represents a problem for consumers since the human digestive system lacks the enzyme α-galactosidase. Thus this raffinose family of oligosaccharides passes into the large intestine where sugars are fermented anaerobically to produce gas.

H. Ash and Minerals

The ash content of pulses varies from 2–5% (Table 18.2). Quantitatively, pulses contain significant amounts of potassium, phosphorus, magnesium, and calcium (10). The high potassium-low sodium ratios of pulses are desired for people with hypertension. Pulses could be good dietary sources of calcium and phosphorus but the ratio is 1:2 while the desired balance is 2:1. Also, a high proportion of phosphorus in pulses is present in phytic acid bodies in the cotyledons which, during digestion, bind calcium as an insoluble salt that is not absorbed in the digestive tract (12). Pulses can provide a high proportion of daily requirements of iron, magnesium, manganese, and copper, but soluble minerals can leach into the cooking water and be lost during drainage.

I. Vitamins

Pulses are excellent sources of the water-soluble B vitamins, particularly thiamin, folic acid, and pantothenic acid, and contain significant quantities of nicotinic acid, riboflavin, and vitamin B6 (1,10). Differences between pulse species and environmental effects are large, and losses during domestic and commercial processing are significant. Pulse seeds are low in vitamin C and fat-soluble vitamins, although green seeds and pods can be good sources of carotenes, vitamin C and E.

J. Tannins and Polyphenols

The hulls of pulses contain about 50% cellulose, 20% hemicellulose, 20% pectin-like and water-soluble carbohydrates, and 2–12% lignin, condensed tannins, and procyanidin. The hydroxyl groups of the latter compounds form cross-links with proteins to cause seed hardening during storage and decreased protein digestibility during cooking (5).

The combination of slow or incomplete cooking, digestive enzyme inhibitors, low protein digestibility, and oligosaccharides are limiting factors in pulse utilization and contribute to the flatulence problem. Techniques for reducing the content of flatulence-producing constituents include breeding of low-oligosaccharides cultivars, germination before cooking, and use of hydrolytic enzymes.

V. PULSE PROCESSING AND UTILIZATION

A. Harvest and Storage

Some pulse species have an indeterminate growth habit; new flowers and pods are produced continuously until plant growth ceases due to heat, drought, or nutrient stress (14). Early harvested seeds at high moisture content are difficult to thresh, while low-moisture seeds from delayed harvest are susceptible to shattering and mechanical breakage. The optimum moisture content for threshing pulses is between 14% and 19%, wet basis. Variable topography in a field can result in seed moisture contents ranging from 18–55% (15). For some pulses, it is a general practice to swathe or chemically dessicate the crop so that seeds are dried uniformly in the field prior to threshing. Dessication results in more rapid seed drying, but longer cooking times have been reported.

Moisture content of seed has a marked influence on the storage stability of pulses. Thus, it is desirable to adjust the freshly harvested seeds from 19–20% to $<$14% moisture (14, 15). Artificial drying at maximum temperatures of $<$50°C will minimize seed breakage during subsequent handling, while heat treatments above 75°C will decrease seed germination.

Moisture content of the seeds continues to be an important factor influencing the quality of pulses during

storage. Aeration of seeds during storage will reduce heat pockets and mold development. In tropical countries where seeds are stored at high temperature (> 30°C) and relative humidity (> 80%), pulses develop a hard-to-cook (HTC) condition where seeds imbibe water slowly and fail to soften upon cooking. Investigators now distinguish between "hardshell" seeds that fail to absorb water and soften during soaking and those which take up water readily but fail to soften during cooking (HTC). Seedcoat and hilum characteristics determine the development of the hardshell condition while the properties of the cotyledon cell walls affect cooking properties. Postharvest losses due to pests, molds, cooking quality, and nutrition are substantial in tropical countries, often up to 50% of the stored pulse crop.

B. Traditional Processing

Pulses have the advantage over many crops in their simplicity of preparation and in the variety of edible forms (1, 10). In many low-income countries, most pulses are consumed in the home by soaking the dry seeds and cooking in boiling water until soft. The cooking time should be sufficient to gelatinize the starch granules in the cotyledons, denature the proteins, and inactivate antinutritional factors.

Traditionally, pulses are soaked in cold water overnight (8–24 h) (10). Hydration can be enhanced by heating but microbial growth is also favored at elevated temperatures. As well, leaching or diffusion of low-molecular-weight constituents from the seed is accelerated by heat. Pulses with thick, tough seedcoats are abraded and cracked mechanically before soaking to promote moisture uptake. If seedcoats are unpalatable or contain undesirable constituents like tannins, the soaked seeds are hand-rubbed to remove the seedcoat and provide faster cooking and more digestible cotyledons.

In many African and Asian countries, pulses are commonly dehulled (dehusked) by cracking or milling the seeds, splitting the cotyledons, and even polishing the abraded surfaces (10). Both dry and wet decortication methods are practiced to produce dhal. Unfortunately, the yields of split dhal at the rural level may be as low as 65%. Industrial dehulling equipment to produce split peas, pigeon peas, lentils and chickpeas is available commercially. These units are generally expensive because the technical requirements include high yield of splits with minimal abrasion on the cotyledon surfaces. Polishing with organic solutions is necessary for commercial trade.

Dhals have a short cooking time and so are suitable for cooking with vegetables, condiments, and spices (10). Commonly, the dhals are cooked to a soft texture, mashed, and then boiled again with added water and other ingredients. Other home and industrial processing methods involve roasting, puffing, or parching the pulse seeds or dhal by applying dry heat at temperatures of 100–200°C for 1–5 min. There are efficient roasters designed to apply direct heat with hot sand or ceramic beads. Roasted whole seeds or dhal have an appealing nutty flavor along with improved protein quality.

In Asian countries, food legumes are soaked and held at ambient temperatures for several days to facilitate germination (10). Enzymes activated during germination partially hydrolyze (digest) proteins, starch, and oligosaccharides, inactivate antinutrients, release minerals, and synthesize many vitamins. The sprouted grains may be consumed directly, or dehulled, roasted, and ground for use in blends with other foods.

The Japanese make extensive use of fermented soybean and soy flours for preparing a variety of nutritious food products. There is a similar range of Indonesian and Indian dishes prepared from germinated or fermented soybean, peanut, mung bean, and chickpea.

Canning greatly increases the convenience of using pulses in urban areas but the cost of industrial processing may be too high for low-income consumers. The dry peas, beans, lentils, chickpeas, and cowpeas may be soaked in brine or hot-water hydrated to inactivate enzymes, partially cooked, blended with sauce combinations, canned, sealed, and autoclaved, depending on the final product (10). Pork and beans are popular in North America while refried beans are a staple in Mexico.

C. Recent Advances in Starch Functionality

Pulses are occasionally ground into a flour for use in soups, gruels, infant foods, porridges, and blended food products. Unfortunately, the pulse flours hydrate poorly and form viscous, lumpy slurries that do not cook uniformly. For this reason, pulses are frequently cooked as whole seed or dhal before grinding to a paste and consuming after further steaming, frying, deep-fat frying, or boiling to give a product of uniform consistency. Also, when raw pulses are ground into flour and stored, they soon develop undesirable beany odors and flavors. Grinding releases lipoxygenases that catalyze the formation of peroxides from unsaturated fatty acids, especially linolenic acid, that degrade the fatty acid to low-molecular-weight reactive and volatile compounds. Applying dry heat to seeds for 6–8 min at 105°C will inactivate this enzyme, obviating the need for blanching or steaming that require immediate drying to control microbial contamination.

Refined pulse starches have few industrial or food applications, such as in mung bean noodles or in carbonless paper, because the large granules, often 20–40 μm in length, have a highly ordered crystalline structure with amylose molecules being uniformly distributed throughout the granule (16). In cereals and tubers, amylose occurs in micelles that permit entry of water into the central cavity of the granule and rapid water uptake, granule swelling, and elution of starch molecules. But the pulse

starches exhibit restricted swelling power and solubility and are resistant to α-amylase attack. The high stability of pulse starches to thermal processing results in long cooking times for pulse flours as well as refined starches.

Cooking properties of starches can be evaluated experimentally in a recording viscoamylograph. Dilute slurries of refined native starch granules (6–12%) are stirred and heated at 1.5°C/min from 20–95°C and held at 95°C for 30 min before cooling. Cereal and root starches take up water rapidly, swell to high slurry viscosities, but the open granule structure progressively releases the amylose and amylopectin molecules into solution. Then viscosities drop rapidly as a free molecular slurry of starch is formed. The exposed hydroxy groups on the starch molecules are then free to interact and bond in various food and industrial applications.

The typical lack of strong functional properties in pulse starch products is illustrated in Figure 18.3 (17). The scanning electron micrographs of samples taken from the amylograph slurry of dry pea starch show slow granule swelling and water uptake during heating from 30–95°C. Only at near boiling are the granules expanded enough for amylose molecules to diffuse out. After 30 min at 95°C the slurry is still a mixture of partially disintegrated granules and free molecular starch. On cooling, this mixture forms a firm gel due to intermolecular bonding, but water is not held firmly and syneresis occurs during storage or in food preparations. Therefore, flours or refined starches from corn, waxy corn, wheat, and potato are preferred over legume starches for most food and industrial applications.

Considerable variability in amylograph viscosity curves among pulses has been noted by several investigators. For example, comparisons of the pasting viscosities for navy, northern, kidney, pinto, and black bean (*Phaseolus vulgaris*) identified black bean starch as being similar to cereal starches (16). The somewhat smaller granules of black bean exhibited a substantial increase in granule size and viscosity in the initial sampling at 30°C (Figure 18.4). Between 60°C and 75°C, the elution of molecules, and granule degradation, was substantial. At

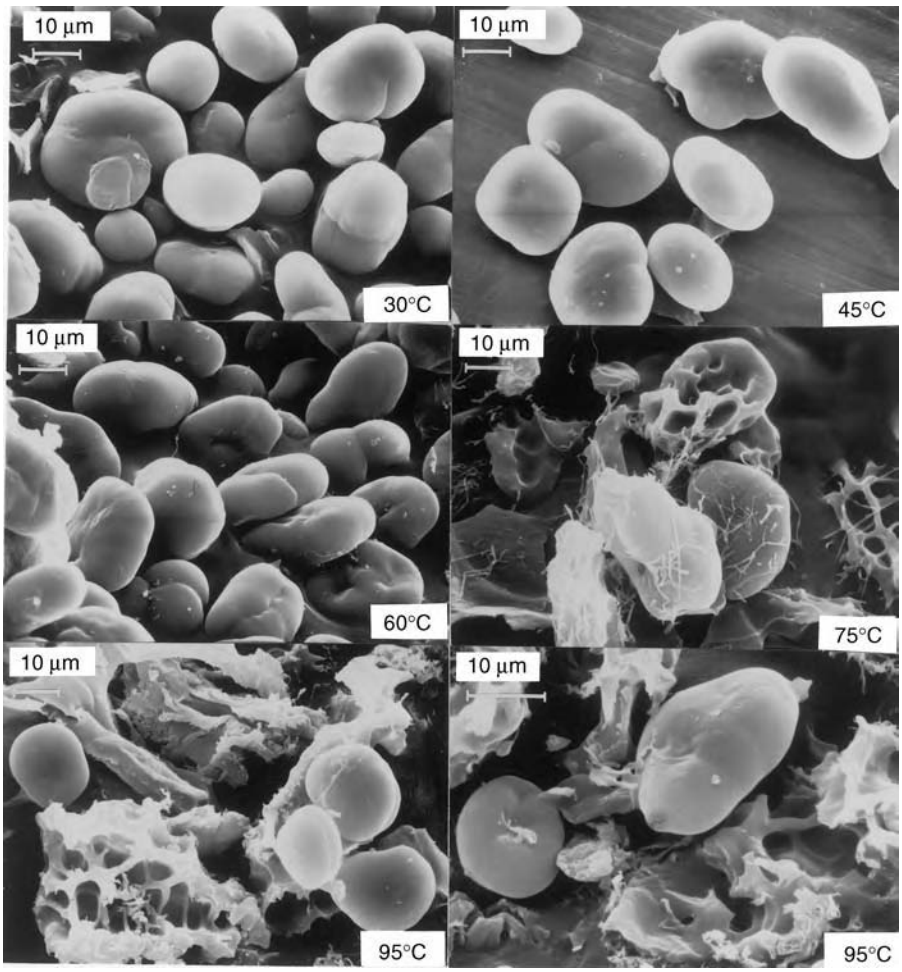

FIGURE 18.3 SEM-micrographs for an 8% slurry of native pea starch sampled during recording of the amylograph at 30°C, 45°C, 60°C, 75°C, 95°C, and after 30 min at 95°C. (From Ref. 17.)

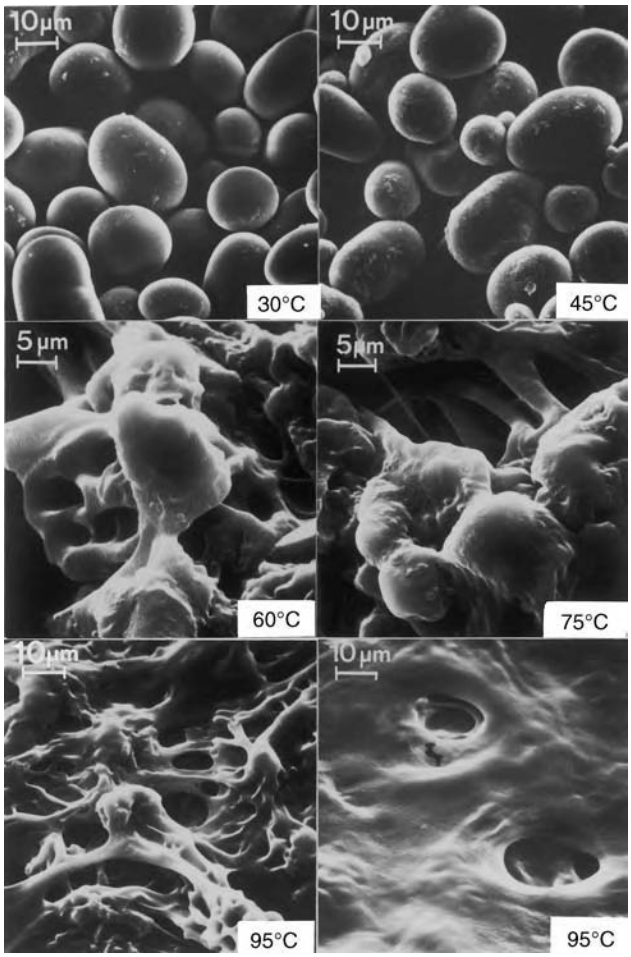

FIGURE 18.4 SEM-micrograph for a 9.5% (w/v) slurry of native black bean starch taken from the amylograph at 30°C, 45°C, 60°C, 75°C, 95°C, and after 30 min at 95°C. (From Ref. 16.)

95°C, there were only remnants of granules remaining, and after 30 min at 95°C, a slurry of free amylose and amylopectin was achieved. Further evaluations of pulse biotypes and cultivars are needed to find genotypes that exhibit better cooking properties in order to open the potential for starch extraction and utilization.

To expand the range in functional properties available for modern food and industrial applications, cereal and tuber starches are modified chemically by substituting low concentrations of reactive groups onto starch chains within the intact starch granule. Among the potential substitution groups used to modify corn starch (Figure 18.5), acetylation and hydroxypropylation improved the cooking properties of pulse starches but cross-linking with phosphorus oxychloride decreased water uptake and granule dissociation (7). The most effective agent for improving the cooking properties of native pulse starches is 3-chloro-2-hydroxypropyltrimethylammonium chloride (17). The formation of the cationic starch ether in a pulse starch results in rapid granule dispersion at near 50°C, yielding a complete molecular dispersion on heating to 95°C (Figure 18.6). On cooling, the gel structure was firm and syneresis was eliminated after storage of the gels at 4°C and −15°C. Cationic starches are widely used as wet-end additives in paper making to improve sheet strength, give better retention of fines and as fillers. Cationization opens the way for pulse starches to compete functionally with modified corn, waxy corn, wheat and potato starches in a variety of industrial applications. However, the markets for these expensive modified starches are limited and highly competitive.

D. Recent Advances in Protein Functionality

Characteristically, legume seeds are rich in protein and contain intermediate to high levels of lysine and threonine which are important in balancing deficiencies of these essential amino acids in cereal diets (Table 18.3) (18). Certain legume proteins, such as soybean, also exhibit strong functional properties, especially water solubility, water and fat binding, and emulsification. Thus soybean flours, protein concentrates, and isolates have been used widely as nutritional supplements and functional ingredients in processed and blended foods.

Due to the structural features of the cell walls and starch granules, starchy legume flours have weaker functional properties than defatted soybean or peanut flours. To overcome the adverse effects of the starch component, wet and dry milling processes have been developed to separate the protein and starch fractions in pulses to better assess the properties and potential uses of the protein.

The impact milling and air classification system (19) is a dry method involving mechanical dehulling on a resinoid disc, abrasive dehuller, followed by fine grinding on an impact mill that reduces the particle size to less than 325 mesh (Figure 18.7). Then the impact-milled flour is fractionated into light (protein) and dense (starch) particles by a single pass through an air classifier at a cut point of 15 micron (800 mesh) diameter between the two fractions. Usually the separated starch granules have considerable protein matrix adhering to their surfaces, in which case the starch fraction can be remilled and classified. The two protein fractions differ in composition, but are usually combined. The second milling will increase starch damage and may not be advisable in certain applications for this major component.

The wet milling process for pulses is adapted from corn and soybean technology (Figure 18.8). The coarsely ground flour is dispersed in dilute alkali, hydrated, screened to remove fiber, and then passed through a wet mill (20). Centrifugation of the slurry separates the starch granules, and the solubilized protein can be precipitated at its isoelectric pH to yield a protein curd. Washing the starch and protein isolates adds to the whey and wash losses.

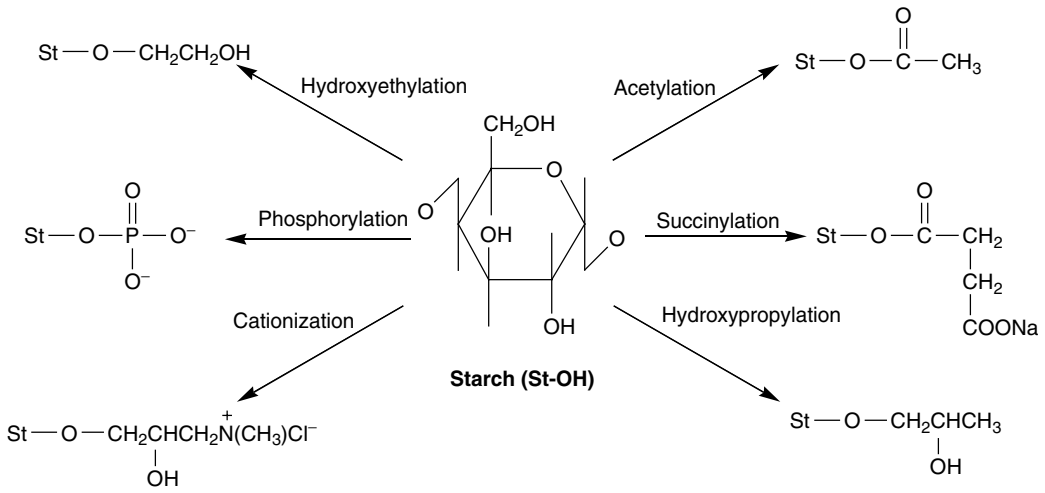

FIGURE 18.5 Chemical modifications of starch with substitution and cross-linking agents that alter the functional properties of starch for food and industrial applications.

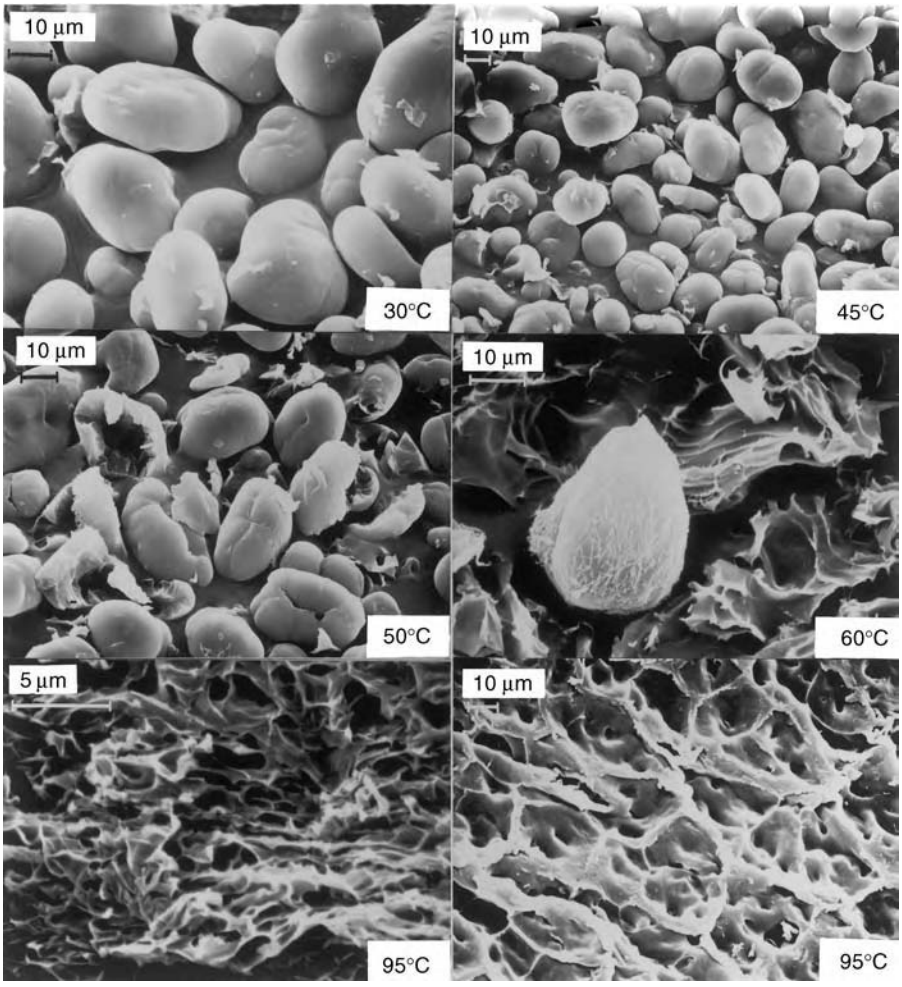

FIGURE 18.6 SEM-micrograph for an 8% (w/v) slurry of cationic pea starch (degree of substitution = 0.042) sampled from the amylograph at 30°C, 45°C, 50°C, 60°C, 95°C, and after 30 min at 95°C. (From Ref. 17.)

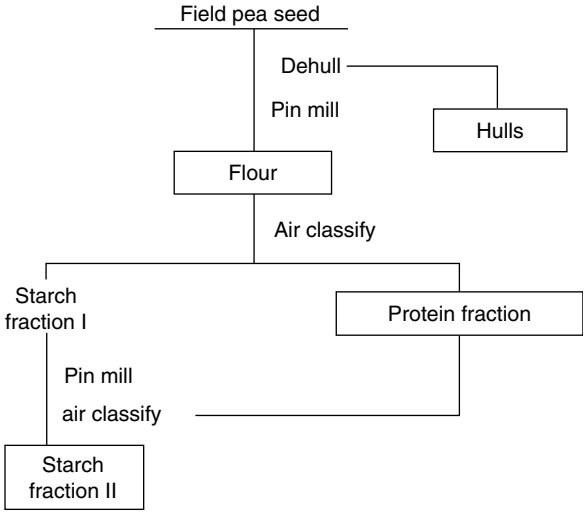

FIGURE 18.7 Flow diagram for pin milling and air classification of pulses into protein and starch fractions. (From Ref. 20.)

In a comparative study of dry and wet milling (20), pea flour containing 22% protein and 55% starch yielded an air-classified fine fraction containing 53% protein and a coarse fraction with 83% starch, dry basis (Figure 18.9). The fines also contained some broken starch granules plus most of the lipid, ash, sugars, flavour and colour compounds in the flour. The recovery of starch in the coarse fraction was very high (93%) but the starch content of 83% was not comparable to commercial corn starch at 95–99%.

The protein isolate from wet milling contained 88% protein, like soy protein isolate, and a refined starch containing <1.0% protein, as in corn starch (Figure 18.9). The refined fiber was light colored and relatively free of other constituents. The principal drawback of the wet milling system was the substantial losses of protein and starch in the whey and washes, and expensive effluent recovery procedures would need to be implemented.

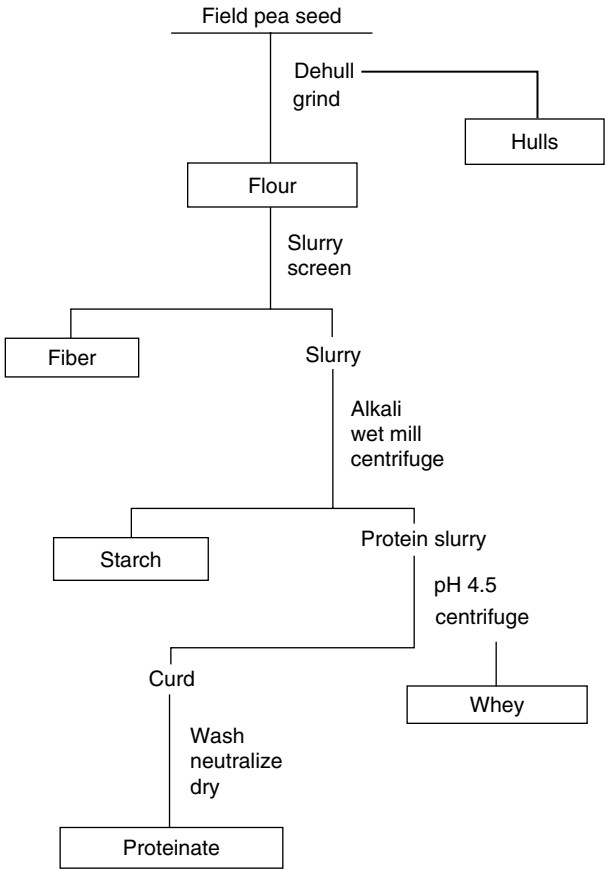

FIGURE 18.8 Flow diagram for preparation of refined fiber, refined starch and proteinate from pulses by wet milling techniques. (From Ref. 20.)

Direct comparisons of functionality in dry pea and soybean proteins have been made (18, 20). The protein fraction from air classification of pea flour was similar in protein content to soybean flour and was very similar to soybean in all functional properties (Table 18.3). The soybean isolate

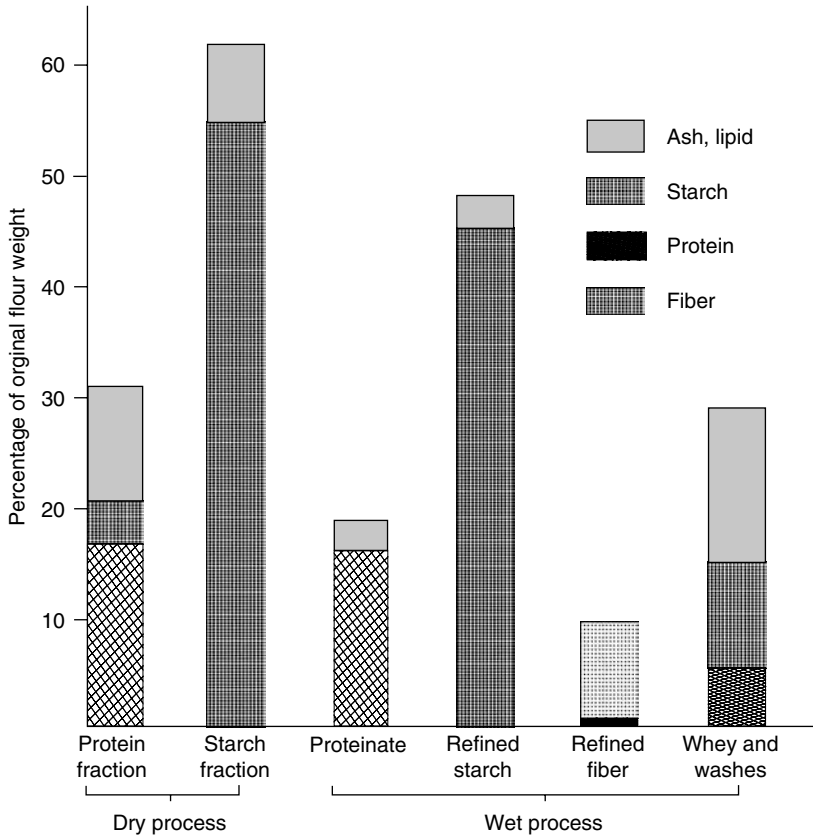

FIGURE 18.9 Yields of products from dry and wet milling of dehulled dry peas. (From Ref. 20.)

was superior to pea isolate in oil emulsification but inferior in foaming properties. The dominant color in all legume products was creamy-yellow and only the pea isolate was slightly darker than the other products.

Natural pea flour exhibited an exceptionally high nitrogen solubility (NSI) at the pH 6.6 used in this test while that of defatted soybean flour was particularly low (Table 18.3). Also the protein isolation procedure decreased the solubility of pea protein quite severely. To assess the effect of impact milling and the alkaline extraction/isoelectric precipitation treatments on nitrogen solubilities of these legumes, the pH dispersibility curves were determined from pH 2–11 (Figure 18.10). The soybean flour and isolate gave almost complete recovery of the product nitrogen as insoluble curd at pH 4–5, indicating the near absence of nonprotein nitrogen material. In dry pea flour and protein (concentrate) fraction, 10–15% of the total nitrogen was soluble protein and nonprotein compounds. During protein isolation, this soluble nitrogen appeared in the whey (Figure 18.9).

At pH levels above and below the isoelectric range, the soybean proteins in both flour and isolate showed only gradual increases in solubility (Figure 18.10). However, the native proteins in pea flour and protein fraction gave high nitrogen solubility values on both sides of the isoelectric pH 4–5. The restricted protein solubility of both isolates between pH 6–9 might be due to the alkaline extraction treatment, acid denaturation, binding with phytin and, in the case of soybean, solvent extraction and desolventizing. For the pea, the alkaline and acid denaturation effect could be minimized by extracting protein at pH 7–8, an advantage over soybean.

In conclusion, the starch in pea flour had an adverse effect on functionality. By removing the starch component, the protein fraction exhibited comparable or superior functional properties to those of soybean flour, and should have potential applications in meat emulsions, bakery and beverage products. Pea protein isolate would also compete favorably with soybean isolate if pea starch has high value uses.

E. Potential for Air Classification

Air classification offers several advantages over wet milling. Only hulls, protein, and starch fractions are manufactured. No water or chemicals are added, so there is no effluent for disposal and microbial problems would be minimal. Electricity is the only essential utility for the two pieces of equipment, and the requirement for engineering skills among operators would be minimal. A seed cleaner

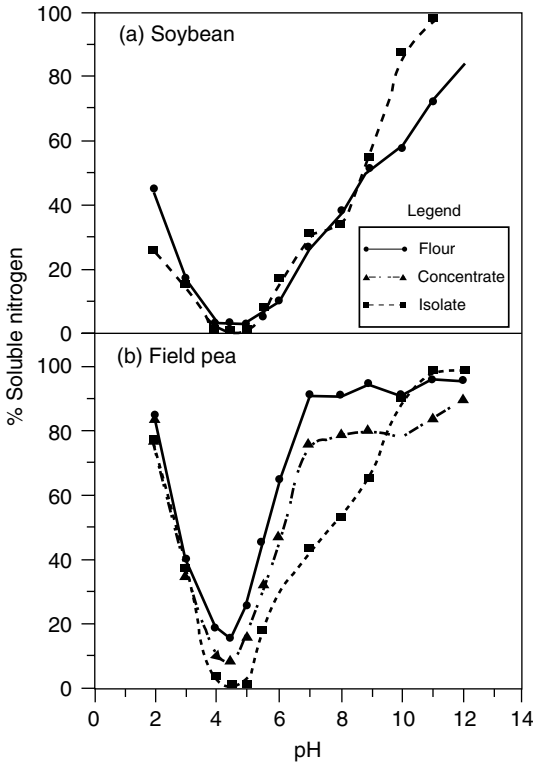

FIGURE 18.10 Nitrogen solubility curves for flours, air classified protein fraction and isolates of a) soybean and b) field pea. (From Ref. 18.)

and grain dryer would be useful optional equipment as well as baggers and loaders.

Since most of the pulses are grown and utilized in low-income tropical and semi-tropical countries, the air classification of pulses should be particularly applicable in these areas. There is great market potential for the high lysine protein fraction in formulated nutritional foods, especially for infants. Also the wet milling of corn into refined corn starch is not done commonly in tropical countries. Therefore a legume starch fraction, manufactured locally, should find markets where a 95% pure starch at $<1.0\%$ protein is not essential.

Numerous studies have shown that nearly all pulses which contain starch can be air classified into fine and coarse fractions. Soybean and lupine yield no coarse fraction (21). Also, the lipids in chickpea interfered with fractionation efficiency and cause plugging of ducts during product transfer. Common bean is the main legume grown in low-income regions and has been evaluated extensively by air classification. As shown in Table 18.4, the intermediate protein level in beans still gives a high yield of fines (40%) with intermediate protein content (53%). The low starch content of the bean results in a low yield of starch fraction, which may be desirable if markets are limited. The starch granules in dry peas and lentils separate fully into high yields of starch fraction with high starch contents and less protein contamination. The dry pea and lentil fines are high in protein content although the yields are low. Fababean is a high protein pulse that gives consistently superior results in protein content of fines. Unfortunately, the vicine and convicine in the flour (about 0.7%) separated into 1.4% in the fines and 0.3% in the coarse fraction. When utilized as a supplement and functional ingredient in foods, susceptible individuals would not easily avoid the bean.

Among more tropical pulses, mung bean gave high yields and composition of protein and starch fraction while cowpea and lima bean were intermediate to the other legumes in air classification efficiency.

F. Applications for Air-Classified Fractions

Characteristically pulses have beany, bitter flavors which are usually removed effectively by aqueous extraction during soaking and cooking or wet milling. Unfortunately, the adverse flavors are concentrated into the protein fractions during air classification. Therefore, any potential applications would need to include appropriate wet heat

TABLE 18.4
Yield and Chemical Composition of Fine and Coarse Fractions from Air Classification of Impact-Milled Pulse Flours, % Dry Basis

	Flour		Fine Protein Fraction			Coarse Starch Fraction		
Legume	Protein[a] %	Starch %	Yield %	Protein %	Starch %	Yield %	Protein %	Starch %
Common bean	25	46	40	53	1	60	7	76
Dry pea	22	55	34	55	3	66	6	84
Fababean	31	52	37	70	2	63	8	81

treatments to remove steam-volatile constituents. For example, blends of pea and fababean protein fractions with wheat flour at the 15% substitution level were mixed into dough, proofed, and baked by normal bread-making procedures (22). Despite the high levels of dilution with wheat flour, beany and grassy flavors did develop during dough fermentation, but these were driven off during baking. Loaf volumes and crumb textures were adversely affected by the supplements, but the addition of 2% vital gluten and 1% of dough conditioner per 100 g flour gave satisfactory bread volume and structure. Glycolipids like sucrose monolaurate and polyoxyethylene-8-stearate were the most effective conditioners.

Numerous attempts to prepare high-protein snack foods and breakfast cereals by extrusion cooking have not had commercial success. The protein fractions gave limited expansion, and the heat treatments in the barrel failed to fully debitter the product. With a lower flavor profile, extrusion of the starch fraction appeared feasible. Recently, Wang et al. (23) used a twin-screw co-rotating extruder to develop a pasta-like product from the pea starch fraction. Screw configurations were designed to gelatinize the starch, denature residual proteins, vent off adverse flavors, and texturize the extrudate. The product exhibited superior integrity, flavor, and texture after cooking than wheat semolina pasta, although cooking losses were higher. This product made entirely from the pea starch fraction by twin-screw extrusion would be a nutritional and functional alternative to wheat-based products for consumers who cannot tolerate wheat gluten.

19 Asian Fermented Soybean Products

Li Lite
Department of Food Science and Nutritional Engineering, China Agricultural University

CONTENTS

I. INTRODUCTION

It is well known that soybean is originated in China, and has been cultivated there for over 5,000 years. Soybean is considered one of the five basic grains, along with rice, wheat, barley, and millet, which are essential to the Chinese diet and civilization. During the Qin Dynasty (about 200 A.D.), soybean was introduced to Korea from Northern China, and then to Japan and Southeast Asia. Soybean did not appear in Europe and North America until the 18th and 19th centuries, respectively. It is now cultivated all over the world (1).

Fermented soybean foods use either whole soybeans or soybean products as substrates, sometimes along with other cereals. Fermented soyfoods are produced by specific microorganisms or by several microorganisms acting in a sequential manner. The ultimate aim of fermentation is to develop food products having certain desirable characteristics such as flavor, aroma, texture, and keeping quality. During fermentation, protein and carbohydrate fractions are hydrolyzed into smaller constituents, which increase digestibility. Vitamins are also accumulated in the fermented products (2).

Despite the widespread cultivation of soybean, traditional fermented foods based on soybean are limited to the Orient. Most traditional soyfoods are known to have originated in China, and were then introduced to other Asian countries. After centuries of preparation, considerable modification and adaptation in processes had been made to suit specific environmental conditions and cultural practices. These traditional foods are increasingly popular in many Asian countries, and have been extensively developed and consumed in China, Korea, and Japan, and to a lesser extent in Indonesia, India, Malaysia, and Thailand. Table 19.1 lists some common indigenous fermented soyfood products consumed in various parts of Asia (2, 3).

Since fermented soyfoods are nutritious and highly digestible, they have played an important nutritional role in the Oriental population in the past, and will continue to do so in the future. Today, the preparation of many traditional fermented soybean products remains a household art, and only a few (such as soy sauce and *natto*) have evolved with modern biotechnological development and are manufactured on a large scale. In this chapter, various fermented soybean products are discussed with respect to their preparation methods and utilization. Only products that have an important influence and are produced in large quantities are described.

II. SOY SAUCE (*JIANGYOU*)

Soy sauce is a dark brown liquid extracted from a fermented mixture of soybean and wheat or soybean only, with aroma and flavor similar to that of *miso*. First produced in the Zhou Dynasty (684–705 A.D.) in China, soy sauce is now widely consumed in China, Japan, Korea, and other Oriental countries, and is also used in North America and Europe as a condiment and coloring agent (4). Soy sauce is known as *jiangyou* (Mandarin) or *chiangyu* (Cantonese) in China, *shoyu* in Japan, *kanjang* in Korea, *Tao-yu* or *kecap* in Indonesia, and *tayo* in the Philippines (5).

A. *Qu* (*Koji*), *Koji* Starter, and Inoculum

Before describing the methods of preparing soy sauce, it is necessary to introduce some terms commonly used in fermented soybean products.

1. *Qu* (*Koji*)

Qu is the Chinese word for *koji*, and is an intermediate product for making soy sauce, soy paste, *douchi* (soy nuggets), *kecap*, and other similar products. *Qu*, which contains a large variety of enzymes, is made by growing molds on rice, barley, wheat, soybean, or a combination.

2. *Koji* Starter

Koji starter, also known as seed *koji*, *koji* seeds, or *tane-koji*, provides spores of microorganisms to make *koji*. Traditionally, wild spores of different molds were used as the starter for soy sauce, soy paste, and soy nuggets. However, in modern manufacturing, the making of *koji* starter begins with the growth of a selected mold strain, such as *Asperigillus oryzae* or *A. sojae*, in pure culture.

TABLE 19.1
Traditional Fermented Soybean Foods in Asia

Product	Region	Substrates	Microorganism(s)	Nature of Product	Product Use
Douchi (*Hamanatto, tao-si, tao-tjo*)	China, Japan, Philippines, East India	Whole soybean, wheat flour, salt, seasoning	*Mucor* spp., *Aspergillus oryzae, Bacillus subtilis, Pediococcus* spp., *Streptococcus* spp.	Solid beans, retain individual form, soft, raisin-like	Seasoning, snack
Kecap	Indonesia and vicinity	Soybean, wheat	*Aspergillus oryzae*, *Hansenula* spp., *Lactobacillus* spp., *Saccharomyces* spp.	Liquid	Condiment, seasoning
Kinema	Eastern Nepal, India (Sikkim, Darjeeling)	Soybean	*Bacillus subtilis*	Solid	Fried curry, side dish
Meitauza	China, Taiwan	Soybean	*Actinomucor elegans*	Solid	Fried in oil or cooked with vegetables
Meju	Korea	Soybean	*Asperigillus oryzae, Rhizopus* spp.	Paste	Seasoning
Fermented soybean paste *(Doujiang, miso, chiang)*	China, Japan other cereals, salt	Soybean and rice or *Lactobacillus* spp.	*Aspergillus oryzae, Torulopsis etchellsii,*	Paste	Soup base, seasoning
Natto	Japan	Whole soybean	*Bacillus natto*	Solid beans	Snack
Fermented soybean milk	China, Japan	Soybean	Lactic acid bacteria	Liquid	Drink
Soy sauce (*Jiangyou, shoyu, kecap*)	China, Japan, the Philippines, other parts of the Orient	Soybean and wheat, salt	*Aspergillus oryzae or A. soyae, Lactobacillus* spp., *Zygosaccharomyces rouxii*	Liquid	Seasoning for meat, fish, cereals, vegetables
Sufu (Doufuyu, furu, taokaoan, tao-hu-yi)	China	Soybean curd, salt, seasoning, pigment	*Actinomucor elegans, Mucor hiemalis, M. silvaticus, M. subtilissimus*	Solid	Soybean cheese, condiment
Tauco	West Java (Indonesia)	Soybean, cereals	*Rhizopus oligosporus, Aspergillus oryzae*	Liquid	Drink
Tempeh	Indonesia and vicinity, Surinam	Soybean	*Rhizopus* spp., *principally R. oligosporus*	Solid	Fried, roasted, used as meat substitute in soup.

Different raw materials are used and sterile conditions are needed to avoid contamination.

3. Inoculum

Traditionally, in the making of soy sauce, soy paste, and soy nuggets, fermenting product from a previous batch was used as an inoculum to be mixed with salted *koji* and cooked soybeans. In recent years, pure cultures of *Zygosaccharomyces rouxii*, *Torulopsis* sp., and certain lactic acid bacteria such as *Pediococcus halophilus* and *Streptococcus faecalis* were used as inoculum, which speeds up fermentation and reduces contamination by weed yeasts and bacteria.

B. Classification of Soy Sauce

Differences among soy sauce samples are due to many factors, such as raw ingredients, microorganisms used in fermentation, processing conditions, and additives such as sweeteners and preservatives (6). According to the preparation principles, soy sauce can be divided into three groups: fermented soy sauce, chemical soy sauce, and semi-chemical soy sauce. It can be further divided based on differences in raw ingredients, methods of preparation, or duration of aging. There are two major kinds of fermented soy sauce in China according to fermentation procedures: 1) high-salt-high-water fermentated soy sauce, in which soybeans or defatted soybean flakes and wheat flour are used as raw materials; and 2) low-salt-semidried-state fermentated soy sauce, in which defatted soybean flakes and wheat bran are used as fermentation substrates. Chemical soy sauce is made by acid hydrolysis and will not be described in this chapter. To improve quality, chemical soy sauce is often blended with fermented soy sauce to semi-chemical products before being sold.

Five types of *shoyu* are available in Japan: *koikuchi*, *usukuchi, tamari*, *shiro*, and *saishikomi*. Of all the *shoyu* consumed in Japan, 85% is of the *koikuchi* type (7). *Koikuchi* is made from a mixture of soybean and wheat kernels in almost equal amount and is characterized by a deep reddish brown color and a strong, pleasant aroma (7). *Usukuchi*, the second most popular type of *shoyu*, is commonly used to preserve the original flavor and color of foods. The remaining three types of *shoyu* are produced and consumed only in isolated localities for special uses. *Tamari shoyu* is similar to traditional Chinese soy sauce, with a soybean:wheat ratio of about 9:1 to 8:2. In contrast, *shiro shoyu* is made with a soybean:wheat ratio of 1:9 to 2:8, and fermentation is controlled to prevent color development. *Saishikomi shoyu* is produced similar to *koikuchi*, but the *koji* is mixed with raw soy sauce instead of a brine solution.

Traditional Indonesian *kecap* is a Chinese style soy sauce. However, industrial Indonesian *kecap* is a Japanese-type product (8).

TABLE 19.2
Sugar Contents in Soy Sauce

Sugar	Content (% w/w)
Glucose	2.05
Galactose	0.17
Mannose	0.06
Xylose	0.06
Arabinose	0.08
Unidentified sugars	0.23
Disaccharides	0.65
Polysaccharides	1.15
Total	4.45

C. Preparation of Soy Sauce

1. Chinese *Jiangyou*

Traditionally, Chinese soy sauce is produced from soybean only, but for industrial preparation, wheat flour or bran is added.

a. Traditional household method

The following is a typical method used in Northern China. The raw materials for *jiangyou* making are soybean, salt, and water. Soybean is selected and washed, and then boiled until the beans are soft enough to mash. The mashed soy mud is shaped into bean loaves of about 1–4 kg. The loaves are often made around the Chinese Spring Festival, acting as *qu*. They are placed in a warm room for spontaneous fermentation until the beginning of summer. The fermented loaves are crushed into lumps and mixed with water and salt in earthen vats. The vats are placed outdoors and exposed to sunlight to increase the temperature. The later stage fermentation lasts for at least 30 days, and the mixture is stirred thoroughly daily. The *moromi* becomes thick and dark after fermentation, and has a pleasant fermentative aroma and taste. The liquid is separated and transferred to another jar, and exposed to sunlight for several weeks. A premium grade soy sauce can then be made. Fresh brine can be added to the mash two or more times to extract the second and third grades soy sauce. This is also followed by several weeks of exposure to the sun.

b. Modern methods

Defatted soy meal and wheat bran are mixed at a ratio of 8:2 to 6:4, and the mixture is soaked in water and steamed. After cooling, the mixture is inoculated with a small amount of seed spores of *Aspergillus sojae* and/or *A. oryzae* to make *qu* in about 22–30 hours at 35°C.

For low-salt-semidried-state fermented soy sauce, the *koji* is mixed with 12–13°C Bé brine to make a *moromi*, with a water content of about 50% and a salt content lower

than 10%. The *moromi* is fermented at a higher temperature (40–45°C) for half a month, and mixed with additional brine solution to increase the salt content to at least 15%. The *moromi* is in a semi-liquid state. Lactic acid bacteria and yeasts are added to the brine solution, and fermentation is allowed to continue for half a month or longer at 30–35°C.

For high-salt-high-water fermented soy sauce, the *koji* is mixed with 18°C Bé brine, and fermentation is carried out at 30°C or at room temperature for 3–6 months. This method is adopted by most manufacturers.

A combination of the above two methods has also been used. The low-salt-semidried-state *moromi* is first fermented at 40–42°C for 2 weeks, and then mixed with brine to form a high-salt-high-water *moromi*, fermented at 35–37°C for 15–20 days, followed by fermentation at 28–30°C for 30–100 days. In order to save rice and wheat grains, liquid hydrolysates of broken rice or wheat flour, produced by α-amylase and β-amylase from wheat bran, are used by some producers. The fermented mash is heated to more than 80°C and the liquid product is separated by gravity. The soy sauce may be pasteurized or mixed with benzoic acid before being clarified, bottled, and shipped to the market.

2. Japanese *Shoyu*

Although there are some variations in making different types of Japanese soy sauce, the basic steps are the same, including the treatment of raw materials, *koji* making, brine fermentation, pressing, and refining (Figure 19.1).

a. Treatment of raw materials

Soybeans or defatted soybean flakes are soaked in water to increase the moisture content to about 60% and then cooked with steam at 0.8–1.0 kg/cm^2 gauge pressure for 40–45 minutes, or by a high temperature short time (HTST) process (6–7 kg/cm^2, 20–30 seconds). The wheat kernels are heated with hot air at 150°C for 30–45 seconds at atmospheric pressure, and the roasted kernels are cracked into 4 to 5 pieces. When wheat flour and wheat bran are used, they are steamed after being moisturized (5), then the cooked soybeans are mixed with the roasted wheat (9).

b. Preparation of koji

The treated raw materials are inoculated with 0.1–0.2% seed spores of *Aspergillus sojae* and/or *A. oryzae*. After 2 to 3 days of solid culture at 25–28°C, the mixture becomes a greenish yellow mass as a result of mold growth and sporulation, and is called *koji*.

c. Brine fermentation

Matured *koji* is mixed with an equal amount of brine to make *moromi*. In general, the salt content is kept at around 17% (10). At the initial stage, *Penicillum halophilus* is added to the mash to produce lactic acid which lowers the pH, and to prepare the appropriate conditions for yeast fermentation to produce ethanol. The microorganism also plays an important role in the quality control of the mash, and has an influence on *shoyu* flavor and taste. To control growth rate, it is necessary to keep the fermenting mixture at 15°C in the first month, allowing the pH of the mash to decrease slowly from 6.5 to 5.0. Then *Zygosaccharomyces rouxii* and *Candida* species are added as starters. The temperature of the *moromi* is allowed to rise slowly from 15°C to nearly 28°C for vigorous alcoholic fermentation, and this temperature is kept for 4 months. After the completion of alcoholic fermentation, the temperature is kept at 15°C for 1 month (9, 10).

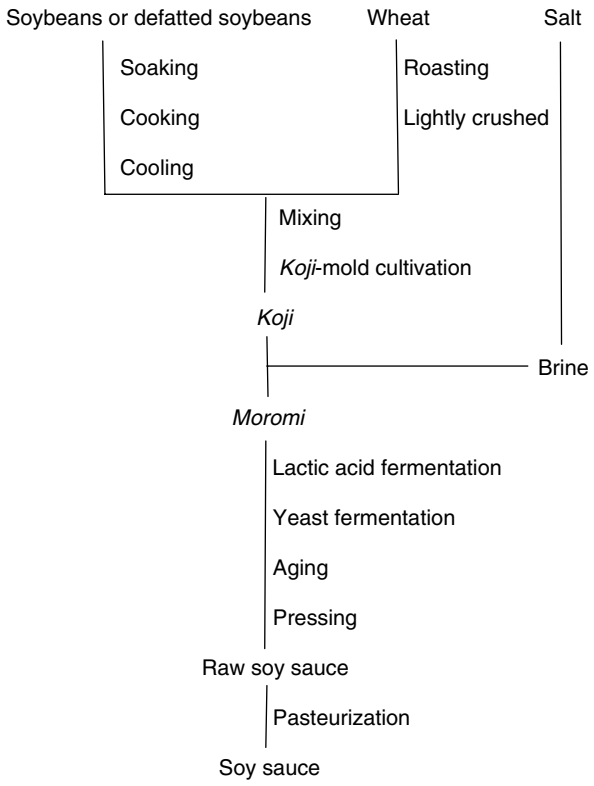

FIGURE 19.1 Flow chart of soy sauce manufacturing.

Lactic acid bacteria and yeast cells interact in a mash, and this affects the production of both lactic acid and ethanol (11). Immobilization of lactic acid bacteria and yeast cells in separate fermentors has been found to be effective for speeding up the production of *shuyo* (12, 13).

d. Pressing and refining

The next step in *shoyu* processing is pressing and refining, involving filtration, pasteurization, and packaging. The aged *moromi* is pressed to separate the soy sauce from the residue. The residue can be extracted with additional 20% brine to increase the yield. After pressing, the filtered raw soy sauce is pasteurized at 70–80°C for a few minutes to inactivate residual enzymes and undesirable microorganisms. It may be necessary to clarify the soy sauce further by centrifugation or sedimentation. The product is treated with caramel as a coloring agent and then packaged (9).

3. Indonesian *Kecap*

Kecap is a liquid seasoning widely used in Malaysia and Indonesia. In Indonesia, *kecap* is usually made by small-scale producers in a traditional manner. Black soybeans are used as the raw material (14). Commercial soy sauce factories have been established in Indonesia, and they apply modern Japanese technology for *kecap* production. Defatted soybean flakes and wheat are used instead of black soybeans (15).

