CONTENTS

I. GENERAL INFORMATION

Dr. George Pigott coined the phrase "aquatic food products" because it was difficult to find one word to adequately define edible animals and plants from the aquatic environment. "Seafood" denotes only food from the sea or marine environment, omitting freshwater plants and animals. Similarly "fish" is not an all encompassing term for all of the different animals (both vertebrate and invertebrate) and plant products humans take from the water and eat. The FDA recently defined fish to mean:

> "fresh or saltwater finfish, crustaceans, other forms of aquatic life (including, but not limited to, alligator, frog, aquatic turtle, jellyfish, sea cucumber, and sea urchin and the roe of such animals) other than birds or mammals, and all mollusks, where such animal life is intended for human consumption." (Title 21 of the Code of Federal Regulations. Part 123.3(f)).

Over 350 species of mollusca (*e.g.* clams, oysters, snail, octopus), arthropoda (*e.g.* lobsters, crabs, shrimp and crayfish), reptilia (*e.g.* turtles, alligators), amphibia (frogs), gastrapoda (whelks), holothurians (sea cucumbers), and chordata (finfish) are used as food (1,2). Furthermore, aquatic plants and marine mammals are important components in the diets of people from many cultures.

Interesting, unconventional, unique and somewhat bizarre traditional foods are made from aquatic products. Numerous tissues are consumed besides the muscle from aquatic animals. Some examples of the wide variety of aquatic food products are presented in Table 159.1 using

TABLE 159.1
Examples of Aquatic Foods

Item	Source	Examples
Whole animal	Mollusc	Clams, oysters, octopus, limpet
	Crustacea	Small crab
	Fish	Sardines, smelt
	Insects	
Plants	Marine plants, various	Sea vegetables, nori
	Marine plants	Food additives (agar, carrageenan)
Liver/hepatopancreas	Finfish, various	Cod, pollock, salmon
	Marine mammals	Seal, walrus, whale
	Crustacea	Lobster, crab
Tongue	Finfish, various	Cod, halibut
	Marine mammal	Seal, whale
Heart/kidney	Finfish, various	Salmon, tuna
	Marine mammal	Seal, whale
Stomach/throat	Finfish, various	Cod
Brain/head	Finfish, various	Salmon, cod halibut (cheeks)
	Marine mammal	Whale
Spinal column	Finfish, various	Sturgeon
Eyes	Finfish, various	Salmon
Gills	Finfish, various	Salmon
Gonadal tissue, roe	Mollusk	Sea urchin
	Fin fish	Sturgeon, herring, salmon
	Crustacea	Lobster, crab, shrimp
	Reptile	Turtle eggs
Gonadal tissue, milt	Mollusk	Oyster
	Finfish	Salmon
Testicles	Marine mammal	Seal
Penis	Marine mammal	Seal (East Asian medicinal)
Skin	Finfish, various	Salmon, rockfish
Connective tissue	Finfish, various	Shark (cartilage)
Adipose tissue	Marine mammal	Seal, whale
Oil (head or adipose)	Finfish, various	Herring, salmon, shark, cod
	Marine mammal	Whale (blubber), seal (blubber and extracted oil)
Bodily fluids	Mollusks	Squid (ink)
	Finfish	Blood
Fin	Finfish, various	Shark
Shell	Mollusk, various	Oyster (as nutritional supplement)
Exoskeleton	Crustacea, various	Shrimp
Bone	Finfish, various	Smelt, sardine

species common to Westerners. This is nothing close to an exhaustive list of the different types of products made from aquatic plants and animals, but it provides some insight into how diverse aquatic food products can be.

For many species the muscle tissue plus certain organs are eaten together. For example, lobster, crab or scallop meat is eaten with the hepatopancreas and roe (if present) by individuals who like it.