In *kecap* processing, the cooked soybeans are made into *koji* by mixing with mold inoculum consisting of various species of *Aspergillus*. The *koji* is incubated for 48 hours in a room with controlled temperature and relative humidity. At the end of the solid-state fermentation, the *koji* is transfered to a fermentation tank containing brine at a concentration of 20–25%. This process, *moromi* fermentation, lasts at least 2 months, and the pleasant aroma of *kecap* is formed. *Pediococcus halophilus* is the dominant microorganism during the brining stage in *kecap* fermentation (16). *Kecap* liquid is withdrawn at the end of *moromi* fermentation and transferred to a sedimentation tank to precipitate the dispersed particles of raw *kecap*. Based on the formulation, liquid *kecap* can be blended with other ingredients to produce condensed *kecap*. The product is pasteurized for 15 minutes to destroy spoilage microbes. Finally, bottling and labeling of the end product are carried out.

D. Chemical and Biochemical Changes during Soy Sauce Processing

Soy sauce is made by a two-step fermentation process with a mixture of molds, yeasts, and bacteria using soybean and wheat flour as raw materials. The first step involves fermentation with *Aspergillus sojae* and/or *A. oryzae* to make *koji* (9). During this period, enzymes from *koji*, such as proteinases, peptidases, and amylases, hydrolyze most of the proteins to peptides and amino acids, and almost all of the starches to simple sugars. These become the nutrients for the yeasts and lactic acid bacteria in the subsequent step of brine fermentation.

The second stage of fermentation involves *Pediococcus halophilus*, *Zygosaccharomyces rouxii, Candida versatilis*, and *Candida ethellsii*. All the microorganisms can tolerate a salt concentration of 18–20%. However, the brine effectively prevents the growth of undesirable microorganisms. Sugars are fermented by the salt-tolerant microorganisms into lactic acid, ethanol, and various aroma components (10). *Z. rouxii* produces ethanol and 4-hydroxy-2 (or 5)-ethyl-5 (or 2)-methyl-3 (2H)-furanone (HEMF). The latter is considered one of the important compounds for soy sauce flavor (12), reaching a maximum concentration at 16% NaCl when fermented by *shoyu* yeasts (13). Ethanol (2–3%) and many aromatic components are produced by *Z. rouxii*. The *Candida* yeasts produce phenolic compounds such as 4-ethylguaiacol and 4-ethylphenol, which add characteristic aroma to soy sauce (10).

The yeasts and *koji* culture have strong esterase activities which could be responsible for the decomposition of the flavor esters during soy sauce brewing, lowering ester flavor in the product. Glutamic acid and aspartic acid are the major amino acids present in soy sauce, and the levels of arginine, tryptophan, and cystine are decreased during fermentation. The total acid content in soy sauce is about 0.95%, dominanted by lactic and acetic acids (9). The glucose content in Japanese soy sauce is about 2.05%, different from the Chinese traditional soy sauce which has little fermentable sugars left for yeast growth after the growth of *Tetragenococcus halophilia* cells (18).

III. Fermented Soybean Paste (*Doujiang* and *Miso*)

Fermented soybean paste is a popular traditional seasoning in Asia, especially in East Asia. It is commonly known as *jiang* or *doujiang* in China, *miso* or *misho* in Japan, *jang* in Korea, *tacho* in Indonesia, and *taosi* in the Philippines. Chinese *jiang* is believed to be the oldest form of fermented soy paste. According to the ancient Chinese book, *Analects of Confucius*, it has a history of more than 3,000 years (19). *Miso* and *jang* are considered to be derived from *doujiang*.

Fermented soybean paste is a light yellow to dark brown thick paste. It has a very salty taste due to high salt content (normally 12–15%, and ranges from 5% to 20%), and has a special flavor of fermented soybean. It is usually served with other foods as a seasoning or used as a condiment in food preparation.

The process of *doujiang* making is very similar to that of soy sauce preparation. The main steps include the preparation of starter, *qu or koji*, mixing the starter with salt and water, and fermentation. Figure 19.3 shows the flow chart of *doujiang* making using pure culture starter.

A. Preparation of *Doujiang*

1. Traditional Household Method

The traditional method of making *doujiang* is almost the same as making *jiangyou*, but the liquid is not separated from the paste. Another household method of *doujiang* making differs from the former one mainly in the preparation of *qu*. Boiled soybean is mixed with a small amount of wheat flour. The mixture is then spread onto a bamboo tray and kept in an incubation room for a week to make *qu.*

2. Pure Culture Method

a. Preparation of starter

A mixture of soybean and wheat flour (in 2:3 to 3:2 ratios) is used for making *qu*. The wheat flour is usually cooked

by baking or steaming, which is labor and energy intensive. Many producers therefore use raw flour directly. The washed, soaked, steam-cooked, and cooled soybean is mixed with the flour, and inoculated with 0.15–0.3% seed spores. The process of *qu* making is the same as that in soy sauce processing (Figure 19.2).

b. Fermentation

Figure 19.3 shows the fermentation steps involved in *doujiang* making. Matured *qu* is poured onto a fermentation container and pressed slightly. The temperature will soon increase spontaneously to 40°C, and brine (14.5°C Bé) at 60–65°C is added. After the brine penetrates evenly into the *qu*, small amount of fine salt is dusted on the surface. The temperature of the *qu* will reach 45°C, and fermentation is carried out at this temperature for 10 days. Brine (24.0°C Bé) and fine salt are added, and the mixture is thoroughly stirred with a mechanical mixer or by compressed air. After fermentation for another 4–5 days, the *doujiang* can be bottled and marketed.

B. Preparation of *Miso*

The basic steps of *miso* manufacturing are similar to those of *doujiang* making, including treatment of raw materials, preparation of *koji*, mixing of ingredients, and fermentation. However, *miso* is quite different from *doujiang* in terms of raw materials, sensory characteristics, and usage (20). The raw materials for *miso* making can be soybean alone or soybean with rice or barley. The taste of *miso* is sweeter than *doujiang*. *Miso* is often used to prepare various types of soup, whereas *doujiang* is usually used as a seasoning.

There are three kinds of *miso*, based on the use of raw materials: soybean *miso*, rice *miso*, and barley *miso*. Rice *miso* is used to illustrate the processing steps involved in *miso* making (Figure 19.4). Unlike Chinese *qu*, rice is used as the raw material for *koji* making. The washed and soaked rice is steam-cooked and cooled. The cooked rice is inoculated with *tane-koji* (*Aspergillus oryzae*). The soybeans are washed, soaked, steam-cooked (or boiled), mashed, and cooled. The matured rice *koji* is mixed with the cooked soybean paste, together with salt and other species of microorganisms in the fermentation containers. The mixture is fermented for more than 6 months, and the rice *miso* is ready to be packed.

Since excessive salt intake is regarded as one of the causes of hypertension, there has been increasing interest in developing low-salt fermentated soy pastes. A salt-free *miso* can be prepared by supplementing the *koji* with ethanol (21), or ethanol with sugars and polyols (22). Supplementation of ethanol in *miso* not only enables low-salt fermentation but also enhances flavor formation (23).

C. Chemical and Biochemical Changes during *Miso* Processing

Due to enzymatic hydrolysis of macromolecules such as polysaccharides and proteins, fermented soy paste contains digestible, small-molecular-weight components. Unpasteurized *miso* has been found to have a vitamin B_{12} content ranging from 0.15–0.25 μg/100 g (24). During fermentation, complex metabolites are formed and contribute to the aroma and taste of the product. One of these metabolites is HEMF, formed by *Zygosaccharomyces rouxii*, with a strong cake-like aroma and a threshold value of less than 0.04 ppb, and is regarded as the most effective component in enhancing the aroma of *miso* (25).

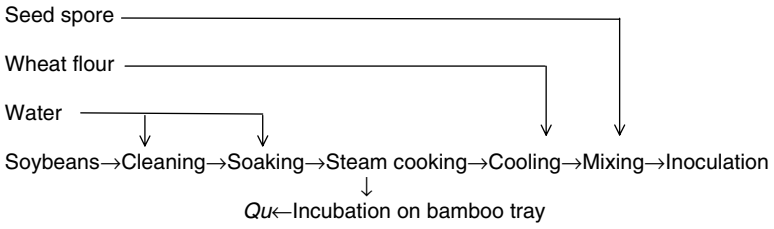

FIGURE 19.2 Pure culture method to make *qu*.

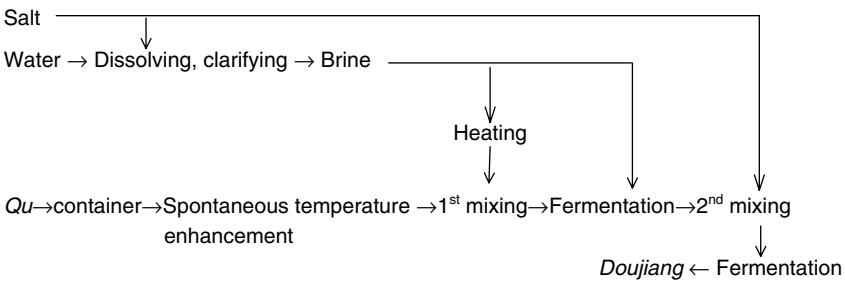

FIGURE 19.3 Pure culture method for *doujiang* making.

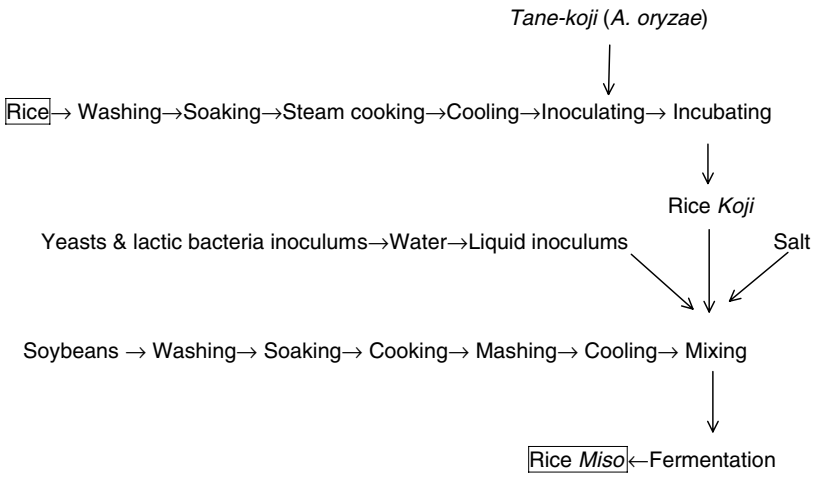

FIGURE 19.4 Flow chart of rice *miso* manufacturing.

Free amino acids are also very important components contributing to the taste of fermented soy paste.

IV. *SUFU (DOUFURU)*

Sufu is a soft cheese type product made from soymilk curd (*tofu*) by the action of microorganisms (26). It has a long history and written records date back to the Wei Dynasty (220–265 A.D.) in China (27). *Sufu* has been widely consumed by Chinese in a way similar to cheese by Westerners, mainly as an appetizer or a side dish, e.g., with breakfast rice or steamed bread (26).

Because of the numerous dialects in China and difficulties of phonetic translation from Chinese to English, *sufu* has appeared in the literature under many different names, such as *tosufu, fu-su, fu-ru, toe-fu-ru, tou-fu-ru, dou-fu-ru, teou-fu-ru, fu-ju, fu-yu, jiang-dou-fu, and foo-yue* (27). Officially, *sufu* should be named *doufuru* or *furu* in Chinese.

There are many types of *sufu* prepared by various processes in different parts of China. Three main types of *sufu* can be identified according to processing methods and fermentation microorganisms: mold-fermented *sufu*, bacteria-fermented *sufu*, and enzymatically ripened *sufu*. *Sufu* can also be classified based on color and flavor, due to different dressing mixtures used in the ripening stage. According to the color and flavor of the products, *sufu* can be classified as red *sufu*, white *sufu,* grey *sufu*, sauce *sufu*, and colored *sufu* (28). Figure 19.5 shows the different types of commercial *sufu* products.

FIGURE 19.5 Commercial *sufu* products.

A. Manufacturing Processs of *Sufu*

1. Mold-Type *Sufu*

Four steps are involved in the manufacturing of mold-type *sufu*: preparation of soybean curd (*tofu*), preparation of *pehtze* with a pure mold culture (fermentation), salting, and ripening. Figure 19.6 shows the flow chart of *sufu* manufacturing.

a. Preparation of tofu

Soybeans are washed, soaked in water overnight or at 25°C for 5–6 hours, and ground. After removing the residue by filtering, soybmilk is collected. In order to inactivate the growth inhibitors and to remove some of the beany flavor, the soymilk is heated to a boil. The curdling process is initiated by the addition of salts, such as calcium sulfate and magnesium chloride when the milk has

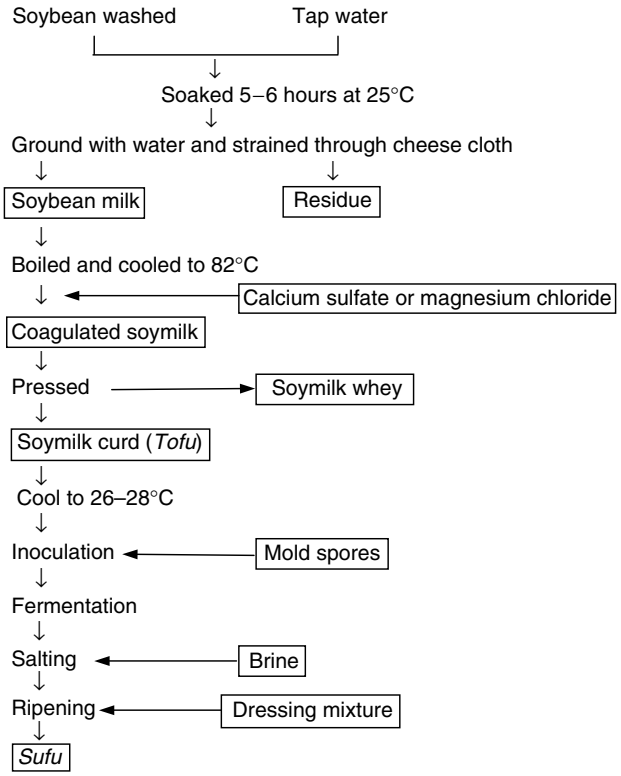

FIGURE 19.6 Flow chart of *sufu* manufacturing.

been cooled to about 82°C. Generally, 20% more coagulant is used to produce *tofu* for *sufu* than for regular *tofu* production. Coagulant is added at a concentration of 2.5–3.5% (coagulant/dry soybean, w/w). The mixture is agitated vigorously to obtain a homogenous coagulum, and then set aside for 15 minutes to complete the coagulation. The coagulum is pressed to remove excess whey, and the resulting *tofu* is cut into cubes of desired sizes.

b. Preparation of pehtze (pizi)

The *tofu* cubes (2.5 × 3 × 3 cm) are placed in a tray with pinholes at the top and bottom to aid air circulation. They should be separated from one another since the mold mycelia must develop on all sides of the cubes. When the cubes are cooled to 35–40°C, they are inoculated by spraying on their surfaces with a pure culture of an appropriate fungus. The inoculated cubes, *pehtze* (or *pizi*) are usually incubated at 20–24°C for 3 to 7 days, with temperature and time dependent on the fungal starin used. For *Actinomucor taiwanensis* and some *Mucor* strains, the best fermentation temperature is above 30°C (29, 30). During incubation, the *pehtze* cubes are covered with white mycelia (Figure 19.7).

c. Salting

After the *pehtze* cubes are separated from each other and the mycelia on the surface are rubbed down, they are piled up in a jar with salt spread between layers. During the salting period, the *pehtze* absorbs salt (not over 15%) and loses water, resulting in shrinkage and increase in hardness. Normally, the salting period lasts for 7–12 days, and the salted *pehtze* is washed with salty water. After being air-dried, it is transferred to another jar for further processing. The added salt not only retards mold growth, but most importantly, the salt solution releases mycelia-bound proteases which are not extracellular and can be easily eluted by salt or other ionic solutions, but not by water (31).

FIGURE 19.7 *Pehtze.*

d. Ripening

Ripening involves a series of biochemical reactions catalyzed by microbial enzymes. The differences among various types of *sufu* are mainly due to the use of different dressing mixtures during ripening. The basic and most common brine contains 12% NaCl and rice wine with about 10% ethyl alcohol. Other ingredients include yellow wine, red kojic rice, soy mash, pimiento, fennel, garlic, shallot, ginger, etc. The ripening time varies for different *sufu* types with different dressing mixtures. Normally it is allowed to age for 2 to 6 months. The product is then bottled with brine and marketed.

2. Bacterial-Type *Sufu*

The preparation of *tofu* is the same as in the mold-type *sufu*. The *tofu* cubes are steamed at 1 kg/cm^2 for 20 minutes. After cooling to 20–30°C, the cubes are salted for 24 hours and washed with water, put into fermented trays, and incubated at 28–30°C for 5 to 6 days after inoculation. When the *pehtze* is covered with bacteria and secretes a yellow liquid, it is dried at 50–60°C for 8 to 10 hours. The dried *pehtze* is placed into jars with a dressing mixture of salt, red kojic rice, rice wine containing 50% ethyl alcohol and other seasonings. The jars are sealed and incubated at 35°C for 20 days. More dressing mixture is then added and a further 50 days of fermentation is carried out, resulting in the production of a red *sufu* (32).

B. Microorganisms for Fermentation

Usually, the microorganisms for mold-type *sufu* are *Mucor* spp. (33), and for bacteria-type *sufu Bacillus* spp. or *Micrococcus* spp. (34). The organisms must develop enzyme systems having high proteolytic and lipolytic activities, and also have white or light yellowish mycelium to ensure that the final product has an attractive appearance. The texture of the mycelial mat should also be dense and thick to prevent any distortion in the shape of the fermented cubes. Of course, the mold growth should not develop any disagreeable odors, astringent tastes, or mycotoxin. *Actinomucor elegans* (35), *Mucor hiemalis*, *M. silvaticus*, *M. prainii* (36), *M. sufu* (35), and *M. subtilisimus* all possess these characteristics. Among them, *Actinomucor elegans* and *A. taiwanensis* seems to be the best organisms and are used commercially in Beijing and Taiwan, respectively.

In addition to *Mucor* spp., *Rhizophus* spp., *Aspergillus oryzae* and *Monascus* spp. which are found in red *sufu*, many other species of microorganisms have been isolated, such as *Penicilium*, *Cladosporium*, *Alternaria*, *Bacillus*, *Staphylococcus*, *Micrococcus*, and *Corynebacterium*. Some researchers suggested that yeasts and bacteria play a role in the flavor and texture of *sufu*, and the predominant halophile is identified as *Tetragenococcus halophila*. Microorganisms isolated from *sufu* made in different regions of China are listed in Table 19.3.

Han found that *Bacillus cereus* in a few *sufu* samples was over 10^5 CFU/g, and *Staphylococcus aureus* enterotoxin A was detected in some of the white and grey *sufu* samples, indicating a potential hazard to consumers (37).

C. Chemical and Biochemical Changes during *Sufu* Processing

During *sufu* manufacturing, glycerol esters are hydrolyzed to fatty acids and glycerol, and glycerol is transformed into organic acids by bacteria. Glutamic acid and leucine are notably present in the water-soluble fraction. Alcohol is produced during the brining and ripening process, and esters are then chemically or enzymatically synthesized from alcohol and fatty acids. Nucleic acids, such as guanidine nucleotide, are the degradation products after the thalli have autolyzed, providing the delicious taste and aroma of *sufu* along with the free fatty acids, organic acids, esters, and seasonings in the dressing mixture such as pimiento, pepper, curry, and sesame oil. The complex flavor has been reported to contain 22 esters, 18 alcohols, 7 ketones, 3 aldehydes, 2 pyrazines, 2 phenols, and other volatile compounds (38). The sugar content of ripen *sufu* is about 5%, so it has a somewhat sweet taste. The added salt imparts a salty taste to the products.

In spite of the differences in color and flavor, most types of *sufu* have a similar proximate composition. As shown in Table 19.4, *sufu* is a nutritious food. The vitamin B_2 content in red *sufu* is 0.42–0.78 mg/100 g, and in grey *sufu*, it is up to 9.8–18.8 mg/100 g, lower only than that in animal livers. Moreover, *sufu* contains vitamin B_1 at 0.04–0.09 mg/100 g and nicotinic acid at 0.5–1.10 mg/100 g. Minerals are abundant in *sufu*, especially calcium, iron, and zinc (39).

V. SOY NUGGETS (*DOUCHI*)

Soy nuggets (*douchi* in Chinese) are made by fermenting soaked and boiled whole yellow soybeans or black

soybeans with microorganisms, and are consumed as seasonings (40). *Douchi* production involves two distinct steps of fermentation. The first, which occurs during *koji* making, is by fungi or bacteria (similar to *natto* making), leading to enzyme production. The second is by yeast and lactic acid bacteria, with added salt and seasonings such as shallot, ginger, or garlic, and results in the production of a delicious flavor.

Douchi is the first traditional fermented soyfood to be described in written records. It originated in China before the Han Dynasty (206 B.C.). The first record of *douchi* was in *Si Ji*, which was written by Si Maqian (about 104 B.C.). In *Ben Cao Gang Mu* (Chinese Materia Medica), written by Li Shizhen in the Ming Dynasty (1368–1644 A.D.), some health-enhancing functions of *douchi* were recorded, such as the enhancement of appetite, promotion of digestion, inducement of sweat and recovery from fatigue, soothing of the mood, and prevention of asthma, etc. Products similar to *douchi* are also produced in other Asian countries, for example, *hamanatto* in Japan, *tao-si* in the Philippines, and *tao-tjo* in Eastern India (5).

A. Douchi Varieties

There are various types of *douchi* produced in China (see Figures 19.8 and 19.9). According to the water content, *douchi* can be classified into dry *douchi* and water *douchi*. Dry *douchi* is fermented loose whole soybeans, produced mainly in Southern China. Water *douchi* is fermented soybeans with additional water, and the final products are sticky, somewhat like *natto*. It is made in Northern China and the family-made products (Figure 19.9) belong to this type (40). According to the selection of fermentation microorganisms, *douchi* can be classified into three varieties: *Aspergillus*-type, *Mucor*-type, and bacteria-type. Among them, the *Aspergillus*-type is the earliest and most common type.

B. Preparation of *Douchi*

Douchi has been produced in China for a long time. Because of the diversity of climate, some famous brands are produced in various regions of China using different processing methods. Figure 19.10 shows the flow chart for the preparation of *Aspergillus*-type *douchi*.

1. Pre treatment of Raw Materials

Soybeans are cleaned to remove foreign matter and damaged or decomposed beans. They are soaked in water for 2–7 hours at a temperature below 40°C, until the water content reaches 45% (41). Boiling of soybeans is necessary to destroy contaminating bacteria that could interfere with fermentation, and to release nutrients required for mold growth. Traditionally, soybeans are boiled at 100° for 5 hours. For industrial preparation, soybeans are steamed at 0.1 MPa for 45 minutes to 1 hour. For bacterial-type *douchi*, soybeans are boiled at 100°C for 30–40 minutes.

The water content of soybeans should be controlled after boiling, so that the microorganisms can multiply and the beans remain intact. The best water content differs for different *douchi* varieties, about 50% for *Aspergillus*-type *douchi* and 45% for *Mucor*-type *douchi* (41).

2. Making of *Qu*

a. Aspergillus qu

Boiled soybeans are cooled to 35°C and inoculated with 0.3% *Aspergillus oryzae* or other *Aspergillus* spores, then incubated at about 25°C. If the temperature of soybeans is increased to 35°C, they should be cooled down by turning them over. When the soybeans are covered with yellow-greenish mycelium, usually the fermentation time is about 72 hours, and the *qu* is matured.

FIGURE 19.8 Commerical *douchi* products.

FIGURE 19.9 Homemade *douchi.*

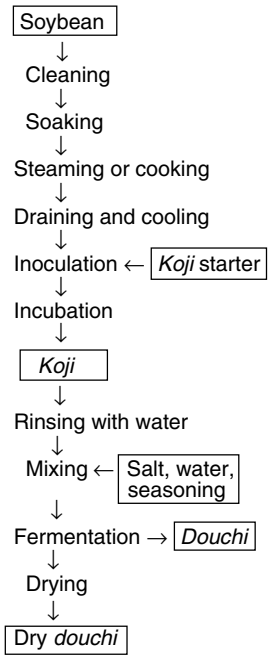

FIGURE 19.10 Flow chart of *Aspergillus*-type *douchi* manufacturing.

b. Mucor qu

Boiled soybeans are cooled to 30°C and inoculated with 0.5% *Mucor* strain spores, then incubated at 2–7°C, keeping the internal temperature of the beans below 18°C by ventilation. After 10–12 days, when the mycelium color changes to grey with a few black spores, the product is ready for harvest (41).

c. Bacteria qu

After boiling and draining, the soybeans are sealed and incubated at a high temperature (over 25°C) for 3–4 days. When the soybeans are covered with mucilage with a special flavor, the *qu* is matured.

3. Fermentation

Washing with water is a special processing step for the preparation of *Aspergillus*-type *douchi*. The *koji* is washed with water to remove the spores, mycelia, and part of the enzymes. Spores will impart a bitter and astringent flavor to the final product. Too much enzymes on the surface tend to hydrolyze the macromolecules excessively, causing soluble materials to increase, and the surface texture becomes coarse. Ordinarily, the washing time is about 10 minutes and the water content of the washed beans is 33–35%. After washing, the soybeans are stacked in containers without cover, and water is sprinkled occasionally to adjust the water content to about 50%.

Salt (18% w/w, soybean weight basis), a small amount of sugar, and a selected flavoring such as capsicum paste are mixed with the *koji* in order to obtain the desirable flavor (42). The mixture is put into jars, and one layer of soybean is loaded on top of another up to about 80% by volume. The jars are then sealed with plastic film.

The *Aspergillus*-type *douchi* is fermented in the jars at 30–35°C for 4–6 months, traditionally under sunlight. After fermentation, *douchi* are dried to 30% water content.

For *Mucor*-type *douchi*, the soybeans are not washed with water, but mixed with salt and flavoring directly. Fermentation is carried out at about 20°C for 10–12 months.

Salt is added to the soybeans to prevent metamorphose and to improve flavor, but the enzyme activities are inhibited, with an increase in fermentation time. Non-salt fermentation, carried out at a higher temperature (55–60°C), can shorten the fermentation time to 3–4 days.

C. Chemical and Biochemical Changes during *Douchi* Processing

The protein, fat, carbohydrate, and vitamin contents in *douchi* (Table 19.5) indicate that it is a nutritive food (43). During fermentation, the levels of free amino acids increase gradually (43). Glutamic acid is the predominant amino acid, contributing to the delicious flavor of *douchi*. Other types of flavor components are organic acids. In *douchi*, lactic acid content is high, followed by acetic and L-pyroglutamic acids (Table 19.5) (43).

VI. *Natto* and *Kinema*

Natto is a whole or fractional, slimy, fermented soybean product (Figure 19.11) which has a characteristic aroma. It is made with soaked and steamed soybeans fermented by *Bacillus* species. *Natto* was originated from China in the Tang Dynasty, and was introduced to Japan along with Buddhism (44). In Northeastern Japan, it has been produced for about 1000 years. It is now widespread in Japan, and is also prepared in Korea, Thailand (*thua-nao*), and India (*kinema*) (45). *Natto* is served for breakfast and dinner along with rice, and is sometimes consumed with

Source: Adapted from Ref. 43.

FIGURE 19.11 *Natto.*

shoyu and mustard. It can also be used as an ingredient for sauce production or as a flavoring agent.

A. Preparation of *Natto*

Natto preparation is relatively simple when compared to other fermented soybean products which employ a series of microorganisms, such as *sufu* and soy sauce. Only one organism, *Bacilli subtilis,* an aerobic Gram-positive rod bacterium, is involved in the fermentation of *natto*. *Bacillus natto*, classified as a related strain of *B. subtilis*, is the most commonly used strain. Many new strains have been bred and are used to make *natto*, such as strains with high γ-glutamyltranspeptidase (GTP) activity (46), high thrombolytic activity (47), and high elastase activity (48), or strains that produce highly viscous products.

The traditional and industrial manufacturing processes for *natto* are shown in Figure 19.12. Round and small soybeans with high content of soluble sugars are the ideal raw materials to produce *natto*. Since these soybeans have a small diameter, the steaming time can be shortened. Meanwhile, soluble sugars provide a carbon source for microbial growth, as well as a sweet taste to the final product. Soybeans are cleaned and soaked overnight in water, then cooked at 1.5 kg/cm^2 pressure for 30–40 minutes. Traditionally, the cooked soybeans are wrapped with rice straw, and kept in a warm place for 1–2 days. The rice straw provides *B. subtilis* and absorbs the unpleasant ammonia odor. In the industrial process, soybeans are inoculated with 1–3% pure culture suspension of *B. natto* and then packed in trays. After fermentation at 40°C for 18–24 hours, the beans are covered with a white sticky coating, and the products are ready for harvesting. In addition to refrigeration, drying at a low temperature is another effective method for prolonging the shelf life of *natto*.

B. Chemical and Biochemical Changes during *Natto* Processing

One characteristics of *B. subtilis* is that it can secrete many extracellular enzymes such as proteases, amylases, GTP (49), levansucrase, and phytase (50). During fermentation, the quantity of soluble and dialyzable matters increases from 22% and 6% to 65% and 40%, respectively (51). Some chemical reactions are catalyzed by these enzymes, with the formation of flavors and sticky materials, including 2, 3-butanediol, acetic acid, propionic acid, iso-butyric acid, and γ-polyglutamic acid (52). A 60-fold increase in free amino acids was observed during fermentation, which accounted for about 26% of the total amino acid content (53). Since there is no lipase, the fat and fiber content of soybeans are kept almost constant (54). The content of soluble sugars, the carbohydrate source for *B. natto*, is very low. The levels of oligosaccharides such as sucrose, raffinose, and stachyose decreased during soaking, boiling, and fermentation (55).

C. *Kinema*

Kinema is an indispensable dietary component in Nepal and the hilly regions of the Eastern states of the Indian subcontinent, where it has long been used as a meat substitute. *Kinema* is fried in oil, then cooked in water with vegetables and spices to prepare a thick curry, and eaten as a side dish with rice (56).

1. Preparation

To make traditional *kinema*, soybeans are washed, soaked overnight in water until soft and crushed lightly to dehull, boiled for about 90 minutes, crushed to grits, wrapped in fern leaves and sackcloth, and left to ferment for 1–3 days in a warm place (25–30°C) until the beans have a typical alkaline, *kinema* flavor and a desirable sticky consistency (57).

TABLE 19.6
Organic Acid Content in Different *Douchi* Products

Douchi Type	Product	Acetic Acid	L-Pyroglutamic Acid	Lactic Acid
Aspergillus type	Tianmashan *koji*	8.70	3.61	9.41
	Tianmashan *douchi*	38.94	7.98	88.89
	Yipinxing *koji*	5.87	1.10	2.94
	Yipinxing *douchi*	19.24	5.10	80.82
Mucor type	Yongchuan	3.40	5.10	12.89
	Black soybean	1.51	4.22	1.80

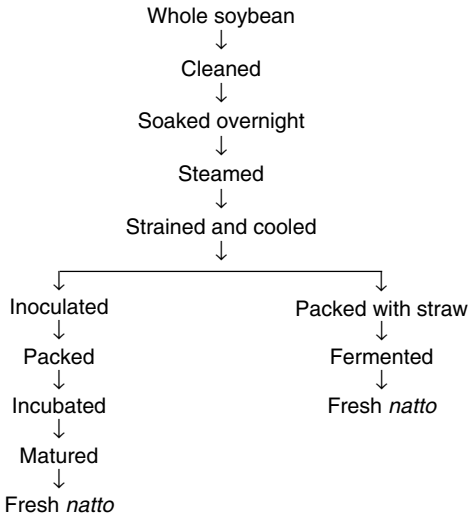

FIGURE 19.12 Traditional and industrial processes of *natto* making.

2. Microorganisms

Bacillus subtilis is the dominant microorganism and the sole fermentation organism found in *kinema*. *Enterococcus faecium, Candida parapsilosis*, and *Geotrichum cadidum* are the accompanying flora in *kinema* samples (58, 59). Among all starter cultures isolated from *kinema*, *Bacillus subtilis* KK2:B10 and GK-2:B10 are the best strains for improved *kinema* production (60). Organoleptically, the monoculture fermentation of soybean by *B. subtilis* produced the best quality *kinema* (61).

3. Microbiological Safety

Although *Staphylococcus aureus* has not been detected in any of the tested *kinema* samples, *Bacillus cereus* and *Escherichia coli* were present in several market samples, and some of them have the ability to produce diarrhoeal enterotoxin. *Enterobacteriaceae* and *Coliform* bacteria exceeded 10^5 CFU/g in most samples. It has been concluded that the traditional way of making *kinema* and its culinary use in curries is safe. However, for novel applications of *kinema*, safety precautions are advisable (58).

VII. *TEMPEH*

Tempeh is a fermented soyfood consisting of dehulled and tender-cooked soybeans bound together by a dense cottony mycelium of fragrant white *Rhizopus* mold into compact cakes or patties (62). It is a popular traditional Indonesian food produced by solid state fermentation (SSF). The technology was introduced by immigrants from Southeast China, and the product is similar to the Chinese *douchi*. *Tempeh* was then introduced to Malaysia, the Netherlands, and North America by Indonesian immigrants. It has now become quite popular in the United States and attracts attention in Japan and many European countries, particularly in the vegetarian market as a substitute for meat (63).

A. Types of *Tempeh*

Depending on the raw materials, several types of *tempeh* are produced in Indonesia, including the soybean *tempeh*, okara *tempeh*, velvet *tempeh*, and coconut or peanut presscake *tempeh,* or mixtures of these. In other countries, *tempeh* is made with other raw materials, such as common bean, lupin, horsebean, chickpea, and wheat.

Sold fresh, refrigerated, or frozen, *tempeh* is usually sliced and fried until its surface is crisp and golden brown, and it has a nice flavor and texture, which can be compared to those of fried chicken or fish sticks. Hence, *tempeh* is often consumed as a main dish or as a meat substitute, and has become a key source of protein in vegetarian diets. Most of all, the high vitamin B_{12} content led to its popularity among vegetarians in the Western world since plants do not contain this type of vitamin (64).

Tempeh can be served with grains and eggs for breakfast, or after frying, in salads, sandwiches, burgers, sauces, and soups for lunch or dinner.

B. Manufacturing Process of *Tempeh*

Tempeh can be homemade or produced in factories. There are two dehulling methods, namely wet dehulling and dry dehulling. Figure 19.13 shows the flow chart of *tempeh* production in temperate climate regions (62).

1. Pretreatment of Raw Materials

Soybeans are cleaned and dehulled. Cleaning will remove damaged beans and foreign matter. Since the fermentating microorganism *Rhizopus oligosporus* cannot grow on whole soybeans, dehulling is essential. Wet dehulling is performed by hands or foots after precooking and the hulls are separated by skimming (65). Dry dehulling is performed by cracking the seeds with a stone or burr mill, followed by separation of the hulls with an air stream or by gravity separation (66).

2. Acidification and Cooking

Acidification lowers the pH, normally to 4.8–5.0, favoring mold growth and restricting the growth of potential spoilage bacteria (67, 68). Traditionally, soybeans are soaked in hot (initially at 100°C) or room temperature water for 8–22 hours, and bacterial fermentation results in acidification. Nowadays, acidification of soybeans is done by the addition of an acidulant such as vinegar, lactic acid, or acetic acid to the cooking water (66).

A basic boiling period, typically 40–60 minutes, is required to soften the beans and to kill spoilage bacteria and their spores. The cooked soybeans are drained, cooled to about 38°C, and dried till the moisture content reaches 45–55% (66, 69).

3. Inoculation and Incubation

After cooling, the cooked soybeans are inoculated. Usually 10^6 viable spores of *Rhizopus oligosporus* per 100 g of cooked soybeans gave optimal mold growth (70). Then the soybeans are packed and placed in a warm place for fermentation. Traditionally, banana leaves or other large leaves are used as *tempeh* containers. Nowadays, perforated polyethylene bags, *tofu* tubs, aluminum trays, or slatted wooden trays covered with perforated polyethylene sheets are used (71).

Temperature, time, and relative humidity are the three crucial factors in *temeph* fermentation. The best relative humidity is between 70 and 85%. Fermentation can be carried out at a temperature ranging from 25 to 37°C. The standard procedure in Indonesia is fermentation at 25°C for 44–52 hours, but moderate temperature fermentation (31°C) and high temperature fermentation (37°C) are recommended as well (69, 71). High temperature fermentation favors growth of *R. oligosporus* and *Klebsiella pneumoniae*, and the products contain more vitamin B_{12} than those with moderate temperature fermentation, but the shelf life is shortened and temperature control is more difficult (62).

4. Harvesting, Storage, and Preservation

When soybeans are covered with and bound together by white mycelia, fermentation is completed. Fresh *tempeh* can last for several days at room temperature without obvious changes, and its shelf life can be prolonged by freezing, drying, frying, dehydration, canning, or other preservation methods. In addition, blanching or steaming is also an effective means to extend shelf life.

C. Microorganisms for *Tempeh* Making

Wet dehulling *tempeh* production involves two distinct stages of fermentation. The first stage, which occurs during soaking, is bacterial, resulting in acidification and the growth of *Bacillus cereus* is prevented. The second stage

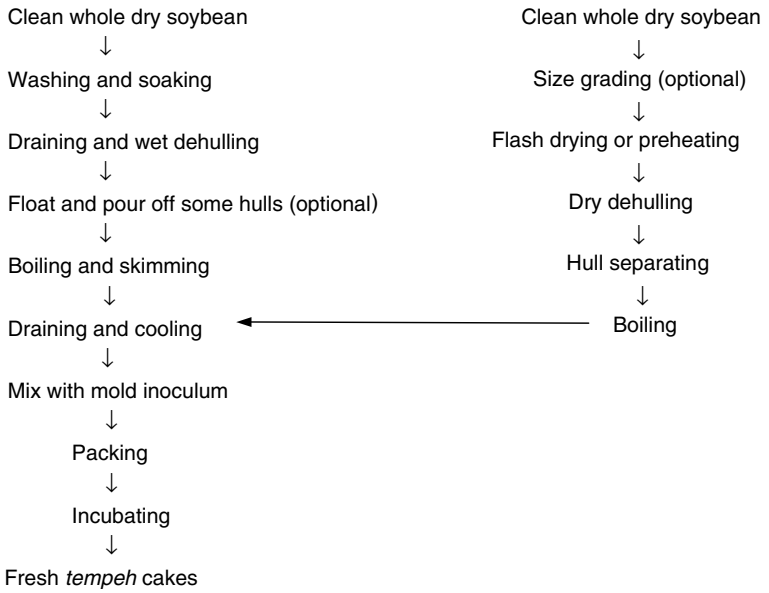

FIGURE 19.13 Wet and dry dehulling methods of *tempeh* making in temperate climate regions

is fungal, resulting in the growth of white mycelium on the bean cotyledons (68).

1. Microorganisms for Acidification

Lactic casei, *Enterococcus faecium*, *Streptococcus dysgalactiae*, and *Staphylococcus epidermidis* are the predominant species responsible for acidification (72), and *Citrobacter diversus*, *Enterobacter agglomerans*, *E. cloacae*, *Klebsiella pneumoniae*, and *K. oacenae* are present during soaking (73). *Lactic* and *Streptococci* spp. dominate the flora in both the unacidified and the acidified soaking water, while yeasts and coliforms are found only in unacidified water (74).

2. Microorganisms for Solid State Fermentation

There are three basic types of starters for *tempeh* fermentation: 1) pure culture mold starters typically containing only *Rhizopus oligosporus* spores, 2) mixed pure culture starters such as *R. oligosporus* and *Klebsiella pneumoniae,* and 3) mixed culture starters for traditional *tempeh*, containing a mixture of molds, bacteria, and/or yeasts. Because of its strong protease and lipase activity, *R. oligosporus* is the principal mold species used to make *tempeh*, and *R. oligosporus NRRL 2710* is the recommended commercial strain (72). Other *Rhizopus* species such as *R. oryzae*, *R. chinensis*, *R. arrhizus*, and *R. stolonifer* are also considered suitable for *tempeh* making (75, 76).

The *Rhizopus* strains form riboflavin, nicotinic acid, nicotinamide, ergosterol, and vitamin B_6, but do not produce physiologically active vitamin B_{12} (75, 76). Vitamin B_{12} is synthesized by bacterial strains of *Propionibacterium, Pseudomonas, Clostridium,* and *Streptomyces* (77), and include *Klebsiella pneumoniae*, *K. terigena, K. planticola*, and *Enterobacter cloacae* (72). *K. pneumoniae* and *Citrobacter freundii* show the best vitamin B_{12} formation capability. In order to increase vitamin B_{12} content, the mold and bacterium mixed pure culture starters have been used (69).

3. Microbiological Safety

Rhizopus oligosporus inhibited the growth, sporulation, and aflatoxin production of *Asperigullius flavus*, and no botulinal toxins were produced during the normal fermentation time of 24 hours or less (67). In early commercial *tempeh* production, *Enterobacteriaceae* and lactic acid bacteria were found in a majority of the samples, and *Staphylococcus aureus*, *Bacillus cereus*, and *Escherichia coli* were found in some samples at a level of 10^5 CFU/g. *Yersinia enterocolitica* was found in several samples, whereas *Salmonella* was not observed (63). Regardless, traditional *tempeh* is regarded as a safe food (69).

D. Chemical and Biochemical Changes during *Tempeh* Processing

The composition of soybean is significantly altered by the physical and chemical treatments and the action of enzymes during fermentation in the making of *tempeh* (Table 19.7). *Rhizopus* spp. produces a variety of enzymes, including carbohydrases, lipases, proteases, endocellulase, xylanase, arabinase, α-D-galactosidases, etc. (72). Solid and nitrogen losses occur mainly during dehulling, soaking, and cooking, with little loss during fermentation. The initial pH increases to a high level after fermentation, hence biological acidification does not resulted in a sour tasting product (68). *Tempeh* is a nutritive food, as shown by its nutrient composition (Table 19.7). There is no marked difference in protein content between *tempeh* and unfermented soybeans, but an increase in free amino acid content can be observed during fermentation.

Tempeh is virtually non-flatulent since raffinose, stachyose, and other flatulence-causing carbohydrates found in soybeans are reduced. *Tempeh* is easily digested and can be tolerated by patients suffering from dysentery and nutritional edema (78).

R. oligosporus and *R. oryzae* have strong lipase activities and can break down soybean lipids into stearic, oleic, linolenic, linoleic, and palmitic acids, with linoleic acid predominating (79). The concentrations of calcium, phosphorus, iron, copper, zinc, magnesium, and manganese tend to be increased during fermentation, but potassium concentration decreases to a large extent (80). The bioavailability of zinc, calcium, iron, and magnesium increases due to their strong chelating properties, leading to a decrease in phytic acid content.

TABLE 19.7
Chemical Compositions of *Tempeh* Products

Tempeh	Moisture (%)	Protein (%)	Fat (%)	Carbohydrate (%)	Fiber (%)	Ash (%)
Fresh	60.4	19.5	7.5	9.9	1.4	1.3
Deep-fried	50.0	23.0	18.0	8.0	2.0	1.0
Freeze-dried	1.9	46.2	23.4	25.8	2.7	2.7
Fermented with *Rhizopus* sp. T-3	8.3	40.8	19.7	19.4	5.4	6.4
Cooked soybean	63.5	16.0	9.0	7.6	2.1	1.8

Source: Adapted from Refs. 2 and 73.

Riboflavin, pyridoxine, and nicotinic acid concentrations increase significantly over the 72-hour fermentation period as a result of their synthesis by different strains of *Rhizopus*, but the thiamine concentration decreases slightly (81). The highest reported value of vitamin B_{12} content in *tempeh* was 6.2 μg/1370 g. During fermentation, the total amount of vitamin E remains constant but the content of free tocopherols decreases (81).

VIII. HEALTH BENEFITS OF FERMENTED SOYBEAN PRODUCTS

Fermented soyfoods have some beneficial effects on human health, arising mainly from certain metabolically transformed components. Some examples of the health benefits of fermented soyfoods are illustrated below.

Angiotension inhibitory enzyme (ACE) activity has been detected in soy sauce, leading to reduced blood pressure in hypertensive rats after oral administration (82). Peptides with ACE activities were also found in water soluble fractions of *sufu* (83), water extracts of *douchi* (43), and *natto* extracts (84).

Isoflavones exist as aglycon in fermented soybean products. Isoflavones, genistein in particular, inhibit the activity of protein tyrosine kinases, thus reducing the risk of cancer (85). 8-Hydroxydaidzein, 8-hydroxygenistein, and syringic acid isolated from *miso* had high DPPH (1, 1-diphenyl-2-picrylhydrazyl) radical-scavenging activities (86). 6, 7, 4′-Trihydroxyisoflavone, and glycitein (87), 6, 7, 4′-trihydroxyisoflavone, daidzein, and genistein may be responsible for the antioxidant activity of *tempeh* (88). *Natto* also has antioxidation activity on unsaturated fatty acids, and shows protective effects on the free radical-mediated cellular damage induced by cumene hydroperoxide (89). Certain components such as saturated hydrocarbons (C30–C32, especially hentriacontane) are present in *natto* and they have possible antitumor-promoting activity (90). Lactic bacteria from *miso* could bind hereroccyclic amines, which are mutagenic and exist in cooked foods, especially fried and toasted foods rich in protein (91).

The insoluble peptides in *sufu* can lower cholesterol level in blood serum (85). Moreover, peptides with the capacity of binding cholic acid were found in water-insoluble fractions of *sufu*. A water-solube extract of *douchi* was found to exert a strong inhibitory activity against rat intestinal α-glucosidase (92). It was found that *douchi* has an anti-hyperglycemic effect and may have potential uses in the management of type-2 diabetic patients (93).

A strong fibrinolytic enzyme, nattokinase, and at least three pro-urokinase activators (PUA) which are different from nattokinase, have been purified from *natto* (94, 95). An enzyme with a strong fibrinolytic activity was purified from *douchi* (96). *Natto* is the only food known that naturally contains vitamin K2 (97), which may contribute to the relatively lower fracture risk in Japanese women (98). *Bacillus natto* is effective in restraining the growth of *Salmonella* spp., *Escherichia coli* O157:H7, and microorganisms that can induce typhoid fever and diarrhea. Staphylococcal enterotoxin A (SEA) was fragmented into small peptides by subtilisin, an extracellular proteinase produced by *Bacillus natto* (99).

Department of Horticulture, Chinese Culture University

CONTENTS

I. DEFINITION OF VEGETABLES

A vegetable is defined as "an edible, usually succulent plant or a portion of it eaten with staples as main course or as supplementary food in cooked or raw form" (1).

II. IMPORTANCE OF VEGETABLES

More than 10,000 plant species are eaten as vegetables worldwide. Among these species, only 50 or so are commercially important (2). Vegetables contribute to humans essential minerals, vitamins, dietary fibers, proteins, fats, starches, and energy. Vegetables are a major source of vitamin C. The amounts of carotenes in pumpkins, capsicum peppers, and tomato are useful to mankind. Dietary fibers in vegetables include cellulose, hemicellulose, pectic substances, and lignin that are important in preventing several human diseases. Vegetables also neutralize the acid substances produced by other high-energy food (3). While organic acids and volatile compounds are responsible for flavor and aroma, chlorophyll, carotene, and anthocyanin make up the colors. Vegetables not only form an essential part of a well-balanced diet, but the flavor, aroma, and color also make them important in human diet and appetite (4).

III. DOMESTICATION OF VEGETABLES

All modern crops had their earliest beginnings as wild plants. These wild plants with specific characteristics attracted humans to harvest them for medicinal (5), herbal, or food purposes. Then the seeds and other plant parts were dispersed. It was the beginning step during plant domestication. Vegetables were brought into cultivation 10,000 years ago, so humans produced sufficient vegetables of their own. The following artificial selection creates gene recombination of higher yield and better quality (6). Evolution of consumption, production techniques, socio-economic interest, general political climate, production policy, international competition, and trade agreements made the structure of today's vegetable exploitation heterogeneous (7).

IV. CLASSIFICATION OF VEGETABLES

Vegetables are commonly grouped according to botany, edible parts, life cycle, sensitivity to temperature, family grouping, or accepted use (2). Other classification schemes include sensitivity to soil pH and chilling damage, tolerance to nutrient levels and salt, and depth of rooting (2–4, 8–10).

A. Botanical Classification

Botanical classification is based on morphology, anatomy, embryology, physiology, biochemistry, etc. The successive groupings of plants are kingdom, division, subdivision, phylum, subphylum, class, subclass, order, family, genus, and species (2, 8), Predominant vegetables belong to the class Angiospermae that is grouped into subclasses Monocotyledoneae and Dicotyledoneae. Most vegetables belong to the Dicotyledoneae. There are fewer monocot vegetables, i.e., sweet corn, asparagus, yam, onion, etc. The genus and species make up the scientific name that is accepted worldwide. The climate requirements, the use for economic purposes, the disease and insect controls of a particular family or genus are often similar. Well-known families of vegetables are Solanaceae, Brassicaceae, Fabaceae, Alliaceae, and Apiaceae (10).

B. Classification Based on Edible Part

Classification of vegetables by edible part informs a grower or handler about specific cultural or handling techniques. Common groupings includes root, stem, leaf, immature flower bud, fruit, and sprout. Root crops include carrot, radish, beet, turnip, and sweet potato. Stem vegetables are asparagus and potato. The yield and quality of root and stem vegetables are affected by soil texture, fertility, and irrigation. Leafy crops include lettuce, cabbage, celery, spinach, kale, and mustard that are very perishable. Edible parts of cauliflower, broccoli, and artichoke are immature flower buds. Immature fruits are harvested from pea, snap bean, lima bean, summer squash, cucumber, okra, sweet corn, and eggplant, but actually we eat the immature seeds of lima bean and sweet corn. Edible parts of cucurbits (pumpkin, white gourd, squash, muskmelon, and watermelon), tomato, and pepper are mature fruits (1–3, 8–10).

C. Classification Based on Temperature

Vegetables are separated into warm-season and cool-season vegetables based on temperature requirements for optimum growth and development. Warm-season crops are adapted to 18~29°C, intolerant to frost and mostly grown for edible fruits. Exceptions are sweet potato for storage root and New Zealand spinach for leaves. Cool-season vegetables have optimum growth at cooler temperature and are shallower rooted and smaller sized. Cool-season crops are grown for edible stems, leaves, roots, and immature flower parts. Asparagus, Brussel sprouts, broccoli,

cabbage, celery, garlic, onion, pea, radish, artichoke, and spinach are cool-season vegetables. Harvested parts are usually stored near 0°C except potato (2, 8–10).

The sub-groupings of cool-season crops into hardy and half-hardy vegetables, and warm-season crops into tender and very tender vegetables, are based on the ability of young plants to withstand frost, and the ability of seeds to germinate at low temperatures. Hardy vegetables generally tolerate moderate frost without injury. Tender vegetables are susceptible to damage during cold weather. The very tender vegetables are easily damaged by light frost (10).

D. Classification Based on Life Cycle

Vegetables are also classified based on their life span. Most vegetables are annuals that complete life cycles within one growing season. Biennial vegetables require two seasons for completing their life cycle. Many cole crops such as broccoli, cauliflower, cabbage, and root crops such as carrot are biennials but grown as annuals. Perennial vegetables complete their life cycle in more than two years. Rhubarb, globe artichoke, and asparagus are grown commercially as true perennials. Tomato, pepper, eggplant, potato, and sweet potato are perennials in their native environments but are grown as annuals for production in temperate regions (2, 3, 8–10).

V. TYPES OF VEGETABLE GROWING

There are several types of vegetable growing such as home gardening, commercial production, and processing production. Commercial vegetable production, includes at least three categories: fresh market, processing, and controlled environment production (5, 11).