The entire organism is commonly consumed (*e.g.* oysters, limpets, some clams, small fish). For some species only certain organs are consumed, such as sea urchin roe. Roe is eaten in a salted or seasoned form as caviar from a variety of different fish and invertebrates. The most common vertebrate species for the production of roe products are flying fish roe (for tobiko used on sushi), sturgeon and paddlefish for black caviar, salmon for salmon caviar or ikura, herring roe for kosunoko, cod roe for tarako, and pollock roe for mentaiko (also spelled mentiko). Salted fish roe from cod or capelin are used as a component of pastes or spreads. Lower grade sturgeon can also be pressed and sliced or mixed with butter or soft cheese and used as a spread. Roes can be partially dehydrated; for example, sujiko, which made by salting and then pressing skeins of sockeye salmon roe. A dried roe product is made from mullet roe and is called karasumi. High levels of wax esters give mullet roe a unique chewy texture. Flavored or seasoned roes are becoming increasingly popular. For example, chili flavored mentaiko is a widely used

condiment in Korea, and salmon roe treated with soy and other seasonings is popular in Japan and throughout Asia. Sauces and salad dressings often contain fish roe. Fish roe and milt are served in soup or lightly sautéed. Milt can be smoked and made into spreads. Uni, is a colored, flavored alum treated gonadal tissue from the sea urchin used primarily for sushi.

Steamed fish, soups and stews are made from the whole fish, with tissue from the head (such as the cheeks and tongue) and the eyes reserved for special guests.

Cheek tissue, particularly from larger fish such as halibut are commonly served separately. Halibut cheeks are the muscle from underneath the eye of the fish. Since halibut can reach up to 250 pounds, the cheeks can be several ounces each. In the recent past, halibut cheeks were sometimes mislabeled as scallops or sea scallops, but with the current high demand, halibut cheeks are a popular food in their own right.

Certain tissues of a fish may be fried (skin, intestines) and served as such. Skin and intestine are often incorporated into stews, soups, or ground meat preparations. These tissues are dried for use in a seasoning or base. In addition, fish skin can be cured into leather for belts, wallets and shoes. The most common types of leather in Western markets are from shark and skate, sturgeon, eel and salmon.

Specialty dishes use fish connective tissue as a featured ingredient. Fish maw soup (from finfish stomach and throat tissue) and shark fin soup both take advantage of the thickening properties of these connective tissues for the preparation of various dishes. Gelatin can be recovered from fish skin and connective tissue for use in traditional foods and, if appropriately manufactured, as kosher gelatin. Shark cartilage is both a food component, and when dried, a nutritional supplement.

A wide variety of condiments, sauces and seasoning are made from aquatic animal tissues. Most common are fish oils forming the base for margarine, dressings, sauces and condiments. The omega-3 fatty acids in high quality stabilized fish oil are a nutritional supplement commonly sold in capsule form and more recently as a stabilized ingredient in functional foods. The importance of fish oil in the diet is a continuation of a longstanding trend. Prior to the widespread availability of vitamin supplements and fortified milk, cod liver oil was a primary source of vitamin D. Oil from marine mammal tissue (*e.g.* seal oil or ooksook, and whale blubber) remains popular in the traditional diets of people above the 47th parallel in reflecting the dietary patterns of the samoyed peoples who migrated throughout Alaska, the Pacific Northwest, Scandinavia, British Isles, Russia and Japan. Marine mammal oils can be rendered at room temperature or rendered with heat. These oils may be consumed fresh or aged. These oils serve as a condiment or dipping sauce and are used in a similar fashion as olive oil in Mediterranean cuisines.

Aquatic animal foods are valuable, and in some cases, incredibly expensive. Because of the value, widespread poaching of shark and sturgeon have led to severe restrictions and closures in these fisheries. Fortunately, sturgeon can be cultivated, hopefully saving important Caspian Sea species from extinction. Reasonably good Beluga sturgeon caviar at retail routinely runs $200 per ounce or more. The most expensive aquatic food product however is gold “Almas” caviar from Beluga sturgeon (*Huso huso*) purported to be over 100 years old, is packaged in 24 karat gold tins and sells for US$ 23,000+ per kilogram (3).