A. Home Gardening

People grow vegetables in their own gardens to save money, for outdoor leisure, for fresher tasting and better quality vegetables, and for better nutrition and improved health (2).

B. Commercial Production

The goal of commercial production of vegetables, either for fresh use or processing is only for economic profit.

Fresh Market. The harvested vegetables are sold for fresh use (2, 5, 11).

a. **Market Garden.** Market gardens are located near but on the outskirts of population centers. A wide variety but small scales of high-profit crops are grown intensively and year-round. The harvested vegetables are for local consumption (2, 5, 11).
b. **Truck Farm.** Truck farms are often located in inexpensive rural areas and near transportation systems. One or two crops are grown on a large acreage for distant markets. Transport over large distances permits specialization and the de-localization of production (2, 11).
c. **Controlled Environment Production.** Vegetables are grown in the modified environment for optimal plant growth. Light, temperature, humidity, nutrients, and even composition of atmosphere may be controlled. Investment and production costs including heating and cooling are expensive (5).

C. Processing Production

Vegetables are highly perishable. Post-harvest decay is estimated to be more than 20~50% in the tropics and subtropics. Processing is one of the various feasible technological measures to reduce high post-harvest losses of vegetables (3). Now in processing production, vegetables are grown in the field as raw materials for processing, usually on large acreage, harvested by machines and through contracts. The contract specifies some production techniques, price at a given quality, and standards for acceptance of harvest. Growers usually have a low margin of profit (11).

VI. CONSUMPTION OF VEGETABLES

The per capita consumption of vegetables varies among countries and regions, according to people's eating habits and the supply. The average world consumption of vegetables is around 85 kg per person per year, with around 120 kg per capita in industrialized countries (12), and around 30 kg per capita in developing countries such as in sub-Saharan Africa and 150 per capita in China (7).

VII. COMMERCIALLY IMPORTANT VEGETABLE CROPS

A. Root Crops

Several root crops are grown especially for their edible storage roots. They belong to different botanical families. Only one enlarged (fleshy) underground root is produced per plant for carrot (Apiaceae), table beet (Chenopodiaceae), radish, turnip, and rutabaga (Brassicaceae). Several fleshy roots are produced from one plant for sweet potato (Convolvulaceae). They are consumed either fresh or in processed forms. Most root crops have long storage life and extend the market supply over a long period. There are other minor root crops produced more on a regional basis, such as salsify (*Tragopogon porrifolius*) and black salsify (*Scorzonera hispanica*) of Compositae, parsnip (*Pastinaca sativa*) and celeriac (*A. graveolens* var.

rapaceurm) of Apiaceae, yam bean (*Pachyrrhizus erosus*) of Fabaceae, and horseradish (*Armoracia rusticana*) of Brassicaceae (13, 14).

The carrots, table beet, radish, turnip, and rutabaga are all direct-seeded to well-prepared seedbeds. After emergence, plants are thinned to desired population density. The crops are established more easily under cool-moist conditions (14).

1. Carrots [*Daucus carota* L. ssp. *sativus* (Htoffm.) Arcang]

Cultivated carrots, originating in Afghanistan and central Asia, became popular in Europe around the 13th century. European settlers brought carrots to the U.S. in the 17th century (15, 16). Carrots are now mainly grown in Asia and Europe. The Eastern/Asiatic carrots have reddish purple (anthocyanin-containing) or yellow roots, pubescent leaves, and a tendency for early flowering. Western carrots have orange, yellow, red, or white roots, less pubescent leaves and also a tendency to bolt. The western orange type developed as selections from yellow carrots for high carotenoid content were developed into modern cultivars. In the U.S. carrots are mainly grown for the fresh market with California being the leading state of acreage. For processing, Washington State leads the production (14).

Carrot is a cool-season crop with optimal mean growing temperatures ranging between 16 and 21°C. At these temperatures, root color and shape are also optimized. At a mean temperature of 12~13°C, roots tend to grow relatively long and slender, whereas at a constant 24°C, roots are shorter and thicker. Alternating low night and moderate day temperature also tends to produce long and slender roots. Temperature greater than 30°C, particularly in later stages of development, induces undesirable strong flavor and coarseness in the roots (16).

Carrot cultivars are classified by root shape and date of maturity (14):

a. Danvers: roots medium to long with broad shoulders, tapering toward the tip (tapered tips).
b. Imperator: roots slender, slightly longer and smoothly tapered, late maturing, good for storing, grown for winter market consumption.
c. Nantes: roots nearly cylindrical shaped, medium to long, early maturing, eaten fresh in summer.
d. Chatenay: medium to short and tapered with blunt end, maturing by mid-summer.

Carrots are usually mechanically harvested in 90~120 days of planting. Large-scale carrots are eaten raw, cooked, or processed into juice. The harvest stage is judged by suitability, before carrots achieve their full potential size or weight. Fresh carrots are marketed either topped or bunched with attached tops. Fresh cut-and-peel baby carrots are also available; they may also be cut into short pieces from mature carrots. Carrots are a good plant source of provitamin A, containing about 5~8 mg/100 g of β-carotene (14).

2. Radish (*Raphanus sativus* L.)

Radish is unknown in the wild state. Its origin may be in the eastern Mediterranean or in China, with a long history of cultivation. Now radishes are grown worldwide but consumed in great quantities by the Chinese, Korean and Japanese. Large variations exist in the shape, size, and color of the roots. Radishes were among the first European crops introduced into America by the Spaniards and grown by the early colonists (14, 16).

Radish is a cool-season vegetable crop with optimum growing temperature ranging between 15 and 20°C. At higher temperature, the enlargement of roots is retarded and results in coarseness and pungency (14).

Radishes are commonly grouped into four types (16):

a. Western or small radishes, usually consumed raw as relishes.
b. Oriental radishes, with mild-flavored large roots, usually cooked or pickled in the East.
c. Leaf radishes, consumed as greens by the Chinese, also cultivated for fodder.
d. Rat-tailed radishes, cultivated in Asia with young pods consumed raw, cooked, or pickled.

In the U.S. garden radishes are very popular in home gardens because of short growth cycle and easiness to grow. The white, long-rooted types are also popular in many regions.

3. Table Beets (*Beta vulgaris* L. Crassa Group)

Originating in Europe and Western Asia, the garden beet or table beet is one of the various forms of *Beta vulgaris* of the Chenopodiaceae family (17). It is closely related to Swiss chard, sugar beet, and fodder beet. The leaf beets were developed before the root beets, but the red root beets were cultivated by the Romans. The root beet is grown throughout Europe and America. The red pigment, betanin (a nitrogen-containing anthocyanin), can be used for food coloring. The table beet, introduced in 1800, is one of the most popular home garden crops in the U.S.

Table beets prefer a cool climate with sunny days. Temperatures for optimum growth range between 16 and 19°C. During hot weather, the roots may become tough. Beets are very sensitive to soil acidity, and require a pH of 6.2 to 6.8 (17).

Beet roots may vary in color and shape. The oblate to globe-shaped, red-rooted types are most popular. Most of the commercial production is for processing (14).

4. Turnip [*Brassica rapa* L. var. *rapa* (DC.) Metzz.] and Rutabaga [*B. napus* L. var. *napobrassica* (L.) Reichb.]

Both turnip and rutabaga are members of the Brassicaceae family. They are similar in plant size and general characteristics. Turnip is an ancient crop with its exact origin unknown while rutabaga is a crop of European origin known as Swede in Europe (13, 14). The turnip roots have little or no neck and a distinct taproot, while rutabagas have a thick neck bearing a number of leaf-base scars, and roots containing the taproot and those originating from the underside of the edible root.

Turnips and rutabagas are both cool-season crops, requiring 15~18°C for best root growth. Turnips are easy to grow and require a 2-month growth period. Rutabagas grow less rapidly and require an additional 4 weeks of growth.

Both turnip and rutabaga have swollen roots of different colors or shapes. However, most turnip cultivars are round and white-fleshed, and rutabaga cultivars are globe-shaped with yellow flesh. There are also turnip cultivars grown for green foliage (14).

5. Sweet Potato [*Ipomoea batatas* (L.) Lam]

Sweet potato, a member of the Convolvulaceae family, was originated from tropical America. It was grown for its storage roots in the New World long before Columbus arrived. Storage root of sweet potato is a major carbohydrate source in developing nations. It contains about 27% carbohydrate, provitamin A, vitamin C, calcium, and iron. Tender leaves and shoot tips are also used as vegetables in Southeast Asia. Other than food, sweet potato has industrial applications: as a source of starch, glucose, syrup, and alcohol. It is also used as livestock feed. Older vines are fodder for cattle, swine, and fish. Some vining cultivars can be used as ground cover or for ornamental purposes (18).

Sweet potato is a tender, warm-season crop. The best growing temperatures are 29°C days and 21°C nights, with an optimum mean of 24°C (14, 18). It is a perennial but commonly grown as an annual. Adventitious buds arise from fleshy storage roots, and develop into branching vines quickly covering the ground (18).

Sweet potato is vegetatively propagated by slips or vine cuttings. Thin skin of storage roots is easily broken. Four to seven days of 26.6~29.4°C and 85~90% RH curing promotes the formation of cork layers on wounded surfaces that prevent decay (18).

Storage roots of sweet potato as food have two types: soft-fleshed and firm-fleshed (18):

a. Soft-fleshed (wet): sweeter, softer, medium to deep orange flesh, commonly used for baking.
b. Firm-fleshed (dry): yellow skin with white, yellow, or light orange flesh, mostly used for boiling and frying.

B. Stem and Tuber Crops

Stem vegetables are those grown for their succulent tender shoots (asparagus, bamboo shoots), fleshy stems (kohlrabi, celtuce, strumous mustard), starchy underground tubers (potato), corms (taro), and succulent rhizomes (ginger). Among them, kohlrabi, celtuce, strumous mustard, and asparagus are seed propagated, and others are asexually propagated. The latter have low multiplication rate and need reliable sources for healthy growing materials. In the United States, asparagus and potatoes are of more commercial importance.

1. Potato (*Solanum tuberosum* L.)

The potato, native to the Andean regions of Peru and Bolivia, has been cultivated since early civilization (19). It is one of the most important food crops in the world. The Spaniards introduced it to Europe and Irish immigrants brought potatoes to New England in 1718. The potato is referred to as the "Irish potato" because of its association with the potato famine in Ireland in 1845–1846. Idaho and Washington State are the largest producers of potatoes in the United States (20).

Potatoes are grown for their tubers, the enlarged underground storage stems. In addition to their starch content, the tubers serve as a good source of vitamin C. The potato is also a source of moderate levels of protein and minerals. The protein of potato is richer in lysine than that of cereal, and its biological value is high. Potatoes can be cooked in a great variety of ways. They can also be processed into chips, French fries, flakes, and dehydrated products. French fries and potato chips are popular food items worldwide (19).

Potatoes are asexually propagated by healthy tubers, which are obtained from certified disease-free stocks grown in favorable cool areas. The young shoots develop from the buds or "eyes" of the seed tubers. It is a cool-season crop. The interaction of photoperiod and temperature are the most important factors affecting plant and tuber development. Long days delay the start of tuberization, and temperatures above 30°C prevent tuber initiation. Tubers are usually initiated about 45 days after planting. Following tuberization, tuber enlargement is ideal at mean temperatures of 17°C (19).

Based on skin color and texture, potato cultivars are classified as white, red, or russet. Russet tubers tend to be oblong and relatively dark colored and thick skinned at maturity. There are early, midseason, and late cultivars according to maturity time. Based on starch content or specific gravity, potatoes are grouped into baking, boiling,

and processing types. Russet Burbank, the leading cultivar grown in the U.S., is excellent for frying and baking. Kennebec is an excellent all-purpose potato (20).

2. Asparagus (Asparagus officinalis L.)

Asparagus, a dioecious perennial monocot, is a member of the Liliaceae family (21). The region between the eastern Mediterranean and eastward to the Caucasus Mountains is the center of origin of asparagus (22). It has been cultivated for medicinal and food use for more than 2,000 years. In the 1600s it was introduced to America. Commercial production is centered in California, Washington State, and Michigan (23).

Priced as a gourmet item, asparagus produces tender spears, unexpanded shoots each year. Nutritionally, asparagus is a source of vitamins A and C (22). The plant is composed of ferns, a crown, and a root system. The fern is a photosynthetically active modified stem called a cladophyll. The crown is a series of rhizomes (underground root-like stems) attached to the plant base. Upper portions of the horizontal rhizome contain the buds from which spears arise. Fleshy and fibrous roots develop from the lower portion of the rhizome. The fleshy roots act as storage organs. The carbohydrates stored in crown and roots support spear growth in the spring.

Asparagus grows best under conditions of high light intensity, warm days, cool nights, low relative humidity, and adequate soil moisture. Optimum productivity occurs at 25~29°C during the day and 13~19°C at night (22).

Female plants generally produce larger spears than males, but the males produce more smaller-diameter spears. All male lines are developed for superior productivity with reduced seed production (23).

C. Bulb Crops

Bulb crops are all herbaceous monocot species of Allium and are members of Alliaceae family. The genus Allium contains about 500 species, mostly wild. The few species cultivated as vegetables are grown for their fleshy leaf bases and/or tender leaves. Only onions and garlic have prominent bulbs; all others have "pseudostems." All bulb crops contain the thio-allyl compound alliin which breaks down to give a number of volatile sulfur-containing compounds and give the characteristic odor and pungency of the crop. The chemical substances in onion and garlic especially are believed to be associated with reduced risks of cardiovascular diseases and certain cancers (21, 24).

The bulb crops are propagated by seeds (onion, Welsh onion, and Chinese chives), cloves (garlic), or division (Welsh onion and Chinese chive).

1. Onion (*Allium cepa* L. Cepa Group)

Originating in Central Asia, the common onion has been cultivated for more than 4,000 years (24, 25). As an important flavoring, onion is a very popular crop worldwide. Asia is the largest producer, with Japan and China taking a share of 27%. Columbus introduced the onion to America and it soon spread to all parts of the Americas. Onions have many culinary uses. They can also be processed into dry products such as rings, flakes, and powder for the food processing industry. Quercetin, a flavonoid in onions, provides the protective effect against cancer. Onions can be planted using sets (small bulbs produced in previous season), transplants, and seeds.

Onions are cool-season crops with optimum growth temperature ranging between 13 and 24°C. Onion bulbing is usually favored by long days. However, the length of day required for specific cultivars is different. Under favorable day length, temperatures of 21~27°C are favorable for bulb development. Low relative humidity extending into the harvest and curing periods are desirable (24, 25).

Onions are usually grouped by their day length requirement for bulbing. Within the group, there are early and late maturing cultivars. Onions can also be grouped into mild or pungent (26):

a. Short-day type (European onion): bulbing in response to 10~11 h of day length, mild, soft-fleshed bulbs for fresh use.
b. Intermediate-day type: bulbing in response to 12~13 h of day length, pungent, soft-fleshed for fresh use.
c. Long-day type (Spanish onion): bulbing in response to 14 or more hours of day length, pungent, hard, good for storage.

Bulbs vary in skin color, shape, and size. There are more yellow or brown onion cultivars than red or white cultivars.

2. Garlic (*Allium sativum* L.)

Originating in Central Asia, garlic has been cultivated from at least 2000 B.C. Widely grown in Asia, garlic is eaten not only for the bulbs, but also for its foliage and flower stalks. Each plant develops the bulb underground, and 8~20 cloves together form a cluster covered by white or purplish papery sheath. Garlic has long been believed to have medical advantages in addition to its flavoring use. It is dehydrated to produce garlic powder and garlic oil capsules made of garlic extracts as a diet supplement. In the U.S. most garlic is produced in California for the bulbs. The planting is carried out in late summer and fall from clean and healthy cloves. The plants overwinter in the field and resume rapid top growth after spring. Large cloves produce greater yields than small cloves.

Garlic is a cool-season crop with cloves germinating best in temperatures of 20~25°C. The optimum temperatures for plant growth and bulb development are 18~20°C and 20~25°C, respectively. Bulbing is initiated as temperatures and day length increase (24, 25).

Garlic cultivars can be grouped by their day length requirement for bulbing (26). Into "Late" and "Early" types. They can also be grouped into hardneck and softneck types. In the Orient, the softneck type is preferred for foliage production (27).

D. Cole and Related Crops

Cole crops originated along the East Mediterranean and Asia Minor. They are all members of the species *Brassica oleracea* of the family Brassicaceae. During domestication, many cultivated types with distinct edible parts have formed, including cabbage and Brussel sprouts (head), kohlrabi (thickened stem), cauliflower and broccoli (inflorescence), and kale and Chinese kale (foliage) (28–31).

1. Cabbage (*Brassica oleracea* L. *Capitata* Group)

Cabbage has been used as food for more than 3,000 years. The ancient Greeks held cabbage in high esteem. Cabbage was probably introduced by the Romans or Celts from the coastal regions of the Mediterranean Sea to the chalky coasts of England and northwestern France. Present-day cultivars most likely originated from wild non-heading types. Now cabbage is very popular worldwide and is grown extensively in Eastern Europe and the Far East (30).

Cabbage is a herbaceous biennial but grown as an annual. During vegetative development, the plant produces a succession of out-spreading leaves on a stem with very short internodes. About 20 new leaves incurve, overlap, and form a compact head. Leaves are broad, thick, fleshy, heavily veined, and covered with wax. Cabbage is durable for storing and shipping. It ranks higher than tomato but lower than spinach in mineral content (30).

Cabbages are grown for three types of markets: fresh market, late or stored market, and the sauerkraut market. There are several types of cabbage head (31):

a. Wakefield: pointed, small, pointed head, early maturing.
b. Copenhagen market: round, medium-large head, early maturing.
c. Flat Dutch: large, flat, very solid head.
d. Danish Ballhead: round-oval, medium-sized head, relatively late maturing, storable.
e. Savoy: medium-large, flat-globe-shaped head, crinkly leaves, good quality for fresh market.
f. Red: round, medium-sized heads, reddish-purple leaf.

2. Cauliflower (*Brassica oleracea* L. var. *botrytis* L.)

Both cauliflower and broccoli are of the cabbage family with cauliflower being more exact in environment and cultural requirement. Cauliflower is grown for the curd (head), which is the shortened shoot with bracts and undifferentiated flower parts at the terminal end of the plant axis. The curd may be white, creamy, yellowish green, purple or orange. However, pure white curds are preferred. Cauliflower was first mentioned in the U.S. in 1806. California leads in commercial production (30).

Optimum temperatures for growth are 15~20°C with an average maximum of 25°C and minimum of 8°C. Many tropical cultivars are early matured and require higher temperature and long days for good vegetative growth before forming curd. After the white head has developed to 5~7.5 cm, it is protected from sunburn and turning green by tying the outer leaves together over the head center or just bending a few outer leaves to cover. In Asia, blanching is achieved by covering the developing head with a piece of spun-bonded material which can be reused (28, 29).

Cauliflowers are generally grouped into three major types by maturity (30):

a. Super Snowball (early): dwarf with medium sized leaves and somewhat flattened, and maturing in 50~55 days after transplanting.
b. Snowball (mid-season): larger and later, large rounded and very dense curd, maturing 70~80 days after transplanting.
c. Winter (later): grown where winters are mild, maturing 150 or more days after transplanting.

The later the maturity is, the larger the curd. In California cauliflowers may also be grouped by curd size and density.

3. Broccoli (*Brassica oleracea* L. var. *italica* Plenck)

Broccoli evolved from wild cabbage earlier than cauliflower and was cultivated by the ancient Romans (28). However, it was relatively unknown in England until the 18th century. It was grown in the U.S. in the early 1800s (28–30), but its popularity came much later.

Broccoli is similar to cauliflower in the structure of its flower head. Unlike cauliflower, the edible plant portion is the inflorescence consisting of fully differentiated immature flower buds and the tender portion of the upper stem. These flower buds form a compact head. If the terminal inflorescence is removed, secondary inflorescences may develop in the axils of lower leaves.

Broccoli is the most nutritious of the cole crops in vitamin content, calcium, and iron. Its anticancer properties have been often reported. Per capita consumption

continues to increase. California is the largest producer in the U.S. (30).

Broccoli is adapted to a range of soil types and can tolerate heat to a greater degree than cauliflower. The optimum temperatures for plant growth are 20~22°C and 18°C for head development. It is sensitive to boron deficiency (28, 29).

There is no major subgroup for broccoli. Cultivars of Calabrease, Green Comet, Green Duke, and Premium Crop are popular (30).

E. Other Leafy Vegetables

Greens are grown for leafy portions both for cooking and salads. They are high in mineral and vitamin contents. All greens are more of specialty crops except spinach, which is produced on a large commercial scale. All greens in North America are cool-season crops except New Zealand spinach which is a warm-season crop (32).

Lettuce, endive-escarole, and chicory are leafy salad vegetables. Their tender leaf blades with a little petiole and stem are used fresh or raw in salads. They are excellent dietary sources of bulk and fiber. Only lettuce is grown on a large scale (34).

1. Chinese Cabbage, Pe-tsai (*Brassica rapa* L. Pekinensis Group)

Chinese cabbage is native to China and eastern Asia (32). Its recent popularity has resulted in a considerable increase in production in Europe and the U.S. It produces an elongated head. Moderate day and cool night temperatures are essential for productivity and quality. Temperatures ranging between 13~21°C are suitable for its growth (28).

High temperature during head formation causes a loose head and increased incidence of tipburn. There are several types of head: elongated, shorter, tall, and short and compact (28, 32).

2. Spinach (*Spinacia oleracea* L.)

Spinach is thought to be native to Central Asia. It ranks second only to broccoli in total nutrient concentration. Spinach is used fresh and for canning, freezing, and pureed baby food. Due to a short growth period of 30~50 days, annual spinach is cultivated between planting of other vegetable crops (33).

Spinach is usually dioecious, rarely monoecious. Dioecious types produce extreme male and vegetative male. The extreme male plant is small. While vegetative male and female plants produce more foliage and flower later, they are the preferred types for commercial production (33).

Spinach is a hardy, cool-season vegetable. It prefers 15~20°C for growth, 15°C for seed germination. Spinach is direct-seeded. Sized seed and specialized belt seeders are used to reduce seeding rate (33).

Cultivars of spinach are classified into three types (33):

a. Savoy type: large, fresh market use, suitable for long distance shipment for less anaerobic respiration.
b. Smooth-leaved: mostly for processing, preferred for easy washing of leaves.
c. Semi-savoyed type: for both fresh market and processing into frozen packs.

3. Lettuce (Lactuca sativa L. var. capitata)

Lettuce is native to the Mediterranean and inner Asia Minor. Until the 18th century, lettuce was widely used in the Americas. Now the U.S. leads in the production and consumption of lettuce in the world. Lettuce cannot be processed. It is a leafy salad vegetable (34).

Lettuce prefers 24°C for seed germination, and 18~23/7~11°C of day/night temperatures for growth. Lettuce is direct-seeded or transplanted. Coated or pelleted seeds are direct-seeded by seeders. Osmo-conditioning of seeds and fluid drilling are also used (34).

There are four distinct types of lettuce (34):

a. Crisphead type (Iceberg): large and solid head, usually over 0.9 kg and 15.2 cm in diameter, brittle and crisp leaves with prominent veins and midribs, very large outer leaves in medium to dark green, inner leaves tightly folded in light color, most durable for shipping and handling.
b. Butter-head type (Boston, Bibb, or semi-heading): smooth, soft, pliable leaves forming a loose head, better table quality and more delicate flavor than crisp-head type, leaves easily torn and bruised, mainly for local markets, often for greenhouse production.
c. Cos type (Romaine): long and narrow leaves, upright plant, long and somewhat loose heads, more tolerant to stress, best for local markets.
d. Loose-leaf type (bunching): not heading, early, easy to grow, popular in home garden, not suitable for long distance shipment because of its short market life, produced primarily in greenhouses in winter.

Stem lettuce or celtuce (*L. sativa* var. *asparagina* Bailey) is grown for its thick, succulent stem. It is usually cooked in stews and other dishes, or pickled. Stem lettuce is popular in the Far East, but not widely grown in the U.S.

4. Celery (Apium graveolens L. var. dulce)

Celery originated in Sweden. It was initially used for medicinal purposes. Now the long, fleshy, but low nutritive content petiole is harvested for its flavor and texture,

mostly for the fresh market. It is used mainly as a salad crop, in soups, and a small portion is dehydrated. The seeds are also used as a condiment for flavor (35).

Celery is a biennial but grown as an annual. Outer ribs along the petiole's abaxial length are composed mainly of thick-walled collenchyma cells responsible for mechanical strength and stringiness. Celery demands a particular climate. It prefers 15.6~18°C for growth. The production costs per acre are the highest among all vegetable crops (35).

Celery cultivars are classified into two types (2).

a. Golden (yellow or self-blanching) type: golden foliages, earlier, less vigorous, thinner petioles, more sharply ribbed, stringy, more inferior in eating and keeping quality, primarily for specialty markets.
b. Green type: green foliages.
   (i) Utah type: predominate, many attractive and well-overlapped petioles, a well-developed heart.
   (ii) Summer Pascal type: excellent eating quality, generally lacking compactness, few petioles, poor heart development, less affected by cold, less likely to bolt in early planting.
   (iii) Slow Bolting type: less affected by cold, less likely to bolt in early planting.

Celeriac or knob root celery (*Apium graveolens* var. *rapaceum*) is grown for its enlarged roots. Smallage (*A. graveolens* var. *secalinum*), grown long before celery, is most popular in Asian and Mediterranean regions. It produces rosettes of long, thin petioled leaves (16, 36).

F. Fruit Vegetables

Fruit vegetables are grown for their fruits for consumption. They are mainly grouped into cucurbits, legumes, and Solanum fruits. Within the same botanical family, different crop species have similar cultural requirements and pest problems. Other fruit vegetables include okra and sweet corn.

1. Cucurbitaceae

The Cucurbitaceae, a very important food crop family, has been consumed and utilized by human beings for more than 10,000 years. The gourd family consists of 118 genera, only 9 of which are used as vegetables. Among them, three genera, i.e., *Cucumis, Citrullus*, and *Cucurbita,* are of more commercial importance in the world; however, the others are of greater importance in Asia or other regions. These include the genera *Benincasa, Lagenaria, Luffa, Momordica, Sechium*, and *Trichosanthes*. The genera *Cucurbita* (pumpkin and squash) and *Sechium* (chayote) were domesticated in the Americas while the others were of old World origin (originating in Asia and Africa). All are warm season crops and very susceptible to cold injury. However, some types adapt to cool and dry climates. They are herbaceous annuals except chayote which can be grown as perennial. These cultivated species of the Cucurbitaceae family have similar plant habits and cultural methods. They are also known as cucurbits or vine crops. The plant is either a climbing or trailing vine or a bush type. The bush type is of determinate growth and usually bears earlier than vine type. The root system consists of a deep taproot and highly branched short laterals with horizontal distribution similar to the range of plant canopy. They are grown mainly for their fruits. Other parts of the plant may also be consumed for food such as the seeds of watermelon and squash, the flowers of squash and luffa, and the shoots of chayote. Indeterminate vines continue to grow until the plant dies. Side shoots emerge from the leaf axils. Large leaves are borne singly and alternate (38–41).

Most cucurbits are monoecious, producing female and male flowers at separate nodes in the same plant. Usually female flowers are borne singly and male flowers either singly or in cluster in the leaf axils. Melons have andromonoecious type, producing perfect flowers and male flowers in the same plant. The gynoecious types, producing only female flowers, are also available in cucumber. The sex expression, a genetic trait, can be modified by environmental factors and growth regulators. High temperature and long days favor male blooms, while low temperature and short days favor female flowers. The use of ethephon induces female flowering while gibberellic acid and silver nitrate promote male flowers. The plants can be manipulated for the purpose of seed production (38–41).

Most cucurbits can be grown from direct seeding or by transplanting; however, special care is required for the latter practice (43). The seedlings are grown in individual containers to 3~4 true leaf stage to be transplanted. Most crops are direct-seeded in the field in the U.S. The plant spacing varies according to the plant types, with closer in-row spacing for small vined and bush types than for large vined ones. The plastic mulch can be used in the field to raise the temperature for early plantings. A critical period for water occurs during blooming and early fruit set. For sufficient pollination of the plants, the beehives may be brought into the field after female flowers bloom. Cultivation, weed control, irrigation, and pest control are managed similarly to all vine crops (39, 42).

a. Bitter melon (Momordica charantica L.)

Bitter melon, indeginous to the tropics of India or Southeast Asia, is very popular in tropical areas. It is distinct from other vegetable cucurbits by its delicate foliage, slender stems, and simple tendrils. The fruit surface is studded with protuberance. The bitterness of the fruit is due to momordicosides, glycosides of tetracyclic triterpenoids. Immature fruits are less bitter and can be

eaten raw or cooked. They may also be picked or dried for later use. At maturity the fruits turn orange and split open at the blossom end, to expose the bright red fleshy arils surrounding the seeds. The sweet arils can be eaten. Young shoots, leaves, and flowers are eaten as potherbs in India and southeast Asia. All parts of the whole plant are employed as folk medicine. The fruit of bitter melon is a good source of vitamin C, and has been also investigated as an agent inhibiting growth of the HIV virus.

Bitter melon requires warm, sunny areas with fertile, high water-retaining soils of pH 5.5~6.5. The optimum temperatures for seed germination are 30~35°C, for vine growth and fruiting, 25°C. Commercial crops are produced either on ground or on support in arch shape or in triangle shape. The fruits are usually protected from light and fruit flies with paper bags or crude fibers (42, 44).

The cultivated forms of bitter melon are grouped by fruit color into white, light green, and green; by fruit shape into spindle, pear-shaped, or elongated; by fruit size shape into regular (up to 30 cm long and 10 cm in diameter) and wild (up to 8 cm long and 4 cm in diameter); and by the shape of protuberence.

b. Pumpkins and squashes (Cucurbita spp.)

Pumpkins and squashes consist of four of the five cultivated species of the genus *Cucurbita*. They originated in tropical and subtropical America and have been cultivated for thousands of years. However, different types of pumpkins and squashes are not easily distinguished by botanical names or by morphological characteristics. The inter-crossability among different types and among species makes clear classification difficult. The classification is largely based on culinary use and stage of maturity. *C. moschata* is believed to have originated in Central America or northern South America, *C. maxima* in the Andes Mountains of South America, and both *C. pepo* and *C. argyrosperma* in northern Mexico and the southwestern U.S. After pumpkins were introduced to China and Japan, they became important vegetable crops there and many Oriental types were derived. This gives much diversity in fruit shape color and size to the crop (42, 44).

The crop requires a warm season with temperatures between 18 to 30°C for optimum growth. Optimum temperatures for seed germination are 25~30°C, and for fruit development, 25~27°C. Growth period from planting to harvest ranges from 40~60 days for summer squash to 80~140 days for pumpkins and winter squash. For early production, a light loamy soil is desired. Sunny, dry weather is important for successful pollination by honeybees and good fruit development (39, 42, 43).

C. maxima, in general, has better fruit quality in flavor and texture than *C. moschata*. But *C. moschata* has disease resistance and with stands high temperature better than *C. maxima*.

In the U.S. *Cucurbita* species with round and orange fruits are called pumpkins, while those that have fruits of other colors and shapes are called squashes (39, 43):

(i) Summer squash: Commonly *C. pepo*, grown for their immature fruits with soft skin, including yellow crook neck and straight neck, scallop squash, cocozelle, and zucchini.
(ii) Winter squash: including all four *Cucurbita* species, grown for mature fruits usually with hard rind, such as acorn, hubbard, butternut, banana, and orange marrow.
(iii) Pumpkins: mostly *C. pepo* and *C. moschata*, grown for their ripe fruits used as an ingredient in pies.

The naked-seeded pumpkins are grown for their seeds to be roasted for snacks. *C. maxima* can grow to jumbo size (22~45 kg) for exhibition purposes.

c. Cucumber (Cucumis sativa L.)

Both cucumber and melon are members of genus *Cucumis*; each belongs to a different subgenus. Cucumber is indigenous to India and has been cultivated for more than 3,000 years. It also has a long history in China where it is considered a secondary center of genetic diversification. Early travelers brought cucumber to Mediterranean countries (42). In the early 14th century, cucumber was cultivated in the U.K. It was introduced to the U.S. by 1539. Now cucumber is widely used as fresh and processed products. The leading U.S. States for fresh market cucumbers are Georgia and Florida, while Michigan, North Carolina, and Texas lead in processing type production (43).

Cucumber requires temperature of 30°C during the day, 20°C at night for optimum plant growth. The seeds germinate best in 25~30°C, and in this range, fruits develop rapidly. The crop growth rate increases steadily as the temperature increases to 32°C (42, 43). Glasshouse cultivation is also common for the cucumber in Northern Europe, Asia, and the Middle East.

Cucumbers are divided by use into slicing type and pickling type, by culture into outdoor type and greenhouse type (39, 43):

(i) Pickling cucumber: fruits cylindrical in shape with blocky ends and a medium green color.
(ii) Slicing cucumber: smooth, symmetrical, and white-spine fruits longer than pickling type, with glossy, dark-green skin.
(iii) Greenhouse cucumber: mostly parthenocarpic (set fruit without pollination).

d. Wax gourd (Benincasa hispida (Thunb.) Cogn)

Wax gourd is the only species of the genus *Benincasa*, which is named for Italian botanist Count Benincasa. The

species name refers to the pubescence on the foliage and immature fruit. Of Indo-Malayan origin, wax gourd is an important vegetable in India, China, the Philippines, and elsewhere in Asia. Both mature and immature fruits are consumed, either cooked or picked. The mature fruits harvested in summer can be stored at 13~15°C and 70~75% RH for over 6 months. The name winter melon refers to its long storage life. The fruits are especially valued for their high water content, bland taste, and cooling properties. The sliced pulp is dried for later use, and sometimes candied in sugar syrup. The candied fruits are boiled to make the popular summer drink, wax gourd tea, served as a seasonal and festival specialty. The Chinese steam the entire mature fruit as a soup tureen with various stuffed ingredients. In addition to the food value, wax gourd is also important in traditional medical practices. The rinds and seeds are part of various medications throughout Southern Asia. The fruit wax is sometimes collected to make candles. Mo-kwa (*B. hispida* var. C*hieh-qua* How.), a botanical form of wax gourd, is usually grown for its immature fruit which is about 0.4~0.7 kg and 18~25 cm long. It is high yielding and more heat tolerant.

Wax gourd grows best in sunny, moderately dry areas. It requires fertile, well-drained soils of pH 5.5~6.4. The optimum temperatures for seed germination are 30~32°C and for plant growth and fruiting 24~27°C (42, 44). The cultivated forms of wax gourd can be divided by fruit shape into long cyclindrical and short cylindrical; by fruit size into small (1.5~5 kg) and large (7~20 kg); and by skin color and the presence of waxy white bloom on fruits into dark green, light green, and waxy.

e. *Other Cucurbits*

As many Asian immigrants moved to the U.S. other cucurbits of Asian or African origin become common in areas with large Oriental populations. These crops include immature fruits of smooth luffah (*Luffa aegyptaca* Miller), angled loofah [*L. acutangula* (L.) Roxb.], bitter melon (*Momordica charantia* L.), bottle gourd [*Lagenaria siceraria* (Mol.) Standl.], wax gourd or Mo-kwa, the immature fruits of *Benincasa hispida.* Among these, bitter melon also has medical use (42, 44).

2. Legumes

Vegetable legumes, all dicotyledonous annuals, are members of the Leguminosae (Fabaceae) family. The immature fruits are important vegetables and the dry seeds are an important staple food. In some, the leaves, tender shoots, or the roots are harvested and used as vegetables (47). Legumes may be classified according to the position of the cotyledons in the germinated seedlings. Epigeal is the type where cotyledons are above the ground; hypogeal is the type where cotyledons remain underground. Many legumes can assimilate their own source of nitrogen as a result of a symbiotic relationship with bacteria of *Rhizobium* in their root nodules. However, before successful symbiotic relationship is established, the crop still needs adequate supply of nitrogen in the soil for growth (46, 47).

Peas and broad beans are cool season crops while beans are warm season crops, intolerant of frost. Each legume species has strains or varieties adapted to a particular range of conditions. All vegetable legumes are direct-seeded to the field. The pole type or the tall cultivars are usually supported or trained to poles. Generally bush types require less time for flowering than the pole cultivars (48).

a. *Common bean, Snap bean (Phaseolus vulgaris L.)*

Common bean is the most widely cultivated bean in the genus *Phaseolus*. Over 7,000 years ago, on common bean originated in Central and South America. It was introduced to Europe in the 16th century and soon spread to other parts of the Old World (47). Beans are marketed fresh, canned, or frozen. Wisconsin is the largest bean-producing state for processing and Florida leads in fresh market production (48, 49).

The optimum soil temperature range for germination is 25~30°C. The optimum temperature range for growth is 16~30°C. Temperature above 30°C at flowering can cause flowers to abort. Vine types are adapted to cooler temperatures than bush types. The desirable maturity characteristics are undersized seed development and low sidewall fibers (47–49).

Common beans are divided into bush and vining types according to growth habits, and fresh market and processing cultivars according to uses. Based on pod color, common beans are either green-podded or yellow-podded, sometimes even purple-podded. Beans may also be classified by shape of the pod or color of the seeds (48).

b. *Lima bean (Phaseolus lunatus L.)*

There are two types of lima beans, the large-seeded and small-seeded types. They originated in both Central and South America before 5000 B.C. (47). The Native Americans spread the crop and it became an important vegetable crop in the U.S. It can be consumed fresh, frozen, or canned. The lima bean growth habit is similar to the common bean. California is the only state to harvest dry lima beans, both baby lima beans and large-seeded ones (48, 49).

Lima beans require a slightly warmer climate than common beans (47). They germinate at 15~30°C with an optimum soil temperature of 25°C. Mean monthly temperatures of 15~24°C are necessary to grow the crop. The small seeded type, being less restrictive, can tolerate hotter and drier conditions than the large-seeded one (47).

The U.S. cultivars have seed coats of white, creamy, buff, or light green. The large-seeded type is narrowly adapted, but is of better quality. The small-seeded type is grown widely (48):

(i) Bush type: productive with small seeds, ex. Henderson, Early Thorogreen.

(ii) Pole type: largely for home gardens (Pierce), producing small seeds.

c. *Peas (Pisum sativum L. ssp. sativum)*

As one of the most ancient crops, peas originated in the eastern Mediterranean region and Near East. Peas can be dated to 7,000~9,000 years ago (47, 48). Dry peas were utilized as food in Europe from very early days and green peas were not used until the 16th century (46). The edible podded types evolved in more recent times. In the Orient, the tender shoots of peas are used as greens (50). The term English pea reflects many cultivars of peas developed and grown in England. Columbus brought the pea to North America where it quickly spread to all parts. Commercial production in the U.S. is primarily for processing, including canning and freezing. Seeds are either smooth or wrinkled; the former is starchy and the latter is sweeter (48, 49).

Peas thrive in cool and moist weather. The crops grow best at mean temperatures of 13~18°C. Long days and cool temperature accelerate flowering. The smooth-seed types are more adapted to cool weather conditions than the wrinkle-seeded types. The edible podded types are more adapted to warm conditions than the green pea types. Heat units are commonly used to predict harvest dates for the processing industry (47).

There are several types of peas, including shelled peas, edible podded peas, and dry peas. Pea cultivars are classified by seed color, growth habit, seed quality, and pod appearance (48, 49):

(i) Dry peas: light green seed color, starchy.
(ii) Canning peas: most determinate, light green and sugary seeds.
(iii) Freeze peas: most determinate, dark green and sugary seeds.
(iv) Edible podded peas: pods lacking the stiff, papery inner parchment, the whole pods consumed.
  (a) Snow peas: sugary seeds slightly enlarged.
  (b) Snap peas: sugary seeds more developed and pod wall thickened.

d. *Southern pea [Vigna unguiculata (L.) Walp. ssp. unguiculata (L.) Walp.]*

The origin of Southern pea is rather obscure. It is possibly of tropical African origin (47) or from India (47, 48). There are three distinct cultivar groups in *Vigna unguiculata*, characterized by growth habit and pod character (48). The immature pods of all three are used as vegetables. The yard-long bean is more popular to the Southeast Asians with pods ranging from 30 to 75 cm in length. Catjang cowpea has erect small pods 7~12 cm long with small and cylindrical seeds. It is more common in India. Southern peas, also known as black-eye peas, are mostly confined to the southern U.S. They are grown primarily for the green shelled seeds, a large amount of which are processed and canned or frozen (48).

Southern pea grows best in hot, dry climates. Optimum temperatures for growth are 27~30°C during the day and 17~22°C at night. It tolerates heat better than common beans or lima beans. Fresh market peas may be harvested 16~17 days after bloom (47).

Cultivars of southern pea differ in maturity, in pod color, crowding of seeds in the pods. Black-eye peas refer to those having a dark outline or eye around the hilum. Other major types include purple hulled and creamy yellow. The large cultivars are well suited for pick-your-own and local sale (49).

3. Solanum Fruits

Solanum fruit crops, all of tropical origin, are members of the Solanaceae family. They include tomato, peppers (both bell pepper and chili), and eggplant, all grown as annuals for commercial production. Tremendous phenotype variations are available in fruit shape, size, and color. They are warm season crops with eggplant being more heat tolerant than pepper and tomato. Chili pepper can grow in higher temperature than bell pepper. The potato, in the same genus as the eggplant, is discussed under stem and tuber crops (20, 52).

These crops share similar disease problems. In some countries, grafting culture of tomato and eggplant on resistant stocks is used to combat soil-borne diseases. Early production can be forced by planting transplants to fields mulched by plastics. Direct seeding can be successfully used for later, especially processing, production. Transplants are usually greenhouse grown in plugs. Tomato and bell pepper are grown in glasshouses or other protective structures in some regions where climate limits field production (20).

a. *Tomato [Lycopersicon esculentum (L.) Mill]*

The tomato originated in the Andes of South America and evolved from the cherry tomato (*L. esculentum* var. *cerasiforme*). However it was introduced from Mexico to Europe early in the 16th century (37, 52). Early use of tomato was hampered by the belief that it was poisonous, because many of the Solanum species contain alkaloids. The tomato was introduced to the U.S. in 1710, and was produced in New Orleans in 1779 (51, 52).

On a worldwide basis, tomato is one of the most important vegetables or salad plants (37). The acid sweet taste and unique flavor account for its popularity and diverse usage. Although not among the most valuable crops in nutrient contents, tomato is an important source of vitamins A and C because of the substantial per capita consumption. The U.S. leads in total tomato production and processing. California

and Florida lead the nation in fresh market and processing tomato, respectively (20).

Tomato requires temperatures of 25~30°C for optimum germination. Day temperatures of 25~30°C with night temperatures of 16~20°C are optimal for growth and flowering (20, 51, 52). Fruit set is best between 18~24°C with night temperatures more critical than day temperatures. Cultural practices of pruning, staking, and caging are used to increase light interception and aeration for production enhancement.

Tomatoes are classified as determinate and indeterminate in growth. Higher planting densities are given to the former type to compensate for their lower yield potential. Tomatoes are grouped into fresh market, processing, and home garden types according to use. Processing cultivars are usually determinate and ready for harvest in 75 days after field setting. The greenhouse tomatoes are indeterminate and the home garden types may be either determinate or indeterminate. Variation in shapes (globe to pear), fruit color (yellow, pink, and red), and size (cherry, beef) exist in different cultivars (20).

b. Pepper (Capsicum annuum L.)

With a long history of cultivation of more than 7,000 years, peppers are native to tropical and subtropical America (52). Among the five domesticated species in the genus *Capsicum*, *C. annuum* is the most widely cultivated and economically important species and includes both bell pepper and chili pepper. *C. frutescens* has small fruits. Tabasco is the best known cultivar and is grown commercially for making Tabasco sauce (20, 54).

Columbus introduced peppers to Europe, and subsequently to Africa and to Asia. Peppers were soon integrated into people's cuisine due to the characteristic flavor and pungency. In addition to use as food or spices, peppers are also used in pharmaceutical products such as pepper plaster. The pepper is an indispensable food in many countries. Asia is the largest producer with China leading in world production (53). In the U.S. New Mexico leads in chili pepper production while California leads in bell pepper production (55). Peppers are good sources of vitamins C and A.

The pepper is a warm-season crop. The optimum temperature for pepper growth and development is higher than that for tomato. The seeds germinate rapidly in 25~30°C. The base growing-degree-days temperature is 18°C. The average temperature for optimum growth is 21~30°C, for fruit set 20~25°C, and for color development 18~24°C. The plants are not photoperiod sensitive for flowering. The small fruit cultivars are more tolerant to high temperature extremes (51–53).

Peppers are classified into two main types, the sweet-fleshed fruit and the pungent fleshed fruit. They can also be grouped by fruit appearance and use. Classified by pod type, there are bell, pimiento, cheese, ancho, cayenne, Cuban, jalapeno, serrano, wax, and cherry, among others. Important commercial types are listed as follows (20, 54):

(i) Bell type: large blocky fruit with three to four lobes and thick flesh, mature green fruits harvested for fresh market, mature colored fruits in red, orange, or gold also in commercial markets.
(ii) Cherry peppers: round or slightly flattened fruits, orange to deep red when harvested, sweet or hot, small or large.
(iii) Chili type: pungent and thin flesh fruit, from cherry size to slender fruit up to 20 cm long.
(iv) Pimento peppers: fruit sweet with thick wall, conical or heart-shaped, turning red at maturity.
(v) Tabasco peppers: fruits 2.5~7.5 cm long, slim, tapered, and highly pungent.

Peppers can be fresh, canned, brined/pickled, frozen, fermented, dehydrated, and extracted for oleoresin (53).

c. Eggplant (Solanum melongena L.)

Native to India, eggplant is not as popular as tomato or pepper as a vegetable. However, it is widely used in China, India, Japan, and many Mediterranean countries. The name eggplant is believed to reflect the early forms with small, white fruits resembling eggs. There are in general three forms of eggplants: round egg-shape fruits, long slender fruits, and dwarf plant form (20, 51, 52). Fruit tissues contain high levels of phenolics; upon cutting they are quickly oxidized by enzymes, resulting a brown discoloration of the flesh (51).

Introduced to American gardens in 1806, the eggplant was primarily an ornamental curiosity until the 20th century. Commercial eggplant acreage is primarily located in Florida and New Jersey (20).

Eggplant is very sensitive to low temperatures and it requires a relatively long, warm growing season. Optimum temperatures for seed germination are 24~32°C, for growth and development, day temperatures of 22~30°C and night temperatures of 18~24°C. The elongated fruit type tends to be more resistant to high temperature than the round fruit type. To have high yield, plants require high light intensity (51, 52).

There are two basic types of eggplants based on fruit shape (52):

(i) Standard oval shaped type: large, smooth, glossy purplish-black fruit.
(ii) Oriental type: long slender purple-black fruit.

There are also types with white, yellow, or apple-green-colored fruits.

4. Sweet Corn (*Zea mays* L.)

Sweet corn is a monocot of the Poaceae (Gramineae) family. An ancient crop dating from about 5,000 B.C., corn originated in the highlands of central and southern America. Sweet corn originated from a mutation of grain corn (56). Corn was not popular initially because it was difficult to store. Commercial sweet corn production began about 200 years ago in the U.S. The U.S. leads the world in sweet corn production. In addition to fresh use, a considerable volume is processed by canning and freezing of kernels after removal from the cob (57).

Corn plants are monoecious with male flowers borne as the terminal inflorescence on the main stem and female flowers borne as lateral ear shoots. The basal nodes of an ear shoot are concentrated with little internode space. They form a tight husk around the developing ear. Each individual kernel is a single-seeded fruit composed of a small embryo and a large endosperm. Sweet corn kernels contain less starch, and more sugar and water-soluble polysaccharides which are responsible for the creamy texture (56).

The optimum temperature range for corn growth is 24~30°C. In general, the warmer the air temperatures, the faster the corn will grow to maturity (57). However, moderate temperatures are optimum for carbohydrate accumulation. Cool nights are particularly important at harvest time. Plants flower sooner when days are short. The crop is sensitive to soil acidity, requiring a soil pH of 6.0~6.8. It requires high water, but not waterlogging and high fertilization.

Sweet corn cultivars are classified by kernel color (yellow, white, and bicolor), maturity date (early and late), and use (market, freezing, canning, or shipping) Classified by kernel sweetness, there are the following (57):

(a) Standard sweet corn: containing the recessive *su 1*, traditional sweet corn flavor and texture.
(b) Modified sugary sweet corn: containing the sugary enhancer gene *se*, high sugar, thin pericarp.
(c) Supersweet corn: containing recessive *sh* 2 gene, higher in sugar, lower in starch, tougher skinned.

G. Bean Sprouts

Bean sprouts are produced mostly from germinated seeds of mungbean [*Vigna radiata* (L.) Wilcz] and soybean [*Glycine max* (L.) Merr]. The use of bean sprouts has long history in China. The seeds are soaked for 24 h, sprouted, and allowed to grow in the dark for several days before harvest for consumption. The etiolated hypocotyls and young cotyledonary leaves are eaten with other vegetable dishes (58). The sprouts are a good source of vitamins B_1 and B_2 and dietary fiber. More than 20 kinds of sprouts have been developed. Among them, pea sprouts and alfalfa sprouts are popular vegetable sprouts grown from legume seeds. Light exposure a few days before harvest produces pea sprouts green in color. Sprouts are grown under light to harvest green sprouts. Daily watering is necessary. The growth of sprouts does not require supplemental nutrients but depends on the storage reserve of the seeds. Given optimum temperature for seed germination, water for sprouts to grow, and proper aeration, bean sprouts can be produced year round in controlled environments (58).

ACKNOWLEDGMENT

21 Nutritional Value of Vegetables

C. Alan Titchenal and Joannie Dobbs
Department of Human Nutrition, Food and Animal Sciences, University of Hawaii

CONTENTS

I. INTRODUCTION

Vegetables are considered a significant part of all major dietary guidance systems. Their many chemical elements and compounds are known to affect thousands of physiological functions and to promote health (1). This chapter provides an overview of nutrients and non-nutrient phytochemicals commonly found in vegetables, along with a description of the basic nutrient profile for vegetables in general. Factors affecting nutrient variations, both naturally occurring and due to processing, are summarized. Lastly, this chapter reviews many of the purported health benefits derived from various vegetable phytochemicals.

II. NUTRIENTS

A. Nutrients

About a century ago, researchers observed that growth and survival of animals was directly affected by various individual components in foods. These components were termed nutrients and were to be considered required for normal growth and health. In the early 1900s, researchers began to focus on the disease-preventing properties of vegetables. McCollum and colleagues realized that the addition of vegetables to a seed diet was necessary to prevent deficiency conditions in omnivore species (2). Researchers then realized that a diet deficient in even a single essential nutrient (required from food), could result in a dietary deficiency disease or even death (3).

Strictly speaking, nutrients are compounds that cannot be synthesized by the human body from other chemicals or cannot be synthesized rapidly enough to meet the needs of the body. Thus, by the classical definition of nutrient, the term "essential nutrient" is redundant. However, the terms "non-essential nutrient" or "dispensable nutrient" are sometimes used to describe chemical compounds that are contained in foods and have a function in the body, but are typically synthesized by the body in adequate amounts.

As nutrition science evolved, a third category of nutrients has been identified as "conditionally essential." This terminology is used to describe substances that may become essential under specific conditions that reduce the body's capability to synthesize adequate amounts of the compound. This may be caused by changes in physiological demands due to a genetic defect, a disease condition,

the stress of surgery, or the use of certain drugs such as statins and Co-enzyme Q10 (4,5).

Presently, there are approximately 50 individual food elements and chemical compounds identified as essential nutrients. These nutrients are classified into six broad chemical categories based on chemical structure and functions including water, proteins, fats, carbohydrates, vitamins, and minerals. Table 21.1 lists nutrients by essentiality category and the basic physiological functions of providing energy, structure, or regulation of the body's thousands of chemical reactions.