There have been few efforts to cultivate shark. Sharks are slow growing and breed after several years of age. Some sharks bear live young, meaning that the number of offspring from each female is small. Fishing pressure on large sharks is threatening the viability of sub-populations, particularly in the waters surrounding Southern Asia. The value of dried shark fin varies greatly by size and appearance, but for good specimens, the value exceed hundreds of dollars per pound.

A variety of nutritional supplements and traditional medicines are made from aquatic organisms. Besides fish oil, calcium supplements are made from oyster shell. Oyster milt and other reproductive tissues are purported to have medicinal properties. This includes the use of the seal penis in Asian medicine, a suitable, albeit a misbranded substitute for tiger penis in traditional Chinese medicine. Numerous marine plants and their extracts are common sources of vitamins, minerals, and phytoactive components with alleged beneficial properties.

Aquatic products have been consumed from ancient times and were probably the first animal sources of protein in the human diet. Humans settled near water and have captured fish and harvested mollusks since prehistoric times. Commercial fishing was part of the ancient culture of Egypt where ancient fishing vessels have been unearthed that vary little from designs of vessels used in artesian fisheries today. Asian and European civilizations have consumed fish for thousands of years before recorded history. Native Americans can trace their use of fishery products back 3,500–10,000 years. Numerous archeological sites containing bone, shell, fishing hooks from bone and stone net weights have been recovered in the United States (4) with important sites at Lake Ozette in Washington state verifying the use of cedar bark nets among coastal tribes going back several hundreds of years. In addition to wild harvest, culturing fish and ranching or impounding fish in ponds dates back a thousand years or more. Among the Makah, live fish were harvested off the northern most tip of the continental United States and then placed into ponds and held until consumed. This technique provided the people with a source of food when the weather was too rough to fish. It also provided a means to have fish species that would otherwise be out of season. Similarly aquaculture and impounding of fish have been practiced for centuries on the islands of Hawaii and in

Polynesia. Commercial aquaculture and fishing were key industries in ancient Asian socities and in the West during the Roman Empire with archeological sites indicating the widespread use of aquaculture in Italy and North Africa.

Today aquatic food products are the major source of high quality animal protein to a quarter of the world's population. The consumption of aquatic food products is increasing internationally, with aquaculture being the source of any new product to meet market demand. By 2020, a deficit of 10% or more in the world-wide supply of aquatic foods is predicted, even with the growth of cultured product increasing rapidly.

International trade in aquatic food products is critical to the balance of trade of many countries. For example, the US imports 3.9 billion pounds of aquatic food products from over 160 different countries with half of this from China, Ecuador, Chile, Canada and Thailand. Imported seafood constitutes more than half of the seafood consumed in the United States (5). Rights to fish and the control of critical fisheries (*e.g.* cod in the North Atlantic) have provided the basis for numerous protracted trade disputes, and sometimes, all out war.

II. PROCESSING TECHNOLOGIES

The primary advantages of preservation of seafood products are to extend product shelf life, ensure product safety and nutritional value, and maintain product quality. Specific market advantages obtained by preserving aquatic food products include: the ability to distribute food over long distances far from the point of harvest; to hold product when it is no longer in season, or to hold it in a form suitable for later processing or consumption.

III. COLD STORAGE

To make these products widely available, aquatic food products are often refrigerated or frozen. The widespread use of refrigeration, freezing, and cold storage has meant that aquatic food products, normally available only seasonally and within a small region, can now be sent around the world any time of the year. Because of reliable integrated transport, live and high value products can be air shipped from relatively remote locations to major metropolitan areas within 48 hours of harvest. Shipping costs often exceed the value of the product.