Nutrients frequently act in concert to regulate specific physiological functions. For example, calcium, magnesium, and potassium regulate muscle contraction and relaxation (7,8). Vitamins B-6, B-12, and folate function in concert to prevent the excessive accumulation of homocysteine, which in turn reduces the risk of coronary artery disease (9).

The proper proportion of specific nutrients is also important in maintaining health. For example, the ratio of omega-3 fatty acids (primarily from fish oils and some vegetable oils) to omega-6 fatty acids (primarily derived from many vegetable oils) is an example of the essentiality of correct nutrient proportions. Both types of fatty acid are essential for regulating eicosanoid synthesis which in turn affects physiological functions such as blood pressure, inflammation, and blood clotting. The appropriate proportion of omega-3 to omega-6 fatty acids is 1 to 4 up to 1 to 10. An imbalance of these fatty acids appears to be related to various chronic health problems (10).

Nutrients, even essential nutrients, are known to be harmful in excessive amounts. The Institute of Medicine has published both the recommended levels of intake and the tolerable upper intake levels for many nutrients. These recommendations provide guidelines on what constitutes generally safe ranges of intake and what levels of a nutrient may be excessive and even harmful to humans (11–14).

The use of certain drugs may require nutrient intake to be maintained within a more narrow range. For example, excess vitamin K intake, even from naturally occurring plant sources, can interfere with the function of common blood anticoagulant drugs (15).

B. Nutrient Profiles

Foods from various common food groups (meat and poultry, milk products, fruits, vegetables, grains, and beans) have classic nutrient profiles or distinctive nutrient fingerprints. Typically, these nutrient profiles are expressed as the amount of various key nutrients typically contained in 100 grams of edible portion.

Compared to other food group nutrient profiles, vegetables provide the nutrient characteristics that most consumers perceive as health promoting (Table 21.2). Vegetables contain no cholesterol, very little fat, sugar, and sodium, yet provide concentrated sources of many vitamins and minerals. There are literally hundreds of vegetables, with the majority of these cultivated in Asia (17). Table 21.3 presents representative nutrient ranges and means for 38 of the more commonly consumed vegetables in America (18).

C. Factors Affecting Nutrient Composition of Vegetables

Biological, chemical, and physical factors all affect the nutrient composition of vegetables. For these reasons, nutrient values for any particular vegetable may differ significantly from published values commonly used in databases. Table 21.4 presents a partial list of factors that can significantly affect variability of nutrient content in foods. Comprehensive texts and research papers (as well as references cited within) are referenced in this table for those interested in a deeper understanding of any single production factor.

Because of the virtually endless possibilities of factor combinations, there is no definite set of rules dictating how the exact nutrient composition of any single plant may vary from the usual. Vitamins and minerals, rather than protein, fat, and carbohydrates, are the nutrients likely to have the greatest variation even within a single plant species.

Vitamins, functioning as cell regulating cofactors, will continue to be utilized by the plant even after being harvested (24). Other factors such as heating, acid, or alkaline exposure, and processing techniques that cause oxidation can decrease the vitamin concentration to a fraction of the initial value (25).

The content of some minerals in plants is dependent upon the amount of a particular element available in the soil for the growing plant. For example, depending upon the selenium content in the soil, plants may have very low levels of selenium or contain toxic amounts.(26).

D. Bioavailability

Even though vegetables may contain ample quantities of nutrients and phytochemicals, some vegetables also contain chemicals that bind with nutrients and phytochemicals making the beneficial compounds unavailable for absorption. An understanding of these bioavailability considerations is essential to avoid using nutrient data of vegetables in a misleading way (27,28).

Nutrient antagonists can significantly decrease the bioavailability of nutrients from foods. High levels of one mineral may competitively reduce the absorption of another mineral element. For example, magnesium interferes with calcium absorption (29). Zinc also is known to interfere with magnesium absorption (30). Phytochemicals, like

TABLE 21.1
Human Essentiality and Physiological Function of Nutrients Found in Plants

Nutrient	Essentiality	Physiological Function: Energy	Structure	Regulation	Examples of Key Specific Functions
Water	Essential		x	x	Provides fluid structure for every cell
PROTEIN—AMINO ACIDS:					Source of kilocalories; protein
Histidine, Isoleucine, Leucine, Lysine, Methionine	Essential	x	x	x	structure of all cells; regulate
Phenylalanine, Threonine, Tryptophan, Valine	Essential	x	x	x	chemical reactions through
Alanine, Arginine, Asparagine, Aspartic Acid	Dispensable	x	x	x	enzymes; necessary for
Glutamic Acid, Glycine, Proline, Serine	Dispensable	x	x	x	DNA systhesis
Cysteine, Glutamine, Tyrosine	Conditional	x	x	x	
LIPID—FATTY ACIDS:					Source of calories; cell membrane
Linoleic: omega-6, alpha-Linolenic: omega-3	Essential	x	x	x	structure; eicosanoid synthesis;
Other Fatty Acids	Dispensable	x	x		
CARBOHYDRATES:					Energy source especially essential
Glucose	Dispensable	x			for red blood cells and brain
MINERAL ELEMENTS:					
Calcium, Fluoride, Magnesium, Phosphorus	Essential		x	x	Bone and tooth structure
Chloride, Chromium, Copper, Iodine	Essential			x	Miscellaneous physiological and
Iron, Manganese, Molybdenum	Essential			x	regulatory functions including: energy
Potassium, Selenium, Sodium, Zinc	Essential			x	metabolism; synthesis and transport of red blood cells and hormones; water balance; and immune system functions
Arsenic, Boron, Nickel, Silicon	Essential			x	Functions unclear
VITAMINS:					
Biotin, Choline, Folate, Niacin (B-3), Pantothenic acid	Essential			x	Miscellaneous regulatory functions including: preventing oxidation;
Riboflavin (B-2), Pyridoxine (B-6), Thiamin (B-1)	Essential			x	energy metabolism; blood clotting; and eye health
Vitamin A (carotenoids), Vitamin C (ascorbic acid)	Essential			x	
Vitamin E (tocopherol), Vitamin K	Essential			x	

Essential nutrients not present in vegetables include Vitamin D and Vitamin B12. Dietary fiber is commonly classified as a non-digestible form of carbohydrate. However, it is not a nutrient and has been included in Table 5 as a phytochemical.

dietary fiber and phytic acid, can reduce the bioavailability of minerals such as iron or calcium.

Minerals are the nutrient class most commonly affected by decreased bioavailability. Most commonly, the low availability of the mineral to the body is due to the mineral's chemical form or to other components in the diet. Bioavailability for each mineral can vary extensively. For example, on the average, a human absorbs from the diet about 1 to 10% of the iron and manganese, 1 to 20% of the zinc, and 15 to 40% of the magnesium and calcium. These percentages will vary based on the quantity of food components such as dietary fiber and oxalic acid which bind with minerals making them unavailable for absorption. Spinach is a good example of a vegetable with relatively high levels of calcium that are virtually unavailable to the body due to the high oxalate concentration in the spinach. Consequently, listing spinach as a food that is high in calcium is technically correct, however, it is deceiving because it is not a good source of calcium for humans (31).

Another factor that can affect the bioavailability of minerals is the physiological status of a person. For some minerals, the efficiency of absorption is increased (within certain limits) during times of dietary deficiency and the absorption efficiency is decreased during times of high intake (32).

III. NON-NUTRITIVE PHYTOCHEMICALS

A. PHYTOCHEMICALS

Many components of foods are not strictly required by the body for growth and daily maintenance, yet some of these components may promote health and help prevent disease. It has become common to call these compounds by the general term phytochemicals when present in plant foods or zoochemicals when present in animal foods. Some phytochemicals are conspicuous by their colors (carotenoids) or flavors (tannins); however, the presence of many other phytochemicals is not as evident.

In 1919, E.V. McCollum wrote in his book *The Newer Knowledge of Nutrition*, "A plant structure, or an animal body is an exceedingly complex mixture of chemical substances many of which are themselves individually as complicated in their structure as the most complex machine. The first step in the direction of reaching an understanding of the chemistry in the living mass, must involve the separation and the study of the structural units of which the tissues are composed" (2, p. 2).

Although McCollum was likely writing this about nutrients, his statement is as true today as nearly a century ago. Presently the field of nutrition is identifying and quantifying thousands of non-nutritive phytochemicals.

TABLE 21.4
Factors That Can Affect Nutrient Content of Foods or Reported Nutrient Values

General References Relating to Multiple Factors (19–22)

Agriculture Production
Genetics: species and plant variety

Harvesting, Shipping, and Storage
Plant maturity, harvesting time and method; Ripeness of plant, Harvesting time and temperature, Time before, during, and after processing

Level and Type of Processing
Fresh, Canned, Frozen, Concentrated, Dehydrated, Dried, Fermented, Salted, Smoked, With/without sweeteners, salt, fat, added liquid

Heat Processing
Pasteurization, Irradiation, Ultra-high temperature, High-temperature short term, Microwave, Pressure

Environmental
Geography, Altitude, Climate, Pest control, Season, Sunlight, Soil composition/fertilization, Water

Added Food Ingredients and/or Supplemented with Nutrients

Preparation Methods
Whole or cut, Cut/grind size, Mixed/whipped/blended, hot/cold preparation, Dry or moist heat frying, Cooled/frozen

Laboratory Analysis (23)
Sampling scheme, Chemical analysis methods, Laboratory procedures, Use of calibration standards, Intra-laboratory variation, Inter-laboratory variation, Data transcription

Source: Refs. 18–23.

Many of these plant chemicals have been identified as having health-promoting qualities. A partial list of vegetable phytochemicals linked to beneficial biological activities is presented in Table 21.5. Other phytochemicals have negative effects upon health either by inhibiting specific nutrient utilization or by being toxic (57).

B. Phytochemical Profiles

The development of chemical profiles for vegetable phytochemicals is in its infancy. Due to the enormity of the task, it will likely be decades before good phytochemical profiles exist.

C. Factors Affecting Phytochemical Composition of Vegetables

Many of the factors that affect nutrient composition (i.e., genetics, environmental factors, and processing) likely also affect the phytochemical composition of vegetables. This is especially true for the phytochemicals functioning as antioxidants. However, information on this topic is extremely limited.

IV. HEALTH BENEFITS DERIVED FROM VEGETABLES

Modern society has dramatically affected how we eat. Since the introduction of T.V. dinners, it appears that convenience greatly influences people's food choices. Researchers have found that monkeys or apes foraging in the wild appear to get far higher levels of many essential nutrients and beneficial phytochemicals relative to their body weight than the average American (58).

Without a doubt, vegetables can be considered more nutrient dense (nutrient content per kilocalorie of food) than foods from other food groups. However, the phytochemicals in vegetables may provide equally important benefits for the prevention of chronic diseases like cancer and heart disease (59).

Research on the purported health benefits of vegetables focuses on two main areas of study:

1) Maintenance of gastrointestinal tract health and
2) Reduction of chronic disease risk

A. Gastrointestinal Tract Health

The gastrointestinal tract (GI-tract) is the gateway through which the body transports nutrients and phytochemicals into the circulation for delivery to body cells. A complex network of internal organs and tissues is responsible for the digestion or breakdown of food components into compounds and elements that can be absorbed into the body. In addition, the GI-tract serves as a protective barrier to prevent some substances from entering the body (60).

Due to the extremely active and chemically hostile internal environment necessary to accomplish the digestive process within the GI-tract, cells along the 25–30 feet of intestine are exposed to a great deal of chemical and physical damage. Consequently, many of these cells have only a three- to five-day life span. This constant turnover of GI-tract cells results in continuous cellular replacement and repair of damage.

TABLE 21.5
Some Important Non-Nutrient Phytochemicals in Vegetables

Phytochemical	Anti-cancer	Antioxidant	Anti-inflamatory	Blood Clotting	Detoxifi-cation	Eye Health	G.I.-Tract Health	Heart Health	Immune System	Osteo-porosis	Examples of Food Sources	Ref.
Capsaicin	+/−			+							Hot chile peppers	33
Carotenoids alpha-carotene, beta-carotene, beta-cryptoxanthin, lutein, lycopene, zeaxanthin	+/−	+				+		+			Orange, yellow, & green vegetables	34–36
Curcumin (phenolic)	+	+	+						+		Turmeric, mustard	37
Coumarins				+							Vegetables, tonka bean, sweet clover, licorice	38,39
Dietary fiber	+						+	+			Wide variety of vegetable sources	33,40–43
Glucosinolates (glucobrassicin) Isothiocyanates (sulphorophane) Indoles (indole-3-carbinol)	+	+									Cruciferous vegetables, broccoli sprouts	36,37,40, 44–46
Inositol phosphates (phytate)	+	+									Whole grains, beans	47
Monoterpene (limonene)	+										Citrus fruit peel	36,37,40
Organosulfur compounds diallyl sulfide, allyl methyl disulfide, allyl methyl trisulfide, S-allyl cysteine, diallyl trisulfide, and others	+/−										Garlic, onions, and other allium vegetables; mustard and horseradish	33,48,49
Protease inhibitors	+/−										Legumes, cereals, vegetables	36,50
Tannins	+/−	+							+		Grapes, tea, lentils, wine	51,52
Flavonoids apigenin, catechins, chrysin, kaempferol, myricetin, quercetin	+	+	+		+			a		+	Green vegetables, onions, garlic, tea	40,47,48, 53
Isoflavonoids, biochanin A, daidzein, formononetin, genistein, glycitein	+/−							+		+	soybeans, clover sprouts, alfalfa sprouts	54,55
Lignans	+										flaxseed, berries, whole grains	54,56
Coumestans	+										soybeans, clover sprouts, alfalfa, beans	54,56

There is a significant amount of nutrient recycling from injured GI-tract cells which allows many nutrients to be digested and absorbed along with new food components. This combination of recycled and dietary nutrients is utilized to support adequate replacement of the cell lining of the GI-tract.

Over the last decade there has been an increase in the number of reported cases of various gastrointestinal diseases. Two of the most common GI-tract diseases are diverticulitis (inflammation of small pouches formed along the gastrointestinal tract) and gastro-esophageal reflux disease (GERD), the common cause of indigestion which causes the pain popularly called "heartburn" (61). In fact, GERD is so common and chronic in the United States that Prilosec® was one of the world's top-selling drugs in the year 2000.

Diverticulitis and GERD have one significant dietary factor in common. Both of these conditions appear to be related to years of inadequate dietary fiber intake (61,62). Ironically, fiber is the most abundant phytochemical in vegetables.

Vegetables contain both soluble and insoluble forms of dietary fiber. The physiological effects of these two dietary fiber types have both similarities and some significant differences.

Both soluble and insoluble fiber types hold water and create bulk inside the GI-tract. Soluble fibers slow the rate of stomach emptying into the small intestine. It is thought that the stomach distension caused by fiber bulk and the slower stomach emptying produces an extended feeling of satiety after a meal (63,64). Intake of high soluble fiber also tends to decrease the overall nutrient absorption rate and may also reduce the amount of nutrients and phytochemicals absorbed. This can benefit those with problems in the management of blood glucose and may reduce the absorption of cholesterol (65). Excessively high intake of dietary fiber can interfere with the absorption of minerals.

B. Immune System Health

The immune system is part of the body's natural defense system against disease and disease-producing conditions. Approximately 80 percent of the immune system is located directly adjacent to the GI-tract. Ordinarily, undigested food molecules, microorganisms, and many toxins cannot readily cross through the intestinal lining and do not enter the circulatory system. However, disruptions to the integrity of the GI-tract can challenge the immune system beyond its capacity to maintain health (60).

C. Chronic Disease

Many phytochemicals have been associated with preventing or decreasing the incidence of disease. Disease conditions and related mechanisms that are purported to be affected by various phytochemicals are summarized in Table 21.5.

No doubt there are numerous triggers in the initiation of cancer and heart disease. And although there may be many varied mechanisms of phytochemicals with anticancer and heart promoting properties, one mechanism may be related to the antioxidant property shared by many of these compounds. The process of normal cellular metabolism produces chemicals that are reactive oxygen species like hydrogen peroxide and the superoxide anion free radical. It is thought that free radical production causes a secondary oxidative stress whenever there is an imbalance of antioxidants to oxidants. This can occur with an excess of oxidation stress or an inadequate amount of antioxidants in the diet.

Research has shown that antioxidants are involved in delaying many diseases and conditions that are associated with aging such as cancer, heart disease, decreased immune functioning, and visual and cognitive impairment (66). A number of vitamins, minerals, and phytochemicals provide antioxidant protection in the body. Based on a per gram or per kilocalorie basis, vegetables contain significant amounts of antioxidants.

Dietary phytoestrogens may help reduce the risk of developing certain hormone-stimulated cancers such as breast and prostate cancers. However, much more research on this relationship is needed since some studies indicate that phytoestrogen compounds may stimulate progression of some types of cancer (67).

Flavonoids such as those found in onions, tea, and red wine also are under study for potential cancer prevention. The possible mechanisms of action may vary from one flavonoid to another. They may prevent cancer cell proliferation through specific enzyme inhibition (68).

V. SUMMARY

As a major category of foods, vegetables have a variety of qualities and characteristics that supports common recommendations to include them as a significant part of a balanced and varied diet. They serve as important sources of a wide variety of vitamins and minerals essential for normal human nutrition.

Vegetables supply these nutrients in forms that are generally low in energy and fat, making them more "nutrient dense" than most other food sources. The nutrient content of a particular vegetable can vary, with the extent dependent on the nutrient, and a variety of factors including plant genetics, agricultural factors, storage and handling, processing, packaging, and preparation. Nutrient content values in databases generally reflect averages.

The extent to which a vegetable food is a good source of a nutrient also depends on type of processing and the bioavailability of the nutrient. In some cases, a vegetable can contain high levels of a mineral such as calcium or iron, but the form of the mineral or interfering compounds in the vegetable allow very little of the mineral to be

absorbed into the body. Some nutrients are not found in vegetables, including vitamins D and B-12 and the long chain omega-3 fatty acids commonly found in fish oils and some species of algae.

In addition to nutrients, vegetables provide a great variety of non-nutrient chemical compounds commonly called phytochemicals. The potential benefits and risks of various phytochemicals found in vegetables represent an increasingly active area of nutrition research. The body of scientific research to date supports the inclusion of a wide variety of vegetables in the human diet for reducing the risk of developing a number of disease conditions that tend to develop with age. Additional research is needed to clarify more specific risks and benefits of various types of chemical compounds found in vegetables.

ACKNOWLEDGMENT

The information in this chapter has been derived from "Nutritional Value of Vegetables," by C.A. Titchenal, J. Dobbs. In *Handbook of Vegetable Preservation and Processing*, edited by: Y.H. Hui et al., Marcel Dekker, New York, 2004.

22 Canned Vegetables: Product Descriptions

Peggy Stanfield
Dietetic Resources

CONTENTS

I. INTRODUCTION

This book is not the proper forum to present the manufacturing process for all categories of canned vegetables being marketed in the United States. This chapter provides a short description of requirements for the major commercial canned vegetables.

In the United States, two federal agencies have the responsibility to make sure that the canned vegetables in the market are safe and do not pose any economic fraud. The U.S. Food and Drug Administration issues regulations to achieve both goals. The U.S. Department of Agriculture issues voluntary guides to achieve the same goals. The information in this chapter has been modified from such regulations and guidelines.

II. CANNED CORN

Canned sweet corn is the product prepared from clean, sound kernels of sweet corn packed with a suitable liquid packing medium which may include water and the creamy component from corn kernels. The tip caps are removed. The product is of the optional styles.

III. CANNED GREEN BEANS AND CANNED WAX BEANS

A. General Description

Canned green beans and canned wax beans are the foods prepared from succulent pods of fresh green bean or wax bean plants conforming to the characteristics of *Phaseolus vulgaris* L. and *Phaseolus coccineus* L. Such food is so processed by heat, in an appropriate manner before or after being sealed in a container as to prevent spoilage.

Requirements are provided for optional color and varietal types; styles of pack; ingredients; and labeling.

Optional color types are Green or Wax. Optional varietal types include:

1. Round. Beans having a width not greater than 1-1/2 times the thickness of the bean; or
2. Flat. Beans having a width greater than 1-1/2 times the thickness of the bean.

Optional styles of pack:

1. Whole. Whole pods of any length.
2. Shoestring or sliced lengthwise or French style. Pods sliced lengthwise.
3. Cuts. Transversely cut pods not less than 19 mm (0.75 in) long as measured along the longitudinal axis, which may contain the shorter end pieces that result from cutting such pods.
4. Short cuts. Pieces of pods cut transversely of which 75 percent, by count, or more are less than 19 mm (0.75 in.) in length and not more than 1 percent by count are more than 32 mm (1-1/4 in) in length.
5. Diagonal cuts. Pods cut in lengths as specified, except the pods are cut at an angle approximately 45 deg. to the longitudinal axis.
6. Diagonal short cuts. Pods cut in lengths as specified, except the pods are cut at an angle approximately 45 deg. to the longitudinal axis.
7. Mixture. Any mixture of two or more of the styles specified.

Optional ingredients are:

1. Salt.
2. Monosodium glutamate.
3. Disodium inosinate.
4. Disodium guanylate.
5. Hydrolyzed vegetable protein.
6. Autolyzed yeast extract.
7. Nutritive carbohydrate sweeteners.
8. Spice.
9. Flavoring (except artificial).
10. Pieces of green or red peppers or mixtures of both, either of which may be dried, or other vegetables not exceeding in total 15 percent by weight of the finished product.
11. Vinegar.
12. Lemon juice or concentrated lemon juice.
13. Glucono delta-lactone.
14. Mint leaves.
15. Butter or margarine in a quantity of not less than 3 percent by weight of the finished product.
16. When butter or margarine is added, emulsifiers or stabilizers, or both, may be added.
17. No spice or flavoring simulating the color or flavor imparted by butter or margarine is used.

B. Labeling

The name of the food is "green beans" or "wax beans" as appropriate. Wax beans may be additionally designated "golden" or "yellow."

A declaration of any flavoring that characterizes the product:

1. A declaration of any spice, seasoning, or garnishing that characterizes the product, e.g., "with added spice," or, in lieu of the word "spice," the common name of the spice, e.g., "seasoned with green peppers."
2. The words "vacuum pack" or "vacuum packed" when the weight of the liquid in the container is not more than 25 percent of the net weight, and the container is closed under conditions creating a high vacuum in the container.
3. The name of the optional style of bean ingredient, if a product consists of a mixture of such styles, the words "mixture of" the blank to be filled in with the names of the styles present, arranged in the order of decreasing predominance, if any, by weight of such ingredients.
4. If the product consists of whole beans and the pods are packed parallel to the sides of the container, the word "whole" may be preceded or followed by the words "vertical pack," or if the pods are cut at both ends and are of substantially equal lengths, the words "asparagus style" may be used in lieu of the words "vertical pack."
5. If the product consists of short cuts or diagonal short cuts, a numerical expression indicating the predominate length of cut in the finished food may be used in lieu of the word "short," e.g., "1/2 inch cut."

The following may be included in the name of the food:

1. The word "stringless" where the beans are in fact stringless.
2. The name of the optional varietal type, or the specific varietal name, e.g., "Blue Lake Green Beans," or both.
3. If a term designating diameter is used, it should be supported by an exact graphic representation of the cross section of the bean pod or by a statement of the maximum diameter in common or decimal fractions of an inch and, optionally, by the millimeter equivalent stated parenthetically. The diameter of a whole, cut, diagonal cut, or short cut is determined by measuring the thickest portion of the pod at the shorter diameter of the bean perpendicular to the longitudinal axis.

IV. CANNED MUSHROOMS

A. Legal Requirement

The FDA has established a standard of identity for canned mushrooms. Some aspects are presented below.

1. Definition

Canned mushrooms is the food properly prepared from the caps and stems of succulent mushrooms conforming to the characteristics of the species *Agaricus (Psalliota) bisporus* or *A. bitorquis*, in one of the optional styles, packed with a suitable liquid medium which may include water; and may contain one or more safe and suitable optional ingredients. The food is sealed in a container and, before or after sealing, is so processed by heat as to prevent spoilage.

2. Styles

The optional styles of the mushroom ingredient are:

1. Buttons—consisting of whole mushrooms with attached stems not exceeding 5 millimeters (0.2 inch) in length, measured from the bottom of the veil.
2. Whole—consisting of whole mushrooms with attached stems cut to a length not exceeding the diameter of the cap, measured from the bottom of the veil.
3. Quarters—consisting of buttons or whole style cut into four approximately equal parts.
4. Slices or sliced—consisting of buttons or whole style of which not less than 50 percent are cut parallel to the longitudinal axis of the stem and 2 millimeters to 8 millimeters (0.08 inch to 0.32 inch) in thickness.
5. Random sliced—consisting of buttons or whole style sliced in a random manner.
6. Pieces and stems—consisting of pieces of caps and stems of irregular shapes and sizes.

3. Optional Ingredients

Optional ingredients are:

1. Salt.
2. Monosodium glutamate.
3. Disodium inosinate.
4. Disodium guanylate.
5. Hydrolyzed vegetable protein.
6. Autolyzed yeast extract.
7. Ascorbic acid (vitamin C) in a quantity not to exceed 132 milligrams for each 100 grams (37.5 milligrams for each ounce) of drained weight of mushrooms.
8. Organic acids (except no vinegar is permitted), only where the inside metal of the container is fully enamel-lined and in glass containers with fully enamel-lined caps. Ascorbic acid is an example.
9. Calcium disodium ethylenediaminetetraacetate ($CaNa_2$ EDTA) in a quantity not to exceed 200 parts per million for use to promote color retention.

4. Fill of Container

1. The fill of the mushroom ingredient and packing medium container is not less than 90 percent of the total capacity of the container.
2. The drained weight of the mushroom ingredient is not less than 56 percent of the water capacity of the container.

B. General Processing

Canned mushroom is considered a low acid canned food and there are stringent regulations govering its manufacture. This section provides some background information. A commercial processor must comply with basic federal requirements.

1. Types and Varieties

All cultivated mushrooms belong to the species *Agaricus campestris*. Various bracket fungi, puffballs, and other fungi have been used as food, but none has been grown commercially in this country. Mushrooms are classified as white, cream, or brown, depending on the color of the cap. Those grown for canning are almost exclusively of the white variety. In the East and Midwest the white variety is also the principal kind grown for fresh mushroom

consumption, while in the West and in Canada a fair quantity of the cream variety is used. Of course, in the last two decades or so, many varieties of mushrooms are available from imports, e.g., countries in the Pacific Rim.

2. Growing Requirements

Since mushrooms, like all fungi, do not possess chlorophyll with which to manufacture carbohydrates from CO_2 absorbed from the air, they must obtain carbohydrates and other nutrients by growing on organic material containing these ingredients. Compost is the favorite growing medium in commercial mushroom houses.

Unlike plants possessing chlorophyll, mushrooms can grow in tare in darkness. A cool, moist atmosphere is most favorable for their development. Caves and abandoned mines have been used extensively for the growing of mushrooms.

Most mushrooms are grown in houses constructed especially for the purpose. Cinder blocks are a favorite construction material. The houses should be well insulated against cold in winter and heat in summer, and should have heating facilities for use in winter and means for keeping the air moist when the outside humidity becomes low.

Most houses produce two distinct crops a year. Each crop consists of several "breaks." After the mushrooms are harvested the north beds are covered with a new layer of "casing" soil and watered down for the next growth of mushrooms. After several such "breaks," the beds are cleaned out and filled with fresh compost. The entire cycle area may be completed in as little as three months or even less, up to as long as seven months, depending largely on temperature.

Higher temperatures usually mean a greater proportion of small land mushrooms.

Artificial air conditioning enables some growers to obtain three crops a year.

The months of October to May, inclusive, are the months of heaviest production. Harvesting is light during the warm weather months. A few growers maintain production during the summer by means of artificial air conditioning.

3. Harvesting and Delivery

Most canners grow the greater part of the mushrooms they use, purchasing the remainder of their requirements from other growers. Some canners grow for canning exclusively; others grow both for the fresh market and for processing.

Mushrooms are pulled from the beds with roots attached before the "veil" or membrane breaks open and exposes the "gills." Depending upon the contract between the packer and grower, the mushrooms may be delivered to the plant either with or without roots attached. In the latter case, the roots are cut from the mushrooms in the growing houses by the harvesters. In either case they are placed in baskets holding from three to as much as ten pounds for delivery to the plant. Obviously, unlike small growers, large corporations use a more advanced system to handle this harvesting and delivery.

Freshly harvested mushrooms with the root portion attached will remain fresh longer than if the root portion has been removed. Mushrooms frequently grow in clusters, which may contain from three to five or more units. The units may vary in size from tiny to large in the same cluster that developed from one root.

Mushrooms deteriorate rapidly after picking, becoming discolored and wilted. They should be delivered to the cannery or processor promptly after picking. When mushrooms cannot be processed promptly after delivery to the cannery, they should be placed in a refrigerated room at a temperature of 36° to 37°F until needed. Refrigeration permits the supplies to be carried overnight to begin canning operations the following morning, or late weekend deliveries may be carried over to Monday morning.

Mushrooms must be handled carefully at all times to avoid bruising, which results in dark discolored areas.

C. Preparation and Canning

The following description of a canned mushroom operation is reasonably typical. The order, methods, and equipment may vary from plant to plant, especially a small versus a big one.

After delivery to the plant, mushrooms which cannot be processed immediately are placed in refrigerated storage until they can be processed.

The baskets of mushrooms are taken to the cutting line for removal of root stubs and stems. In most plants the cutting operation is performed mechanically, although some plants may still be cutting by hand. The stem may undergo one or two cuttings, depending on the style of mushrooms desired, whether whole or button.

In the case of whole mushrooms, only the root portion of the stem is removed by the mechanical cutter. If the style of buttons is desired, the cutters first remove the root portion of the stem which is carried away for waste. The rest of the stem is then removed by cutting immediately below the veil. This portion of the stem is used in the style of *stems and pieces*.

1. Washing, Trimming, and Sorting

After cutting, both the caps and stems are conveyed to a spray washer which removes the clinging bits of casing soil or other dirt. The mushrooms then pass over an inspection belt where seriously blemished mushrooms may be trimmed or sorted out. Misshapen, blemished, trimmed, and broken mushrooms are sorted out and placed with other mushroom material for the stems and pieces style.

Mushrooms with partially open veils may be placed with the pieces delivery material, or be added to the buttons or whole mushrooms intended for one of the sliced styles.

2. Sizing

Mushrooms intended for whole mushrooms or buttons are conveyed by means of water flume or other techniques to the sizers.

The mushrooms may be sized in a revolving drum sizer submerged in water. Rotary size graders which are not immersed in water may also be used. A submerged sizer minimizes bruising and gives the mushrooms an additional washing. The caps float upward from the sizer and each size is floated off into a separate holding tank.

The buttons may be separated into six different sizes. The larger sizes are generally sliced and the smaller sizes packed as buttons. Price lists of packers may quote sizes in terms of number of buttons per 8-ounce can as 20/40, 40/60, 60/80, or l00/120. The same size designations apply when the mushrooms are packed in smaller sized cans. For example, the 40/60 size would pack between 20 to 30 buttons in a 4-ounce can.

3. Slicing

Mushrooms intended for slicing are generally sliced prior to blanching; however, slicing may be performed after blanching. The mushrooms are passed through a mechanical slicer with circular knives which cut them into slices of predetermined thickness. A shaker screen removes the small pieces after slicing.

Three styles of sliced mushrooms are produced: 1) Sliced Whole; 2) Sliced Buttons; and 3) Random Sliced Whole.

"Sliced Whole" style is prepared by aligning the mushrooms prior to slicing so that the mushroom is sliced lengthwise from stem to apex.

"Sliced Buttons" style is prepared by positioning the mushrooms prior to slicing so that the mushroom is sliced parallel to the longitudinal axis.

"Random Sliced Whole" style is prepared by slicing the mushroom in any direction.

4. Blanching

The mushrooms are flumed from the holding tanks or slicer to the blancher. The purpose of blanching is to shrink the mushrooms in order to obtain the proper fill. Shrinkage is due to loss of mushroom juice. Mushrooms may shrink as much as 30 to 40 percent in size in blanching

Mushrooms may be blanched by immersing in water at a temperature of 200°F or more. The usual method, however, is to pass the mushrooms through a continuous steam blancher where they are exposed to live steam for a period of 5 to 8 minutes. In some cases the mushrooms may be filled into the cans and then blanched in the cans. Since iron tends to discolor mushrooms, the blancher should be made of stainless steel or other non-corrosive metal. During blanching, the color of some white varieties may change from near-white to a light tan or buff color.

5. Filling and Weighing

Whole or Button styles are generally filled into the can by hand while a semi-automatic filler is usually used for slices and piece pack. After filling, the cans are moved by belt conveyor in front of the weighers, who weigh the individual cans and adjust the fill so that the finished product will meet the required minimum drained weight.

As a safety factor, weighers generally overfill the cans, usually in accordance with a schedule of overfill weights which vary according to can size and style of pack.

Cans may vary considerably in weight, particularly in the smaller sizes. Deficient drained weights have been found to be due in some cases to the use of an unusually light can as tare by the weigher. The weigher should choose a tare can of average weight.

6. Brining and Cooking

After weighing, a salt tablet which may also contain ascorbic acid is added and cans are moved under taps of hot water, the temperature of which may range from 190° to 200°F. The taps are adjusted to fill cans to overflowing. A hot brine solution is sometimes used instead of the water and salt tablet. It is generally unnecessary to use an exhaust on the filled cans since a sufficiently high vacuum is obtained for most purposes by the addition of hot water.

After closing, the cans are processed in retorts under steam pressure. After processing, the cans may be cooled by water in the retort or a cooling tank. The cans should be cooled to 90° to l00°F, in order to check the cook but leave cans warm enough to dry off readily and prevent rusting.

7. Modern Technology and FDA Regulations

The information in this section on mushrooms must be interpreted in terms of the following premises:

1. Depending on the size and operation of a processor, the use of new equipment and machinery has eliminated a lot of problems that used to accompany the processing of mushrooms.
2. If used properly, food additives can contribute to the proper processing of mushrooms.
3. Always be concerned that mushrooms in a container are subject to the important regulations promulgated by the FDA for low acid canned and acidified foods.

V. CANNED ONIONS

A. Production

1. Varieties

Yellow globe onions, a commercial term applied to several different varieties and strains of onions, are preferred by processors of onions. The more acceptable varieties are the Southport yellow globe and the yellow globe Danver. Western processors for the most part use only the yellow globe Danver.

2. Harvesting

The customary period at which to harvest onions for canning is in the fall when the tops of the onions have begun to turn greenish yellow. Usually the crop is dug by a hoe or an implement which turns the ground exposing the onions to the surface. After the onions are taken from the ground they are thrown in windrows or piles in the field, where they remain until the tops are completely dry. After curing sufficiently, the tops are cut or pulled off close to the bulbs. The onions are then placed in sacks or crates and are placed in storage or shipped.

B. Preparation and Canning

1. Receiving

Onions are usually delivered to the cannery in sacks or crates, and are placed in storage until used. Well-cured onions will keep for several months if stored in a well-ventilated place. In some areas it may be necessary to store them in an enclosed shed for protection against freezing. Onions will sprout within a few months if stored in a warm place. Badly spoiled onions become soft. The fresh fruit and vegetable inspection service inspects a large volume of onions for shippers and buyers at time of shipment or in receiving markets. Onions delivered to canners may or may not have been officially inspected.

Generally the onions are emptied from sacks onto a belt conveyor, carrying them to a sizer which eliminates over- and under-sized onions. From the sizer the onions are placed in buckets or pans on a "merry-go-round" sorting table where ends of the onions are trimmed and onions possessing rot, decay, or other serious defects are discarded.

2. Peeling

From the "merry-go-round" sorting table, the onions are conveyed to a carborundum peeler which tends to loosen the outer skin of the onion bulb. As the onions leave the carborundum peeler they pass through a continuous lye peeler containing a three to ten percent lye solution, depending upon the variety and character of the onions, which further loosens the outer scales of the onion bulb.

3. Washing

Following the peeling process, the onions pass through a rotary screen washer where adhering portions of the outer loosened scales are washed off under a strong spray of water. A closely controlled check is necessary to assure complete removal of the lye solution from the onion bulbs.

4. Pre-Removing of Blemishes and Defects

After washing, the onions are moved by conveyer belt to an inspection table where onions containing blemishes are removed.

5. Sizing

Normally onions are separated into three size classifications: tiny, small, and medium. Each processor has developed his own particular sizing operation. However, for the most part onions exceeding an inch and one-half in diameter and those with a diameter of less than 5/8 of an inch are not used for canning.

6. Final Removing of Blemishes and Defects

As the onions come from the sizer, they are conveyed onto a final inspection table where loosened scales, loose centers, onions possessing blemishes, or excessive discolored onions are removed.

7. Filling

The onions are then filled into cans or glass jars and a sufficient amount of hot brine is added for proper fill. After the cans or glass jars are filled they are quickly closed. In packing onions, the product is acidified to assure sterilization and to prevent spoilage. A pH of 4.5 is most desirable. The acid solution may be used as a dip, or may be added direct to the containers in the filling operations.

8. Defects

a. General

Immediately after ascertaining the uniformity of size and shape, segregate any defects in the following groups in accordance with the definitions outlined by the USDA.

b. Extraneous vegetable material

Remove from each container the pieces present and arrange all the extraneous material such as loose skins and dried onion tops. Extraneous vegetable material refers to harmless vegetable material and the material falling into this category is evaluated with respect to its effect on the overall requirements for the grade classification. No tolerance is provided for extraneous vegetable material of a different origin than the onion plants such as weeds and weed seeds. When such extraneous material is found the supervisor should be contacted.

c. Blemished onions

A blemished onion is one that is affected by surface or internal discoloration to such an extent that the appearance or eating quality is materially affected. The following are examples of onions scoreable as being blemished:

1. **Staining**. Onions that show brown or streaked discoloration from lying on the ground.
2. **Seed Stems**. Onions often throw up stalks on which to bear seeds during the later part of their growth. When harvested the seed stems are cut or broken off leaving thick tough stems extending through the centers of the onions. Onions possessing tough or woody seed stems should be considered blemished onions.
3. **Sunburn**. Sunburn is a green discoloration caused byexposure of the bulb to the sun and is normally present only on the outer scale of the onion bulb. This condition should not be confused with the natural greening of certain varieties of onions wherein the green color may be present in the outer scales of the onion bulbs.
4. **Sunscald**. This injury takes place at harvest time when the bulbs are exposed to heat and bright sunlight. The tissue of the exposed area of the bulb will scald and become soft and slippery. When temperatures are reduced and the onions are exposed to the air, the scalded tissue loses moisture by evaporation and leather-like areas are produced which may be bleached almost white.
5. **Freezing injury**. This injury is recognized by the watersoaked appearance, soft feel, and discoloration appearing in a portion of the scales or scales. The affected area normally has a translucent or paper-like appearance.
6. **Smudge**. Smudge is characterized by black blotches or aggregations of minute black or dark-green dots on the outer scales. These dots are often arranged in concentric rings. Generally the lesions are on the outer scales but they may be found on inner scales. On the fleshy scale of the bulb the fungus produces sunken yellowish spots.
7. **Surface Molds**. Surface molds may be black, blue, or gray in color and may be found growing either on the outer scales or frequently between the outer scales of the bulb.
8. **Rot**. Several types of rot may be present in onions, some of which are bacterial soft rot, blue mold rot, fusarium rot, and green mold rot. Normally onion bulbs affected by rot have a water-soaked appearance with various discolorations of outer or inner scales. Canned onions should not contain any units showing rot other than an accidental unit.

d. Seriously blemished onion

A seriously blemished onion is an onion that is affected by surface or internal discoloration to such an extent that the appearance or eating quality is seriously affected. Insect injury, wherever the insect bite extends through the scale of an onion bulb, is very noticeable and should be considered seriously blemished. Dark pathological areas which are unsightly are considered seriously blemished.

9. Mechanical Damage

Onion bulbs mechanically damaged by crushing, gouging, or trimming should be classified as damaged only when the condition materially affects the eating appearance or quality of the bulb.

10. Loose Scales or Pieces of Scales

Loose scales or pieces of scales are those not attached to an onion bulb. Do not aggregate pieces of scales to give the equivalent of one loose scale.

11. Detached Center

Detached center is when the center portion of the onion bulb has become detached. The onion bulb thus damaged is scored as a defect and the loose centers which have become detached are disregarded.

12. Well Trimmed

Determining whether onions are well trimmed is judged entirely on an appearance basis. In meeting the requirement for well trimmed the top and root of the onion should be neatly removed. Onion bulbs with off-slant cuts that materially affect the appearance of the unit are not considered well trimmed.

VI. CANNED PEAS AND DRY PEAS

Canned peas is the food prepared from fresh or frozen succulent seeds of the pea plant of the species *Pisum sativum* L. but excluding the subspecies *macrocarpum*. Only sweet wrinkled varieties, smooth-skin varieties, or hybrids thereof may be used. The product is packed with water or other suitable aqueous liquid medium to which may be added one or more of the other optional ingredients. Such food is sealed in a container and, before or after sealing, is so processed by heat as to prevent spoilage.

In addition to the optional packing media, the following safe and suitable optional ingredients may be used:

1. Salt.
2. Monosodium glutamate.
3. Disodium inosinate.

4. Disodium guanylate.
5. Hydrolyzed vegetable protein.
6. Autolyzed yeast extract.
7. One or any combination of two or more of the dry or liquid forms of sugar, invert sugar syrup, dextrose, glucose syrup, and fructose.
8. Spice.
9. Flavoring (except artificial).
10. Color additives.
11. Calcium salts, the total amount of which added to firm the peas should not result in more than 350 milligrams/kilogram (0.01 ounce/2.2 pounds) of calcium in the finished food.
12. Magnesium hydroxide, magnesium oxide, magnesium carbonate, or any mixture or combination of these in such quantity that the pH of the finished canned peas is not more than 8, as determined by the glass electrode method for the hydrogen ion concentration.
13. Seasonings and garnishes.
14. Pieces of green or red peppers or mixtures of both, either of which may be dried, or other vegetables not exceeding in total 15 percent of the drained weight of the finished food.
15. Lemon juice or concentrated lemon juice.
16. Mint leaves.
17. Butter or margarine in a quantity not less than 3 percent by weight of the finished food, or other vegetable or animal fats or oils in a quantity not less than 2.4 percent by weight of the finished foods.
18. When butter, margarine, or other vegetable or animal fats or oils are added, emulsifiers or stabilizers or both may be added, but no color, spice, or flavoring simulating the color or flavor imparted by butter or margarine may be used.

A. Labeling

The name of the food is "peas" and may include the designation "green." The term "early," "June," or "early June" should precede or follow the name in the case of smooth-skin peas or substantially smooth-skin peas, such as Alaska-type peas or hybrids having similar characteristics. Where the peas are of sweet green wrinkled varieties or hybrids having similar characteristics, the name may include the designation "sweet," "wrinkled," or any combination thereof. The term "petit pois" may be used in conjunction with the name of the food when an average of 80 percent or more of the peas will pass through a circular opening of a diameter of 7.1 millimeters (0.28 inch). If any color additive has been added, the name of the food should include the term "artificially colored."

The following should be included as part of the name or in close proximity to the name of the food:

1. A declaration of any flavoring that characterizes the food.
2. A declaration of any spice, seasoning, or garnishing that characterizes the product, e.g., "seasoned with green peppers," "seasoned with butter," "seasoned with _____ oil," the blank to be filled in with the common or usual name of the oil, "with added spice," or, in lieu of the word spice, the common or usual name of the spice.
3. The words "vacuum pack" or "vacuum packed" when the weight of the liquid in the container is not more than 20 percent of the net weight, and the container is closed under conditions creating a high vacuum in the container.

VII. CANNED PUMPKIN AND CANNED SQUASH

A. Production

1. Varieties

The names pumpkin and squash are popularly applied to the fruits of the species of the genus *Cucurbita*, namely *C. pepo*, *C. maxima*, and *C. moschata*. In general, the term pumpkin is applied to the late maturing or fall varieties of *C. pepo* and *C. maxima*. The principal varieties of *C. pepo* and *C. maxima* used for canning are the Connecticut field pumpkin, Dickinson pumpkin, Kentucky field pumpkin, the Boston marrow squash, and the Golden Delicious squash.

2. Harvesting

Pumpkin and squash should not be harvested for canning until fully matured. Harvesting is usually done after the leaves begin to turn yellow. Mature pumpkin or squash have a hard rind which can be dented only with difficulty with the thumbnail. If picked too green the under portions of the pumpkin will have a greenish color and this may be carried over into the finished product. Pumpkin and squash are usually harvested starting approximately September 15 in the Midwest and Northeast States, and October 1 in the Pacific Northwest.

B. Preparation and Canning

1. Receiving

Pumpkin and squash are usually delivered as harvested and stored at the cannery until used. Well-matured pumpkin or squash will keep for several weeks if stored in a well-ventilated place. In some areas it may be necessary to store them in an enclosed shed for protection against freezing. Normally no inspection is made of pumpkin or squash received by the plants.

2. Washing

Whole pumpkins or squashes are fed by hand or conveyed into a combined tank and spray washer, consisting of a rotary drum partially submerged in a tank of water. The combined soaking and rotary motion loosens adhering dirt which is removed by strong sprays of water. Grit sometimes becomes embedded in the rind, necessitating thorough washing.

3. Trimming

From the washer the pumpkins or squash pass to the inspection belt where stems are knocked off by hand and blossom ends, scar tissue rot, and other blemishes are trimmed out.

4. Cutting

In some canneries the trimmers also cut the pumpkin or squash into halves or quarters with long knives and scrape out the seeds and stringy pulp by hand. In many plants mechanical cutters are used into which the whole units (or halves) are fed by a conveyor cutting the units in pieces. Strong sprays of water help knock out most of the seeds, which drop from the cutter through small perforations.

Where the units are cut and the seeds and pulp removed in separate operations, the cut pieces pass to a revolving drum where they are tumbled under strong sprays of water which remove most of the seeds and pulp.

Where seeds are to be saved for planting, they may undergo further washing to separate them from the pulp.

Cut pieces are in some cases passed over an inspection belt where imperfect pieces and internal rot, not visible from the outside, may be picked out by hand.

5. Wilting (Steaming)

The cut pieces are cooked in live steam until they are tender all the way through. The length of time necessary depends upon the size of the pieces and the nature of the equipment in which the steaming is done. The following are examples in which the wilting or steaming may be accomplished:

1. In metal baskets in retorts, either under pressure or at atmospheric pressure.
2. In continuous metal box wilters. The pieces are carried through on a continuous belt and are subjected to live steam.
3. In wilting towers. These are tall cylindrical silo-like structures into which the cut pieces are fed continuously at the top by conveyor and removed at the bottom by a screw conveyor. The pumpkin or squash is continuously treated with live steam as it passes through the wilting tower.

6. Pressing

The wilted pumpkin or squash is soggy with liquid which is a mixture of condensed steam and pumpkin or squash juice. The product is treated to remove excess liquid in order to attain the desired consistency in the canned product. This is done by putting the wilted pumpkin or squash through an adjustable press. In certain plants the pressing and wilting are done simultaneously by the use of augers inside of cone-shaped perforated screens.

7. Pulping

The pressed pumpkin or squash goes to the pulper or cyclone to remove hard particles, pieces of stems, seeds, fiber, and other extraneous material. In some cases the product is first put through a coarse, heavy cyclone to remove the bulk of extraneous material and an ordinary cyclone to reduce the size of the particles. For the latter a screen with perforations 1/8 inch in diameter is commonly used.

Some processors use what is commercially known as a Fitz mill. This machine, constructed with hammer and knife edges on opposite sides, reduces or pulps pumpkin by a combined impact mashing action.

8. Finishing

From the pulper the product goes to the finisher which removes the finer bits of seeds or other material and gives the final product the desired physical character. There is a difference of opinion among canners as to the most desirable size of the particles of pumpkin in the finished product. Some prefer a very smooth product which can be obtained by using a very fine finisher; others feel that the canned pumpkin or squash should have a noticeable amount of grainy structure and, therefore, use a finisher that is relatively coarse.

9. Preheating

The filling temperature of the prepared pumpkin or squash is an important part of processing. Heat penetration of the product is very slow because of its physical character, and the temperature at the beginning of the process is correspondingly important. By use of the preheater, it is possible to fill all of the cans at a uniform high temperature.

The preheater is usually a straight piece of pipe surrounded by a larger pipe. The product is pumped through the smaller internal pipe and the space between the two pipes is filled with steam, the temperature of which can be controlled. The rate of flow of the product through the pipe and the temperature of the steam determines the temperature at which it goes to the filler. The preheater normally raises the temperature of the product to 190–200°F. To prevent scorching the preheater is usually constructed so that it will shut off automatically if, for any reason, the flow through the inside pipe is stopped.

10. Filling

The hot pumpkin or squash goes directly to the filler and into cans. If the thickness of the product at this point is too great, the product may not be handled properly by the filler. If, for any reason, the filler or closing machine is forced to stop for any length of time all of the pumpkin material should be put back with the material going through the preheater. Pumpkin or squash has a corrosive action on tin-plate and should be packed in enamel-lined cans. It is important to fill the cans completely so that the product is in contact with the entire inner surface of the cover when the can is sealed. Even a small headspace may result in some discoloration after processing.

11. Processing

The filled cans should be processed promptly. High closing temperature may be offset by undue delay between closing and starting of the process time. A partially filled crate of cans should be sent at once to the retort rather than waiting any length of time for additional cans.

12. Cooling

Prompt and adequate cooling is especially important since canned pumpkin has a slow heating and cooling rate. Failure to cool the product promptly may result in overcooking and loss of color and may be directly responsible for spoilage by thermophilic bacteria. Cooling is usually accomplished by moving the metal retort baskets through a long tank of water by means of an overhead endless chain. The speed of the chain is regulated according to the degree of cooling desired. Cold water is kept continuously flowing into the tank to hold down the temperature. Immediately after cooking, while the cans are distended by heat and internal pressure, minute openings in the double seams may be present. Cooling water contaminated with bacteria may be drawn through seam openings as pressure in the cans is replaced by vacuum; therefore, water in the cooling tank should be kept clean. Some canners cool by means of a water spray in order to reduce the contamination hazard.

VIII. CANNED VEGETABLES

Additional production descriptions are provided for the following vegetables: artichokes, asparagus, bean sprouts, shelled beans, lima or butter beans, beets, beet greens, broccoli, Brussels sprouts, cabbage, carrots, cauliflower, celery, collards, dandelion greens, kale, mustard greens, leaves of the mustard plant, okra, onions, parsnips, peas, black-eye or black-eyed peas, field peas, green sweet peppers, red sweet peppers, pimientos (pimentos), potatoes, rutabagas, salsify, spinach, potatoes, sweet, Swiss chard, truffles, turnip greens, turnips.

Table 22.1 provides a basic description of each canned vegetable. Column I describes the canned vegetable. The vegetable ingredient in each such canned vegetable is obtained by proper preparation from the succulent vegetable described in column II of the table. If two or more forms of such ingredient are designated in column III of the table, the vegetable in each the form is an optional ingredient. To the vegetable additional ingredients (required or permitted) are added, and the food is sealed in a container and so processed by heat as to prevent spoilage.

Water is added to the vegetable ingredient may be added except that pimientos may be canned with or without added water, and sweet potatoes in mashed form are canned without added water. Asparagus may be canned with added water, asparagus juice, or a mixture of both. Asparagus juice is the clear, unfermented liquid expressed from the washed and heated sprouts or parts of sprouts of the asparagus plant, and mixtures of asparagus juice and water are considered to be water when such mixtures are used as a packing medium for canned asparagus. In the case of artichokes, a vinegar or any safe and suitable organic acid, which either is not a food additive as defined or if it is a food additive as so defined, is used in conformity with regulations established, is added in such quantity as to reduce the pH of the finished canned vegetable to 4.5 or below.

The following optional ingredients may be added in the case of the vegetables in Table 22.1.

An edible vegetable oil, in the case of artichokes and pimientos, and snaps, in the case of shelled beans, black-eyed peas, and field peas.

In the case of all vegetables (except canned mashed sweet potatoes), one or more of the following optional seasoning ingredients may be added in a quantity sufficient to season the food.