Until quite recently, aquatic foods were primarily harvested and consumed locally. These foods were generally available only during a limited season. These limited seasons or "fish runs" were critical to the human survival in many parts of the world. Entire cultures developed around the annual salmon runs in Asia, Alaska and the Pacific Northwest. Also important to the survival of many cultures have been the seasonal migrations of huge schools of fish such as herring, smelt, sardines or anchovetta and the larger pelagic fish and the mammals that feed upon them. Harvests were primarily restricted to coastal areas as there were few methods available for preserving fish on-board high seas fishing vessels. An exception to this was the North Atlantic salt cod fishery that started in the 14th century and continues today.

Animal food products deteriorate rapidly at ambient temperatures, and aquatic food products are generally even more susceptible to deterioration. Refrigeration works by slowing metabolic processes. Reducing temperature slows the growth of pathogenic and spoilage microorganisms and reduces the rate of deteriorative biochemical and chemical reactions in the muscle and other edible tissues (6). However, many animals and plant foods from the aquatic environment, particularly marine fish, are poikilothermic and are adapted to living at low temperatures (−1–10°C). Tropical fish are also poikilothermic since water temperatures for these species rarely exceeds 20°C. The endogeneous enzymes in these cold adapted "naturally" work at refrigeration temperatures, so spoilage reactions occur at a relatively rapid rate since refrigeration does little to impede them. In addition, spoilage bacteria associated with poikilothermic organisms continue to grow. This is why products from aquatic animals and plants deteriorate more quickly than foods from terrestrial sources and must be processed quickly and held under proper conditions to maintain highest quality.

IV. LIVE HANDLING

With the exception of aquaculture where the fish can be harvested with limited stress, finfish are most commonly "stressed" when captured. In the capture fisheries, finfish are literally still "hunted" and capture techniques still include the use of nets (for example, seine, trawl, and gill nets to catch salmon, herring, or pollock); hooks and lines (for example, to catch halibut or swordfish); traps (for crab and shrimp), even harpoons (for bluefish tuna and marlin). This harvest induced stress leads to a reduced level of glycogen in the flesh when the fish are brought on board. New methods of reduced temperature and moderate amounts of carbon dioxide as an anesthesia prior to slaughter can reduce the stress to fish and improve muscle quality.

As the fish pass through rigor, the ultimate pH of the fish tissue is higher than for meat, generally pH 6.4–6.6. Little glycogen is left in the muscle tissue for conversion to lactic acid during the glycolytic process that accompanies rigor. In contrast, land animals are generally rested prior to slaughter and have higher levels of glycogen, and a lower ultimate pH, around 5.5 for mammalian muscle and 5.9 for chicken. The higher ultimate pH in fish is one reason why fishery products are relatively more susceptible to microbial spoilage than other muscle foods stored under the same conditions. The endogeneous enzymes in

the fish muscle and viscera of most commercially important species are highly active at refrigeration temperatures. Also, the microbes that grow on the external surfaces, gills, and in the viscera are adapted to growing at relatively low temperatures and can cause rapid spoilage.

Other factors specific to the biology of aquatic animals causes the muscle tissue to be in less than prime condition when harvested. These biological factors make proper refrigeration and freezing critical for maintaining product quality. Salmon, for example, are commonly captured as they return from the ocean to spawn in a fresh water stream, often many hundreds of miles inland. With salmon, the fish have stopped eating, and have also had to physiologically "readapt" to swimming in fresh water. The fish must mobilize their energy reserves (adipose fat, muscle fat, and muscle protein) for migration as well for producing roe (eggs) or milt (sperm). At a certain point during the spawning process, the salmon flesh becomes pale, soft, and flavorless. This severity of this problem is species, gender, and run dependent.

Any aquatic food product should be refrigerated or cooled on ice as soon as possible after harvest. Live mollusks should be placed in refrigerated seawater, held in cold storage at 10°C or lower, or be placed in salt water ice. Live marine mollusks can be placed ON THE SURFACE of fresh water ice; however, placing live marine mollusks in fresh water ice will kill them. Mollusks can remain alive under these conditions for five days or more.

V. HANDLING AND SHIPPING LIVE FISH

Handling and shipping live invertebrate fish is a common practice. Molluscan shellfish (clams, scallops, oysters, mussels, snails), crustaceans (crabs and lobsters) and other invertebrates (limpets, sea cucumber) are shipped by keeping the animals moist by wrapping them in seaweed, moist paper or liners, and reducing temperature slightly. Often these creatures are placed into circulating water tanks at the point of sale. The large marine Alaskan and Tasmanian king crab are available for retail sale as live animals and sell for over $100 per animal.

Live transport of finfish is becoming more common. Here, fish are shipped in temperature controlled tanks with air or oxygen circulation and then transferred and held in "live tanks" at retail facilities or in restaurants. More exotic foods animals including live frogs and turtles are transported in a similar fashion. Most of the recent advances in oxygen permeable packaging for life fish transport have come from the pet trade with these techniques becoming more important for food fish.

VI. HARVESTING

"White fish" such as cod, pollock, or whiting, are commonly harvested on the high seas by trawl and held on board in refrigerated seawater until they have gone through rigor. Certain species of larger and high value fish are harvested by hook and line including swordfish and halibut. Pacific cod are harvested using a long line technique, headed and gutted and frozen shipboard within 2.5 hr at −20°F in a prerigor state. Product frozen prerigor is preferred in the Japanese market. If handled properly, fish caught by hook and line can be of higher quality than those harvested by net.

Warm water aquacultured fish such as catfish or tilapia are collected from ponds and stunned by dropping the water temperature. Another way of stunning the fish is to place the fish into carbon dioxide saturated water (600 ppm or greater). After this, the fish are bled by cutting the gill rakers or by cutting the artery anterior of heart. This allows the heart to remain functioning and pump the blood out of the body. The fish are then placed circulating ice water for 5–20 min. so the blood can be completely removed, further processed for the fresh market or frozen. Bleeding a fish greatly improves muscle color, storage stability and flavor.

Clearly the post harvest stress in cultured fish is less, since struggle can be reduced when the fish are harvested. To improve quality, cultured fish can be fasted for up to a couple of days before harvest, reducing the metabolic activity of the digestive enzymes. Fish generally pass through rigor "whole" and still retain visceral enzymes, and if these are present at high levels they can cause deterioration of the meat during storage.

Besides stress, and the affect of harvest method used, seasonal variations play an important role. Wild caught fish can vary greatly in product quality depending upon when in the breeding cycle harvesting occurs. For Alaska pollock (*Theragra chalcogramma*), the fish harvested during the breeding season for mentaiko (or mentiko) have poorer quality flesh than fish harvested at other times during the year. Similarly, large variations in muscle quality are seen in salmonids. For example, the flesh texture of pink salmon (*Oncorhynchus gorbuscha*) tends to remain firmer for male compared to female fish in the same run, as a result of the mobilization of fat and energy reserves by the female fish for egg production. Also, salmon within the same run harvested at a mouth of a river contain more fat and have a much higher quality than fish harvested closer to the spawning grounds. Fish harvested at the mouth of a river from short runs also tend to be of lower quality than fish from longer runs. This is because fish with longer migration patterns require larger energy stores for migration and tend to have a higher fat content and a richer flavor.

Normally, fish are allowed to pass through rigor before they are processed and are commonly held at 4–10°C until rigor has resolved. For the best quality product, fish should be processed as soon after resolution of rigor as possible. Because these animals and their accompanying microflora are adapted to cooler temperatures, deleterious biochemical reactions can occur quickly in fish. Care must be

taken to ensure that butchering operations are as clean and sanitary as possible to avoid cross contamination between viscera and meat. Eviscerating must be conducted under cool conditions. Often fish processing facilities are kept at 45–50°F to maintain product quality.