1. Refined sugar (sucrose).
2. Refined corn sugar (dextrose).
3. Corn syrup, glucose syrup.
4. Dried corn syrup, dried glucose syrup.
5. Spice.
6. A vinegar.
7. Green peppers or red peppers, which may be dried.
8. Mint leaves.
9. Onions, which may be dried.
10. Garlic, which may be dried.
11. Horseradish.
12. Lemon juice or concentrated lemon juice.
13. Butter or margarine in a quantity not less than 3 percent by weight of the finished food. When butter or margarine is added, safe and suitable emulsifiers or stabilizers, or both, may be added. When butter or margarine is added, no spice or flavoring simulating the color or flavor imparted by butter or margarine is used.

TABLE 22.1
Canned Vegetables, Source, and Optional Forms of Vegetable Ingredients

I—Name or Synonym of Canned Vegetable	II—Source	III—Optional Forms of Vegetable Ingredient
Artichokes	Flower buds of the artichoke plant	Whole; half or halves or halved; whole hearts; halved hearts; quartered hearts
Asparagus	Edible portions of sprouts of the asparagus plant, as follows:	
	3 and 3/4 in. or more of upper end;	Stalks or spears
	3 and 3/4 in. or more of peeled upper end	Peeled stalks or peeled spears
	Not less than 2 and 3/4 in. but less than 3 and 3/4 in. of upper end	Tips
	Less than 2 and 3/4 in. of upper end	Points
	Sprouts cut in pieces	Cut stalks or cut spears
	Sprouts from which the tip ha been removed, cut in pieces	Bottom cuts or cuts—tips removed
Bean sprouts	Sprouts of the Mung bean	
Shelled beans	Seed shelled from green or wax bean pods, with or without snaps (pieces of immature unshelled pods)	
Lima beans or butter beans	Seed shelled from the pods of the lima bean plant	
Beets	Root of the beet plant	Whole; slices or sliced; quarters or quartered; dice or diced; cut; shoestring or French style or julienne
Beet greens	Leaves, or leaves and immature root, of the beet plant	
Broccoli	Heads of the broccoli plant	
Brussels sprouts	Sprouts of the Brussels sprouts plant	
Cabbage	Cut pieces of the heads of the cabbage plant	
Carrots	Root of the carrot plant	Do
Cauliflower	Cut pieces of the head of the cauliflower plant	
Celery	Stalks of the celery plant	Cut; hearts
Collards	Leaves of the collard plant	
Dandelion greens	Leaves of the dandelion plant	
Kale	Leaves of the kale plant	
Mustard greens	Leave of the mustard plant	
Okra	Pods of the okra plant	Whole; cut
Onions	Bulb of the onion plant	Do
Parsnips	Root of the parsnip plant	Whole; quarters or quartered; slices or sliced; cut; shoestring or French style or julienne
Black-eye peas or black-eyed peas	Seed shelled from pods of the black-eye pea plant, with or without snaps (pieces of immature unshelled pods)	
Field peas	Seed shelled from pods of the field pea plant (other than the black-eye pea plant), with or without snaps (pieces of immature unshelled pods)	
Green sweet peppers	Green pods of the sweet pepper plant	Whole; halves or halved; pieces; dice or diced; strips; chopped
Red sweet peppers	Red-ripe pods of the sweet pepper plant	Do
Pimientos or pimentos	Red-ripe pods of the pimiento, pimento, pepper plant	Whole; halves or halved; pieces; dice or diced; slices or sliced; chopped
Potatoes	Tuber of the potato plant	Whole; slices or sliced; dice or diced; pieces; shoestring or French style or julienne; French fry cut

(*Continued*)

TABLE 22.1
(*Continued*)

I—Name or synonym of Canned Vegetable	II—Source	III—Optional Forms of Vegetable Ingredient
Rutabagas	Root of the rutabaga plant	Whole; quarters or quartered; slices or sliced; dice or diced; cut
Salsify	Root of the salsify plant	
Spinach	Leaves of the spinach plant	Whole leaf; cut leaf or sliced; chopped
Sweet potatoes	Tuber of the sweet potato plant	Whole; mashed; pieces or cuts or cut (longitudinally cut halves may be named on labels as halves or halved in lieu of pieces or cuts or cut)
Swiss chard	Leaves of the Swiss chard plant	
Truffles	Fruit of the truffle	
Turnip greens	Leaves of the turnip plant	
Turnips	Root of the turnip plant	Whole; quarters or quartered; slices or sliced; dice or diced; cut

In the case of all vegetables, the following optional ingredients may be added:

1. Salt.
2. Monosodium glutamate.
3. Disodium inosinate.
4. Disodium guanylate.
5. Hydrolyzed vegetable protein.
6. Autolyzed yeast extract.

In the case of all vegetables flavoring (except artificial) may be added.

In the case of bean sprouts, lima beans, carrots, green sweet peppers, red sweet peppers, and potatoes, any safe and suitable calcium salts may be added as a firming agent.

In the case of canned artichokes packed in glass containers, ascorbic acid may be added in a quantity not to exceed 32 milligrams per 100 grams of the finished food.

In the case of canned asparagus, ascorbic acid, erythorbic acid, or the sodium salts of ascorbic acid or erythorbic acid may be added in an amount necessary to preserve color in the "white" and "green-tipped and white" color types.

In the case of canned asparagus packed in glass containers, stannous chloride may be added in a quantity not to exceed 15 parts per million calculated as tin (Sn), except that in the case of asparagus packed in glass containers with lids lined with an inert material, the quantity of stannous chloride added may exceed 15 parts per million but not 20 parts per million calculated as tin (Sn).

In the case of canned black-eyed peas, disodium EDTA may be added in a quantity not to exceed 145 parts per million.

In the case of potatoes, calcium disodium EDTA may be added in a quantity not to exceed 110 parts per million.

A vinegar or any safe and suitable organic acid for all vegetables (except artichokes, in which the quantity of such optional ingredient is prescribed by the introductory text) in a quantity which, together with the amount of any lemon juice or concentrated lemon juice that may be added, is not more than sufficient to permit effective processing by heat without discoloration or other impairment of the article.

The name of each canned vegetable is designated in column I of the table.

When two or more forms of the vegetable are specified in column III of the table, the label should bear the specified word or words, showing the form of the vegetable ingredient present, except that in the case of canned spinach, if the whole leaf is the optional form used, the word "spinach" unmodified may be used in lieu of the words "whole leaf spinach."

If the optional ingredient specified is present, the label should bear the statement "_____ oil added" or "With added _____ oil," the blank being filled in with the common or usual name of the oil.

If asparagus juice is used as a packing medium in canned asparagus, the label should bear the statement "Packed in asparagus juice."

If the optional ingredient specified is present, the label should bear the statement "With snaps."

The name of the food should include a declaration of any flavoring that characterizes the product as specified, and a declaration of any spice or seasoning that characterizes the product; for example, "with added spice," "seasoned with red peppers," "seasoned with butter."

Wherever the name of the vegetable appears on the label so conspicuously as to be easily seen under customary conditions of purchase, the words and statements specified should immediately and conspicuously precede or follow such name, without intervening written, printed, or graphic matter, except that the varietal name of the vegetable may so intervene.

IX. CANNED CHILI SAUCE

Chili sauce is the product prepared from mature, clean, sound, tomatoes of the red or reddish varieties which are peeled and chopped or crushed, or all (or a portion) of the tomatoes may be chopped, crushed, or macerated and the peelings screened out in a manner so that at least a substantial portion of the seed remains in the product, to which is added salt, spices, vinegar, nutritive sweetening ingredients, and to which may be added vegetable flavoring ingredients such as chopped onion, chopped green or red pepper, chopped green tomatoes, chopped celery, and sweet pickle relish in such quantities as will not materially alter the appearance of the product with respect to the predominance of the tomato ingredient, and any other ingredients permissible under FDA regulations and standards. The chili sauce is processed in accordance with good commercial practice; is packed in hermetically sealed containers; and is sufficiently processed by heat, before or after sealing, to assure preservation of the product. The refractive index of the filtrate of the chili sauce at 20°C is not less than 1.3784.

A. Ingredients

1. Tomato Pulp

The primary ingredient in chili sauce is red tomatoes. The tomatoes may be hand peeled and broken up by stirring or the tomatoes may be prepared by any one of a number of machines especially designed for the purpose, or there may be a combination of whole peeled tomatoes and more or less macerated tomatoes from which the peelings have been removed by screening. These machines are usually similar to the tomato pulper or finisher, except that the holes through which the tomato material is forced are usually quite large. They are not nearly as efficient as the usual finishing machine at removing the peeling and defects from the tomatoes. For economic reasons some manufacturers have resorted to using a large amount of cyclone pulp and a small amount of hand-peeled or mechanically peeled tomatoes or tomatoes which have been forced through small openings. In general the more of the larger pieces of tomato material present, the better the pulp is for chili sauce.

2. Sugar

The use of any of the nutritive sweetening ingredients is permitted in this product. The usual sweetener is sugar (sucrose). The solids of chili sauce are usually brought up higher by the use of sugar and lowered by concentrating the tomatoes than is usual with catsup. Some manufacturers use as much as 1/2 more sugar than they do with catsup yet finish at about the same point with respect to soluble solids.

3. Spices, Salt, and Acids

Most of the same spices are used in chili sauce as in the manufacture of catsup, except that garlic is seldom used in chili sauce. The proportions of the various spice ingredients are not standardized between manufacturers. Salt and vinegar are used in about the same proportions as with catsup.

4. Other Ingredients

The other ingredients, such as onion, bell peppers, celery, and sweet pickle relish, contribute to the flavor of the product and also provide body to the finished product; that is, they provide part of the consistency and most of the chewiness of the finished chili sauce. The ingredients used and the proportions of the ingredients used vary widely from packer to packer; therefore, quite a variety of flavors can be expected in chili sauces. The onion ingredient is often dehydrated onion flakes. Red or green diced dehydrated peppers are often used.

5. Manufacture

Most important in the manufacture of chili sauce is the preparation of the tomato pulp.

6. Tomato Pulp

Where peeled tomatoes are used for a part or all of the tomato pulp they are usually taken from the regular canning lines after at least a partial preparation by mechanical or hand peeling, trimming, and coring. There is usually some selection of the raw tomatoes that are to be run through chili sauce preparation machines. Some packers divert very ripe tomatoes that need no trimming to the chili sauce lines while others box-sort or load-sort the tomatoes and trim them on the conveyer belts. This trimming removes defective parts and stems that would become defects in the sauce. The trimmers may or may not remove most of the green portions of the tomatoes depending on the machinery used and the manufacturer's desires with respect to the appearance of chili sauce. If green pepper, pickle relish, or green tomatoes are added green shouldered tomatoes are not usually trimmed. Manufacture consists of combining the ingredients in a manner so that the finished chili sauce will have the desired qualities of color, consistency, finish, absence of defects, and flavor. The tomato pulp, whether from broken peeled tomatoes or from special chili sauce machines, or cyclone juice to which some tomato material containing tomato seed is added, is run to kettles, usually steam jacketed, and reduced by boiling to about one-half the original volume. Concentration in vacuum pans is particularly satisfactory for this operation.

7. Adding Other Ingredients

Onion is often added at the beginning of the boil. The other ingredients may be added at any time but the

sugar is usually added late to prevent caramelization. Spices, if in the form of oils or cream of spice, are usually added late to prevent evaporation of the flavor ingredients.

8. The Finishing Point

Because of the nature of the ingredients there is no accurate means of determining a correct finishing point which will apply to all formulae. The first batches when starting, or after any major change in formula, are dropped when they appear to be about correct. As with tomato catsup the consistency of the hot sauce may be measured by any suitable device and the refractive index may be taken. Succeeding batches can then be adjusted by these instruments by increasing or decreasing the boiling or by adjusting the amounts of pulp and sugar to the desired result.

9. Processing

Chili sauce is usually closed at about 180°, at which temperature further processing is usually not necessary. Foaming may occur at higher temperatures and an additional process is usually given if the sauce is closed at lower temperatures.

X. CANNED TOMATOES

Canned tomatoes is the food prepared from mature tomatoes conforming to the characteristics of the fruit *Lycopersicum esculentum* P. Mill, of red or reddish varieties. The tomatoes may or may not be peeled, but should have had the stems and calicies removed and should have been cored, except where the internal core is insignificant to texture and appearance.

Canned tomatoes may contain one or more of the safe and suitable optional ingredients, be packed without any added liquid or in one of the optional packing media, and be prepared in one of the styles. Such food is sealed in a container and before or after sealing is so processed by heat as to prevent spoilage.

One or more of the following safe and suitable ingredients may be used:

1. Calcium salts in a quantity reasonably necessary to firm the tomatoes, but the amount of calcium in the finished canned tomatoes is not more than 0.045 percent of the weight, except that when the tomatoes are prepared in one of the styles specified the amount of calcium is not more than 0.08 percent of the weight of the food.
2. Organic acids for the purpose of acidification.
3. Dry nutritive carbohydrate sweeteners whenever any organic acid is used, in a quantity reasonably necessary to compensate for the tartness resulting from such added acid.
4. Salt.
5. Spices, spice oils.
6. Flavoring and seasoning.
7. Vegetable ingredients such as onion, peppers, and celery, that may be fresh or preserved by physical means, in a quantity not more than 10 percent by weight of the finished food.

A. Packing Media

Packing media includes:

1. The liquid draining from the tomatoes during or after peeling or coring.
2. The liquid strained from the residue from preparing tomatoes for canning consisting of peels and cores with or without tomatoes or pieces thereof.
3. The liquid strained from mature tomatoes (tomato juice).
4. Tomato paste, or tomato puree, or tomato pulp complying with the compositional requirements.

1. Styles

Styles may be:

(a) Whole.
(b) Diced.
(c) Sliced.
(d) Wedges.

2. Name of the Food

The name of the food is "tomatoes," except that when the tomatoes are not peeled the name is "unpeeled tomatoes."

The following should be included as part of the name or in close proximity to the name of the food.

(a) A declaration of any flavoring that characterizes the product as specified.
(b) A declaration of any added spice, seasoning, or vegetable ingredient that characterizes the product, (e.g., "with added _____" or, "with _____" the blank to be filled in with the word(s) "spice(s)," "seasoning(s)," or the name(s) of the vegetable(s) used or in lieu of the word(s) "spice(s)" or "seasoning (s)" the common or usual name(s) of the spice(s) or seasoning(s) used) except that no declaration of the presence of onion, peppers, and celery is required for stewed tomatoes.
(c) The word "stewed" if the tomatoes contain characterizing amounts of at least the three optional vegetables listed.

(d) The styles: "Diced," "sliced," or "wedges" as appropriate.
(e) The name of the packing medium: "tomato paste," "tomato puree," or "tomato pulp" or "strained residual tomato material from preparation for canning." The name of the packing medium should be preceded by the word "with."
(f) The following may be included as part of the name or in close proximity to the name:

The word "whole" if the tomato ingredient is whole or almost whole, and the weight of such ingredient is not less than 80 percent of the drained weight of the finished food as determined in accordance with the method prescribed.

The words "solid pack" when none of the optional packing media are used.

The words "in tomato juice" if the packing medium is used.

The name of each ingredient used should be declared on the label as required.

The standard of quality for canned tomatoes is as follows:

The drained weight is not less than 50 percent of the weight of water required to fill the container

The strength and redness of color is not less than that of the blended color of any combination of the color discs.

Blemishes per kilogram (2.2 pounds) of the finished food cover an area of not more than 3.5 cm (0.54 square inch) which is equivalent to 1.6 cm (0.25 square inch) per pound based on an average of all containers examined.

If the quality of canned tomatoes falls below standard with respect to only one of the factors of quality specified, there may be substituted for the second line of such general statement of substandard quality ("Good Food—Not High Grade") a new line to read as follows:

"Poor color" or
"Excessive peel" or
"Excessive blemishes."

3. Fill of Container

The standard of fill of container for canned tomatoes is a fill of not less than 90 percent of the total capacity of the container.

If canned tomatoes fall below the standard of fill of container, the label should bear the general statement of substandard fill

XI. CANNED TOMATO JUICE

Tomato juice is the food intended for direct consumption, obtained from the unfermented liquid extracted from mature tomatoes of the red or reddish varieties of *Lycopersicum esculentum* P. Mill, with or without scalding followed by draining. In the extraction of such liquid, heat may be applied by any method that does not add water thereto.

Such juice is strained free from peel, seeds, and other coarse or hard substances, but contains finely divided insoluble solids from the flesh of the tomato in accordance with current good manufacturing practice. Such juice may be homogenized, may be seasoned with salt, and may be acidified with any safe and suitable organic acid. The juice may have been concentrated and later reconstituted with water and/or tomato juice to a tomato soluble solids content of not less than 5.0 percent by weight.

The food is preserved by heat sterilization (canning), refrigeration, or freezing. When sealed in a container to be held at ambient temperatures, it is so processed by heat, before or after sealing, as to prevent spoilage.
The name of the food is:

1. "Tomato juice" if it is prepared from unconcentrated undiluted liquid extracted from mature tomatoes of reddish varieties.
2. "Tomato juice from concentrate" if the finished juice has been prepared from concentrated tomato juice as specified or if the finished juice is a mixture of tomato juice and tomato juice from concentrate.

Each of the ingredients used in the food should be declared on the label as required.

The standard of quality for tomato juice is as follows:

The strength and redness of color complies with specific requirement.

Not more than two defects for peel and blemishes, either singly or in combination, in addition to three defects for seeds or pieces of seeds, defined as follows, per 500 milliliters (16.9 fluid ounces):

(a) Pieces of peel 3.2 millimeters (0.125 inch) or greater in length.
(b) Blemishes such as dark brown or black particles (specks) greater than 1.6 millimeters (0.0625 inch) in length.
(c) Seeds or pieces of seeds 3.2 millimeters (0.125 inch) or greater in length.

If the quality of the tomato juice falls below the standard, the label should bear the general statement of substandard quality.

In lieu of such general statement of substandard quality when the quality of the tomato juice falls below the standard in one or more respects, the label may bear the alternative statement, "Below Standard in Quality _____," the blank to be filled in with the words:

(i) "Poor color"
(ii) "Excessive pieces of peel"
(iii) "Excessive blemishes."
(iv) "Excessive seeds" or "excessive pieces of seed."

The standard of fill of container for tomato juice is not less than 90 percent of the total capacity, except when the food is frozen.

If the tomato juice falls below the standard of fill, the label should bear the general statement of substandard fill.

XII. CANNED TOMATO CONCENTRATES, "TOMATO PUREE," "TOMATO PULP," OR "TOMATO PASTE"

Tomato concentrates are the class of foods each of which is prepared by concentrating one or any combination of two or more of the following optional tomato ingredients:

1. The liquid obtained from mature tomatoes of the red or reddish varieties (Lycopersicum esculentum P. Mill).
2. The liquid obtained from the residue from preparing such tomatoes for canning, consisting of peelings and cores with or without such tomatoes or pieces thereof.
3. The liquid obtained from the residue from partial extraction of juice from such tomatoes.

Such liquid is obtained by so straining the tomatoes, with or without heating, as to exclude skins (peel), seeds, and other coarse or hard substances in accordance with good manufacturing practice. Prior to straining, food-grade hydrochloric acid may be added to the tomato material in an amount to obtain a pH no lower than 2.0. Such acid is then neutralized with food-grade sodium hydroxide so that the treated tomato material is restored to a pH of 4.2 $\pm$ 0.2. Water may be added to adjust the final composition. The food contains not less than 8.0 percent tomato soluble solids as specified.

The food is preserved by heat sterilization (canning), refrigeration, or freezing. When sealed in a container to be held at ambient temperatures, it is so processed by heat, before or after sealing, as to prevent spoilage.

One or any combination of two or more of the following safe and suitable ingredients may be used in the foods:

1. Salt (sodium chloride formed during acid neutralization should be considered added salt).
2. Lemon juice, concentrated lemon juice, or organic acids.
3. Sodium bicarbonate.
4. Water.
5. Spices.
6. Flavoring.

The name of the food is:

1. "Tomato puree" or "tomato pulp" if the food contains not less than 8.0 percent but less than 24.0 percent tomato soluble solids.
2. "Tomato paste" if the food contains not less than 24.0 percent tomato soluble solids.
3. The name "tomato concentrate" may be used in lieu of the name "tomato puree," "tomato pulp," or "tomato paste" whenever the concentrate complies with the requirements of such foods, except that the label should bear the statement "for re-manufacturing purposes only" when the concentrate is packaged in No. 10 containers (3.1 kilograms or 109 avoirdupois ounces total water capacity) or containers that are smaller in size.
4. "Concentrated tomato juice" if the food is prepared from the optional tomato ingredient described and is of such concentration that upon diluting the food according to label directions as required, the diluted article will contain not less than 5.0 percent by weight tomato soluble solids.

The following should be included as part of the name or in close proximity to the name of the food:

1. The statement "Made from" or "Made in part from," as the case may be, "residual tomato material from canning" if the optional tomato ingredient is present.
2. The statement "Made from" or "Made in part from," as the case may be, "residual tomato material from partial extraction of juice" if the optional tomato ingredient present.
3. A declaration of any flavoring that characterizes the product and a declaration of any spice that characterizes the product, e.g., "Seasoned with _____," the blank to be filled in with the words "added spice" or, in lieu of the word "spice," the common name of the spice.

The label of concentrated tomato juice should bear adequate directions for dilution to result in a diluted article containing not less than 5.0 percent by weight tomato soluble solids, except that alternative methods may be used to convey adequate dilution directions for containers that are larger than No. 10 containers (3.1 kilograms or 109 avoirdupois ounces total water capacity).

A. Fill of Container

The standard of fill of container for tomato concentrate, as determined by the general method for fill of container, is not less than 90 percent of the total capacity, except when the food is frozen.

XIII. TOMATO CATSUP

Catsup, ketchup, or catchup is the food prepared from one or any combination of two or more of the following optional tomato ingredients:

1. Tomato concentrate as described.
2. Lemon juice, concentrated lemon juice, or safe and suitable organic acids may be used in quantities no greater than necessary to adjust the pH.

3. The liquid derived from mature tomatoes of the red or reddish varieties *Lycopersicum esculentum* P. Mill.
4. The liquid obtained from the residue from preparing such tomatoes for canning, consisting of peelings and cores with or without such tomatoes or pieces thereof.
5. The liquid obtained from the residue from partial extraction of juice from such tomatoes. Such liquid is strained so as to exclude skins, seeds, and other coarse or hard substances in accordance with current good manufacturing practice. Prior to straining, food-grade hydrochloric acid may be added to the tomato material in an amount to obtain a pH no lower than 2.0. Such acid is then neutralized with food-grade sodium hydroxide so that the treated tomato material is restored to a pH of 4.2 ± 0.2.

The final composition of the food may be adjusted by concentration and/or by the addition of water. The food may contain salt (sodium chloride formed during acid neutralization should be considered added salt) and is seasoned with optional ingredients (see above).

The food is preserved by heat sterilization (canning), refrigeration, or freezing. When sealed in a container to be held at ambient temperatures, it is so processed by heat, before or after sealing, as to prevent spoilage.

One or any combination of two or more of the following ingredients in each category is added to the tomato ingredients:

1. Vinegars.
2. Nutritive carbohydrate sweeteners.
3. Spices, flavoring, onions, or garlic.
4. Labeling.
5. The name of the food is "Catsup," "Ketchup," or "Catchup."

The following should be included as part of the name or in close proximity to the name of the food:

1. The statement "Made from" or "Made in part from," as the case may be, "residual tomato material from canning" if the optional tomato ingredient or tomato concentrate containing the ingredient is present.
2. The statement "Made from" or "Made in part from," as the case may be, "residual tomato material from partial extraction of juice" if the optional tomato ingredient or tomato concentrate containing the ingredient is present.

The name "tomato concentrate" may be used in lieu of the names "tomato puree," "tomato pulp," or "tomato paste" and when tomato concentrates are used.

A. Fill of Container

The standard of fill of container for catsup is not less than 90 percent of the total capacity except when the food is frozen, or when the food is packaged in individual serving-size packages containing 56.7 grams (2 ounces) or less.

23 Frozen Vegetables: Product Descriptions

Peggy Stanfield
Dietetic Resources

CONTENTS

I. INTRODUCTION

This book is not the proper forum to discuss the manufacture of every processed vegetable available in the market. However, regulatory agencies such the Department of Agriculture (USDA) and the Food and Drug Administration (FDA) have issued some minimal criteria for each processed vegetable such as what they are, what types and styles are available and so on. The information in this chapter describes each available frozen vegetable product and has been modified from the product grades (USDA) and product standards (FDA). Product standards and product grades are established to achieve two objectives: assure product safety and minimize economic fraud.

The information provided here has one major objective: to remind a commercial processor what each frozen vegetable is and the applicable criteria for particular products.

II. FROZEN ASPARAGUS

Frozen asparagus consists of sound and succulent fresh shoots of the asparagus plant (*Asparagus officianalis*). The product is prepared by sorting, trimming, washing, and blanching as necessary to assure a clean and wholesome product. It is then frozen and stored at temperatures necessary for preservation.

1. TYPES

1. Green or all-green consists of units of frozen asparagus which are typically green, light-green, or purplish-green in color.
2. Green-white consists of frozen asparagus spears and tips which have typical green, light-green, or purplish-green color to some extent but which are white in the lower portions of stalk.

2. STYLES

Spears or stalks style consists of units composed of the head and adjoining portion of the shoot that are 3 inches or more in length. Tips style consists of units composed of the head and adjoining portion of the shoot that are less than 3 inches in length. Center cuts or cuts style consists of portions of shoots (with or without head material) that are cut transversely into units not less than one-half inch in length and that fail to meet the definition for cut spears or cuts and tips style.

Cut spears or cuts and tips style consists of the head and portions of the shoot cut transversely into units 2 inches or less but not less than one-half inch in length. To be considered this style head material should be present in these amounts for the respective lengths of cuts:

1. 1-1/4 inches or less. Not less than 18 percent (average), by count, of all cuts are head material.
2. Longer than 1-1/4 inches. Not less than 25 percent (average), by count, of all cuts are head material.

III. FROZEN LIMA BEANS

Frozen lima beans are the frozen product prepared from the clean, sound, succulent seed of the lima bean plant without soaking, by shelling, washing, blanching, and properly draining. They are then frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

1. TYPES

1. Thin-seeded such as Henderson, Bush, and Thorogreen varieties.
2. Thick-seeded Baby Potato such as Baby Potato, Baby Fordhook, and Evergreen. Thick-seeded, such as Fordhook variety.

IV. FROZEN BEANS, SPECKLED BUTTER (LIMA)

Frozen speckled butter (lima) beans are the frozen product prepared from the clean, sound, freshly-vined (but not seed-dry) seed of the speckled butter (lima) bean plant (*Phaseolus limensis*). The skins of the seed are pigmented and the external colors range from variegated speckling of green, pink, red, and/or lavender to purple. The product is prepared by shelling the pods; by washing, blanching, and properly draining the seeds that have been sorted and blended or otherwise prepared in accordance with good commercial practice. They are frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

V. FROZEN BROCCOLI

Frozen broccoli is the product prepared from the fresh, clean, sound stalks or shoots of the broccoli plant [*Brassica oleracea* (Italica group)] by trimming, washing, blanching, sorting, and properly draining. The product is frozen in accordance with good commercial practice and maintained at temperatures necessary for its preservation.

1. STYLES

1. Spears or stalks are the head and adjoining portions of the stem, with or without attached leaves, which may range in length from 9 cm (3.5 in.) to 15 cm (5.9 in.). The spears or stalks may be cut longitudinally.
2. Short spears or florets are the head and adjoining portions of the stem, with or without attached leaves, which may range in length from 2.5 cm (1 in.) to 9 cm (3.5 in.). Each short

spear or floret must weigh more than 6 g (0.2 oz). The short spears or florets may be cut longitudinally.

3. Cut spears or short spears are cut into portions which may range in length from 2 cm (0.8 in.) to 5 cm (2 in.). Head material should be at least 62.5 g (2.2 oz) per 250 g (8.8 oz) and leaf material should not be more than 62.5 g (2.2 oz) per 250 g (8.8 oz).
4. Chopped spears or short spears are cut into portions which are less than 2 cm (0.8 in.) in length. Head material should be at least 12.5 g (0.4 oz) per 50 g (1.8 oz) and leaf material should not be more than 12.5 g (0.4 oz) per 50 g (1.8 oz).
5. Pieces or random cut pieces are cut or chopped portions of spears or short spears or other units which do not meet the requirements for cut or chopped styles.

VI. FROZEN BRUSSELS SPROUTS

Frozen Brussels sprouts are the frozen product prepared from the clean, sound succulent heads of the Brussels sprouts plant (*Brassica oleracea* L. var. *gemmifera*) by trimming, washing, blanching, and properly draining. The product is frozen in accordance with good commercial practice and maintained at temperatures necessary for its preservation.

VII. FROZEN CARROTS

Frozen carrots are the clean and sound product prepared from the fresh root of the carrot plant (*Daucus carota*) by washing, sorting, peeling, trimming, and blanching, and are frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

1. Styles

Wholes (or whole carrots) retain the approximate confirmation of a whole carrot.

Halves or halved carrots are cut longitudinally into two units.

Quarters or quartered carrots are cut longitudinally into four approximately equal units. Carrots cut longitudinally or cut longitudinally and crosswise into six or eight units approximating the size and appearance of quartered carrots are also permitted in this style.

Slices or sliced carrots are sliced transversely to the longitudinal axis.

Diced carrots consist of approximate cube-shaped units.

Double-diced carrots consist of approximate rectangular shapes that resemble the equivalent of two cube-shaped units.

Strips are carrots that consists of approximate French-cut shapes, with flat-parallel or corrugated-parallel surfaces, one-half inch or more in length.

Chips are carrots that consist of predominately small-sized units (such as less than one-half cube) and variously shaped pieces or slivers in which the longest-edge dimension approximates not more than one-half inch.

Cut carrots consist of cut units that do not conform to any of the forgoing styles.

VIII. FROZEN CAULIFLOWER

Frozen cauliflower is prepared from fresh flower heads of the cauliflower plant (*Brassica oleracea botrytis*) by trimming, washing, and blanching, and is frozen and maintained at temperatures necessary for preservation of the product.

1. Styles and Requirements

1. Clusters are individual segments of trimmed and cored cauliflower heads, which measure not less than 20 mm (0.75 in.) in the greatest dimension across the top of the unit. A maximum of 10%, by weight, of clusters less than 20 mm (0.75 in.) in the greatest dimension across the top of the unit are allowed.
2. Nuggets or small clusters are individual segments of trimmed and cored cauliflower heads, which measure from 6 mm (0.25 in.) to less than 20 mm (0.75 in.) in the greatest dimension across the top of the unit. A maximum of 20%, by weight, of clusters, 20 mm (0.75 in.) or greater, and a maximum of 10%, by weight, of clusters less than 6 mm in the greatest dimension across the top of the unit are allowed.

IX. FROZEN CORN ON THE COB

Frozen corn on the cob is the product prepared from sound, properly matured, fresh, sweet corn ears by removing husk and silk, by sorting, trimming, and washing to assure a clean and wholesome product. The ears are blanched, then frozen and stored at temperatures necessary for the preservation of the product.

1. Styles

1. Trimmed. Ears trimmed at both ends to remove tip and stalk ends and or/cut to specific lengths.

2. Natural. Ears trimmed at the stalk end only to remove all or most of the stalk.

2. Lengths

1. Regular. Ears which are predominantly over 3-1/2 inches in length.
2. Ears which are predominantly 3-1/2 inches or less in length.

Colors of frozen corn on the cob: Golden (or yellow); white.

X. FROZEN LEAFY GREENS

Frozen leafy greens are the frozen product prepared from the clean, sound, succulent leaves and stems of any one of the plants listed below by sorting, trimming, washing, blanching, and properly draining. The product is processed by freezing and maintained at temperatures necessary for its preservation. Any functional, optional ingredient(s) permissible under the law may be used to acidify and/or season the product.

1. Types

Beet greens.
Collards.
Dandelion greens.
Endive.
Kale.
Mustard greens.
Spinach.
Swiss chard.
Turnip greens.
Any other "market accepted" leafy green.

2. Styles

1. Leaf consists substantially of the leaf, cut or uncut, with or without adjoining portion of the stem.
2. Chopped consists of the leaf with or without adjoining portion of the stem that has been cut into small pieces less than approximately 20 mm (0.78 in.) in the longest dimension but not comminuted to a pulp or a puree.
3. Pureed consists of the leaf with or without adjoining portion of the stem that has been comminuted to a pulp or a puree.

XI. FROZEN OKRA

Frozen okra is the product prepared from the clean, sound, succulent, and edible fresh pods of the okra plant (*Hibiscus esculentus*) of the green variety. The product may or may not be trimmed, is properly prepared and properly processed, and is then frozen and stored at temperatures necessary for preservation.

1. Styles

1. Whole okra consists of trimmed or untrimmed whole pods of any length that may possess an edible portion of the cap. The length of a whole pod is determined by measuring from the outermost point of the tip end of the pod to the outermost point of the stem end of the pod, exclusive of any inedible stem portion that may be present.
2. Cut okra is trimmed or untrimmed whole pods, which may possess an edible portion of cap, and which have been cut transversely into pieces of approximate uniform length. The length of a unit of cut okra is determined by measuring the longitudinal axis of the unit.

XII. FROZEN ONION RINGS, BREADED, RAW OR COOKED

Frozen breaded onion rings, hereinafter referred to as frozen onion rings, is the product prepared from clean and sound, fresh onion bulbs (*Allium cepa*) from which the root bases, tops, and outer skin have been removed. The onion bulbs are sliced and separated into rings, coated with batter (or breaded), and may or may not be deep fried in a suitable fat or oil bath. The product is prepared and frozen in accordance with good commercial practice and maintained at temperatures necessary for the proper preservation of the product.

1. Types

The type of frozen onion rings applies to the method of preparation of the product, and includes:

1. French fried onion rings that have been deep fried in a suitable fat or oil bath prior to freezing.
2. Raw breaded onion rings that have not been oil blanched or cooked prior to freezing.

XIII. FROZEN PEAS

Frozen peas is the food in "package" form, prepared from the succulent seed of the pea plant of the species *Pisum sativum* L. Any suitable variety of pea may be used. It is blanched, drained, and preserved by freezing in such a way that the range of temperature of maximum crystallization is passed quickly. The freezing process should not

be regarded as complete until the product temperature has reached −18°C (0°F) or lower at the thermal center, after thermal stabilization. Such food may contain one, or any combination of two or more, of the following safe and suitable optional ingredients:

XIV. PEAS, FIELD AND BLACK-EYE

Frozen field peas and frozen black-eye peas, hereafter referred to as frozen peas, are the frozen product prepared from clean, sound, fresh, seed of proper maturity of the field pea plant (*Vigna sinensis*), by shelling, sorting, washing, blanching, and properly draining. The product is frozen and maintained at temperatures necessary for preservation. Frozen peas may contain succulent, unshelled pods (snaps) of the field pea plant or small sieve round type succulent pods of the green bean plant as an optional ingredient used as a garnish.

XV. FROZEN PEPPERS, SWEET

Frozen sweet peppers are the frozen product prepared from fresh, clean, sound, firm pods of the common commercial varieties of sweet peppers, which have been properly prepared, may or may not be blanched, and are then frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

1. TYPES

Type I, green.
Type II, red.
Type III, mixed (green and red).

2. STYLES

1. Whole stemmed: whole unpeeled pepper pods with stem and core removed.
2. Whole unstemmed: whole unpeeled pepper pods with stems trimmed to not more than 1/2 inch length.
3. Halved: whole stemmed, unpeeled pepper pods which have been cut approximately in half from stem to blossom end.
4. Sliced: whole stemmed, unpeeled pepper pods or pieces of pepper pods which have been cut into strips.
5. Diced: whole stemmed, unpeeled pepper pods or pieces of pepper pods which have been cut into approximate square pieces measuring 1/2 inch or less.
6. Unit: a whole unpeeled pepper pod or portion of a pepper pod in frozen sweet peppers.

XVI. FROZEN POTATOES, FRENCH FRIED

Frozen French fried potatoes are prepared from mature, sound, white or Irish potatoes (*Solanum tuberosum*). The potatoes are washed, sorted, and trimmed as necessary to assure a clean and wholesome product. The potatoes may or may not be cut into pieces. The potatoes are processed in accordance with good commercial practice which includes deep frying or blanching in a suitable fat or oil and which may include the addition of any ingredient permissible under the law. The prepared product is frozen and is stored at temperatures necessary for its preservation.

1. TYPES

Frozen French fried potatoes are of two types, based principally on intended use, as follows:

1. Retail type. This type is intended for household consumption. It is normally packed in small packages that are labeled or marked for retail sales. It may be otherwise designated for such use.
2. Institutional type. This type is intended for the hotel, restaurant, or other large feeding establishment trade. Primary containers, usually 5 pounds or more, are often not as completely labeled as for retail sales.

2. STYLES

Styles of potatoes are grouped into general, strips, slices, dices, and Rissolé.

The style of frozen French fried potatoes is identified by the general size, shape, or other physical characteristics of the potato units. Styles with cut units may be further identified by substyles as follows:

1. Straight cut refers to smooth cut surfaces and
2. Crinkle cut refers to corrugated cut surfaces.

The strips style consists of elongated pieces of potato with practically parallel sides and of any cross-sectional shape. This style may be further identified by the approximate dimensions of the cross-section, for example:

1/4 × 1/4 inch
3/8 × 3/8 inch
1/2 × 1/4 inch, or
3/8 × 3/8 inch

Shoestring refers to strip, either straight cut or crinkle cut, with a cross section predominantly less than that of a square measuring 3/8 × 3/8 inch.

Slices is a style that consists of pieces of potato with two practically parallel sides, and which otherwise conform generally to the shape of the potato. This style may also contain a normal amount of outside slices.

Dices consists of pieces of potato cut into approximate cubes.

Rissolé is a style that consists of whole or nearly whole potatoes.

Any other individually frozen French fried potato product may be designated as to style by description of the size, shape, or other characteristic that differentiates it from the other styles.

3. Length Designations

The length designations described in this section apply to strip styles only.

Frozen French fried potato strips are designated as to length in accordance with the following criteria. Percent, as used in this section, means the percent, by count, of all strips of potato that are 1/2-inch in length, or longer.

1. Extra long. Eighty (80) percent or more are 2 inches in length or longer; and 30 percent or more are 3 inches in length or longer.
2. Long. Seventy (70) percent or more are 2 inches in length, or longer; and 15 percent or more are 3 inches in length or longer.
3. Medium. Fifty (50) percent or more are 2 inches in length or longer.
4. Short. Less than 50 percent are 2 inches in length or longer.

XVII. FROZEN POTATO, HASH BROWN

Frozen hash brown potatoes are prepared from mature, sound, white or Irish potatoes (*Solanum tuberosum*) that are washed, peeled, sorted, and trimmed to assure a clean and wholesome product. The potatoes so prepared are blanched, may or may not be fried, and are shredded or diced or chopped and frozen and stored at temperatures necessary for their preservation.

1. Styles

1. Shredded. Shredded potatoes are cut into thin strips with cross-sectional dimensions from 1 mm by 2 mm to 4 mm by 6 mm and formed into a solid mass before freezing.
2. Diced. Diced potatoes are cut into approximate cube shape units from 6 mm to 15 mm on an edge and loose frozen. They contain not more than 90 grams, per sample unit, of units smaller than one-half the volume of the predominant size unit.
3. Chopped. Chopped potatoes are random cut pieces predominantly less than 32 mm in their greatest dimension and loose frozen.

XVIII. FROZEN VEGETABLES, MIXED

Frozen mixed vegetables consist of three or more succulent vegetables, properly prepared and properly blanched; may contain vegetables (such as small pieces of sweet red peppers or sweet green peppers) added as garnish; and are frozen and maintained at temperatures necessary for the preservation of the product.

1. Kinds and Styles of Basic Vegetables

It is recommended that frozen mixed vegetables, other than small pieces of vegetables added as garnish, consist of the following kinds and styles of vegetables as basic vegetables:

1. Beans, green or wax: Cut styles, predominantly of 1/2 inch to 1-1/2 inch cuts.
2. Beans, lima: Any single varietal type.
3. Carrots: Diced style, predominantly of 3/8 inch to 1/2 inch cubes.
4. Corn sweet: Golden (or Yellow) in whole kernel style.
5. Peas: Early type or sweet type.

2. Recommended Proportions of Ingredients

It is recommended that frozen mixed vegetables consist of three, four, or five basic vegetables in the following proportions:

1. Three vegetables. A mixture of three basic vegetables in which any one vegetable is not more than 40 percent by weight of all the frozen mixed vegetables.
2. Four vegetables. A mixture of four basic vegetables in which none of the vegetables is less than 8 percent by weight or more than 35 percent by weight of all the frozen mixed vegetables.
3. Five vegetables. A mixture of five basic vegetables in which none of the vegetables is less than 8 percent by weight or more than 30 percent by weight of all the frozen mixed vegetables.

CONTENTS

I. INTRODUCTION

Fruits, either fresh or processed, form an important part of our daily diet, and demand is increasing in all affluent countries of the world. This has become possible because of the availability of the improved quality and extended variety of fruits throughout the year. Recent advances in agricultural technology have contributed significantly to the improved production of fruits throughout the world. In addition, the critical advances in fruit processing technologies, refrigeration, transportation, storage and distribution have made it possible for consumers to enjoy these products year-round. The emphasis in fruit processing is shifting now from traditional methods like canning, freezing and dehydration to "fresh cut" or "minimal processing." Because present-day consumers prefer food products that contain fruit, food processors are using more fruits as value-added ingredients (fruit concentrates, pulps, candied pieces, etc.) in their formulations, like snacks, baby foods, baked goods and many other processed foods. At the same time, the variety of fruits available for extended periods throughout the year in developed countries has increased. Many tropical fruits that were earlier considered exotic and expensive are now being commonly consumed as fresh produce.

Fruit consumption has witnessed unprecedented growth during the past few decades. Current nutrition studies are making consumers more informed about the health benefits of various fruit constituents. The importance of vitamins, minerals, antioxidants, dietary fiber and a long list of phytochemicals present in fruits are being discussed daily in the print and television media. Now, the idea of nutrient clusters also supports the need for a varied healthy diet that contains recommended servings of fruits and vegetables (1). A diet that lacks fruits and vegetables rarely supplies the levels of nutrients needed for optimal health. The world population is also ageing and life expectancy is increasing with every passing decade. This prompts us to understand the relationship of nutrition to ageing and to study the effect of dietary requirements on an aged population. The role of phytochemicals present in fruits and vegetables in promoting health and reducing the risk of various chronic diseases among the older adults is now attracting the attention of health professionals (2).

II. BIOLOGY OF FRUITS

Fruit, in strict botanical terms, is the fleshy or dry ripened ovary of a plant, which encloses the seed or seeds. Therefore, mangoes, apricots, bananas, grapes, bean pods, almonds, tomatoes and cucumbers are all technically fruits. However, the term fruit is restricted to the ripened ovaries that are sweet and either succulent or pulpy. A fruit, when developed from only the carpellary structures, is called a true fruit or, if it is developed from a superior ovary, a superior fruit. Fruits with accessory parts are called accessory fruits (grapes, dates and plums), or because of their frequent development from inferior ovaries, are called inferior fruits (bananas, pears and walnuts). Invariably, the true fruits develop from the superior ovaries of hypogynous or perigynous flowers, but the accessory fruits usually develop from the inferior or part-inferior ovaries of epigynous or semiepigynous flowers. The number of ovaries and flowers that constitute the fruits also characterizes fruits. A simple fruit is derived from one ovary (e.g., apples), whereas an aggregate fruit is developed from several ovaries of one flower (e.g., strawberries). A multiple or collective fruit is developed from the structures of ovaries and accessories of several flowers consolidated into a mass (e.g., figs and pineapples). Simple fruits are either true or accessory fruits, but the aggregate and multiple fruits are always accessory fruits.

The classification of fruits is based on numerous criteria, e.g., dehiscence versus indehiscence, dry versus fleshy, textural quality, morphology, development, relationship of ovary to other reproductive parts of the plant and number of carpels and seeds present therein. Fleshy fruits are generally indehiscent, but with a few exceptions. The major types of simple fleshy fruits include a pome with a thin inner part (endocarp) and fleshy outer part (e.g., pear and pomegranate); the latter is a leathery pome. The drupe (stone fruit, e.g., cherry, peach, plum) has an outer exocarp (skin) in the fruit wall, a central fleshy mesocarp (flesh) and an inner stony endocarp or stone. The berry has the entire center of fruit as fleshy (e.g., grapes, bananas, kiwi), whereas hesperidium, a modified berry, has a thick, leathery separate outer rind (e.g., citrus fruits).

Fruits are very perishable in nature because these are living and respiring tissues. Based on the post-harvest patterns of respiration, fruits are classified as climacteric and nonclimacteric (3). Climacteric fruits, such as mango, banana, pear, apricot, guava, kiwi, papaya, peach, fig, plum and apple, produce large amounts of carbon dioxide and ethylene; the production rates of these gases coincide with ripening. These fruits can be harvested at an early mature stage and ripened artificially with ethylene gas (4). The nonclimacteric fruits, such as the orange, strawberry, grape, lime, lemon, pineapple, grapefruit and cherry, show no change in their low production rates of these two gases during ripening and post-harvest storage. Nonclimacteric fruits, if picked too early, are generally sour and of poor quality because they ripen gradually over a long period of time. Environmental factors, like temperature, relative humidity and atmospheric gaseous composition, greatly influence the respiration rate and shelf life of fruits during post-harvest storage. Handling methods should be chosen carefully so that they maintain fruit quality and chemical composition. The delay between harvesting, cooling, processing and consumption may lead to direct losses in

quality (water loss and decay) and indirect losses in flavor and nutritional quality. The harvesting at an appropriate stage of maturity is, therefore, important for better post-harvest shelf life and final fruit quality (5).

III. EDIBLE FRUITS OF THE WORLD

Fruits are grown in temperate, subtropical and tropical climates of the world. Among the fruits grown in temperate and subtropical regions, oranges are the leading groups of fruit in terms of production, which are mainly processed into juice (Table 24.1). Bananas are the second leading fruits and are consumed mainly in fresh form. The major portion of grapes the third leading fruits, goes into juice, wine production and dried fruits, i.e., raisins (6). The major grape-growing countries of the world are Italy, France, the United States, Spain and Russia. The fourth leading group, apples, are mostly eaten as fresh, but reasonable quantities are also processed into juice, dried or canned. Kiwi is another fruit that has become increasingly popular in the international market. The production of fruits is increasing rapidly throughout the world and fruits are becoming great foreign exchange earners for the developing countries.

TABLE 24.1
World Production of Major Fruits (1000 MT)

Fruit	Production	Fruit	Production
Oranges	63,838	Plums	7,836
Bananas	58,975	Peaches	10,923
Grapes	58,466	Papayas	5,024
Apples	56,087	Strawberries	2,682
Mangoes	23,428	Apricots	2,295
Pineapples	12,794	Avocadoss	2,342
Pears	13,318	Grapefruits & Pomelos	5,038
Plantains	29,501	Raspberries	306

Source: Ref. 6.

Banana, mango, papaya and pineapple are the important tropical fruits that have gained commercial importance in international trade (7). Mangoes and lychees are becoming immensely popular fruits among the Asian population all over the world. The United States is the leading producer of fruits in the world, is followed by Brazil, Italy, India, France, Russia and China (6, 8). A few of the important examples of fruits grown in each of the climatic regions of the world (9) are presented in Table 24.2.

IV. COMPOSITION OF FRUITS

Fruits and their processed products are not only colorful, flavorful and appealing to the eye, but are also vital sources of essential vitamins, minerals, dietary fiber and a host of important health-promoting phytochemicals (10). In addition to these nutrients, they also contain complex carbohydrates and proteins (Tables 24.3–24.5). Fruits are good sources of calcium, phosphorus, iron and magnesium. They also supply a major portion of vitamin C in our diets. Green-, yellow- and orange-colored fruits are rich sources of β-carotene (a provitamin A). A substantial portion of the complex carbohydrates in fruits is present as cellulose, hemicellulose, pectic substances and lignins, which serve as dietary fiber in our diets. Dietary fiber content and composition of some of the important fruits, determined by the Association of Official Analytical Chemists (AOAC) method (11) as well as the Uppsala method (12), are presented in Table 24.6. The dietary fiber constituents neutralize the acid produced by meats, milk products and other high protein foods in our diets. The presence of polyphenols, anthocyanins and phytochemical constituents is now being examined for their protective role against cardiovascular diseases and certain types of cancer (13).

Water is the most abundant constituent of most fresh fruits, at usually around 80%, but some fruits, like apples and oranges, may contain more than 90% water (15). Some

TABLE 24.2
Classification of Fruits Based on Climatic Region

Temperate Region	Subtropical Region	Tropical Region
Pome fruits: Apple, Asian pear (*Nashpati*), European pear, quince	Citrus fruits: Orange, grapefruit, tangerine, mandarin, lemon, lime, pomelo	Major tropical fruits: Banana, mango, papaya, pineapple
Stone fruits: Peach, plum, nectarine, apricot, cherry, almond, chestnut, lychee, walnut, pecan	Non-citrus fruits: Kiwifruit, figs, olive, pomegranate, cherimoya, ber (*Zizyphus*), bael (*Aegle marmelos*), date fruit (*Phoenix dactylifera* L.), loquat (*Eribotrya japonica* Lindl.), persimmon (*Diospyros*), phalsa (*Grewia subinaegualis* L.), jamun (*Syzygium cuminii* Skeels)	Minor tropical fruits: Cashew apple, guava, carambola, durian, longan, passion fruit, mangosteen, rambutan, tamarind, sapota, coconut, amla (*Phyllanthus emlica* L.), jackfruit (*Artocarpus heterophyllus*)
Small fruits and berries: Grape, strawberry, raspberry, cranberry, blueberry, blackberry, currant, gooseberry

fruits, like bananas, jackfruit, dates and grapes, are rich in carbohydrates (mainly sugars), whereas others, like nuts, dried apricots and figs, are good sources of proteins and amino acids. A few fruits, like avocados, olives and nuts, are exceptionally rich in oils and fats. In general, most fruits typically contain between 10 to 25% carbohydrates, less than 1% proteins and very small amounts (less than 0.5%) of fat. Some exceptions like dates have about 77.97 to 79.39% total sugars at the *kimri* stage of maturity (16), avocados have a fat content ranging from 15.5 to 23.4% (17) and olives have a fat content ranging from 15 to 30% (18).

Sucrose, glucose and fructose are the main sugars found in most fruits, although sorbitol is present in reasonable amounts in some fruits (cherry, plum and pear). The total sugars are present mainly in the cytoplasm, and range from 0.9% in limes to 16% in fresh figs. Sucrose

content could be in traces in cherries to more than 8% in ripe bananas and pineapples. Fructose, being sweeter than sucrose and glucose, has a desirable influence on the taste of fruits. Starch is present as small granules within the cells of immature fruits, which is converted to sugars as the fruit matures and ripens. Cellulose, hemicellulose, pectic substances and lignins are the other polysaccharides, which are the major constituents of cell walls. These compounds are broken down into simpler and more soluble components during fruit ripening (19).

Fruits contain less than 1% proteins, except in fruit nuts, such as almonds, pistachios and walnuts (~20% protein). It is mainly the enzymes that constitute this 1% protein, and these enzymes are responsible for catalyzing various metabolic processes involved in fruit ripening and senescence viz. polygalacturonase hydrolyzes pectic substances, resulting in fruit softening, and polyphenoloxidase catalyzes oxidation of phenolics, leading to browning of cut apples. Ascorbic acid oxidase catalyzes oxidation of ascorbic acid, and thus lowers the nutritional quality of fruits. Chlorophyllase removes the phytol ring from chlorophyll, which leads to loss of green color during ripening of fruits.

Most fresh fruits are low in lipids (0.1 to 0.2%), except avocados, nuts and olives. Lipids are present in the cell membranes, as a part of surface wax and cuticle. The surface wax contributes to fruit appearance, and the cuticle protects against water loss and pathogens. The type of fatty acids present determines the flexibility of cell membranes, with higher saturation resulting in rigid cells.