VII. REFRIGERATION

For this chapter, *refrigerated* is used to describe product temperatures above 0°C and *frozen*, product temperatures below 0°C. Holding and shipping live fish is *technically* a refrigeration process since products are held at temperatures between 3–10°C, depending upon the species.

Rigor begins (onset of rigor) in fish within one to two hours depending upon species and ambient temperature. Onset of rigor is temperature dependent and occurs sooner at higher temperatures. Extremely large fish such as bluefin tuna weighing several hundred pounds go through rigor slowly like other large animals. As a comparison, the onset of rigor in beef muscle is within 10–24 hr postmortem at room temperature, in chicken in 2–4 hr, and in whale muscle, 50 hr (7).

Fish pass through rigor within hours and are generally processed post-rigor. Fish should pass through rigor (resolution of rigor) before fillets are frozen to avoid toughening, shrinkage and to reduce drip loss when the product is thawed out and used (thaw rigor). One exception to processing pre-rigor for certain at-sea longline processors that process high value fish prerigor, is freezing fish within two or three hours of harvest. Another exception is in aquaculture, where fish are often processed prerigor.

Fish must be carefully handled post rigor, since rough handling can tear the muscle tissue causing the myotomes to separate. This phenomenon is called gaping. Gaping is an important quality consideration in finfish harvested from cold waters. Gaping is most prevalent in fish allowed to pass through rigor at elevated temperatures (>17°C). Other manifestations of rough handling include discoloration and softening as a result of bruising, caused by rupturing blood vessels within the muscle tissue. Also, fractures of the vertebrae introduce blood spots into the muscle tissue.

Controlling the temperature of muscle foods is important for maintaining quality during storage. Muscle fibers contract postmortem at physiological temperatures. However, the amount of contraction decreases and is lowest around 10–20°C. At temperatures lower than 10°C, muscle contraction increases again. Contraction of muscle fibers at low temperatures causes the quality defect of cold shortening making muscle tissue tough. Cold shortening occurs in prerigor muscle (below 10°C) because the sarcoplasmic reticulum cannot efficiently store calcium ions at these lower temperatures. Fish muscle, with the exception of that from large pelagic species, is not highly susceptible to cold shortening. However, a related problem is thaw shortening, which occurs when muscle is frozen prerigor and then thawed rapidly. Because ATP is not depleted in the muscle cells when tissue is frozen prerigor, the muscle fibers contract rapidly during thawing releasing large amounts of tissue fluids (drip loss) with accompanying muscle toughening.

There are a number of methods for storing fish at reduced temperatures (15°C or less) including: crushed ice, slush ice (water ice dispersed in water alone or in water containing additives (*e.g.* salt, organic acids, antimicrobials, sugar)), champagne ice (slush ice with gaseous carbon dioxide) and mechanical refrigeration.

Even with refrigeration, aquatic food products have a limited shelf life (Table 159.2). Eviscerated ("dressed" or gutted) whitefish such as cod or halibut, and salmon have a shelf life of a week or less at 4°C, but fatty fish in the "round" containing visceral contents such as mackerel or herring should be stored no longer than a couple of days. The shelf life can be extended significantly using tightly controlled storage conditions at lower temperatures by a process called superchilling. This technique involves holding the product at 0 to −1°C with variations of holding temperature less than ± 0.5°C. Most fish muscle does not freeze above −2°C.

A. Vacuum Packaging

Vacuum packaging also increases shelf life of certain products. Storage of chilled vacuum packaged meats including smoked fish up to 10 weeks is possible at 4°C. The primary, but somewhat unwarranted concern with vacuum packaged seafood products, is the growth of *Clostridium botulinum* type E. This organism can grow at refrigeration temperatures 38°F (3°C) and relatively high concentrations of water phase salt (4.5–6%)(6). However, most products will have signs of decomposition before the risk of botulism becomes significant.