Organic acids are major intermediary products of metabolism and are further oxidized through the Krebs cycle to provide energy for the maintenance of cell integrity. The acidity of most fresh fruits is due to these organic acids. Certain fruits, like lemons, may contain as

much as 4.17 to 4.64% acidity, citric acid being the predominant one (20). Malic and citric acids are the most abundant in most fruits, except the tartaric acid in grapes and the quinic acid in kiwi fruits. The titratable acidity of fruits plays an important role in determining the maturity of most of these fruits. Acid content of fruits usually decreases during the ripening process as these are used in respiration or converted to sugars (21).

Pigments are the chemicals responsible for the characteristic color of skin and the flesh of fruits. In general, peel tissues of white and yellow flesh nectarines and peaches, and yellow and red plums, contain higher levels of phenols; anthocyanins and flavonols are almost exclusively located in this tissue (22). Many changes occur in these pigments during maturation and ripening of fruits. Fruit color is, therefore, used as an index of maturity and stage of ripeness in many fruits. The color of fruits also changes during the period of post-harvest in cold storage. Changes in the color and anthocyanin content have been investigated during the development and ripening of strawberries and pomegranates (23, 24). An increase in phenylalanine ammonia lyase (PAL) activity correlates with anthocyanin production in strawberries. The anthocyanins increase in pomegranate and low bush blueberry fruits during cold storage (24, 25). PAL activity and anthocyanin concentration in the skin of harvested apples increases after irradiation with UV and white light (26). The anthocyanin content in apples is adversely affected by higher carbon dioxide levels (73%) during cold storage (27), but a moderate carbon dioxide atmosphere (10 kPa) prolongs the storage life and maintains the quality of pomegranate, including adequate red color intensity of the arils (28).

β-Carotene is a precursor of vitamin A, and not only imparts color to fruits, but is also important in terms of

nutritional quality. Most of the carotenoid pigments are quite stable and remain intact in fruit tissues, even after senescence, processing and storage. The elucidation of biosynthesis pathway in plants has opened up new possibilities to manipulate/engineer fruit cultivars rich in provitamin A carotenoids (29). A combination of biochemical and genetic approaches has led to the isolation of a key gene, lycopene-epsilon-cyclase, responsible for the relative proportions of β-carotene and lycopene in tomato fruits (30). Among the phenolics, anthocyanins occur as glycosides and are water soluble, unstable during processing as well as to changes in pH. These glycosides are readily hydrolyzed by enzymes to free anthocyanins, which may be further oxidized by phenoloxidases to yield brown-colored oxidation products. The green color imparted to fruits by chlorophyll is influenced by pH changes, oxidation and the action of the enzyme chlorophyllase.

The plant polyphenols occur naturally in plant foods, like teas, fruits, juices and grape seeds. Grape seed tannins are known to exhibit remarkable antioxidant effects (31). The total phenolic compounds are higher in immature fruits than in the mature fruits, and usually range between 0.1 and 2% on a fresh weight basis. These include chlorogenic acid, catechin, epicatechin, leucoanthocyanidins, flavonols, cinnamic acid derivatives and simple phenols. Chlorogenic acid occurs widely in fruits and is responsible for the enzymatic browning of cut or damaged fruit tissues. The phenolic content of red grapes is about 20–50 times higher than of white grapes (32). Apart from nutritional significance, these polyphenols are associated with color in fruits and vegetables and contribute to flavor sensations like astringency and bitterness (33). Anthocyanins are responsible for the bright red and purple colors of fruits and flowers (34). The astringency is directly linked to the phenolic content and decreases during fruit ripening, as the phenolics are converted from soluble to insoluble, nonastringent form (35). These phenolic compounds are plant secondary metabolites and play an important role in plant-derived food quality, as they affect various quality attributes, such as appearance, flavor and health-promoting properties (36).

Fresh as well as processed fruits are important sources of vitamins in the human diet. Apricot, peach, papaya, cherry, orange, cantaloupe and watermelon are good sources of β-carotene (provitamin A), whereas Indian gooseberry, strawberry, orange, grapefruit, kiwi, papaya and cantaloupe are important sources of ascorbic acid. Peach, banana, orange, apricot, avocado, grapefruit and apple also contain appreciable amounts of certain B-complex vitamins. The levels of some of these vitamins may be reduced during processing into various products, as some of these are sensitive to heat, oxygen, light, pH and certain trace minerals. Banana, peach, orange and apple are rich in potassium, whereas orange, banana, peach, raisin and fig are rich in phosphorus. Citrus fruits, like tangerine, grapefruit and orange, contain good amounts of calcium, and strawberry, banana, apple and orange are rich in iron. On a fresh weight basis, the dietary fiber content of fruits ranges from 0.5 to 1.5%. The dietary fiber comprises cellulose, hemicellulose, lignin and pectin, which are derived from the cell wall and skin of fruits (9).

Chemical composition of fruits is affected by a number of preharvest and post-harvest factors. Among the preharvest factors, genetics (like cultivars and rootstocks) are known to influence raw fruit composition, durability and response to processing. As an example, several reports are available on the genetic improvements of grape vines (37, 38). Similarly, climatic factors, like light intensity, significantly affect the concentration of certain vitamins, and temperature influences mineral uptake and metabolism due to its effect on transpiration rate. Cultural practices like fertilizer application affect the mineral content of fruits while pruning/thinning influences nutritional composition by changing fruit density and size (39).

V. STRUCTURAL PROPERTIES OF FRUITS

Fruits are consumed not only for their nutritional value, but also for pleasure. The type of sensations one experiences as the fruit deforms and fractures during the initial stage of chewing determines our acceptance or rejection. Over the years, food processors have developed many methods to evaluate structural properties (such as modulus, fracture stress and strain) and to relate these parameters to the textural quality of fruits. Fruit firmness is another important mechanical property in determining the quality and ripeness behavior of fruits. A more fundamental understanding of the relationship between structural properties and microstructure of fruits is a prerequisite for any improvements in the textural qualities of these food products. Single edge notch bend tests were employed to relate mechanical properties to food texture (40). These workers reported good agreement between the measured (3.4 ± 0.3 MPa) and calculated (3.0) Young's modulus (E values) for apples. The fracture toughness, K_{Ic}, fracture energy, G_c, and yield stress, σ_y, values for apples were reported to be 10.1 ± 1.4 kPa $m^{1/2}$, 39.6 ± 10.5 Jm^{-2} and 0.3 ± 0.1 MPa, respectively. The firmness of pear fruit is a function of the mechanical properties of cell wall, cell properties like turgor and bonding between neighboring cells (41). A sigmoidal relationship between fruit firmness and tensile strength of tissue soaked in isotonic solutions is observed. The major mechanism of tissue failure involves cell wall failure and cell fracture at high firmness and intercellular debonding at low firmness. The stress-hardening of the cell wall in response to an increase in cell turgor increases the cell wall elastic modulus. Fruit firmness decreases from 100 to 20 N and from 60 to 25 N during the ripening of European and Asian pears, respectively. Tissue and cell

extension at maximum force declines as fruit softens. During fruit ripening, the hydrolysis of pectins present in the middle lamella leads to tissue breakdown by cell-to-cell debonding rather than the cell wall rupture.

As the mechanical properties are a function of ripening, these parameters can be used to discriminate between batches of certain types of fruits based on their degree of ripeness. Mechanical parameters can be used in assessing the optimum stage of ripening for harvest of Burlat sweet cherries using a penetration test, a compression test between two plates, and a compression-relaxation test (42). Based on compression-relaxation data, the calculated "apparent secant modulus" seems to be the most useful single mechanical parameter to clearly classify batches and to distinguish different varieties. Data in Table 24.7 show that the maximum penetration force ranges from 6.2 N (for very green cherries) to 1.8 N (for purple cherries). The hardness decreases as the cherries mature, but a sharp reduction in force occurs between stages red and very red, which are used as optimum stages of harvesting.

Firmness is a critical parameter of textural quality of apples. Information on the mechanical properties of apple flesh and intact apples is required to develop suitable methods for the sorting of whole apples according to firmness. Apple firmness is affected by many factors such as pre-harvest factors (genetics, fertilizers and other nutrients, breeding for fruit size, use of plant regulators); and post-harvest factors (maturity at harvest, pre-storage treatment with calcium, heat, plant regulators, storage atmosphere) (43). Calcium chloride treatment (2%) is effective in firming the apples (44). After six months of storage, treated samples had textural characteristics values equal to or better than the control treated with water only. The involvement of calcium ions in the maintenance of apple tissue during storage is suggested (45). The infiltration with calcium ions increases the tensile strength of tissue from air-stored apples to 85% of that of untreated controlled atmosphere-stored fruits. Both the movement of calcium ions from the middle lamella and loss of its binding sites occur during fruit softening, thus affecting the fruit texture. The softening of apricots during canning is accelerated when chelators, such as organic acid anions, remove structural calcium from the cell wall once the cell membrane is lyzed during heat processing (46). Infiltration of these apricot fruits, susceptible to softening, with calcium chloride before processing gives firmed canned products.

The stone cells also influence the firmness of Asian, European and Chinese pears (47). Fruit firmness increases with the increase in weight of stone cells, but soluble solid content is not affected. Weight of stone cells (per g of fruit) is negatively correlated with fruit size. Different cultivars show differences in the weight and size of stone cells. The degree of ripeness, specimen orientation and location within the apple tissue affect the failure stress, strain and energy and apparent modulus of elasticity (Young's modulus). Failure stress is the highest in vertical direction and lowest in tangential direction (48). Young's modulus is significantly ($p < 0.05$) higher in radial samples than in tangential and vertical samples. The bottom sections give the largest values for failure stress and Young's modulus, and the top sections give the lowest values for Young's modulus. A non-destructive method has been developed to determine fruit elasticity using the coefficient of elasticity (49). The coefficient of elasticity is the ratio of compressive stress to deformation. While using different types of penetrometers, coefficient of elasticity shows a close correlation with compressive stress and an acceptable correlation with rupture stress for apples. The coefficient of elasticity can be used to characterize stress-strain behavior of fruits, as it is a good indicator of firmness for both scientific and practical evaluation.

Size of individual fruits among their class is an important parameter that determines the textural attributes and consumer acceptability. Among the three size classes, ≤ 8 mm, 9–10 mm and 11–12 mm of Maine wild blueberries, consumers prefer the largest size (50). The compression test using an Instron testing machine measuring force and deformation to the point of rupture of individual blueberries relates to consumer acceptance. The consumers prefer larger 11–12 mm berries as these show lower stress and strain values, i.e., easier to chew. The compression tests reveal significant differences among all three size classes with respect to apparent modulus. A linear relationship is observed between the sensory texture and the elastic modulus (Tables 24.8 and 24.9).

The curve generated by the texturometer by plotting force as a function of time is known as a texture profile. This curve when analyzed in conjunction with the sensory texture parameters defined by Szczesniak (51), such as fracturability, hardness, cohesiveness, adhesiveness, springiness, gumminess and chewiness, is known as texture profile analysis technique and still used for food samples. Mechanical parameters of food samples measured by a texturometer correlate well with the sensory scores obtained by using a trained texture profile panel. This correlation indicates that the food texturometers have the capability to measure certain characteristics in a similar manner to those perceived by the human mouth. This texture profile analysis technique has been employed in a number of fruits such as pears (52), peaches (53) and apples (54). A typical texture profile curve is presented in Figure 24.1. Five measured and two calculated parameters, originally suggested by Szczesnaik (55) and Friedman et al. (56), modified by Bourne (57) are described as follows:

1. *Fracturability* (earlier called *brittleness*) is defined as the force at the first significant break in the first positive bite area (PA1).
2. *Hardness* is defined as the peak force (PP1) during the first compression cycle.
3. *Cohesiveness* is defined as the ratio of the positive force area during the second compression cycle to the positive force area during the first compression cycle, or PA2/PA1.
4. *Adhesiveness* is defined as the negative force area for the first bite (NA1), representing the work required to pull the plunger away from the food sample.
5. *Springiness* (originally called *elasticity*) is defined as the height to which the food recovers during the time that elapses between the end of the first bite and the start of the second bite.
6. *Gumminess* is defined as the product of hardness and cohesiveness.
7. *Chewiness* is defined as the product of gumminess and springiness.

Texture profile analysis (TPA) is a useful technique to evaluate such structural properties of fruits. For more information on TPA, the reader is referred to the book by Rao and Rizvi (58).

Fresh-cut fruit slices have become quite popular among consumers in the U.S. Apart from type of cultivars and storage conditions, fruit size and firmness are the other two important parameters that affect the quality of fresh-cut fruits. Among the factors affecting the quality of fresh-cut pears, fruit ripeness based on flesh firmness of 44 to 58 N is optimal for fresh-cut pear slice processing (59). The pear slices obtained from smaller size fruits (122–135 g) undergo a greater cut surface discoloration and deteriorate faster than slices obtained from larger fruits (152 g). Similarly, the optimal ripeness for preparing fresh-cut peach slices is the ripe stage having greater than 13–27 N flesh firmness (60). However, the optimal ripeness for preparing fresh-cut nectarine slices is the partially ripe (greater than 27–49 N) or ripe (greater than 13–27 N flesh firmness) stages. The size of fruits also determines their acceptance among consumer populations. Hampson et al. (61) reported that age groups differed slightly in apple fruit size preference. Fruit diameter considered ideal for dessert use ranged from 7.4 to 7.6 cm among various age groups.

Volatile compounds extracted from hyuganatsu fruits (*Citrus tamurana* Hort. ex Tanaka) vary with a fruit size of 100 to 350 g (62). Sesquiterpene contents are the highest in larger fruits, trans-beta-farnesene is lower in middle range fruits and l-carvone tends to increase with fruit size. As fruit size has a great influence on market price, processing quality and consumer acceptance, fruit breeders aim to produce larger fruits with better quality through the application of various plant growth regulators (63). The application of thidiazurin (TDZ) increases the fresh fruit weight and yield of kiwifruit nearly 13 and 22% with 2 and 10 ppm TDZ, respectively (64). A higher dose (10 ppm) gives slightly rounder fruits than the control and during ripening, no significant change in soluble solids, flesh firmness, glucose, fructose, sucrose and starch is observed. The application of CPPU [N-(2-chloro-4-pyridyl)-N′-phenyl urea] at concentration ranging from 4 to 8 mg/l increases maximum fruit size without causing fruit asymmetry in apples (65).

A number of chemical thinning treatments for apples are known to influence their ripeness and processing quality (66). Carbaryl alone, 2-1-naphthylacetic acid (NAA) and ethephon improve fruit size, but the benzyladenine/gibberellic acid is ineffective as a thinner and fruit size is not altered at harvest. Although ethephon shows promise as a fruitlet thinner and a promoter of ripeness in Paula red cv, these beneficial effects must be balanced against possible adverse effects on storage life of this fruit. The application of NAA (30 ppm) plus ethephon (500 ppm) is also beneficial in advancing fruit maturity, enhancing fruit color, increasing fruit size and providing better sensory quality with higher soluble solids and low acidity in pear (*Pyrus communis* L.) cv LeConte (67). As the source-sink balance is critical in the papaya fruit set, fruit development and sugar accumulation, defoliation and fruit removal can be employed to alter fruit size and quality (68). Fruit thinning increases the new fruit set and ripe fruit total soluble solids in papaya. Larger fruit size, faster fruit development and higher sugar contents are observed in immature fruits when old fruits are removed.

Porosity is another important physical property that plays a significant role during fruit processing operations, such as impregnation of fruit chunks in sugar syrups or their own juices. The porosity behavior of a few fruits (apple, strawberry, mango, peach and kiwi fruit) during vacuum impregnation treatments to determine deformation and impregnation levels through the hydrodynamic mechanism (HDM) and the deformation-relaxation phenomena (DRP) is important (69). Porosity and other physical characteristics of these fruits are presented in Table 24.10. The ratio of effective porosity (ε_e) to fruit porosity (ε) obtained from the density data is lower than 1 in almost all the fruits. This indicates that only a fraction of fruit pores is available to HDM action. DRP affects the volume

TABLE 24.10
Some Physical Characteristics of Fruits

Characteristic	Apple, cv Golden	Mango, cv Tommy Atkins	Strawberry, cv Chandler	Kiwi Fruit, cv Hayward	Peach, cv Miraflores
Fruit density[1]	0.787±0.014	1.022±0.005	0.984±0.009	1.051±0.006	1.038±0.005
Solid/liquid density[1]	1.0548±0.0008	1.13±0.02	1.05±0.009	1.076±0.006	1.0654±0.001
Fruit porosity	25.4±1.4	9.9±1.3	6.3±1.6	2.3±0.8	2.6±0.5
Water activity	0.985±0.00	0.9895±0.0007	0.9923±0.0015	0.992±0.000	0.9920±0.0010
Moisture content[2]	0.835±0.016	0.7868±0.0007	0.911±0.007	0.815±0.011	0.820±0.002
Ripeness index[3]	44.1±1.9	43.69±0.16	48.0±1.3	10.0±0.3	31±2
Soluble solids[4]	15.3±0.4	17.8±0.5	7.2±0.6	14.28±0.13	15±2
pH	3.833±0.012	4.29±0.00	3.36±0.02	3.527±0.008	3.91±0.14
Fruit acidity[5]	0.346±0.009	0.408±0.009	0.149±0.010	1.43±0.05	0.49±0.04

fraction of impregnated liquid in all fruits. Post-harvest fruit density can also be used in sorting fruits according to taste, because density is an indicator of dry matter, starch and sugars in unripe and in kiwifruit ripened during storage (70). The soluble solids (being mainly sugars) correlate to fruit density, and can be used for sorting kiwi fruit according to taste. The floating or sinking of this fruit in saline solutions could be used as a rapid method for this purpose.

VI. MORPHOMETRIC PROPERTIES

Fruits come in various shapes, ranging from round to oval, oblique, oblong, oblate, obovate, elliptical, truncate, unequal, ribbed, regular, irregular, cylindrical, conical or pyramidal (71). The morphology of fruits can be evaluated by considering either bulk or individual units, but it is important to have information on the accurate estimate of shape, size, volume, specific gravity, surface area and other physical characteristics. Specific charts can be prepared for different fruits and using these charts, the shape of the fruit can be described either by a number on that chart or by the above-mentioned descriptive terms. The shape of fruits has significance in harvesting, handling, grading, processing and packaging operations. Most of the harvested fruits are graded roughly according to size and appearance. The size and shape of fruits are variable and depend upon the cultivars, climate and agricultural practices followed during growth of crops. Figure 24.2 shows an example of a standard chart describing shapes of fruits and vegetables (72).

VII. MICROSCOPIC PROPERTIES

The study of physical properties of fruits requires some knowledge of their structure as well as their relationship to the chemical composition. As an example, citrus fruit consists of three distinctly different parts: the epicarp consists of the colored portion of the peel, called flavedo, and contains carotenoid pigments as well as oil glands (73). These oil glands contain essential oils characteristic of each citrus cultivar. Immediately under the epicarp is the mesocarp or albedo, a thick, white, spongy layer, rich in pectic substances and hemicelluloses. The combined albedo and flavedo are called the pericarp, but is commonly known as peel or rind. Next to the albedo is the edible portion of citrus fruits or the mesocarp. The mesocarp consists of many segments and, inside each segment, is located juice sacks or vesicles (Figure 24.3).

Many chemical components are distributed among various tissues of the citrus fruit. For example, flavanone glycosides are present in higher concentrations in the albedo than the juice sacks or the flavedo (74), and the bitter principles (limonin) are the highest in seeds and membranes (75). In contrast, grape berries always occur in clusters. A cluster consists of peduncle, capstem, rachis and berries. The grape bunch shape could be cylindrical, conical, pyramidal or globular. The grape berry consists of skin, pulp and seed. The seeds may vary from 0 to 4 per berry and are rich in tannins (5–8%) and oil (10–20%). The skin constitutes 5–12% of the mature grape berry and contains most of the aroma, coloring and flavoring components. The juice accounts for 80–90% of the grape berries.

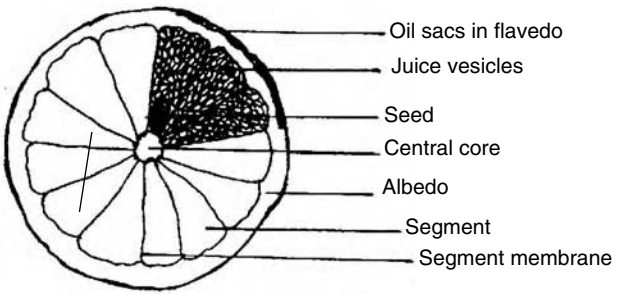

FIGURE 24.3 Cross section of a citrus fruit. (*Source:* Ref. 10.)

In physiological terms, a fruit can be defined as a structural entity arising from the development of the tissues that support the ovule. The basic function of fruit is the dispersal of seeds for the propagation of the species. Unripe fruits generally have rigid, well-defined structures, whereas ripe fruits have soft and diffused cell walls. An early model of the plant primary cell wall, in which cellulose fibrils are coated with hemicellulose and embedded in a matrix composed of pectin and protein (Figure 24.4), has been proposed by Keegstra et al. (76). This model has been further developed over the years and it provides an adequate basis to investigate fruit ripening.

The plant cell consists of a cytoplasm surrounded by a cell wall. Each cell is attached to adjacent cells by a pectin-rich middle lamella. The cytoplasms of these cells are interconnected with each other through plasmadesmata, which, in ripe fruits, provide a degree of cohesion. As long as the cell continues to register growth, its cell walls remain thinner. At this stage of fruit development, it is known as the primary cell wall and consists of roughly 90% polysaccharides and 10% protein. The primary cell wall components can be further classified into pectic polysaccharides (34%), hemicellulose (24%), cellulose (23%) and hydroxy proline-rich glycoprotein (19%). The ratio of these constituents varies in cell walls of different plants (77). The way in which various components of the cell wall are linked with each other is not exactly known yet. It is believed that the various domains of pectic substances are covalently linked together to form complex molecules. It is suggested that the xyloglucan, which is the major hemicellulose in primary cell walls, is strongly held to the surface of cellulose fibers through hydrogen bonds. The glucuronoarabinoxylan may bind to themselves as well as to the cellulose in cell walls (78). Such interactions would help in the formation of cross-links of polymers in primary cell walls.

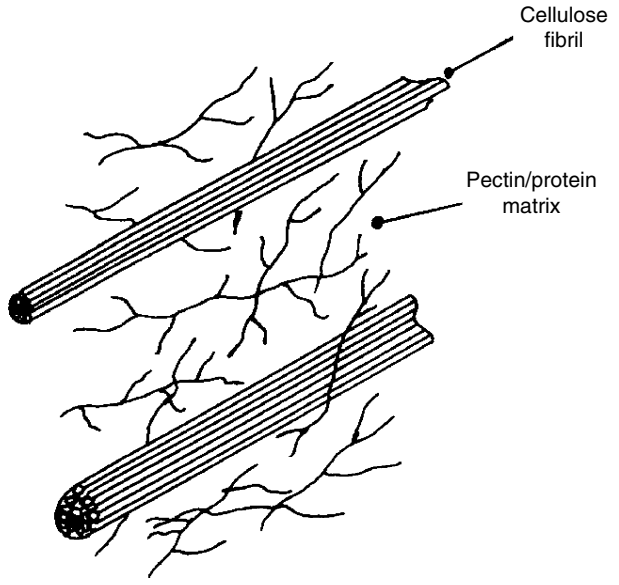

FIGURE 24.4 Idealized cell wall model. (*Source*: Ref. 76.)

The hydroxyproline-rich glycoprotein has regions of helical conformation, which are likely to give a rod-like molecule to serve structural function in plant cells (79). It has also been proposed that glycoproteins could be held in the cell walls by phenolic cross-links, which may be glycoprotein-protein or glycoprotein-polysaccharide in nature (80). A number of phenolic materials, like ferulic acid, p-coumaric acid and other unidentified phenols, have been isolated from plant cell walls. Ferulic acid alone accounts for 0.5% of the cell wall and is suggested to be linked to the nonreducing termini of arabinose and/or galactose-containing regions of pectic substances. Such residues can cross-link to form diferuloyl bridges, which would reduce extensibility of plant cell walls and could also play a role in resistance to fungal pathogens (81).

In addition, a number of cell wall models have been proposed to account for some of the cell wall properties viz. their strength in withstanding turgor pressure; their ability to grow without loss of strength; and their behavior under chemical and enzymatic attack. A modified updated cell wall model is presented in Figure 24.5 (82). The major features of this model indicate that several layers of pectin form an outer network around the cell wall constituting the middle lamella. The pectic molecules are interconnected through covalent bonds as well as calcium bridges. Some regions of pectic molecules are strongly hydrogen bonded with xyloglucans, but the pectins also have some covalently linked glucose and xylose sugars. Under these pectin layers are several layers of cellulose fibers, which are noncovalently associated with xyloglucans. Xyloglucan-associated cellulose is cross-linked through hydroxyproline-rich glycoproteins in a noncovalent manner involving isodityrosine bridges (83).

Cell number, volume and weight that determine fruit weight are hormonally controlled during fruit growth. Most of the fruits develop by cell enlargement accompanied by cell division, which may continue briefly (e.g., in

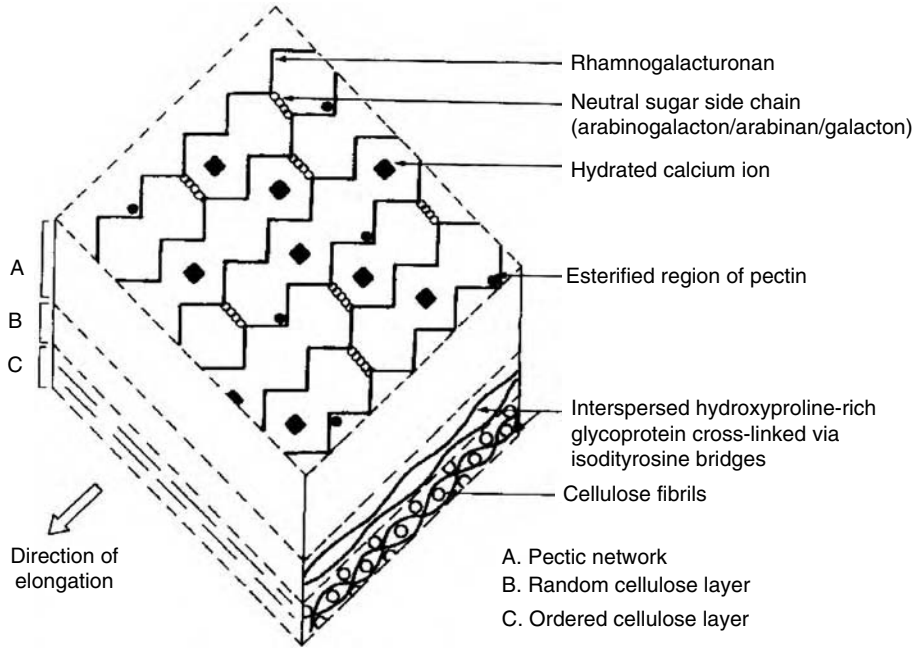

FIGURE 24.5 Modified model of primary cell wall. (*Source*: Ref. 82.)

peaches and other stone fruits) or until the end of fruit maturity (e.g., citrus fruits). Usually, all parts of the fruits do not grow at the same rate. In the case of apples, 25% of the total volume of fruit is contributed by the expansion of intercellular spaces. In the case of kiwi, the cells may enlarge more than 10–15 times. Some fruits (e.g., avocado) may increase 300,000 times in size compared with their flowers. Large fruits generally require additional anatomical features for nutrition or support or both for the developing seeds. Extra phloem in fruit vascular bundles and the increased amount of vascular tissues in the fruit wall and septa supply these nutrients to the developing seeds in large fleshy fruits. Collenchyma and sclerenchyma are common supportive and protective tissues, and the long axes of these cells are oriented crosswise to provide a mechanically strong structure to the fruits.

As large-sized fruits bring higher prices for the growers, the fruit breeders direct their research programs to achieve this objective (84). After the cessation of cell division, peach fruit growth depends mainly on cell enlargement. Mesocarp cells do not grow uniformly during the rapid fruit growth and maturation stage, and the length of radial cells near the stone is greater than that of the outer areas of the peach fruit. Flesh cell division continues 4–5 weeks after blooming, and increases in size only thereafter. In the case of the wild peach Ohatsumomo, cells divide more slowly than the commercial cultivars. This wild peach has the fewest and the smallest cells, thereby, giving a very small fruit. Similar observations by Cano-Medrano and Darnell (85) on blueberry fruits indicated that the differences in final fruit size between pollinated and GA-induced parthenocarpic blueberry fruits were due to differences in cell enlargement rather than increase in cell numbers. Similarly, the size of apple fruits of Jonagold and Fuji cultivars is observed to be a function of cell numbers rather than cell diameter (86). However, in the case of early maturing American Summer Pearmain, Tsugaru and Senshu cultivars, fruit size correlates positively with cell diameter.

The texture of fruits is also affected by the changes in cell wall components that may take place during chilling or heat processing treatments. Various cytochemical and structural changes during cold storage affect the quality of peaches (87). Mealiness in fruits develops due to chilling injury as a result of separation of mesocarp paremchyma cells resulting in increased intercellular spaces and accumulation of pectic substances in the intercellular matrix. No structural change is observed in the cellulosic component of cell walls of peach fruit. In peaches having a leathery texture, mesocarp parenchyma cells collapse, the intercellular spaces increase and the pectin-positive staining in the intercellular matrix is significantly higher. As the internal breakdown progresses, dissolution of middle lamella, cell separation, irregular thickening of the primary cell wall and plasmolysis of the mesocarp parenchyma cells are observed. Addition to cell wall degradation leading to fruit softening, starch hydrolysis (possibly producing cell turgor changes) might also be involved in the softening of kiwifruit during storage at

0°C (88). As the softening of kiwi fruit progresses, more uronic acids and neutral sugars (galactose, arabinose and rhamnose) usually associated with pectic substances are detected.

Cell structure of fruits is related to their fracture behavior. Cell size and intercellular spaces influence the values of fracture toughness and fracture energy (40). In addition to cell size, cell wall chemistry also influences the mechanical properties of fruits and, hence, texture. Currently, there is a lot of interest in the mechanical properties of plant cell walls. Fruits derive their textural qualities from the strength and stiffness of these cell walls, bonding between the adjacent walls and the turgor pressure. Deformation of plant cells by a fine probe provides a measure of cell wall stiffness that is responsible for many of the mechanical properties of fruits (89).

Fruits are generally harvested at the fully mature stage, when the development and growth in size have ceased. In fully mature fruits, many physical as well as chemical changes take place that convert these fruits to a more palatable form. Astringency decreases due to reduced tannin content. Specific flavors are developed due to increased sweetness and lower acid content. The softening caused by breakdown of the cell wall structure in the pulp is often accompanied by a change in coloration. Chlorophyll in the chloroplasts of the outermost cells decreases while the carotenoids and anthocyanins develop in the fully mature fruits. Most of these changes are brought about by the coordinated action of a group of hydrolytic enzymes on the cell wall constituents. Apart from protein (mainly enzymes) synthesis, starch and pectic substances hydrolysis are the major biochemical changes occurring during fruit ripening. During normal ripening, polygalacturonase (PG) activity increases while the pectin esterase (PE) activity decreases. Any imbalance in their activity could lead to inadequate hydrolysis of pectic polymers, with increased accumulation of higher- molecular-weight pectin with low levels of esterification. The woolliness defect in nectarines is possibly due to the accumulation of these pectic polymers (90). Changes in cellulase (endo-β-1, 4-D-glucanase) activity are also associated with the modifications in cell wall structures during fruit ripening (91).

For further detailed description of the physical properties of fruits and food materials, the reader is referred to two excellent books in this area by Mohsenin (72) and Rao and Rizvi (58).

VIII. PROCESSING AND FUNCTIONAL PROPERTIES

Processing and functional properties of fresh fruits are of paramount importance because these affect the acceptability of fresh or processed fruit products by consumers. A set of quality characteristics important for consumer acceptance is associated with each fresh fruit or its processed products. A list of characteristics identified as important for consumer acceptance of fruits and vegetables is reviewed by Kader (92). Unfortunately, no single parameter/property can establish consumer acceptance forever since consumer tastes and preferences change with time and are also influenced by cultural factors. Careful evaluation of fruits in terms of consumer acceptance criteria is essential to identify target markets. As an example, German consumers prefer a fuller-flavored grapefruit, whereas French consumers prefer the one that is sweeter (93). Similarly, regional preferences exist for apples in the United States; New Englanders look for a tart taste, whereas Southerners prefer a sweeter one (94). Most packers and wholesale and retail dealers buy fruits on the basis of grades and standards established by the concerned agencies in each country.

IX. MATURITY INDICES

Maturity at harvest is one of the most important factors affecting the rate of change of quality during post-harvest handling and processing into finished products. Various biochemical and physiological changes occurring at the final stages of fruit development result in making these fruits palatable and acceptable to consumers. Maturity indices for fruits can be determined by estimating duration of development, measuring size, weight or density; physical attributes like color, firmness, moisture or total soluble solids content; chemical attributes like starch, sugar, acidity, flavor and aroma constituents; or the morphological characteristics (95, 96).

A. Size, Mass and Density

Size, mass and density can easily be employed as maturity indices. Each fruit becomes larger as it matures on the plant, although other production factors like moisture and soil fertility also affect the size of fruits. As an example, fruit size is considered the most effective method of segregating strawberries into different maturity classes (97). Similarly, specific gravity is used as an index of maturity in pineapples (98).

B. Color

Color is another useful measure of maturity in many fruits. Uniformity and intensity of color is important for appearance qualities and processing properties. Chlorophyll tends to disappear as the fruit matures on the plant as well as during handling and storage. On the other hand, anthocyanins are synthesized in light while fruits are attached to the plant, but are not affected greatly during post-harvest handling and storage. The pigments of grapes, anthocyanins (red, blue, purple and black), are modified by attachment of a glucose molecule. The basic part of grape

pigments is made up of the five anthocyanins, namely, cyanidin, peonidin, delphinidin, petunidin and malvidin. The red pigments in grapes (anthocyanins) reach their full potential at complete maturity (99). Total anthocyanin content shows the greatest potential as a maturity index for raspberries (100). For the color measurement of horticultural crops, a number of techniques, like visual color matching charts, guides and dictionaries to match, light reflectance meter, light transmission meter, delayed light emission measurement and determination of various pigments (e.g., chlorophyll, carotene, lycopene, xanthophylls, anthocyanins), are now available. Standard color chips are now available for assessing the maturity of peaches (101). Colorimeters can also be used for this purpose (102). The technique of delayed light emission has the advantage of not being affected by orientation of multicolored fruits like papaya (103), cantaloupes (104) and peaches (105).

C. Firmness

Firmness or softness of fruit is an important processing property that is affected by the stage of maturity and storage. Firmness is also an important textural quality attribute and is usually combined with other attributes, such as color and flavor, for use as an index of both maturity and processing quality of fruits. Use of firmness and total soluble solids as an index of maturity of kiwifruit, have been recommended by Crisosto et al. (106). Firmness can be measured using penetration force (Magness-Taylor pressure tester, Effegi penetrometer, Instron universal testing machine); fibrousness and toughness by shear force measurement using Instron, or resistance to cutting by a fibrometer or chemical analysis for crude fiber and lignin content; measurement of water content as an indication of succulence; measurement of extractable juice as an indication of juiciness; or by sensory evaluation for grittiness, crispness, mealiness, chewiness and oiliness. A nondestructive firmness tester is available for assessing the maturity of avacados (107). Firmness is a simple, rapid technique for measuring the harvest maturity of apples (108) and pears (109).

D. Solids Content

Moisture or solid contents are being used effectively as maturity indices of fruits for processing purposes. Iodine staining of starch has been used as a measure of assessing maturity in apples (110). Sugars are the industry standard to assess the maturity of cantaloupe and other melons. Soluble solids have been suggested as a maturity index for sweet cherries (111), and Brix-to-acid ratio for citrus fruits (112), whereas both soluble solids and acidity are used to assess maturity in grapes (113). Mango is another popular specialty fruit of great economic importance to the tropical regions, in which sugars and acids influence its consumer acceptability (114, 115). As a result of starch hydrolysis from increased amylase activity (116), sucrose is the major sugar in ripe mango fruits. Among the reducing sugars, glucose is reported to be the major sugar by Selvaraj et al. (117), whereas fructose was identified as a predominant sugar by Medlicott and Thompson (118) and attributed this contradiction to the varying cultivars and storage conditions used by these workers.

E. Flavor

Flavor is another important processing property and consumption attribute critical to consumer acceptability and hidden attributes of fruits (119). Sweetness is a function of sugar concentration and sourness is a function of acidity, and their ratio determines the flavor of fruits because consumers perceive sweetness or sourness in terms of sugar:acid ratio. Sugar concentration is usually estimated by measuring the percentage of soluble solids (°Brix) using a refractometer (120) and acidity by titration against a standard base. The Brix-to-acid ratio (BAR) is used to assess the relative sweetness or sourness for most of the fruits for processing purposes. Lack of attention to flavor compounds in breeding programs has led to flavor mediocrity in many fruits. The lack of information on flavor compounds available to breeders on this complex trait is the main reason for this. Using gas chromatography, as many as 225 volatile compounds have been reported for grape cultivars (99, 121), although every particular cultivar emits a special aroma. Many fruits contain a single volatile compound, described as character impact compound, that imparts the flavor message by itself. Some examples of these character impact compounds given by Shewfelt (122) are ethyl-2-methylbutyrate in apples, γ-decalactone in peaches and isoamylacetate in bananas. However, the full aroma of any fruit is a subtle combination of many compounds, which makes it difficult for food scientists to duplicate fruit flavors in artificial beverages. A number of volatile compounds have been identified to be associated with the distinctive aroma of fresh as well as processed fruits. These aroma compounds, in combination with sweet, sour, salty, astringent and bitter sensations, endow characteristic flavors to various fruits and their products. The type of cultivars, post-harvest processing and storage treatments are some of the factors that affect the flavor properties of various fruits and their processed products (123, 124). The task of preserving and improving the aroma of fruits will probably be difficult. For example, some treatments currently used to prevent decay or to preserve texture and color can damage aroma quality. A higher concentration of carbon dioxide is usually used to reduce decay in strawberries and other similar crops, but it can induce fermentation (125). Similarly, lower oxygen levels, while extending the shelf life of apples and other pome fruits, can reduce aroma at stress levels, and may even cause off-flavors (126).

X. PROCESSING OF VARIOUS FRUITS

A. Grapes

The grape cultivars are classified according to table, juice, wine and raisin purposes. Table grapes are consumed as fresh fruit or processed into juice. They should have large clusters and berries of appealing appearance, fine flesh with low acidity and high sugar content, and a few or no seeds (99). In the case of colored grapes, heating the crushed berries for 10–15 min at 60–63°C is necessary to extract the coloring matter (127). This heating step is not required in white grapes. Frozen grape juice concentrates are available commercially, but their production is less compared with orange juice concentrate. Wine grapes are processed into juice and fermented by yeast to make wine, or distilled to make a number of beverages (e.g., brandy). The wine grapes should have small clusters with round berries set compactly, with soft, juicy flesh of high acidity and low pH (128). After wine, raisins are the second most important product made from grapes (129). Raisin grapes are a special category of table grapes, having thin skin, firm flesh with higher sugar content and moderate to low acidity, with berries loosely attached in the clusters.

B. Citrus Fruits

Apart from consumption as fresh fruits, citrus fruits are processed mainly into juice, frozen concentrate, jam, marmalade, squash, candied peel and certain by-products, such as pectin, citric acid and peel oil. Juice is the most popular product prepared from citrus fruits and may be canned, frozen or chemically preserved (130). Frozen concentrated orange juice is by far the most important processed product from citrus in the U.S. The popularity of this product has been decreasing recently, as consumers prefer natural or minimally processed food products (131). Sound and mature fruits with the highest possible juice quality are desirable for producing orange juice. The color, flavor, yield and total soluble contents of the fruit increase with the maturity of oranges. The best quality orange juice can be produced if the Brix-acid ratio is between 13 and 19, 15 being the preferred one. Mid-season or late-season oranges give better yield and quality of juice than the early-season fruits (132). An excessive amount of peel oil in juice is undesirable. However, a certain amount of peel oil (0.01–0.02%) is considered to be necessary for obtaining maximum flavor (133).

C. Date Fruit

Date palm (*Phoenix dactylifera* L.) is an important food crop in the Middle Eastern countries. Rygg (134) reviewed the detailed description of the date growing regions of the world, date varieties and general cultivation practices. Four maturity stages have been recognized in date fruits, i.e., *kimri, khalal, rutab* and *tamer* (135). At the *kimri* stage, the fruit is hard in texture, green in color and can be used for making pickle, relish and chutney (16, 136). Depending upon the cultivar, the *khalal* stage fruit develops a yellow, red, purple or yellow-scarlet color, but retains a firm texture and can be used for making jam, butter, dates-in-syrup or for eating as fresh dates (137, 138). The *rutab* stage is characterized by softening of the half portion of the fruit, developing a dark brown color and increased sweetness and can be used for jam, butter, date bars, date paste or eaten as fresh (139). During the *tamer* stage, the whole of the fruit becomes soft in texture, wrinkled, relatively drier, and dark in color and attains maximum sweetness (140). The *tamer* fruits can be further dried for prolonged shelf life during storage. The chemical composition of date fruit varies with maturity. The total sugars in date fruits at the *kimri* stage range from 32.99 to 38.20%, but are increased to 77.97 to 79.39% at the *tamer* stage of maturity. The ranges of protein, fat, ash, pectin, tannin and crude fiber contents of *tamer* stage date fruits are 2.1–2.4, 0.1–0.2, 1.6–2.0, 1.3–1.9, 0.4–0.4 and 2.5–2.9%, respectively (141).

The majority of the date fruit is harvested at the *tamer* stage and enters the trade for consumption as such (142). Recently, the quantities of processed dates have been increasing rapidly as a result of encouragement and support being provided to the date fruit processing industry by governmental agencies. The development of newer processed date fruit products would increase the economic value of this crop immensely (143). Due to increased production and a decreased tendency towards direct consumption of date fruits, the introduction of processed products holds a great future for this important food crop of this arid region of the world.

D. Banana

Bananas are one of the most important fruits grown in the tropics. About 50% of the bananas produced are consumed in Africa as a cooked vegetable and are often called plantains. A number of processed products, such as juice, pulp, puree, concentrate, canned slices, fruit bars, powder, wine, brandy and deep-fried chips, have been prepared from ripe as well as unripe bananas (144). Among all these products, banana puree is by far the most important processed product prepared from the pulp of ripe fruit. Puree finds uses in dairy desserts, bakery items, mixed fruit drinks, sauces and as a part of special diets in hospitals and nursing homes.

E. Apple

Apples are processed into a variety of products, such as juice, concentrate, sauce, butter, preserve, vinegar, cider, wine, brandy, candy, jam, jelly and canned products. Apples are also dried as rings, chips or cubes. Edible pectin is also produced from the waste of the apple processing

industry. Apple juice, in the form of clarified apple juice (made using pectinol enzymes), natural apple juice, pulpy apple juice and as fruit cocktail blends, is second only to orange juice in Europe and North America (145–147). Apple juice contains most of the soluble components of original apples, such as sugars, acids (mainly malic acid) and various other carbohydrates.

F. Mango

India contributes about 64% of the world production of mangoes. The mango fruit is highly perishable, highly susceptible to disease, extremes of temperature and physical injury, and international trade in fresh mango has been limited. However, a number of products, such as canned mango pulp, juice, nectar, squash, beverage, jam, chutney, pickle, mango leather and raw mango powder, are routinely prepared (6). Mango is one fruit that is processed and used at almost every stage of its growth. Raw mango fruit is mainly used for the preparation of raw mango powder, chutney and pickle (148, 149). Mango puree made from ripe mango is one of the most important processed products, which finds further utilization in various other products, such as nectar, squash, jam and ready-to-serve beverages. Puree is canned for long-term storage and marketing worldwide (150). Mango pulp can also be preserved using 350–700 ppm of sulfur dioxide, but there are reservations among consumers towards sulfited foods due to objectionable odor and toxicity (151). Mango fruit beverages are very nutritive drinks and are extremely popular in India and other Asian countries (152). Mango beverages with 20% puree in the formulation and with 20°Brix taste very sweet, so most of these mango drinks are adjusted to only 15°Brix, because less than 15% puree adversely affects the color and flavor of the mango beverages during storage.

Mango, being rich in a desirable strong flavor of its own, lends itself to be blended with a number of other fruits for the preparation of fruit juice cocktails (153). Blends of mango puree with papaya, orange, kinnow, apple, guava, pear, peach and apricot could be used in many foods (154). Peeled slices/cubes obtained from ripe or semiripe mango fruits can be preserved in sugar syrup, especially from some Indian mango cultivars, such as *Saheb Pasand*, having a TSS of 30°Brix that has bright-colored pulp and a firm texture (155). Mango leather, another popular product, is prepared by drying mango pulp to a final moisture content of about 15%. For the preparation of mango leather, an ideal ratio of 25:0.3 for TSS:acid has been suggested (156). Pectin when used at a rate of 0.5 to 0.75% improves the texture of mango leather.

G. Pineapple

The pineapple is one of the most important commercial fruits of the world, and is mainly used in processed form as dessert fruits, or as canned pineapple in the form of slices, rings, chunks, fruit cocktails or in the preparation of juice and jams. Most of the world's pineapple production is canned, largely as slices, juice, chunks and diced pineapple (157). Pineapple juice contains neutral polysaccharides (mainly galactomannan), which are removed using pectinase, cellulase and hemicellulase enzymes (158). Pineapple juice stored at higher temperature (37°C) loses its color rapidly, but it can be stored at room temperature for 12–15 months without any serious loss in quality or nutritive value (159). Pineapple concentrate can also be prepared, which can be stored satisfactorily at 10–38°C by adding sulfur dioxide without any significant loss in color or flavor (160). Although attempts have been made to prepare pineapple juice powder by freeze-drying, the product has not become commercially viable (161).

H. Pear

Pears have been consumed primarily as fresh fruit, although a part of pear production has been processed into juice, wine, candy, dried and canned products (162). Pears are a good source of pectin, sugars and thiamine. Pear fruit is reported to help in maintaining a desirable acid/base balance in the human body. Because of its low sucrose content, pear fruit is also recommended for diabetics. The pear fruit is either canned as juice, or as chunks in fruit cocktail along with other fruits. Puree prepared from pear fruit finds uses in baby foods, pear butter and jams. Pear juice concentrate is finding wider applications in beverages and fruit spreads. Pear candy prepared from sand pear and Bagygosha cultivars are reported to retain about 50% of the ascorbic acid during 40 weeks of storage at room temperature (163). The stone pear is suitable for jam, chutney, clarified juice and preserve (164).

I. Plum

Plums are generally consumed as fresh fruit, and only a small quantity is used for canning, dehydration and beverages. Whole plums fruits with higher sugar content and firm flesh are dried and are called prunes. More than 50% of the total world production of plums comes from the U.S., the former U.S.S.R., China and Romania (6). Apart from canning, plums are used for the preparation of jam, jelly, beverages, wines and brandy. Prune juice produced from dried plums is rich in minerals and acts as a mild laxative. Use of pectolytic enzymes increases the yield of prune juice and aids in easy filtration (165). Pectolytic enzymes not only increase plum juice yield, but also drastically decrease the apparent viscosity and improve the color and clarity without affecting the flavor (166). A natural plum juice containing pulp has also been prepared recently (167). Being high in acidity, no more than 40% of plum juice can be used in the preparation of beverages like sweetened plum juice. About 20% of enzymatically

extracted plum juice with 15°Brix has been found to be optimum for preparing nectar (168).

Preparation of plum juice concentrate is one of the best options of utilizing fruit during glut seasons. Plum juice can be concentrated under vacuum to 73°Brix. This juice concentrate has higher total soluble solids, reducing sugars, total solids, browning and viscosity, but the pectin content and acidity are slightly reduced (169). Firmer fruits are generally preferred for canning than softer fruits. Softening of ripe plums during canning can be prevented using 500 ppm of calcium chloride (170). About 75% of the world supply of dried prunes comes from California and the Pacific Northwest. Dried prunes, prune flakes, nuggets and granules are also produced commercially for use as fillings in bakery products. Low-moisture prune powder is also available for use as a sweetening and flavoring agent in whole wheat and rye bread formulations. The plum pulp is also utilized in ice cream mix, confectionery items and meat sauces (171). Wine or brandy prepared from fruits other than grapes are referred to by the name of that fruit used. Plum wines are quite popular in Germany and many Pacific coastal states of the U.S. The method for making plum wine or brandy is similar to that of grapes (172).

J. Peach

Peach and its smooth-skin mutant nectarine are some of the most important stone fruits in temperate regions of the world. Apart from consumption as fresh fruit, peaches are usually canned. Only a small portion is utilized as frozen or dried or used as jams, peach conserve, marmalade, peach butter, fruit bar, pickle and beverages (173). Peach puree is the basic starting material for the preparation of many other products, such as jam, nectar, juice, baby foods and ready-to-serve beverages. Initial color and viscosity of puree have been considered as important quality characteristics for further processing (174). Commercial canning of peaches is the major industry in the world. Peaches can be canned as whole, halves, quarters or slices, usually in sugar syrup or juices of other fruits (175). The peach fruit for canning should be picked at or near optimum maturity and should be of uniform large size (a dia of 6.03 cm or more), good yellow color and of good cooking quality (176). Steep preservation is another simple technique that could be used for peaches (177).

K. Berries

Juices from berries are widely used for the manufacture of jams, jellies, beverages, wine, fruit yogurt and ice cream (178). To increase juice yield from berries, pectolytic enzymes are added to the pulp (0.1g/kg of fruit). The enzymes are allowed to act on the cell wall pectic substances to release juice. The juice could be preserved by the addition of antimicrobial agents (potassium benzoate or sodium sorbate) followed by pasteurization (179). The juice can also be concentrated, but the susceptibility to undesirable changes in flavor during storage has hindered its application in food and beverages (180). Wines from strawberry, raspberry and kiwifruit are also prepared (181–183). Use of pectolytic enzymes for increasing juice extraction yield is essential for making wine with desirable clarity, color and flavor.

L. Apricot

All of the mechanically harvested apricots (roughly more than 50% of total production) in the U.S. are used for processing, mostly for canning. About 84% of the total production of apricots in the U.S. is canned, dried and frozen (184). The canning process for apricots is the one typically used for most stone fruits. The textural quality of canned apricots is affected by a number of factors, such as sterilization conditions, maturity of fruits and storage conditions. Even immature fruits can be canned after treating them with ethylene for two days (185). Dried apricots are another important snack, becoming popular with present-day consumers because of their desirable color, flavor and nutritive value. Dried apricots are produced from fully ripe and plump fruits (186). High natural sugar level and low pH of dried apricots prevents microbial spoilage and enzymatic deterioration in quality during storage. The apricot fruits unsuitable for canning are utilized for the preparation of juice and concentrates. The juice concentrate can be used for the preparation of nectar and baby foods. The concentrated juice can also be dried to obtain powder that can be used in bakery products, beverages, jellies and desserts (165). Because of excellent natural flavor, apricots are also processed to jams, jellies and preserves. Due to higher susceptibility to browning and oxidation during freezing, frozen apricots are not very popular.

M. By-Products of the Fruit Processing Industry

Fruits are marketed either as fresh produce or processed as frozen, dehydrated, canned, pureed, juices, jams, jellies, marmalades, pickles, chutney and in many more forms. During these processing operations, a large proportion of fruit ends up as residue that needs to be handled properly to avoid environmental pollution while generating additional revenue for the processing industry. The wastes arising out of the fruit processing industry can be utilized for the preparation of human food, animal feed, fertilizers, soil conditioners or for landfill (187).

Dietary fiber is extracted from apple and pear pomace to obtain a product containing 56 and 77% fiber, respectively. This product has the consistency of whole wheat flour with a bland taste and is utilized in baked goods,

breakfast cereals, granola products, laxatives, pharmaceutical preparations and pet foods (188). Peels and cores from apples can be utilized to produce vinegar and jelly juice stock. Apple pomace can be extracted with liquid carbon dioxide to produce an intensely flavored fraction. Pectin is an important by-product from the apple processing waste. Different apple cultivars are reported to vary in pectin yield, jelly grade and other qualities of the extracted pectin (150). Pectin extracted with alcohol from apple pomace can be dried to 5% moisture content and used for jam and jelly-making. About 250 g of citric acid can be obtained by growing *Aspergillus niger* on apple pomace (one kg solids) under controlled conditions. Around 30–35% of the pear fruit ends up as waste during canning operations. The waste from pear fruit processing industries has been used in the preparation of vinegar, brandy, denatured alcohol and sugar syrup or has also been dried for use as cattle feed (170). Kiwifruit peel is another suitable source of citric acid production. In the presence of 2% methanol at 30°C, about 100 g of citric acid per kg of kiwifruit peel can be produced by solid-state fermentation using *Aspergillus niger* (193). Apple pomace can be used as animal feed, either fresh or as dried product (150).

Citrus fruit processing waste can be utilized for the production of citric acid, but the process is uneconomical because citric acid now produced by microbial fermentation is much lower in cost. Citrus peels contain 2.5 to 5.5% pectin, which can be extracted with acidified water. After centrifugation, the clarified pectin solution is dried to obtain pectin powder. By the cold pressing method, fresh orange peel also yields about 0.54% superior quality oil, which finds uses in juice and squash manufacture (199). Guava fruit is another important source of food-grade pectin. During the extraction of pectin by hot water-boiling, use of sodium hexametaphosphate or 1:1 mixture of ammonium oxalate and oxalic acid at 0.25–0.75% concentration gives higher yields of pectin with high jelly grade (200).

About 40 to 60% of the fruit intake ends up as waste in the mango processing factories. This fruit waste consists of 12–15% peel, 5–10% pulp waste and 15–20% mango seed kernel (160). The pectin obtained from mango peel is comparable with the pectin extracted from citrus peel (161). Mango peel is a very good source of sugars (48.1%), pectin (12.9%), protein (3.9%), fiber (8.4%), tannins (2.3%) and minerals (2.9%; all values on dry basis) and constitutes about 13% of the mango fruit (161). Good quality pectin obtained from mango peel can be used in the manufacture of jam, jelly, marmalades and many pharmaceuticals. Depending upon the cultivars, mango kernel (or stone) is about 45.7 to 72.8% of the mango fruit and is a good source of starch (57.8%), fat (13.7%), tannins (10.6%) and protein (7.1%) on a dry basis (162). Among the other by-products, mango kernel fat has attracted major attention because it could be a very good substitute for tallow and cocoa butter in soups and confectionery products (201, 202). Cake left after the extraction of kernel oil could substitute for wheat and maize flour in animal feed as it is a good source of many essential amino acids. Mango peel is also suitable as a supplement in fish feed. The waste from mango processing plants can be used for biogas production. Recently, a mixture of 5-(12-*cis*-hepta decenyl) and 5-pentadecyl resorcinol has been isolated from mango peel, and this has been found to be effective against *Alternaria alternata*, a fungus that causes black spot disease in mango fruit (163).

Guava seeds are usually discarded during processing, but these seeds are rich in oil (5–13%), which can be utilized in salad dressing. Guava seed oil is especially rich in essential fatty acids, such as oleic (54%) and linoleic (29%) acids (203).

Green banana fruit, pseudostems and foliage are good sources of energy and serve as cattle feed after supplementation with a protein source. About 1000 banana plants can yield 20–25 tonnes of pseudostems, which contain about 5% edible starch that finds a number of industrial uses (145). Banana stem waste is another important waste product that can be used for growing food yeast (146). The pineapple processing industry waste can be utilized for the preparation of several products, such as citric acid, cattle feed, sugar syrup, wine, bromolain enzyme, wax and sterols (169). Peach processing generates a lot of waste in the form of peel, seeds and trimmings, which contain proteins, polysaccharides, sugars, amino acids and pectin. After enzymatic treatment, peach solid waste may be utilized for ethanol production (186).

Production of citric acid from fruit processing solid wastes using *Aspergillus niger* in solid-state fermentation has been suggested (193). Apart from these specific by-products of commercial value, the waste from most of the fruit processing plants could be utilized in animal feeds and production of ethanol, biomass and many other chemicals.

XI. NUTRITIONAL AND HEALTH PROPERTIES

Consumption of fruits and vegetables by adults in the U.S. has not reached the recommended level suggested by nutritionists and other health professionals. Unfortunately, children consume even less. Various governmental agencies, professional associations, food processors and health organizations are making efforts to encourage increased consumption of fruits and vegetables (204), because intake of fruits and vegetables has an inverse association with the risk of cardiovascular diseases and mortality in the U.S. population (205). Fruits are rich not only in dietary fiber, vitamins and minerals, but a number of bioactive compounds present therein are strong antioxidants and function to modify the metabolic activation/detoxification of carcinogens.

A. Fruits and Dietary Fiber

A low intake of dietary fiber is associated with a spectrum of degenerative diseases, such as constipation, diverticular disease, coronary heart disease, hiatus hernia, appendicitis, varicose veins, piles, diabetes, obesity, bowel cancer and gallstones (206). Soluble dietary fiber, including pectic substances and hydrocolloids, is present in fruits, vegetables, legumes and oat bran. By-products from fruit processing industries are potential sources of both soluble and insoluble dietary fiber in our diet (207). Association between fruit, vegetable and dietary fiber consumption and colorectal cancer risk in the U.S. population has been observed (208). The total fruit and vegetable consumption is inversely associated with colorectal cancer risk, but subanalyses show this association is largely due to fruit consumption. The association is stronger and the dose-response effect is more evident among those individuals who consume the lowest amounts of fruits and vegetables (less than 1.5 servings) compared with those who consume greater amounts (more than 2.5 servings/d).

To assess the role of certain tropical fruits, such as lychee, guava and ripe mango, in the prevention of cardiovascular diseases, contents of total and water-soluble dietary fiber are determined by Gorinstein et al. (209). Lychee, guava and ripe mango had a total fiber content of 2.2, 5.6 and 3.1 g/100 g fresh fruit and soluble fiber of 1.05, 2.7, 1.51 g/100 g fresh fruit, respectively. Use of lychee, guava and ripe mango could be suitable for the prevention of cardiovascular disease through dietary methods. The non-starch polysaccharides in Starkspur Supreme Delicious apples from Arkansas ranges from 1.41 to 1.98 g/100 g fresh fruit (210). Total fiber contents in four berries (blackberries, cranberries, red raspberries, strawberries) ranges from 1.0 to 7.0% fresh weight (14). Peeling and canning changes the uronic acid and neutral sugar contents of soluble and insoluble fiber fractions of several fruits.

Rosado et al. (211) analyzed 24 fruits for dietary fiber contents. The total dietary fiber (wet weight basis) ranged from 0.3 to 7%, and soluble fiber contents (% of total dietary fiber) ranged from 6 to 44%. The total dietary fiber contents in 47 Italian fruits range from 0.22 to 6.47 g/100 g for fresh fruits and 5.0 to 30.0 g/100 g for dry fruits (212). Marlett (213) analyzed 23 fruits and reported a mean dietary fiber content of 1.4 ± 0.7 g/100 g fresh weight, and 13 to 20% of this was soluble fiber fraction. Pectin constituted 15 to 30% of the total dietary fiber contents among fruits. The total dietary fiber contents of five fruits that are most commonly consumed in Malaysia range from 1.5 to 3.6% on a fresh weight basis (214). The incorporation of prunes in the diet as a source of dietary fiber lowers plasma low-density-lipoprotein cholesterol more significantly (3.9 mM) than when grape juice (4.1 mM) is consumed (215). Prunes also significantly lower fecal bile acid content of lithocholic acid. Fecal output is nearly 20% higher after consuming prunes, but the total bile acid content is unchanged.

B. Phytochemicals in Fruits

Oxygen during normal metabolism yields a number of reactive oxygen species (ROS), most of which are free radicals having an odd number of electrons. These reactive species initiate lipid peroxidation, a chain reaction that can oxidize DNA, proteins (enzymes) and cell membranes (216). It is now proposed that oxygen free radicals are involved in several pathological conditions, such as oxidation of LDL and development of atherosclerosis, different stages of cancer development, autoimmune destruction of β cells leading to diabetes, inflammatory damage in asthma, in rheumatoid arthritis, age-related macular degeneration (AMD) and oxidation of lens proteins leading to cataracts (217). To neutralize these reactive species, the body's defense system is equipped with a few enzymes, some high-molecular-weight antioxidant proteins, and some low-molecular antioxidants, like ascorbate, vitamin E, β-carotene, glutathione and uric acid. If this balance is overwhelmed, oxidative stress builds up and this becomes the underlying cause of aging and some of the age-related diseases, such as cancer, cataracts, AMD and cardiovascular disease (218). Fruits have the ability to protect us against this free radical damage if consumed regularly. Fruits, like prunes, raisins, blueberries, cranberries and blackberries, have the highest antioxidant capacity, followed by strawberries, raspberries, plums, oranges, red grapes, red cherries, kiwi fruit, pink grapefruit, bananas and apples (219).

Many bioactive phytochemicals (or neutraceuticals) present in fruits have the ability to provide immense health benefits to us. These phytochemicals include terpenoids, phenolics, alkaloids and fiber. The role of these compounds against cancers, coronary heart disease, diabetes, hypertension, inflammation, microbial, viral and parasitic infections, ulcers, etc., has been recently reviewed (220). In addition to primary antioxidants, such as ascorbate, vitamin E and carotenes, most of the other phytochemicals present in fruits act as antioxidants to reduce the oxidative damage caused to lipids, proteins, nucleic acids and other cellular targets by reactive oxygen species (ROS). The effect of these antioxidants on changes in oxidative stress status associated with aging and other chronic conditions, like diabetes, cardiovascular diseases, cataracts and age-related macular degeneration, is being actively explored at Tufts Nutrition Antioxidant Research Laboratory (2). Although many other foods (such as vegetables, whole grains and whey proteins) also play an important role, the contribution of fruits to human nutrition and health is equally important.

C. Fruit Intake and Cancer Risk

The relation between cancer risk and the consumption of fruits and vegetables is now gaining a lot of attention

(221). Diets rich in fruits and vegetables are more strongly related to a lower risk of epithelial cancers of the respiratory and digestive tract. However, the intake of fruits and vegetables does not show a strong association with hormonally related cancers such as breast, endometrium, ovary and prostrate. No information is available on the total intake of phenolic phytochemicals. If this group includes anthocyanins, flavanols, isoflavones, phenolic acids and tannins, the total phenolic phytochemical intake may be up to hundreds of milligrams per day (222). This intake could be even higher in populations where red wine, soy products, lentils and beans are consumed. This information on the intake of phenolic phytochemicals would be useful because most of these phenolics have antioxidant properties with similar biological activities. Some of these phenolics trap nitrates and prevent the formation of mutagenic N-nitroso compounds in foods (223). The intake of these N-nitroso compounds is known to induce cancers of the nasopharynx, esophagus and stomach (224). In a recent study, regular consumption of fruits was strongly associated with reduced risk of many types of cancers (225). The strongest evidence correlates with the reduced risk of the mouth, esophagus, pharynx, lung, stomach and colon, whereas moderately strong evidence exists for cancers of the breast, pancreas and bladder.

D Antioxidants/Phytochemicals in Fruits

Until recently, fruits were known only as a source of certain vitamins, minerals and dietary fiber, but now a number of nonessential bioactive compounds (phytochemicals) are attracting the attention of food scientists and health professionals. Among the vitamins present in fruits, ascorbic acid has been investigated extensively. Ascorbic acid is a water-soluble antioxidant, which can easily be oxidized to form a free radical semidehydroascorbic acid that is quite stable. As ascorbic acid can lose an electron very easily, it is a very effective antioxidant in cytoplasm of biological systems (226). Blood levels of vitamin C above 49 μmol/L have been associated with a 64% reduced risk of cataracts in a Mediterranean population (227). Although more than 600 carotenoids have been identified so far, only about 50 of these possess vitamin A activity. Carotenoids, being lipid-soluble, act as antioxidants to protect the cell membranes of biological systems by quenching singlet oxygen and scavenging free radicals. Lycopene has the greatest antioxidant activity, followed by α-carotene, β-carotene, lutein and cryptoxanthin (228). Autumn olive (*Elaeagnus umbellata* Thunb.) bears yellow or brilliant red berries, which are very rich in lycopene (229) containing 15 to 54 mg from naturalized plants and 17 to 48 mg/100 g of fresh fruit from four cultivars with red-pigmented fruit. In contrast, the fresh tomato fruit had only about 3 mg of lycopene per 100 g. In addition, this fruit also contained α-cryptoxanthin, β-carotene, lutein, phytoene and phytofluene. This newly identified fruit (Autumn olive) can become an excellent source of lycopene and other carotenoids in our diet.

Lutein is a well-known carotenoid, whose intake has been shown to be inversely associated with ocular diseases, such as cataracts and age-related macular degeneration (230, 231). Lutein offers protection to the cells of the macula by acting as an antioxidant against the reactive oxygen species (232). The consumption of carotenoids from various sources does not reduce plasma carotenoid concentrations in the medium term, thus suggesting the eating of a diet rich in a variety of fruits and vegetables (233). Limonoids (terpenes) present in citrus fruits are shown to inhibit Phase I enzymes and induce Phase II detoxification enzymes in the liver and provide protection against cancer (234).Vitamin E is another major lipid-soluble antioxidant that protects the polyunsaturated fatty acids in cell membranes against free radicals and singlet oxygen species. Glutathione, selenium and flavonoids are the other water-soluble antioxidants. About 2000 chemical distinct flavonoids (flavonols, flavones, flavanones, isoflavones and flavanols) are present in fruits that may have antioxidant activity.

Phenolics, such as tannins and flavonoids, present in fruits have also been studied extensively as antioxidant protectants for humans. Plant phenolics are mostly produced through phenylpropanoid pathways and comprise a variety of compounds, such as cinnamic acids, benzoic acids, flavonoids, proanthocyanidins, stilbenes, coumarins, lignans and lignins. They are known to be strong antioxidants and prevent oxidative damage to DNA, lipids and proteins, which may play a role in chronic diseases like cancer and cardiovascular disease (235). Ferulic acid (a phenolic compound), a component of the plant cell wall, has the ability to mop up damaging free radicals and reactive oxygen species (236). One possible use for ferulic acid may be as a stimulant for sperm motility in fertility treatments or during *in vitro* fertilization. The polymeric tannins from grape seeds function as antioxidants and neutralize the effects of oxidative stress induced both by the deficiency of other vitamins and an atherogenic diet (31). Flavonoids are known to perform against free radicals, free radical-mediated cellular signaling, allergies, inflammation, platelets aggregation, ulcers, tumors, microbe viruses and hepatotoxins (237). Catechins and gallic acid present in grapes and berries have free radical scavenging activity, and inhibit eicosanoid synthesis and platelet aggregation.

Anthocyanidins are water-soluble flavonoids that are the principal pigments in fruits and are known to have antioxidative properties (238). Among the flavonoids, anthocyanins are reported to possess higher antioxidant activity as measured by oxygen radical absorbance capacity (ORAC) equivalents (239). On a fresh weight basis, the anthocyanin content in fruits, such as blackberries,

blueberries, cranberries, raspberries, strawberries and boysenberries, may range from 200 to 4950 mg/kg. An intake of 100 to 150 g of these fruits could easily give us 100 to 200 mg of anthocyanins, which are well above the suggested levels (240). Intake of two to five servings of fruits and vegetables per day would result in 1200 to 1640 ORAC equivalents for the person and may be responsible for the health benefits achieved with increased consumption of these foods. The polyphenols from blueberries and cranberries possess antioxidative and anti-inflammatory activities in endothelial cells and are reported to be beneficial in reducing initiation or development of cardiovascular diseases (241).

E. Stability of Phytochemicals during Processing

Food technologists are currently busy adding bioactive phytochemicals for developing new food products. These formulated foods will not only meet the nutritional needs of growth and maintenance, but are also expected to provide additional health benefits to consumers. Some of these targeted benefits are preventing disease and improving physical performance and the overall quality of life. The biochemical aspects, physiological effects and health benefits of phytochemicals in fruits were reviewed recently (242). The topics covered are characteristics of major fruit phytochemicals (phenols and carotenoids); physiological effects of phenols, carotenoids and other bioactive compounds (limonoids, ascorbate, limonene and folate) found in citrus fruits; evidence of health benefits, antioxidative and anticancer properties of bioactive compounds present in berries; and composition and physiological effects of phytochemicals in strawberries, apples, melons and some other fruits.

The antioxidant capacity of these phytochemicals is affected not only by various horticultural factors, but also by the food processing practices employed in the industry. The antioxidant capacity due to phenols in blueberries is decreased by food processing practices, such as heating and aeration (243). The composition, antioxidative capacity and levels of anthocyanins and total phenols in cultivated blueberries (*Vaccinium corymbosum* L.) and wild blueberries (*V. augustifolium* Aiton) are influenced by the method of extraction (244). The highest anthocyanin, total phenolic contents and antioxidative capacity are observed when aqueous methanol is used as a solvent. Irrespective of the solvent used, wild blueberries give higher values for these three parameters than the cultivated blueberries.

The temperature, pH and oxygenation during extraction of anthocyanins affect the antioxidative activity of extracted blueberries (245). Extraction of fruits at 60°C gives higher recovery of anthocyanins and antioxidant capacity than the extract obtained at 25°C, but subsequent loss in anthocyanins during room temperature storage occurs only in the former. Antioxidant capacity is higher in pH 1 extracts than those at pH 4 and 7. Oxygenation is detrimental to both the anthocyanins and antioxidant capacity. The antioxidant capacity of these processed products is positively correlated with anthocyanin ($R=0.92$) and phenolic ($R=0.95$) contents, and negatively correlated with percentage polymeric color ($R=0.64$). In general, the higher the extent of processing treatment, the lower is the antioxidant capacity. Simple colorimetric tests for anthocyanins and phenols are available to evaluate their antioxidant capacity in processed food products.

The antioxidant capacity, ascorbic acid, phenolics and anthocyanins of small fruits (strawberries, raspberries, cultivated and wild blueberries) during storage at 0, 10, 20 and 30°C for up to eight days are investigated (246). These four fruits vary significantly in total antioxidant activity, which is strongly correlated with the total phenolics ($R=0.83$) and anthocyanins ($R=0.90$). Antioxidant capacity is three times higher in blueberry species than either strawberries or raspberries. Ascorbic acid contents differ significantly among these fruit species, strawberries and raspberries having almost four times more ascorbate than blueberries. No loss of ascorbate is observed after eight days of storage at any of the temperatures in strawberries or cultivated blueberries, but there are losses in two other fruit species. Storage at a temperature higher than 0°C increases antioxidant capacity of strawberries and raspberries, and it is accompanied by increases in anthocyanins in strawberries, and increases in anthocyanins and total phenolics in raspberries. Ascorbic acid contributes very little (0.4–9.4%) to the total antioxidant capacity of these fruits. The increase in antioxidant capacity through post-harvest phenolic synthesis, therefore, indicates the possibility of enhancing the health benefits of these small fruit crops.

XII. FUTURE CONSIDERATIONS

Fruits are grown universally in almost every part of the world and serve as vital sources of essential vitamins, minerals, dietary fiber and many other bioactive compounds. Fruits are highly perishable in nature, and the growth of post-harvest technology is essential to minimize losses during their production, processing, handling and transportation. Fruits are processed into a variety of products, and are consumed either alone or in combination with grains, milk and milk products to provide maximum nutritional advantages to consumers.

Apart from a botanical basis, fruits have been classified solely on color or other physical properties. Most of these physical properties (viz. size, mass, total solids, firmness, density, color, specific gravity and porosity) are well correlated with the chemical composition, nutritional value and processing quality of finished products. The classification based on color serves as a useful indicator, not only for the fruit breeders, but also for the food scientists to look for

many phytochemicals (e.g., carotenoids from yellow, orange fruits, anthocyanins from colored fruits). This has opened up a vast opportunity for fruit biotechnologists to pursue a significant area of health-based fruit quality modification to selectively increase levels of different vitamins and other phytochemicals in various fruit species in coming years. This will give another boost to the fruit-based agroprocessing industry around the world. Considering the scope of functional foods based on phytochemicals, nowhere is the marketing transformation more visible than among the fruit growers and processors. As most fruits contain bioactive compounds that have extraordinary health-promoting characteristics, the growers, cooperatives and processors are quick to move these products to the frontline of their marketing programs.

While phytochemicals in fruits clearly show promise to prevent many diseases, important scientific questions are yet to be answered. We have to look for the answers to some of the questions like "Which of these phytochemicals are more effective, what is the mechanism of their action, and more importantly, how to preserve these bioactive compounds during processing?" We also need to identify and quantify these bioactive compounds in foods, their bioavailability, pharmacokinetics and metabolism in humans, determination of the relationship between molecular structure and antioxidant capacity, mutual interaction of these phytochemicals in the human digestive tract when consumed together, doses required for their effectiveness, and their stability during processing, storage and distribution of these food products right up to our dining table.

25 Frozen Fruits: Product Descriptions

Peggy Stanfield
Dietetic Resources

CONTENTS

I. FROZEN FRUITS

A. APPLES

Frozen apples are prepared from sound, properly ripened fruit of *Malus sylvesfris (Pyrus malus);* are peeled, cored, trimmed, sliced, sorted, and washed; are properly drained before filling into containers; may be packed with or without the addition of a nutritive sweetening ingredient and any other legally permissible ingredients and are frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

The term "slices" means frozen apples consisting of slices of apples cut longitudinally and radially from the core axis.

B. APRICOTS

Apricots are the food prepared from mature apricots of one of the optional styles specified, which may be packed as solid pack or in one of the optional packing media specified.

Such food may also contain one or any combination of two or more of the following safe and suitable optional ingredients:

1. Natural and artificial flavors.
2. Spice.
3. Vinegar, lemon juice, or organic acids.
4. Apricot pits, except in the case of unpeeled whole apricots and peeled whole apricots in a quantity not more than 1 apricot pit to each 227 grams (8 ounces) of finished frozen apricots.
5. Apricot kernels, except in the case of unpeeled whole apricots and peeled whole apricots, and except when an optional ingredient is used.
6. Ascorbic acid in an amount no greater than necessary to preserve color.

Such food is sealed in a container and before or after scaling is so processed by heat as to prevent spoilage.

1. Optional Styles of the Apricot Ingredients

The optional styles of the apricot ingredients arc peeled or unpeeled: (i) whole, (ii) halves, (iii) quarters, (iv) slices, (v) pieces or irregular pieces.

Each such ingredient, except in the cases of unpeeled whole apricots and peeled whole apricots, is pitted.

2. Packing Media

The optional packing media are (a) water, (b) fruit juice(s) and water, (c) fruit juice(s).

Such packing media may be used as such, or any one or any combination of two or more safe and suitable nutritive carbohydrate sweetener(s) may be added. When a sweetener is added as a part of any such liquid packing medium, the density range of the resulting packing medium expressed as percent by weight of sucrose (degrees Brix) should be designated by the appropriate name for the respective density ranges, namely:

When the density of the solution is 10 percent or more but less than 16 percent, the medium should be designated as "slightly sweetened water" or "extra light syrup," "slightly sweetened fruit juice(s) and water" or "slightly sweetened fruit juice(s)," as the case may be.

When the density of the solution is 16 percent or more but less than 21 percent, the medium should be designated as "light syrup," "lightly sweetened fruit juice(s) and water," or "lightly sweetened fruit juice(s)," as the case may be. When the density of the solution is 21 percent or more but less than 25 percent, the medium should be designated as "heavy syrup," "heavily sweetened fruit juice(s) and water," or "heavily sweetened fruit juice(s)," as the case may be.

When the density of the solution is 25 percent or more but not more than 40 percent, the medium should be designated as "extra heavy syrup," "extra heavily sweetened fruit juice(s) and water," or "extra heavily sweetened fruit juice(s)," as the case may be.

3. Labeling Requirements

The name of the food is apricots. The name of the food should also include a declaration of any flavoring that characterizes the product and a declaration of any spice or seasoning that characterizes the product; for example, "Spice Added," or in lieu of the word "Spice," the common name of the spice, e.g., "Seasoned with Vinegar" or "Seasoned with Apricot Kernels."

When two or more of the optional ingredients specified are used, such words may be combined, as for example, "Seasoned with Cider Vinegar, Cloves, Cinnamon Oil, and Apricot Kernels."

The style of the apricot ingredient and the name of the packing medium preceded by "In" or "Packed in" or the words "Solid Pack," where applicable, should be included as part of the name or in close proximity to the name of the food, except that pieces or irregular pieces should be designated "Pieces," "Irregular Pieces," or "Mixed Pieces of Irregular Sizes and Shapes."

The style of the apricot ingredient should be preceded or followed by "Unpeeled" or "Peeled," as the case may be. "Halves" may be alternatively designated "Halved," "Quarters" as "Quartered," and "Slices" as "Sliced." When the packing medium is prepared with a sweetener(s) that imparts a taste, flavor, or other characteristic to the finished food in addition to sweetness, the name of the packing medium should be accompanied by the name of such sweetener(s), for example, in the case of a mixture of

brown sugar and honey, an appropriate statement would be "_____syrup of brown sugar and honey" the blank to be filled in with the word "light," "heavy," or "extra heavy," as the case may be.

When the liquid portion of the packing media consists of fruit juice(s), such juice(s) should be designated in the name of the packing medium as follows.

In the case of a single fruit juice, the name of the juice should be used in lieu of the word "fruit."

In the case of a combination of two or more fruit juices, the names of the juices in the order of predominance by weight should be used in lieu of the word "fruit" in the name of the packing medium.

In the case of a single fruit juice or a combination of two or more fruit juices any of which are made from concentrate(s), the words "from concentrate(s)" should follow the word "juice(s)" in the name of the packing medium and in the name(s) of such juice(s) when declared as specified.

Whenever the names of the fruit juices used do not appear in the name of the packing medium, such names and the words "from concentrate," should appear in an ingredient statement.

4. Label Declaration

Each of the ingredients used in the food should be declared on the label.

Frozen apricots are prepared from sound, mature, fresh, peeled or unpeeled fruit of any commercial variety of apricot, which are sorted, washed, and may be trimmed to assure a clean and wholesome product. The apricots are properly drained of excess water before filling into containers; may be packed with the addition of nutritive sweetening ingredient(s) (including syrup and/or syrup containing pureed apricots) and/or suitable antioxidant ingredient(s) and/or any other legally permissible ingredients(s).

The apricots are prepared and frozen in accordance with good commercial practice and are maintained at temperatures necessary for the preservation of the product.

5. Styles of Frozen Apricots

(a) Halves are cut approximately in half along the suture from stem to apex and the pit is removed.
(b) Quarters are apricot halves cut into two approximately equal parts.
(c) Slices are apricot halves cut into sectors smaller than quarters.
(d) Diced are apricots cut into approximate cubes.
(e) Cuts are apricots that are cut in such a manner as to change the original conformation and do not meet any of the foregoing styles.
(f) Machine-pitted means mechanically pitted in such a manner as to substantially destroy the conformation of the fruit in removing the pit.

C. Berries

Frozen berries are prepared from the properly ripened fresh fruit of the plant (genus *48 Rubus);* are stemmed and cleaned, may be packed with or without packing media, and are frozen and stored at temperatures necessary for the preservation of the product.

1. Types of Frozen Berries

(a) Blackberries
(b) Boysenberries
(c) Dewberries
(d) Loganberries
(e) Youngberries
(f) Other similar types, such as nectar berries

2. Blueberries

Frozen blueberries are prepared from sound, properly ripened fresh fruit of the blueberry bush (genus *Vaccinium),* including species or varieties often called huckleberries, but not of the genus *Gaylussacia;* they are cleaned and stemmed, are properly washed, are packed with or without packing media, and are frozen and maintained at temperatures necessary for the preservation of the product.

Types of frozen blueberries are (a) native or wild type; (b) cultivated type.

D. Red Tart Pitted Cherries

Frozen red tart pitted cherries are the foods prepared from properly matured cherries of the domestic *(Prunes cerasus)* red sour varietal group that have been washed, pitted, sorted, and properly drained; they may be packed with or without a nutritive sweetened packing medium or any other substance permitted under federal regulations and are frozen and stored at temperatures necessary for the preservation of the product.

II. FROZEN JUICES

A. Apple Juice

Frozen concentrated apple juice is prepared from the unfermented, unsweetened, unacidified liquid obtained from the first pressing of properly prepared, sound, clean, mature, fresh apples, and/or parts thereof by good commercial processes. The juice is clarified and concentrated to at least 22.9° Brix. The apple juice concentrate so prepared, with or without the addition of legal ingredients, is packed and frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

The Brix value of the finished concentrate should not be less than the following for the respective dilution factor of frozen concentrated apple juice:

Dilution Factor Value of Concentrate: minimum Brix (degrees)

1 plus 1 22.9
2 plus 1 33.0
3 plus 1 42.2
4 plus 1 50.8
5 plus 1 58.8
6 plus 1 66.3
7 plus 1 73.3

B. Lemon Juice (for Preparing Frozen Concentrate for Lemonade)

Lemon juice is the unfermented juice, obtained by mechanical process, from sound, mature lemons (*Citrus limon* (L.) Burm. f.), from which seeds (except embryonic seeds and small fragments of seed which cannot be separated by good manufacturing practice) and excess pulp are removed. The juice may be adjusted by the addition of the optional concentrated lemon juice ingredient in such quantity that the increase in acidity, calculated as anhydrous citric acid, does not exceed 15 percent of the acidity of the finished food. The lemon oil and lemon essence (derived from lemons) content may be adjusted in accordance with good manufacturing practice. The juice may have been concentrated and later reconstituted. When prepared from concentrated lemon juice, the finished food contains not less than 6 percent, by weight, of soluble solids taken as the refractometric sucrose value (of the filtrate), corrected to 20°C, but uncorrected for acidity, and has a titratable acidity content of not less than 4.5 percent, by weight, calculated as anhydrous citrus acid.

The food may contain one or any combination of the safe and suitable optional ingredients. Lemon juice may be preserved by heat sterilization (canning), refrigeration, freezing, or by the addition of safe and suitable preservatives. When sealed in a container to be held at ambient temperatures, it is preserved by the addition of safe and suitable preservatives or so processed by heat, before or after sealing, as to prevent spoilage.

1. Optional Ingredients

The optional safe and suitable ingredients are (i) concentrated lemon juice (lemon juice from which part of the water has been removed), (ii) water and/or lemon juice to reconstitute concentrated lemon juice in the manufacture of lemon juice from concentrate, and (iii) preservatives.

2. Labeling

The name of the food is "lemon juice" if the food is prepared from unconcentrated, undiluted liquid extracted from mature lemons; or if the food is prepared from unconcentrated, undiluted liquid extracted from mature lemons to which concentrated lemon juice is added to adjust acidity.

The name is "lemon juice from concentrate" or "reconstituted lemon juice" if the food is prepared from concentrated lemon juice and water and/or lemon juice; or if the food is prepared from lemon juice from concentrate and lemon juice.

Frozen concentrate for lemonade is the frozen food prepared from one or both of the lemon juice ingredients together with one or any mixture of safe and suitable nutritive carbohydrate sweeteners. The product contains not less than 48.0 percent by weight of soluble solids taken as the sucrose value.

When the product is diluted according to directions for making lemonade which should appear on the label, the acidity of the lemonade, calculated as anhydrous citric acid, should be not less than 0.70 gram per 100 milliliters, and the soluble solids should be not less than 10.5 percent by weight.

3. The Lemon Juice Ingredients

Lemon juice ingredients are lemon juice or frozen lemon juice or a mixture of these or concentrated lemon juice or frozen concentrated lemon juice or a mixture of these. For this purpose, lemon juice is the undiluted juice expressed from mature lemons of an acid variety, and concentrated lemon juice is lemon juice from which part of the water has been removed. In the preparation of the lemon juice ingredients, the lemon oil content may be adjusted by the addition of lemon oil or concentrated lemon oil in accordance with good manufacturing practice, and the lemon pulp in the juice as expressed may be left in the juice or may be separated.

Lemon pulp that has been separated, which may have been preserved by freezing, may be added in preparing frozen concentrate for lemonade, provided that the amount of pulp added does not raise the proportion of pulp in the finished food to a level in excess of that which would be present by using lemon juice ingredients from which pulp has not been separated. The lemon juice ingredients may be treated by heat, either before or after the other ingredients are added, to reduce the enzymatic activity and the number of viable microorganisms.

C. Frozen Concentrate for Artificially Sweetened Lemonade

Frozen concentrate for artificially sweetened lemonade conforms to the description for frozen concentrate for lemonade, except that in lieu of nutritive sweeteners it is sweetened with one or more of the artificial sweetening ingredients permitted by law, and the soluble solids specifications do not apply. When the product is diluted according to directions that should appear on the label, the acidity of the artificially sweetened lemonade, calculated

as anhydrous citric acid, should be not less than 0.70 gram per 100 milliliters. It may contain one or more safe and suitable dispersing ingredients serving the function of distributing the lemon oil throughout the food. It may also contain one or more safe and suitable thickening ingredients. Such dispersing and thickening ingredients are not legal food additives.

The name of the food is "frozen concentrate for artificially sweetened lemonade." The words "artificially sweetened" should be of the same size and style of type as the word "lemonade." If an optional thickening or dispersing ingredient is used, the label should bear the statement "_____ added" or "with added _____," the blank being filled in with the common name of the thickening or dispersing agent used. Such statement should be set forth on the label with such prominence and conspicuousness as to render it likely to be read and understood by the ordinary individual under customary conditions of purchase.

D. Frozen Concentrate for Colored Lemonade

Frozen concentrate for colored lemonade conforms to the description for frozen concentrate for lemonade, except that it is colored with a safe and suitable fruit juice, vegetable juice, or any such juice in concentrated form, or with any other legal color additive ingredient suitable for use in food, including legal artificial coloring.

The name of the food is "frozen concentrate for_____lemonade," the blank being filled in with the word describing the color, for example, "frozen concentrate for pink lemonade."

E. Grapefruit Juice

Grapefruit juice is the unfermented juice, intended for direct consumption, obtained by mechanical process from sound, mature grapefruit (*Citrus paradisi* Macfadven) from which seeds and peel (except embryonic seeds and small fragments of seeds and peel that cannot be separated by good manufacturing practice) and excess pulp are removed and to which may be added not more than 10 percent by volume of the unfermented juice obtained from mature hybrids of grapefruit. The juice may be adjusted by the addition of the optional concentrated grapefruit juice ingredients specified, but the quantity of such concentrated grapefruit juice ingredient added should not contribute more than 1 percent of the grapefruit juice soluble solids in the finished food. The grapefruit pulp, grapefruit oil, and grapefruit essence (components derived from grapefruit) content may be adjusted in accordance with good manufacturing practice. The juice may have been concentrated and later reconstituted with water suitable for the purpose of maintaining essential composition and quality factors of the juice. It may be sweetened with the dry nutritive sweeteners. If the grapefruit juice is prepared from concentrate, such sweeteners in liquid form also may be used. When prepared from concentrated grapefruit juice, exclusive of added sweeteners, the finished food contains not less than 10 percent, by weight, of soluble solids taken as the refractometric sucrose value (of the filtrate), corrected to 20°C, and corrected for acidity by adding $(0.012 + 0.193x\text{-}0.0004x)$, where x equals the percent anhydrous citric acid in sample, to the refractometrically obtained sucrose value. Grapefruit juice, as defined in this paragraph, may be preserved by heat sterlization (canning), refrigeration, or freezing. When scaled in a container to be held at ambient temperatures, it is so processed by heat, before or after scaling, as to prevent spoilage.

1. Optional Ingredients

The optional ingredients are (a) concentrated grapefruit juice (grapefruit juice from which part of the water has been removed); (b) water and/or grapefruit juice to reconstitute concentrated grapefruit juice in the manufacture of grapefruit juice from concentrate; and (c) one or any combination of two or more of the dry or liquid forms of sugar, invert sugar syrup, dextrose, glucose syrup, and fructose.

The name of the food is "Grapefruit juice" if the food is prepared from unconcentrated, undiluted liquid extracted from mature grapefruit, or if the food is prepared from unconcentrated, undiluted liquid extracted from mature grapefruit to which concentrated grapefruit juice is added to adjust soluble solids.

"Grapefruit juice from concentrate" is the name if the food is prepared from concentrated grapefruit juice and water and/or grapefruit juice; or if the food is prepared from grapefuit juice from concentrate and grapefruit juice. The words "from concentrate" should be shown in letters not less than one-half the height of the letters in the words "grapefruit juice."

If any nutritive sweetener is added, the principal display panel of the label should bear the statement "sweetener added." If no sweetener is added, the word "unsweetened" may immediately precede or follow the words "grapefruit juice" or "grapefruit juice from concentrate."

F. Orange Juice

Orange juice is the unfermented juice obtained from mature oranges of the species *Citrus sinensis* or of the citrus hybrid commonly called "Ambersweet" [1/2 *Citrus sinensis* × 3/8 *Citrus reticulata* × 1/8 *Citrus paradisi* (USDA Selection: 1-100-29: 1972 Whitmore Foundation Farm)]. Seeds (except embryonic seeds and small fragments of seeds that cannot be separated by current good manufacturing practice) and excess pulp are removed. The juice may be chilled, but it is not frozen.

The name of the food is "orange juice." The name "orange juice" may be preceded on the label by the varietal name of the oranges used, and if the oranges grew in a

single State, the name of such State may be included in the name, as for example, "California Valencia orange juice."

G. Pasteurized Orange Juice

Pasteurized orange juice is the food prepared from unfermented juice obtained from mature oranges, to which may be added not more than 10 percent by volume of the unfermented juice obtained from mature oranges of the species *Citrus reticulata* or *Citrus reticulata* hybrids. Seeds (except embryonic seeds and small fragments of seeds that cannot be separated by good manufacturing practice) are removed, and pulp and orange oil may be adjusted in accordance with good manufacturing practice. If the adjustment involves the addition of pulp, then such pulp should not be of the washed or spent type. The solids may be adjusted by the addition of one or more of the optional concentrated orange juice ingredients. One or more of the optional sweetening ingredients may be added in a quantity reasonably necessary to raise the Brix or the Brix-acid ratio to any point within the normal range usually found in unfermented juice obtained from mature oranges. The orange juice is so treated by heat as to reduce substantially the enzymatic activity and the number of viable microorganisms. Either before or after such heat treatment, all or a part of the product may be frozen. The finished pasteurized orange juice contains not less than 10.5 percent by weight of orange juice soluble solids, exclusive of the solids of any added optional sweetening ingredients, and the ratio of the Brix hydrometer reading to the grams of anhydrous citric acid per 100 milliliters of juice is not less than 10 to 1.

The optional concentrated orange juice ingredients are frozen concentrated orange juice and concentrated orange juice for manufacturing when made from mature oranges; but the quantity of such concentrated orange juice ingredients added should not contribute more than one-fourth of the total orange juice solids in the finished pasteurized orange juice.

The optional sweetening ingredients referred to are sugar, invert sugar, dextrose, dried corn syrup, and dried glucose syrup.

The name of the food is "pasteurized orange juice." If the food is filled into containers and preserved by freezing, the label should bear the name "frozen pasteurized orange juice." The words "pasteurized" or "frozen pasteurized" should be shown on labels in letters not less than one-half the height of the letters in the words "orange juice."

If the pasteurized orange juice is filled into containers and refrigerated, the label should bear the name of the food, "chilled pasteurized orange juice." If it does not purport to be either canned orange juice or frozen pasteurized orange juice, the word "chilled" may be omitted from the name. The words "pasteurized" or "chilled pasteurized" should be shown in letters not less than one-half the height of the letters in the words "orange juice."

H. Frozen Concentrated Orange Juice

Frozen concentrated orange juice is the food prepared by removing water from the juice of mature oranges, to which may be added unfermented juice obtained from mature oranges of the species *Citrus reticulata,* other *Citrus reticulata* hybrids, or of *Citrus aurantiurn,* or both. However, in the unconcentrated blend, the volume of juice from *Citrus reticulata* or *Citrus reticulata* hybrids should not exceed 10 percent, and from *Citrus aurantium* should not exceed 5 percent. The concentrate so obtained is frozen. In its preparation, seeds (except embryonic seeds and small fragments of seeds that cannot be separated by good manufacturing practice) and excess pulp are removed, and a properly prepared water extract of the excess pulp so removed may be added. Orange oil, orange pulp, orange essence (obtained from orange juice), orange juice and other orange juice concentrate or concentrated orange juice for manufacturing (when made from mature oranges), water, and one or more of the optional sweetening ingredients may be added to adjust the final composition. The juice of *Citrus reticulata* and *Citrus aurantium,* as permitted by this paragraph, may be added in single strength or concentrated form prior to concentration of the *Citrus sinensis* juice, or in concentrated form during adjustment of the composition of the finished food. The addition of concentrated juice from *Citrus reticulata* or *Citrus aurantium,* or both, should not exceed, on a single-strength basis, the 10 percent maximum for *Citrus reticulata* and the 5 percent maximum for *Citrus aurantiumi* prescribed by this paragraph. Any of the ingredients of the finished concentrate may have been so treated by heat as to reduce substantially the enzymatic activity and the number of viable microorganisms. The finished food is of such concentration that when diluted according to label directions the diluted article will contain not less than 11.8 percent by weight of orange juice soluble solids, exclusive of the solids of added optional sweetening ingredients. The term "dilution ratio" means the whole number of volumes of frozen per volume of frozen concentrate required to produce orange juice from concentrate having orange juice soluble solids of not less than 11.8 percent by weight exclusive of the solids of any added optional sweetening ingredients.

The optional sweetening ingredients are sugar, sugar syrup, invert sugar, invert sugar syrup, dextrose, corn syrup, dried corn syrup, glucose syrup, and dried glucose syrup.

If one or more of the sweetening ingredients are added to the frozen concentrated orange juice, the label should bear the statement "_____added," the blank being filled in with the name or an appropriate combination of names of the sweetening ingredients used. However, the name "sweetener" may be used in lieu of the specific name or names of the sweetening ingredients.

The name of the food concentrated to a dilution ratio of is "frozen concentrated orange juice" or "frozen orange juice concentrate." The name of the food concentrated to a dilution ratio greater than 3 plus 1 is "frozen concentrated orange juice, _____plus l" the blank being filled in with the whole number showing the dilution ratio; for example, "frozen orange juice concentrate, 4 plus 1." However, where the label bears directions for making 1 quart of orange juice from concentrate (or multiples of a quart), the blank in the name may be filled in with a mixed number; for example, "frozen orange juice concentrate, $4^1/_3$ plus 1." For containers larger than 1 pint, the dilution ratio in the name may be replaced by the concentration of orange juice soluble solids in degrees Brix; for example, a 62° Brix concentrate in 3% gallon cans may be named on the label "frozen concentrated orange juice, 62° Brix."

I. Reduced Acid Frozen Concentrated Orange Juice

Reduced-acid frozen concentrated orange juice is the food that complies with the requirements for composition and label declaration of ingredients prescribed for frozen concentrated orange juice except that it may not contain any added sweetening ingredient. A process involving the legal use of anionic ion-exchange resins is used to reduce the acidity of the food so that the ratio of the Brix reading to the grams of acid, expressed as anhydrous citric acid, per 100 grams of juice is not less than 21 to 1 or more than 26 to 1.

The name of the food is "reduced acid frozen concentrated orange juice."

J. Orange Juice for Manufacturing

Orange juice for manufacturing is the food prepared for further manufacturing use. It is prepared from unfermented juice obtained from oranges as provided earlier, except that the oranges may deviate from the standards for maturity in that they are below the minimum for Brix and Brix-acid ratio for such oranges, and to which juice may be added not more than 10 percent by volume of the unfermented juice obtained from oranges of the species *Citrus reticulata* or *Citrus reticulata* hybrids (except that this limitation should not apply to the hybrid species). Seeds (except embryonic seeds and small fragments of seeds that cannot be separated by good manufacturing practice) are removed, and pulp and orange oil may be adjusted in accordance with good manufacturing practice. If pulp is added it should be other than washed or spent pulp. The juice or portions thereof may be so treated by heat as to reduce substantially the enzymatic activity and number of viable microorganisms, and it may be chilled or frozen, or it may be so treated by heat, either before or after sealing in containers, as to prevent spoilage.

The name of the food is "orange juice for manufacturing."

K. Orange Juice with Preservative

Orange juice with preservative is the food prepared for further manufacturing use. It complies with the requirements for composition of orange juice for manufacturing as specified, except that a preservative is added to inhibit spoilage. It may be heat-treated to reduce substantially the enzymatic activity and the number of viable microorganisms.

The preservatives referred to are any safe and suitable preservatives or combinations thereof.

The name of the food is "orange juice with preservative." Each of the ingredients used in the food should be declared on the label as required by regulations. In addition, the name of each preservative should be preceded by a statement of the percent by weight of the preservative used. If the food is packed in container sizes that are less than 19 liters (5 gallons), the label should bear a statement indicating that the food is for further manufacturing use only.

Wherever the name of the food appears on the label so conspicuously as to be easily seen under customary conditions of purchase, the statement for naming the preservative ingredient used should immediately and conspicuously precede or follow the name of the food, without intervening written, printed, or graphic matter.

L. Concentrated Orange Juice for Manufacturing

Concentrated orange juice for manufacturing is the food that complies with the requirements of composition and label declaration of ingredients prescribed, except that it is either not frozen or is less concentrated, or both, and the oranges from which the juice is obtained may deviate from the standards for maturity in that they are below the minimum Brix and Brix-acid ratio for such oranges: However, the concentration of orange juice soluble solids should not be less than 20° Brix.

The name of the food is "concentrated orange juice for manufacturing, _____" or "_____ orange juice concentrate for manufacturing," the blank being filled in with the figure showing the concentration of orange juice soluble solids in degrees Brix.

M. Concentrated Orange Juice with Preservative

(a) Concentrated orange juice with preservative complies with the requirements for composition and labeling of optional ingredients prescribed for concentrated orange juice for manufacturing by Sec. 146.153, except that a preservative is added to inhibit spoilage. (b) The preservatives referred to in paragraph (a) of this section are any safe and suitable preservatives or combinations thereof. (c) The name of the food is "concentrated orange juice

with preservative, _____," the blank being filled in with the figure showing the concentration of orange juice soluble solids in degrees Brix. (d) Label declaration. Each of the ingredients used in the food should be declared on the label as required by regulations. In addition, the name of each preservative should be preceded by a statement of the percent by weight of the preservative used. If the food is packed in container sizes that are less than 19 liters (5 gallons), the label should bear a statement indicating that the food is for further manufacturing use only.

N. Pineapple Juice

Pineapple juice is the juice, intended for direct consumption, obtained by mechanical process from the flesh or parts thereof, with or without core material, of sound, ripe pineapple *(Ananas comosus* L. Merrill). The juice may have been concentrated and later reconstituted with water suitable for the purpose of maintaining essential composition and quality factors of the juice. Pineapple juice may contain finely divided insoluble solids, but it does not contain pieces of shell, seeds, or other coarse or hard substances or excess pulp. It may be sweetened with any safe and suitable dry nutritive carbohydrate sweetener. However, if the pineapple juice is prepared from concentrate, such sweeteners, in liquid form, also may be used. It may contain added vitamin C in a quantity such that the total vitamin C in each 4 fluid ounces of the finished food amounts to not less than 30 milligrams and not more than 60 milligrams. In the processing of pineapple juice, dimethylpolysiloxane may be employed as a defoaming agent in an amount not greater than 10 parts per million by weight of the finished food. Such food is prepared by heat sterilization, refrigeration, or freezing. When sealed in a container to be held at ambient temperatures, it is so processed by heat, before or after sealing, as to prevent spoilage.

The name of the food is "pineapple juice" if the juice from which it is prepared has not been concentrated and/or diluted with water. The name of the food is "pineapple juice from concentrate" if the finished juice has been made from specified pineapple juice. If a nutritive sweetener is added, the label should bear the statement "sweetener added." If no sweetener is added, the word "unswcetened" may immediately precede or follow the words "pineapple juice" or "pineapple juice from concentrate."

Each of the ingredients used in the food should be declared on the label.

O. Quality

The standard of quality for pineapple juice is as follows: (a) The soluble solids content of pineapple juice (exclusive of added sugars) without added water should not be less than 10.5° Brix as determined by refractometer at 20°C uncorrected for acidity and read as degrees Brix on International Sucrose Scales. Where the juice has been obtained using concentrated juice with addition of water, the soluble pineapple juice solids content (exclusive of added sugars) should be not less than 12.8° Brix, uncorrected for acidity and read as degrees Brix on the International Sucrose Scales. The acidity is not more than 1.35 grams of anhydrous citric acid per 100 milliliters of the juice. The ratio of the degrees Brix to total acidity is not less than 12. The quantity of finely divided "insoluble solids" is not less than 5 percent or more than 30 percent.

P. Blended Grape and Orange Juice

1. Product Description

Frozen concentrated blended grapefruit juice and orange juice is the frozen product prepared from a combination of concentrated, unfermented juices obtained from sound, mature grapefruit (*Citrus paradisi*) and from sound, mature fruit of the sweet orange group (*Citrus sinensis*) and Mandarin group (*Citrus reticulate*), except tangerines. The fruit is prepared by sorting and by washing prior to extraction of the juices to assure a clean product. The juices may be blended upon extraction of such juices or after concentration, and fresh orange juice extracted from sorted and washed fruit, as aforesaid, is admixed to the concentrate. It is recommended that the frozen concentrated blended grapefruit juice and orange juice be composed of the equivalent of not less than 50 percent orange juice in the reconstituted juice; however, in oranges yielding light-colored juice it is further recommended that as much as the equivalent of 75 percent orange juice in the reconstituted juice be used. The concentrated juice is packed in accordance with good commercial practice and is frozen and maintained at temperatures necessary for the preservation of the product.

2. Styles of Frozen Concentrated Blended Grapefruit Juice and Orange Juice

There are two styles: (a) Style I, without sweetening ingredient added. The Brix value of the finished concentrate should be not less than 40° or more than 44°; and (b) Style II, with sweetening ingredient added. The finished concentrate, exclusive of added sweetening ingredient, has a Brix value of not less than 38°; and the finished concentrate, including added sweetening ingredient, should have a Brix value of not less than 40° but not more than 48°.

26 Milk Proteins

Harjinder Singh and John Flanagan
Riddet Centre, Massey University

CONTENTS

I. INTRODUCTION

Bovine milk contains approximately 3.5% protein, and is an important protein source for both man and developing neonate. The protein concentration of milk may vary quite considerably due to a variety of factors; breed and age of cow, stage of lactation, number of lactations and diet of cow exert influence upon both the overall protein concentration of milk and the proportion of the individual milk proteins.

About 100 years ago it was shown that the proteins in milk could be fractionated into two well-defined groups. When the pH of raw milk is adjusted to 4.6 at ~30°C, a precipitate containing 80% of the total milk protein is formed. This fraction is called casein and the remaining soluble material under these conditions is referred to as whey or serum proteins or non-casein nitrogen. Both casein and whey proteins are quite heterogeneous, as outlined in Figure 26.1. These two classes of milk proteins are considered separately due to the large differences in their structures and physico-chemical properties. Many reviews and monographs on the structures and properties of casein and whey proteins have been published (1–6). Most of the existing information on milk proteins has been compiled in the recently published Encyclopedia of Dairy Sciences (7).

This chapter provides an overview of the properties and structures of the main milk protein components. These topics have been covered in a greater detail in several text and reference books mentioned throughout this chapter.

II. CASEINS

For more than 50 years, it was believed that the casein fraction was a pure single entity. The application of moving boundary electrophoresis and sedimentation techniques in the late 1930s demonstrated the heterogeneity of the casein fraction. Three components were demonstrated and named α-, β- and γ-caseins in order of decreasing electrophoretic mobility and represented 75, 22 and 3%, respectively, of whole casein. In 1956, the α-casein

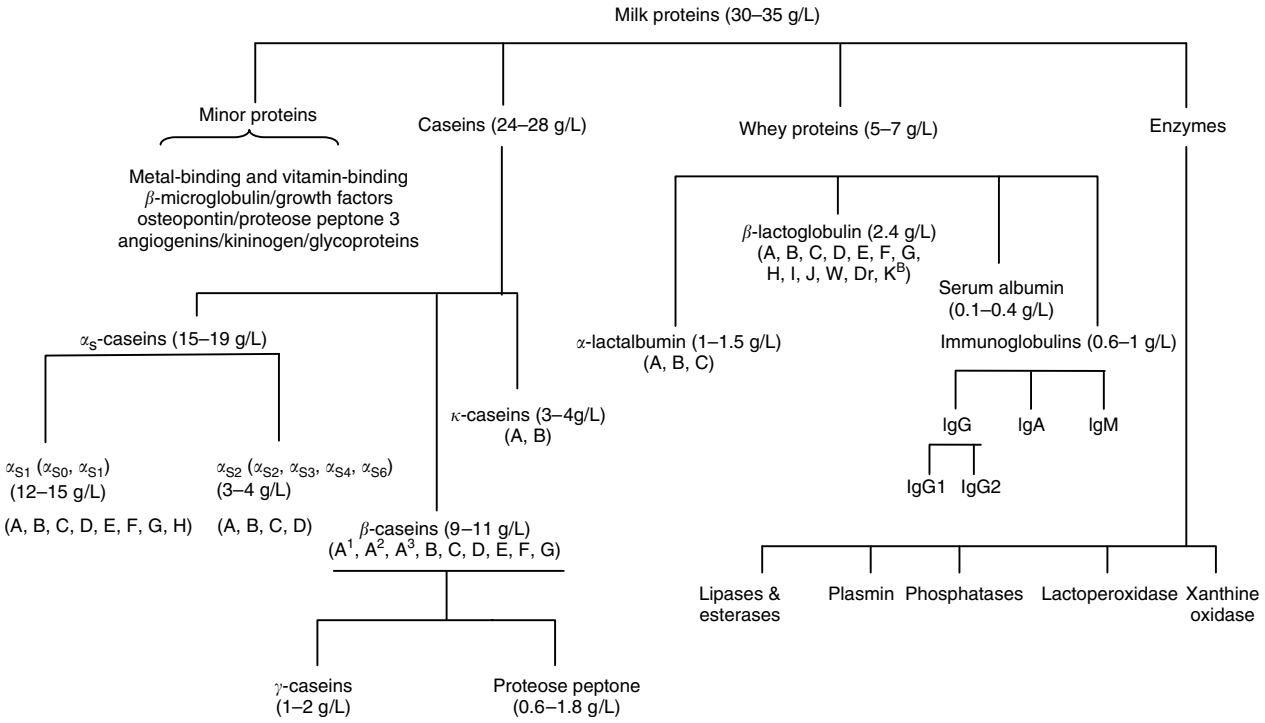

FIGURE 26.1 Distribution of fractions, and approximate concentrations and genetic variants of the major proteins in bovine milk. (Adapted from Ref. 3.)

fraction was shown to contain two proteins, one of which was precipitated by low Ca^{2+} concentration and was called α_s-casein, while the other, which was insensitive to calcium, was called κ-casein (8). α_s-Casein was later shown to consist of two proteins which are now called α_{S1}- and α_{S2}-caseins. Thus, bovine milk contains four major caseins, denoted as α_{S1}-casein, α_{S2}-casein, β-casein and κ-casein, which represent approximately 37, 10, 35 and 12% of the whole casein, respectively (9).

Minor components of the casein system are a heterogeneous group of proteins known as γ-caseins. These caseins occur as a result of limited proteolysis of the C-terminal of β-casein, caused by the action of the indigenous proteinase, plasmin (10). The γ-caseins are classified as γ^1-(β-casein f29-209), γ^2-(β-casein f106-209~11) and γ^3-(β-casein f108-209). The corresponding N-terminal portion of β-casein is the source of the so-called proteose peptones; PP5, PP8 fast and PP8 slow, i.e., β-CN f1-105/7, f1-28 and f29-105/7, respectively (see Figure 26.2). The proteose peptones elute in the whey fraction of milk.

Each of the four major caseins exhibits variability in the degree of phosphorylation and glycosylation. All caseins are phosphorylated: most of the α_{S1}-casein molecules contain 8 PO_4 residues but some contain 9; α_{S2}-casein contains 10, 11, 12 or 13 mol PO_4/mol; β-casein usually contains 5 mol PO_4/mol but occasionally 4 mol PO_4/mol; κ-casein contains 1 mol PO_4/mol but some molecules of κ-casein may contain 2 or 3 PO_4/mol. κ-Casein is the only casein which is normally glycosylated and contains galactose, galactosamine and N-acetyl neuraminic acid which occur as either trisaccharides or tetrasaccharides attached to threonine residues in the C-terminal region. κ-Casein may contain zero to four tri- or tetrasaccharide moieties, resulting in nine forms of κ-casein (4).

A further heterogeneity in caseins arises from the occurrence of genetic polymorphism, which is due to either substitutions or, rarely, deletions of amino acids in the caseins as a consequence of mutations causing changes in base sequences in the genes. Among the 21 variants in caseins (Figure 26.1), two are due to deletion of a segment in the α_{S1}-casein. The variants A and H of α_{S1}-casein differ from variant B by the absence of amino acid sequences 14–26 and 51–58, respectively. The deletion of residues 51–59 in α_{S2}-casein A leads to the occurrence of variant D. All other genetic variants of casein involve amino acid substitutions. As the casein system is very complex and heterogeneous, a logical nomenclature, recommended by the Nomenclature Committee of the American Dairy Science Association, has been adopted. The casein family is indicated by a Greek letter with a subscript (i.e., α_{S1}) followed by CN. The genetic variant is indicated by a Roman letter (A, B, C, etc.) with a superscript, if necessary (e.g., α_{S1}-CN A^2). The degree of phosphorylation is indicated as the number of phosphate residues, e.g., α_{S1}-CNB - 8P.

A. Casein Structures and Properties

The primary structures of the major caseins have been known since the early 1970s and are shown in Figures 26.3 a–d. In comparison to typical globular proteins, the structures of caseins are quite unique. Each of the caseins has distinct areas of positively and negatively charged groups in their primary structures resulting in the amphiphilic nature of the individual proteins (Figure 26.4). In addition, the hydrophobicity of each of the caseins varies considerably as a function of position on the peptide chain (Figure 26.4).

The caseins, compared to typical globular proteins which have mainly α-helical and β-sheet structures, contain less secondary and tertiary structures. Most of the secondary structure is likely to be present in the hydrophobic domains.

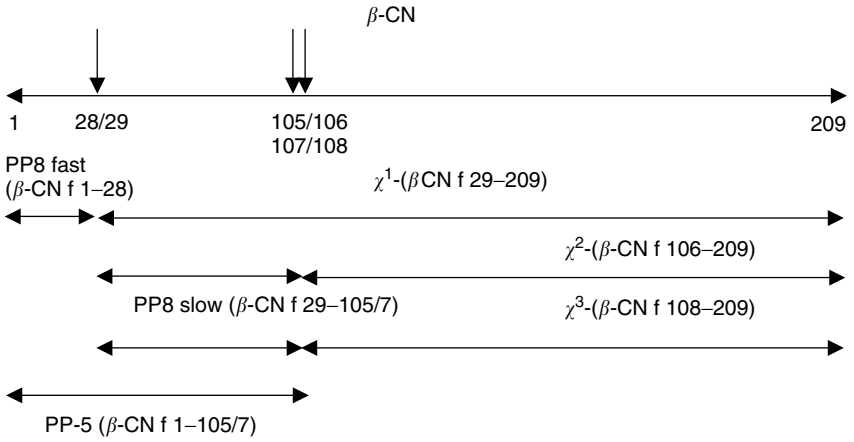

FIGURE 26.2 Principal plasmin cleavage sites on β-casein with resulting peptides.

FIGURE 26.3 (a) Primary structure of bovine α_{S1}-casein B. (Source: Mercier et al., Structure primaire de la caséine α_{S1}-bovine. Eur J Biochem 25:505–514, 1972, Blackwell Publishing Ltd.); (b) Primary structure of bovine α_{S2}-casein A. (Source: Federation of the European Biochemical Societies, from: Complete amino acid sequence of α_{S2}-casein, by Brignon et al., FEBS Lett 76:274–279, 1977.)

1. α_{S1}- and α_{S2}-Caseins

The primary structure of α_{S1}-casein is shown in Figure 26.3a. The α_{S1}-casein molecule contains 199 amino acids and 8 phosphate groups that are esterified to serine groups. It has no cysteine residues. The molecule has a net charge of about −24 at pH 6.7; the sequence 45 →89 which contains 8 phosphate groups and 12 carboxyl groups, has a net charge of about −23 at pH 6.7. Three hydrophobic regions are located in the sequences 1–44, 90–113 and 132–199 (4). The molecule contains 17 proline residues which are almost randomly distributed within the hydrophobic portion of the molecule and these residues disrupt the formation of α-helices and β-sheet structures. Physical methods, such as circular dichroism (CD) or Raman spectral analysis indicate that there is a low level of either α-helix or β-sheet (about 30–40%) (16). Sequence predictions suggest that the likely positions for helix formation are near residues 60, 100 and 125.

α_{S2}-Casein contains 207 amino acids, including 10 proline residues and two cysteines at positions 36 and 40 (Figure 26.3b). Among the caseins, it is the least hydrophobic and most highly and variably phosphorylated. The degree of phosphorylation ranges from 10 to 13 phosphate groups, and these casein forms have been identified as α_{S2}-, α_{S3}-, α_{S4}-, α_{S5}- and α_{S6}-caseins (α_{S5}- is a dimer of α_{S3}- and α_{S4}-). These phosphate groups are located in three regions (7–31, 55–66 and 129–143) of the molecule. There are two large hydrophobic regions: residues 90–120 and 160–207 (4). The C-terminal 47-residue sequence has a net charge of +9.5 while the N-terminal 68-residue sequence has a net charge of −21. The C-terminal half probably has a globular conformation while the N-terminal region probably forms a randomly structured hydrophilic tail.

Eur J Biochem 35:222–235, 1973. Blackwell Publishing Ltd.)

2. β-Casein

β-Casein is made up of 209 amino acids and contains a high proportion of proline residues (35 residues), which are randomly distributed throughout the molecule. The molecule contains no cysteine residues and 5 phosphate groups each as a serine phosphate ester. There are 6 forms of β-casein with 0–5 phosphate groups attached to serine residues (3). It is the most hydrophobic of the intact caseins and has two large hydrophobic regions (55–90 and 130–209). The N-terminal 21-residue sequence has a net charge of −12, while the rest of the molecule is very hydrophobic and has no net charge (4). Consequently, this molecule is very amphipathic with a polar domain comprising one-tenth of the chains but carrying one-third of the total charge and a hydrophobic domain consisting of the C-terminal three-fourths of the molecule.

Theoretical calculations suggest that β–casein could have 10% of its residues in the α-helices, 17% in the β-sheets and 70% in unordered structures (17).

3. κ-Casein

κ-Casein consists of 169 amino acids and is the only protein of the casein family that is glycosylated. About half of the κ-casein molecules are glycosylated at positions 131, 133, 135 or 142, and most of the κ-casein molecules are phosphorylated at Ser 149. Like β-casein, the structure of κ-casein is highly amphipathic. The N-terminal domain comprising residues 1–105 (para-κ-casein) is highly hydrophobic and carries a net positive charge. The

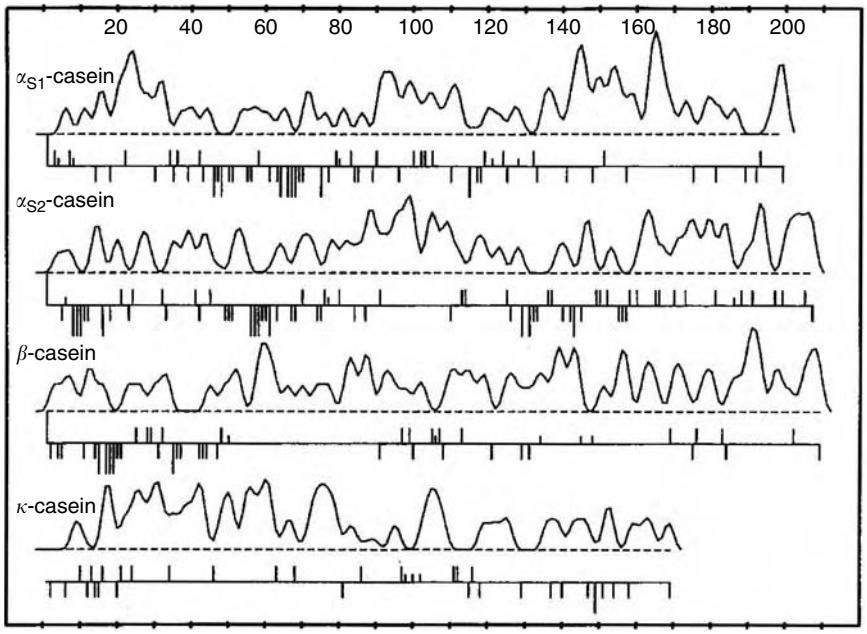

FIGURE 26.4 Hydrophobicity (curved lines with dashed line as baseline) and distribution of charged residues (vertical bars above and below the solid lines) as a function of sequence position of α_{S1}-casein B, α_{S2}-casein A, β-casein A^2 and κ-casein B. The vertical bars below the solid line indicate the phosphoserine (long bars), glutamic and aspartic acid side chains and the C-terminal group. The vertical bars above the solid line indicate the histidine (shorter bars), lysine and arginine side chains and the N-terminal groups (note that κ-casein has a pyroglutamate terminus). (Source: Casein and Caseinates, Swartz et al. In: Encyclopedia of Food Science and Technology. Copyright © (Wiley 1991). Reprinted by permission of John Wiley & Sons, Inc.)

C-terminal 53-residue sequence carries a net negative charge, with a preponderance of polar residues. These two domains are joined by a peptide (residues 96–112) that carries a net positive charge, which is generally predicted to be β-strand and contains a motif that is readily recognised by chymosin (4). Chymosin is able to cleave specifically the Phe105-Met106 bond to form two peptides: a large hydrophobic peptide (para-κ-casein, residues 1–105) and a smaller hydrophilic peptide (caseino-macropeptide, CMP, residues 106–169).

κ-Casein appears to be the most highly structured of the caseins, with 10–20% α-helix, 20–30% β-structure and 15–25% turns (16, 18). Several structural motifs have been suggested including possible anti-parallel and parallel β-sheets or βαβ structure in the hydrophobic domain and a β-turn-β-strand-β-turn motif centered on the chymosin sensitive residues 105–106 (18).

B. Self-Association of Caseins

Due to their peculiar charge distributions and large size of hydrophobic domains, the casein monomers cannot sufficiently remove their hydrophobic surfaces from contact with water. Consequently, the caseins associate with themselves and with each other. The association behavior of caseins has been covered in more detail in a number of reviews, including Rollema (19) and de Kruif & Holt (20).

At low ionic strength (0.003–0.01 M) and neutral or alkaline pH, α_{S1}-casein occurs as a monomer. As the pH is decreased and the ionic strength is increased, this protein shows progressive self-association to dimers, tetramers, hexamers, etc. Dynamic and static light scattering studies indicate that a rod-like chain polymer is formed (21).

The association behavior of monomeric α_{S2}-casein is similar to that of α_{S1}-casein, except for the effect of ionic strength. With increasing ionic strength, the extent of association first increases, but above 0.2 M, the degree of association decreases with a further increase in ionic strength (19). This peculiar behavior has been attributed to the non-uniform distribution of positive and negative charges along the polypeptide chain.

The self-association of β-casein is described by a monomer-polymer equilibrium:

$$n\beta\text{-}CN \rightleftharpoons \beta\text{-}CN_n$$

The association is characterized by formation of detergent-like micelles, with the critical micelle concentration ranging from 0.3 to 0.7 mg mL^{-1} depending on the temperature and ionic strength. The driving forces in micelle formation are the hydrophobic interactions between the C-terminal segments. At 4°C and low ionic strength, β-casein in solution exists as a monomer, but as the

temperature and/or ionic strength is increased, the monomers associate to form polymers, with *n* ranging from 20–60. For the shape of the polymer, a thread-like structure, a spherical particle and an oblate ellipsoid approaching spherical shape have been proposed (22).

In unreduced form, κ-casein is present largely as disulfide-linked polymers. In a reduced form, κ-casein associates according to the monomer-polymer equilibrium in a similar manner to β-casein. At low protein concentrations, a critical micelle concentration (typically 0.2–0.5 mg mL^{-1}) is obser-ved which decreases with increasing ionic strength. At pH 7 and 20°C, the degree of polymerization is independent of temperature between 4 and 20°C and ionic strength between 0.1 and 1.0 M (23). In contrast to β-casein association, κ-casein polymers are of a fixed size irrespective of temperature or ionic strength.

C. Calcium Binding and Precipitation of Caseins

All caseins are able to bind calcium, and the extent of binding is directly related to the number of phosphoserine residues in the molecule. Thus the calcium binding capacity follows the order: α_{S2}- > α_{S1}- > β- > κ-casein (19). Binding of calcium reduces the negative charge on casein molecules, diminishing electrostatic repulsions, and inducing precipitation.

At all temperatures, α_{S1}-casein B, α_{S1}-casein C and α_{S2}-caseins are insoluble in Ca^{2+} concentrations above about 4 mM. α_{S1}-Casein A, in which a relative hydrophobic region is deleted, is soluble at Ca^{2+} concentrations up to 0.4 M and temperatures below 33°C. Above 33°C, it precipitates but redissolves on cooling to 20°C. β-Casein is soluble at high concentrations of Ca^{2+} (0.4 M) at temperatures below 18°C, but above 18°C β-casein is very insoluble, even in the presence of low concentrations of Ca^{2+} (4 mM). κ-Casein, with only one phosphoserine, binds little calcium and remains soluble in Ca^{2+} at all concentrations. κ-Casein is also capable of stabilizing α_{S1}-, α_{S2}- and β-caseins against precipitation by Ca^{2+} and restricts the growth of the aggregates to colloidal dimensions (19).

D. Casein Micelles

In normal milk, about 95% of the casein proteins exist as coarse colloidal particles, called micelles, with diameters ranging from 80 to 300 nm (average ~150 nm). These particles are formed within the secretory cells of the mammary gland and undergo relatively little change after secretion. On a dry weight basis, the micelles consist of ~94% protein and ~6% of small ions, principally calcium, phosphate, magnesium and citrate, referred to collectively as colloidal calcium phosphate (CCP). The κ-casein content of casein micelles is inversely proportional to their size, while the content of CCP is directly related to size. The composition and some of the physico-chemical characteristics of casein micelles are presented in Table 26.1. The structure and properties of casein micelle have been reviewed recently by de Kruif and Holt (20) and Horne (25).

TABLE 26.1
Some Physicochemical Characteristics of Casein Micelles

Diameter	50–300 nm
Surface Area	8×10^{-10} cm^2
Volume	2×10^{-15} cm^3
Density	1.063 g cm^{-3}
Molecular weight (hydrated)	1.3×10^9 Da
Voluminosity	4.4 cm^3 per g protein
Hydration	2 g H_2O per g protein
Water content (hydrated)	63%

Source: Adapted from McMahon and Brown. J Dairy Sci 67:499–512, 1984. American Dairy Science Association.

The micelles are very open and highly hydrated structures containing about 2–4 g H_2O per g protein, depending on the method of measurement. The apparent zeta potential for casein micelles is about −19 mV at 25°C. The structure of the micelle is dynamic, e.g., cooling the milk to about 4°C causes solubilization of a significant proportion of β-casein and some κ-casein and much lower levels of α_{S1}- and α_{S2}-caseins. Almost complete disintegration of micelles occurs by addition of a calcium sequestrant such as EDTA or through the addition of high levels of urea or SDS (20).

The precise structure of the casein micelle is a matter of considerable debate at the present time. A number of models have been proposed over the past 40 years, but none of them can describe completely all aspects of casein micelle behavior. The models include coat-core models which postulate that the interior of the micelle is composed of proteins that are different from those on the exterior (26,27) and sub-unit structure models to which the term sub-micelle is attached (1,28,29).

In the sub-unit models (29), caseins are aggregated to form sub-micelles (10–15 nm in diameter). It has been suggested that sub-micelles have a hydrophobic core that is covered by a hydrophilic coat. The polar moieties of κ-casein molecules are concentrated in one area. The remaining part of the coat consists of the polar parts of other caseins, notably segments containing their phosphoserine residues. The sub-micelles are assumed to aggregate into micelles by CCP which would bind to α_{S1}-, α_{S2}- and β-caseins via their phosphoserine residues. Sub-micelles with no or low κ-casein are located in the interior of the micelle whereas κ-casein rich sub-micelles are concentrated on the surface.

Other models consider the micelle as a porous network of proteins (of no fixed conformation); the calcium phosphate nanoclusters are responsible for crosslinking the

protein and holding the network together (2). More specifically there are no subunits because individual polypeptide chains with two or more phosphate centers provide a network of strong interactions that link together most of the Ca-sensitive caseins in a micelle. The surface layer is a natural extension of the internal structure. A recent model proposed by Horne (30) assumes that the assembly of the casein micelle is governed by a balance of electrostatic and hydrophobic interactions between casein molecules. As stated earlier, α_{S1}-, α_{S2}- and β-caseins consist of distinct hydrophobic and hydrophilic regions. Two or more hydrophobic regions from different molecules form a bonded cluster. Growth of these polymers is inhibited by the protein charge residues, the repulsion of which pushes up the interaction free energy. Neutralization of the phosphoserine clusters by incorporation into the CCP diminishes that free energy as well as producing the second type of cross-linking bridge. κ-Casein acts a terminator for both types of growth, as it contains no phosphoserine cluster or another hydrophobic anchor point.

A common factor in all models is that most of the κ-casein appears to be present on the surface of casein micelles. The hydrophilic, C-terminal part of κ-casein, is assumed to protrude 5 to 10 nm from the micelle surface into the surrounding solvent, giving it a "hairy" appearance and providing a steric stabilizing layer. The highly charged flexible "hairs" physically prevent the approach and interactions of hydrophobic regions of the casein molecules.

E. Casein Micelle Stability

The micelles are stabilized by two principal factors: (1) a surface potential of C. −20 mV at pH 6.7 which alone is insufficient for colloidal stability and (2) steric stabilization due to protruding κ-casein hairs. Casein micelles can be caused to aggregate by several factors. Much attention has been focussed on the curd formation during cheese making brought about by the action of chymosin which destroys the stabilizing effect of κ-casein. Chymosin is highly specific in its action, splitting the κ-casein at the Phe105-Met106 bond, releasing the hydrophilic peptide and destabilising the micelles. This action results in a decrease in the micellar zeta potential from about −20 to –10 mV, and prior to aggregation a decrease in micellar hydrodynamic size as the hairy layer is cleaved off (20). Many other proteases with a more general action can also hydrolyze a specific bond of κ-casein, resulting in micelle aggregation.

Casein micelles aggregate and precipitate from solution when the pH is lowered to about pH 4.6. When the pH of milk is reduced, CCP is dissolved and the caseins are dissociated into the milk serum phase (31,32). The extent of dissociation of caseins is dependent on temperature of acidification; at 30°C, a decrease in pH causes virtually no dissociation; at 4°C about 40% of the caseins are dissociated in the serum at pH ~5.5 (32). Aggregation of casein occurs as the isoelectric point (pH 4.6) is approached. Apparently little change in the average hydrodynamic diameter of casein micelles occurs during acidification of milk to pH~5.0 (31). The lack of change in the size of micelles on reducing the pH of milk to 5.5 may be due to concomitant swelling of the particles as CCP is solubilized. The mobility of casein micelles measured by nuclear magnetic resonance spectroscopy does not change with pH (33).

Casein micelles are very stable at high temperatures, but they can aggregate and coagulate after heating at 140°C for 15–20 min. Such coagulation results from a number of changes in milk systems that occur during heating, including a decrease in pH, denaturation of whey proteins and their association with κ-casein, transfer of soluble calcium and phosphate into colloidal state, dephosphorylation of caseins and a decrease in hydration (34,35).

The micelles are also destabilized by addition of about 40% ethanol at pH 6.7 and by lower concentrations if the pH is reduced. This is due to the collapse and folding of the hairy layer of κ-casein in the non-solvent mixture, allowing micelles to interact and aggregate (36).

Freezing of milk has been shown to cause destabilization of casein micelles which is due to a decrease in pH and an increase in the Ca^{2+} concentration in the unfrozen phase of milk.

III. WHEY PROTEINS

The whey protein fraction accounts for approximately 20% of total protein. Whey proteins are an even more heterogeneous group of proteins than the caseins, containing a greater number of individual proteins. The principal fractions of whey proteins are β-lactoglobulin, bovine serum albumin, α-lactalbumin and immunoglobulins which account for more than 95% of the proteins in the whey fraction (Figure 26.1). These proteins have been well characterized. Major reviews covering structures and properties of whey proteins have been published (5,6,9,37). Unlike the caseins, the whey proteins possess high levels of secondary, tertiary and in most cases, quaternary structures. Most are typical globular proteins and are denatured by heat treatments. Both β-lactoglobulin and α-lactalbumin are synthesized in the mammary gland whereas serum albumin is transported to the mammary gland via the blood serum.

A. β-Lactoglobulin

β-Lactoglobulin is the most abundant whey protein which represents about 50% of the total whey protein in bovine milk. There are 13 known genetic variants of β-lactoglobulin: A, B, C, D, E, F, G, H, I, J, W, Dr and K^B (38). The A and B genetic variants are the most common and exist in almost the same frequency. The primary structure of

FIGURE 26.5 (a) Primary structure of bovine β-lactoglobulin B. (Source: Braunitzer et al., Automatische sequenzanalyse eines proteins (β-lactoglobulin AB). H-S Z Physiol Chem 353: 832–834, 1972, Walter de Gruyter GmbH & Co. KG.) (b) Primary structure of bovine α-lactalbumin B. (Source: Brew et al., The complete amino acid sequence of α-lactalbumin. J Biol Chem 245:4570–4582, 1970, The American Society for Biochemistry and Molecular Biology.)

β-lactoglobulin is shown in Figure 26.5a. The β-lactoglobulin monomer comprises 162 amino acids with one free thiol group (Cys 121) and two disulfide bridges (Cys 106-Cys119 and Cys 66-Cys160) and has a molecular weight of 18,000 Da. The A and B variants differ at positions 64 and 118, where Asp and Val in β-lactoglobulin A are replaced by Gly and Ala in β-lactoglobulin B.

β-Lactoglobulin is a highly structured protein; optical rotary dispersion, circular dichroism, infrared spectroscopy and nuclear magnetic resonance show around 10% α-helix, 50% β-sheet and 40% unordered structure including β-turns. The tertiary structure of β-lactoglobulin consists of nine anti-parallel β-strands, of which eight are wrapped into a β-barrel (Figure 26.6) (40,41). β-Strands A-D form one side of the calyx, and β-strands E-H are also part of strand A from the opposite side. The ninth strand, I, is on the outside, on the opposite side of strand A to strand H. The three-turn α-helix is located on the outside of the barrel and aligned along strands A, G and H.

In milk, native β-lactoglobulin occurs as a dimer. The association behavior of this protein is dependent on several parameters, including pH, temperature, protein concentration and ionic conditions. Below pH 3.5, β-lactoglobulin dissociates into its monomers, whereas between pH 3.5 and 5.2 it reversibly forms tetramers/octamers. Above pH 7.5, it starts to unfold, with a concomitant increase in the reactivity of thiol group. The proportion of dimer increases with increasing protein concentration and ionic strength. At temperatures between 30 and 55°C, the β-lactoglobulin dimer dissociates into monomers and at higher temperature (above 60°C), the monomer unfolds resulting in an increased reactivity of the free thiol group (38).

The biological function of β-lactoglobulin remains unclear but it appears to have at least two roles. Firstly, β-lactoglobulin is capable of binding several hydrophobic molecules, including retinol (vitamin A) (38). Retinol is bound in a hydrophobic pocket of β-lactoglobulin and transported to the small intestine where it is transferred to a retinol-binding protein, which has a structure similar to β-lactoglobulin. This binding also protects retinol against oxidation. Secondly, through its ability to bind fatty acids, β-lactoglobulin stimulates lipase activity.

B. α-Lactalbumin

α-Lactalbumin accounts for about 20% of whey protein and has three known genetic variants. The primary structure of α-lactalbumin is shown in Figure 26.5b. α-Lactalbumin has a molecular weight of about 14,000 Da and contains four intrachain disulphide bonds. It is relatively rich in tryptophan (four residues per mole). There is a considerable similarity between the primary and tertiary structure of α-lactalbumin and chicken egg white lysozyme (43). Its secondary structure at physiological pH consists of 26% α-helix, 14% β-structure and 60% unordered structure. The approximate globular structure of α-lactalbumin (dimensions 23Å × 26Å × 40Å) includes three regular α-helices, two regions of 3_{10} helix, and a small 3-stranded anti-parallel β-pleated sheet separated by irregular β-turns. The bilobal structure is formed by segregation of α-helices in one lobe and a small β-sheet and irregular structures in the other (Figure 26.7).

α-Lactalbumin binds one Ca^{2+} per mole in a pocket containing four Asp residues (45). At pH below 5.0, the Asp residues become protonated which results in the loss of bound Ca^{2+} which makes this protein susceptible to denaturation. Under acidic conditions, α-lactalbumin undergoes a transconformation to a non-native (A state) with altered spectroscopic properties (46). In the A state, the secondary structure of α-lactalbumin is nearly as compact as the native protein but lacks a fixed tertiary structure; this state is commonly referred to as the molten globule state.

The biological function of α-lactalbumin is to modulate the substrate specificity of galactosyltransferase in the lactose synthetase complex which is responsible for the synthesis of lactose in the lactating mammary tissue (45). The concentration of lactose in milk is directly related to the concentration of α-lactalbumin; the milk of some marine mammals which contains no α-lactalbumin, co tains no lactose.

C. Serum Albumin

Serum albumin isolated from milk is identical to the serum albumin found in the blood and represents about 5% of the total whey proteins. The protein is synthesized in the liver and gains entrance to milk through the secretory cells. The protein has the longest single polypeptide chain of the proteins found in milk consisting of 582 amino acid residues and has a molecular weight of 66,000 Da. It has 17 disulphide linkages, which hold the protein in a multi-loop structure, and one free thiol group. The secondary structure of serum albumin has 55% α-helix, 16% β-pleated sheet and 29% unordered structure. The current view of the three-dimensional crystal structure of serum albumin is that the molecule exists in three major domains, each consisting of two large double loops and a small double loop with an overall elliptical shape (47).

Serum albumin appears to function as a carrier of small molecules, such as fatty acids, but any specific role that it may play is unknown.

D. Immunoglobulins

Milk-borne immunoglobulins (Igs) provide the offspring with an immunological protection against microbial pathogens and toxins and protect the mammary gland against infection. Igs are divided into classes and subclasses; essentially there are 5 classes of Ig: IgA, IgG, IgD, IgE and IgM. IgA, IgG and IgM are present in milk. These occur as subclasses, e.g., IgG occurs as IgG_1 and IgG_2. IgG consists of two light (L) polypeptide chains and two heavy (H) polypeptide chains, of molecular weights 22,400 and 50–60,000 Da, respectively; these are linked together by disulphide bonds. IgA consists of two such units (i.e., 8 chains) linked together by a secretory component (SC) and a junction component (J) while IgM consists of five linked 4-chain units. The concentration of different Ig classes in milk and colostrum differs considerably depending on species, breed, age, stage of lactation and health status. As ruminant neonates are born virtually without Ig, ingested Igs are necessary for survival. Consequently, ruminants' colostrum contains considerably higher concentrations of Igs than human milk.

In addition to antigen binding, all Igs exhibit one or more effector functions by linking various parts of the immune system. For example, Igs may bind to leucocytes (which are an integral part of milk and of vital importance in defending the mammary gland against pathogens) or to host tissues. In addition, Igs can prevent the adhesion of microbes to surfaces, inhibit bacterial metabolism, agglutinate bacteria and neutralize toxins and viruses. Milk Igs have also been found to exert a synergistic effect on the activity of non-specific antimicrobial factors such as lactoferrin and lysozyme as well as lactoperoxidase. A more detailed discussion on the structure, origin, transfer and function of Igs has been published by Hurley (48).

IV. Minor Proteins

Several proteins are found in relatively small quantities in the whey fraction of milk. These proteins are referred to as minor protein. They include metal- and vitamin-binding proteins, β_2-microglobulin and growth factors.

A. Metal Binding Proteins

Human milk contains 2–4 mg mL^{-1} of lactoferrin which is specifically involved in metal-binding. Lactoferrin, which appears identical to transferrin found in blood, has also been detected at quite low concentrations in bovine milk (49). Lactoferrin has the ability to bind iron very strongly, indicating that the protein is involved in iron absorption and protection against enteric infection in the neonate (49). Considerable interest has been expressed in supplementing bovine milk-based infant formulae with lactoferrin, as bovine milk contains much lower levels of lactoferrin than human milk and lactoferrin, isolated from human milk, can bind 2 moles of iron per mole of protein (50). The biological importance of lactoferrin has been reviewed recently by Lönnerdal (51).

B. Vitamin Binding Proteins

Milk contains an array of vitamin-binding proteins, including Vitamin B_{12}-binding protein, folate-binding

protein, Vitamin D-binding protein and riboflavin-binding protein. These proteins occur at low concentrations, but may play a significant role in the uptake of vital vitamins from the diet (52,53).

Three different proteins are required for the uptake of Vitamin B_{12} in the gastro-intestinal tract. The milk of several mammalian species (human, rat, pig and rabbit) has been shown to contain one of these proteins (haptocorrin), whereas bovine milk contains a different Vitamin B_{12}-binding protein (transcobalamin) (54).

Milk also contains folate-binding proteins; these proteins are specifically involved in the uptake of folate from the intestine. *In vivo* studies on rats have shown that protein-bound folate is absorbed at a lower rate than free folate, resulting in increased retention time of folate, allowing it to reach its target tissues. Folate-binding protein also reduces the availability of folate to bacteria in the gut and hence may have antibacterial properties (55).

Raw bovine milk contains a riboflavin binding protein (56) and riboflavin bound to this milk protein has been shown to have similar antioxidant activities to riboflavin bound to egg white riboflavin binding protein (57).

C. Growth Factors

Highly potent hormone-like polypeptides, termed growth factors, which play a significant role in the regulation and differentiation of a variety of cells, can be found in milk. These growth factors may modulate growth and differentiation of a variety of cell types, modulate mammary development, and may also modulate neonatal development of the gastrointestinal (GI) tract. The growth factors are predominantly found in developing glands and colostrum, while milk may also contain comparatively lower concentrations of growth factors, depending on stage of lactation.

Growth factors and hormones identified in mammary secretions include lactoferrin (58), epidermal growth factor (EGF), transforming growth factor α (α-TGF) and β (β-TGF), insulin-like growth factor (IGF), insulin (59), basic fibroblast growth factor (basic FGF) (60) and prolactin (61). It is unclear whether many of these growth factors are targeted to promote growth of the mammary gland or the intestinal cells of the recipient neonate.

D. Other Minor Proteins

Several other minor proteins, including β_2-microglobulin, osteopontin, proteose peptone 3, angiogenins, kininogen and milk glycoproteins, have been identified in the whey fraction of milk. At present, relatively little information is available on the biological activities and functions of these proteins.

V. MILK ENZYMES

Milk contains in the region of 60 indigenous enzymes, approximately 20 of which have been isolated and characterized in great detail. The remaining 40 enzymes, whose presence has been demonstrated via their activity, are of little or no technological interest. The principal milk enzymes of technological importance are discussed below, and the details of these and other milk enzymes are detailed in Table 26.2. The reader is directed to Chapter 27 (this volume, "Enzymes of Significance to Milk and Dairy Products") for a comprehensive review of this area.

A. Lipases and Esterases

The ability of milk lipase (EC 3.1.1.) to hydrolyze triglycerides to form fatty acids is well known, and is responsible for the onset of rancidity in milk and milk products. Milk lipase is a lipoprotein lipase, and is similar to the lipoprotein lipase found in the mammary gland, suggesting that it may be transferred to milk from the mammary gland. In bovine milk, about 80% of milk lipase is associated with the casein micelles by electrostatic bonding

TABLE 26.2
Some Enzymes Present in Bovine Milk

Name	EC Number	Optimum		Inactivation[1]
		pH	Temperature (°C)	
Xanthine oxidase	1.1.3.22	~8	37	7 min 73°C
Sulphydryl oxidase	1.8.?	~7	~45	3 min 73°C
Catalase	1.11.1.6	7	37?	2 min 73°C
Lactoperoxidase	1.11.1.7	6.5	20	10 min 73°C
Superoxidase dismutase	1.15.1.1	?	?	70 min 76°C
Lipoprotein lipase	3.1.1.34	~9	33	30 s 73°C
Alkaline phosphatase	3.1.3.1	~9	37	20 s 73°C
Ribonuclease	3.1.27.5	7.5	37	?
Plasmin	3.4.21.7	8	37	40 min 73°C

between negatively charged phosphates on the caseins and positively charged amino acid residues in the heparin-binding sites of milk lipase (63).

Milk lipase is a glycoprotein which is optimally active at pH 9.2 and 37°C, and has a native molecular mass of 100 kDa. Milk lipase is strongly inhibited by the products of its activities (64), i.e., long-chain fatty acids; therefore blood serum albumin (BSA) and Ca^{2+} enhance the activity of milk lipase as BSA and Ca^{2+} bind free fatty acids. The enzyme is inactivated by ultraviolet light, heat, acid and oxidizing agents. Less than 10% of milk lipase remains active after pasteurization.

In milk triglycerides, long-chain fatty acids are attached to the glycerol at the 1 and 2 positions, while shorter-chain fatty acids are found at the 3 position. Milk lipase liberates fatty acids from the 1,3 positions in milk triglycerides. Lipolysis increases the levels of short-chain, volatile fatty acids present in milk. This results in rancid, butyric, bitter, soapy or astringent flavors that render milk and milk products unacceptable for consumption.

Increased lipolysis can result from vigorous agitation or homogenization of milk which causes damage to the milk fat globule membrane and leaves it vulnerable to the action of milk lipase. The extent of lipolysis may be reduced on strict temperature control (< 5°C) and avoiding excessive agitation prior to pasteurization (64).

Milk also contains three types of esterases. These are A-type carboxylic ester hydrolase (which hydrolyzes aromatic residues); B-type esterase (which hydrolyzes aliphatic esters rapidly and aromatic esters slowly); and C-type esterase (which are active on alkaline esters) (65).

B. Plasmin

Plasmin (EC 3.4.21.7), the principal proteolytic enzyme in milk, is mainly found in the form of the inactive zymogen, plasminogen. Through a system of plasmin inhibitors and plasminogen activators (along with their associated inhibitors), plasminogen is converted to active plasmin (10). Plasmin is a serine proteinase with a high specificity for peptide bonds to which lysine or arginine supplies the carboxyl group. β- and α_{S1}-caseins are most susceptible to plasmin hydrolysis; α_{S2}-casein is also attacked, while κ-casein is relatively resistant to hydrolysis. Plasmin cleavage of β-casein yields γ-casein and proteose-peptones (66,67) (see Figure 26.2).

Severe heat treatment of milk, such as ultrahigh temperature (UHT), reduces plasmin activity due to inactivation of plasmin by thiol-disulphide interchange reactions between plasmin and the highly reactive thiol groups of β-lactoglobulin (68). However, high-temperature-short-time (HTST) pasteurized milk stored at 20–37°C displayed significantly increased plasmin activity as storage time increased (69). This increase in plasmin activity, concomitant with a decrease in plasminogen activity, is due to denaturation of inhibitors of plasminogen activator (10).

Plasmin activity may influence the quality of dairy products, such as cheeses, UHT-treated milk products and milk protein products. Increased plasmin activity in cheese has been shown to improve the flavor and overall quality of certain cheeses. Plasmin may also play a role in the age gelation of UHT-treated milk.

C. Phosphatases

Bovine milk contains a number of indigenous phosphatases; the two principal types which have been shown to have a technological significance in milk are milk alkaline phosphatase (EC 3.1.3.1) and milk acid phosphatase (EC 3.1.3.2).

1. Alkaline Phosphatase (ALP)

ALP occurs in all mammalian milk; in bovines milk levels vary between cows and also within the lactation period. The activity of ALP is used as an index of the efficiency of milk pasteurization, because ALP is slightly more resistant to heat than *Mycobacterium tuberculosis* (70). However, the activity of ALP may not always be an accurate indicator of HTST pasteurization of milk for a number of reasons. Under certain conditions, reactivation of ALP may occur, complicating interpretation of test results. The enzyme also appears to be fully inactivated at sub-pasteurization conditions and in addition the relationship between $\log_{10}$ % initial activity and pasteurization equivalent (PE) is less linear than the relationship between PE and lactoperoxidase or γ-glutamyl transpeptidase activities in milk (53). Furthermore, ALP is only partially inactivated during ultra-high pressure treatment of milk, rendering the ALP test an unsuitable indicator of effectiveness of the ultra-high pressure treatment process.

2. Acid Phosphatase (ACP)

The concentration of ACP in milk is dependent on stage of lactation and increased levels have been observed in mastitic milk; however, the activity of ACP is much lower than that of ALP. ACP is a very heat stable enzyme which is not affected by HTST pasteurization, but is completely inactivated following UHT treatment (72).

ACP may play a role in the heat stability of dairy products. As the caseins are phosphoproteins and are good substrates for ACP, the micellar integrity of caseins may be lost on dephosphorylation of casein serine residues. ACP may also influence cheese flavor; several partially dephosphorylated phosphopeptides have been isolated from different cheese types and have been attributed to ACP activity (73,74).

D. Lactoperoxidase

Lactoperoxidase (LPO; EC 1.11.1.7) is a broad specificity peroxidase which is present in high concentrations in bovine milk compared to human milk. LPO exhibits

antibacterial activity in the presence of H_2O_2 and thiocyanate (SCN^-), in which SCN^- is converted to hypothiocyanate ($OSCN^-$) (75). Inactivation of eight different bacteria including *E. coli*, *Pseudomonas fluorescens*, *S. aureus*, *Enterococcus faecalis*, *Listeria innocua* and *Lactobacillus plantarum*, has been shown by LPO (76). LPO may also be used as an indication of mastitic activity, as LPO levels increase during mastitis. Research has focused on activation of the indigenous enzyme for cold pasteurization of milk and protection of the mammary gland against mastitis, and also on addition of isolated LPO to calf or piglet milk to protect against enteritis.

E. Xanthine Oxidase

Bovine milk xanthine oxidase (EC 1.1.3.22) is a dimeric metallo-flavoprotein with a molecular mass of approximately 300 kDa and is a major component of the milk fat globule membrane. It is a non-specific oxidoreductase that plays a metabolic role in purine catabolism, catalyzing the oxidation of hypoxanthine to xanthine, and xanthine to uric acid, with the concomitant reduction of O_2 to H_2O_2. Activity levels of xanthine oxidase differ between species; human milk contains approximately 1–6% of the activity of bovine milk (35 mg/L) (77). About 33% of the iron and all of the molybdenum in human milk is found in xanthine oxidase.

VI. INDUSTRIAL MANUFACTURE OF MILK PROTEINS

A range of protein products can be obtained from milk, and the more commonly used methods for obtaining these products are described in Figure 26.8. The production and utilization of milk proteins has been reviewed recently by Mulvihill and Ennis (78).

A. Casein Products

The manufacture of this protein family of products from milk involves centrifugal separation of the skim milk from the cream, followed by pasteurization. The caseins are then precipitated either by the action of a coagulant such as rennet or by a reduction in pH to the isoelectric point (4.6) by fermentation or direct addition of mineral acid. The coagulated protein is heated to form the curd, and the curd is then separated from the whey by filtration or centrifugation, in combination with countercurrent washing with water. The curd may then be dried as insoluble casein, or first be reacted with alkali, e.g., sodium hydroxide, followed by drying to produce a water-soluble caseinate. A protein product including both the casein and the whey proteins, known as total milk proteinate, may be manufactured by a variation of the process described in Figure 26.8.

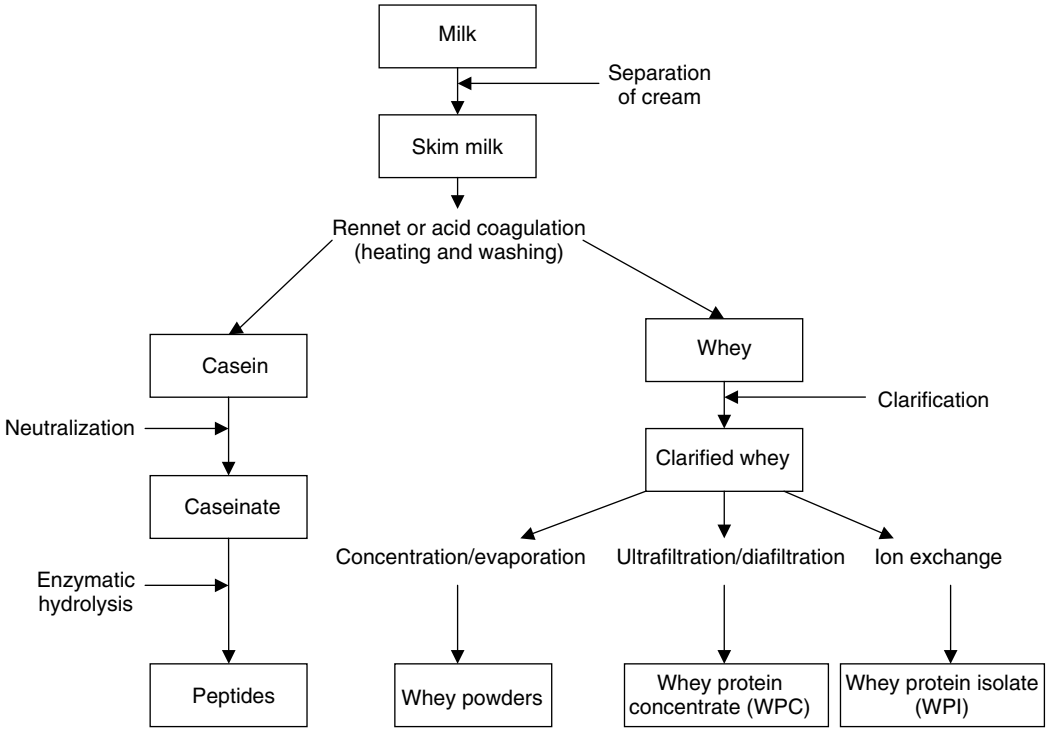

FIGURE 26.8 Outline of principal processes used for the manufacture of casein and whey proteins products.

B. Whey Products

Whey is produced as a by-product of cheese and casein manufacture. There are many possible products and manufacturing processes, some of which are outlined in Figure 26.8. The first step involves separation and selective concentration of residual fat and casein by centrifugation. This is followed by concentration of the whey proteins by the use of membrane separation (ultrafiltration and diafiltration). The protein stream is further concentrated by evaporation and then spray-dried to produce whey protein concentrate, with an approximate protein concentration of 85%. Alternatively, further fractionation and concentration of the whey proteins may be performed using ion exchange to produce whey protein isolates (containing approximately 95% protein).

The protein products described have a wide range of food ingredient and industrial applications, many utilizing the emulsifying, water- and fat-binding, and nutritional properties of the proteins. The decision to incorporate whey protein isolate ahead of whey protein concentrate into a food matrix is based on a balance of cost, fat content, and functional properties differences, among others, between the products.

VII. FUNCTIONAL PROPERTIES OF MILK PROTEINS AND FOOD USES

Protein functionality has been broadly defined as any physiochemical property which affects the processing and behavior of proteins, as judged by the quality attributes of the final product (79). These attributes may include structure, appearance, texture, viscosity and mouthfeel (80). Milk proteins possess functional properties which provide desirable textural or other attributes to the final product and for this reason have found numerous applications in traditional dairy products and in other foods (Table 26.3).

The functional properties of proteins are governed by intrinsic properties, i.e., their structural characteristics, e.g., size and surface hydrophobicity. These intrinsic properties are themselves affected by many extrinsic or environmental factors, such as pH, ionic strength and temperature, and also by interactions between the proteins and other materials in the food system. Not only does milk comprise various proteins with unique intrinsic properties, the milk proteins themselves are commercially available in many different forms. Furthermore, milk proteins may be modified by physical, chemical or enzymatic means, possibly resulting in significant improvements in one or more functional properties (Table 26.4). However, physical and enzymatic methods of modification are currently preferred over chemical methods, mainly due to consumers' concerns over "added chemicals" and the potential risk of occurrence of toxic side-reactions.

A. Solubility

Protein-water and protein-protein interactions in aqueous systems are vitally important and control the dispersibility, viscosity and solubility properties of proteins (81). A sensitive balance between repulsive and attractive intermolecular forces, which are in turn controlled by protein and water structures and affected by environmental factors, controls solubility (82). Generally, proteins are soluble in water and electrostatic and/or hydration repulsion between proteins is greater than the driving forces for hydrophobic interactions. Thus, the polar and ionizable groups of proteins largely confer water solubility (79).

Solubility is often used as a key indicator of a protein's ability to exhibit other functional properties such as

TABLE 26.3
Functional Properties of Milk Proteins Exploited in Food Systems

Functional Property	Potential Food Applications
Solubility	Nitrogen fortification of low pH beverages
Emulsification	Pastries, coffee creamers, milk beverages, milk shakes, high fat powders, butter-like spreads, cheese fillings and dips
Foaming	Egg replacer, whipped toppings, fizzy drinks, ice cream, mousses, meringues, sponge cakes
Heat stability	Imitation pasta, meat products, marshmallow and nougat
Aggregation/Coagulation/Gelation	Cultured milk products, comminuted meat products
Viscosity	Cake mixes, milk-based flavored beverages, frozen desserts
Water-binding and hydration	Imitation cheeses, toffees, fudges

TABLE 26.4
Methods Used to Improve the Functionality of Milk Proteins

Method	Treatments
Physical	Heat, pH, high pressure
Chemical	Phosphorylation, deamidation, glycosylation, covalent attachment of hydrophobic groups, acylation, reduction of disulphide bonds
Enzymatic	Hydrolysis, cross-linking with transglutaminase, glycosylation, phosphorylation, deamidation

emulsifying, foaming and gelation properties, although this general rule may not always apply, particularly in the case of highly hydrolyzed milk proteins. Solubility may be generally defined as the amount of protein that goes into solution or into colloidal dispersion under specified conditions (e.g., pH, ionic strength, protein concentration and temperature) until a maximum concentration is reached, after which the soluble concentration remains constant and a solid phase appears (83).

Solution conditions, such as pH, ionic strength and temperature, also affect the amount of water associated with proteins (82). Solution pH, for example, affects the amount of water associated with proteins by influencing the net charge of the protein. Ionic strength affects the solubility of proteins depending on the number of hydrophobic groups exposed on the protein's surface.

Unlike whey proteins, which exhibit excellent solubility over the entire pH range, caseinates (alkali dispersions of casein which are used in commercial applications) are almost completely insoluble in the region of their isoelectric point (pI: pH 4.0–5.0). However, outside of this region, caseinates possess excellent solubility, resulting in a U-shaped pH-solubility profile (84). Enzymatic hydrolysis has been frequently applied for improving solubility of caseinates in the pI region. Improved solubility is mainly due to a reduction in the molecular weight, increased exposure of polar groups and decreased secondary structure of the peptides formed upon hydrolysis of the intact protein. Enzymatic hydrolysis of food proteins has been thoroughly described by Adler-Nissen (85).

Casein and caseinates are utilized for their high solubility at highly acidic pH values (pH 2–3.5) in fruit juices and carbonated beverages (86), and may also be used for the nitrogen fortification of low pH beverages.

B. Interfacial Properties