Recent concern among regulatory agencies about the safety of vacuum packaged fresh fish and smoked fish products from *Listeria monocytogenes* is also misplaced.

TABLE 159.2
Refrigerated Shelf Life of Fresh and Cured Aquatic Food Products

	Approximate Days Remaining in Good Condition	
Products	**32°F**	**60°F**
Cod, fresh	14	1
Salmon, fresh	12	1
Halibut, fresh	14	1
Finnan haddie	28	2
Kippers	28	2
Herring, salted	1 yr	3–4 mo
Cod, dried salted	1 yr	4–6 mo

Adapted from Pigott and Tucker, 1990 (4).

Packing these foods under vacuum or with nitrogen flushing maintains product quality longer and also provides a packaging that is tamper evident. Concerns with thermal abuse can be addressed by labeling: "keep refrigerated at 38°F or less" and "use or freeze by" dating. Modern time temperature indicators or recorders can be used to ascertain whether a product has been thermally abused possibly jeopardizing its safety, and these monitoring techniques are becoming more common.

VIII. FREEZING

One of the earliest food patents was issued in 1842 for refrigerated fish. However, mechanical refrigeration/freezing did not become a significant method for preserving aquatic food products until the early 1950's. The development of shipboard refrigeration and freezing systems made high seas fisheries possible by permitting vessels to harvest finfish and crustaceans from distant areas and bring these aquatic food products to shore-based processing facilities and distribution centers. In a similar manner, the development of practical freezing technologies and refrigerated/frozen transportation systems allowed shore plants to be constructed near fishing grounds while providing service to worldwide markets (8).

The recent rapid international expansion of aquaculture now provides fresher and less expensive aquatic foods to consumers throughout the year. Important cultured species including salmonids (Atlantic and Pacific salmons, rainbow trout), catfish, tilapia, sea bream, halibut, eels, sole/flounder, striped bass, molluscan shellfish, shrimp, and sea vegetables (*e.g.* nori, the common covering for sushi rolls) are commonly available around the world at any time. This would not be possible if it had not been for the development of practical refrigerated/frozen processing, sophisticated supply chain management and reliable air transportation. Unfortunately *high quality* frozen or refrigerated (fresh) aquatic foods are too often unavailable because of poor handling, poor processing, or inadequate temperature control (9). This is a problem that still plagues the industry and has since its inception.

Refrigeration and freezing also made it possible to introduce new and extremely valuable products into commerce, for example caviar and fish roe products. Caviar products are cured with salt, but with few exceptions, refrigeration or freezing is required to maintain product safety and quality. Other extremely valuable aquatic food products which would not otherwise be available without freezing include king crab with the shell on, giant prawns, magaro (sashimi tuna or tuna to be consumed raw) and lox (lightly salt cured, cold smoked, effectively raw, salmon).

In general, deterioration can be reduced if the temperature is 4°C or less and by ensuring holding temperatures are well controlled. To halt deterioration, the mobility of water within the food must be reduced. This is particularly significant for aquatic food products because the water content is high. Finfish contains 60–80% water on a weight basis and some aquatic products contain over 90% water. Individuals within the industry often remark that they sell some of the most expensive water in the world. Water retains the ability within any food product to serve as a solvent or reactant until a temperature of −40°C is achieved and maintained. Even below −40°C, product quality will still be affected by surface dehydration unless protected by packaging or physical barriers such as an ice glaze.

Freezing muscle foods permits storage for one year or longer at −20°C, assuming that temperature fluctuations in the storage freezer can be controlled [Table 159.3]. Rapid freezing is required for aquatic food products, even more so than for muscle tissue from terrestrial animals. Muscle proteins in fish are less tolerant to changes in the ionic strength of intracellular fluids that occur during freezing than other types of muscle food. Small intracellular ice crystals will form in rapidly frozen samples with less visible tissue damage. For slowly frozen samples, large intracellular ice crystals form which rupture cell membranes, increase drip loss and damage texture.

Fish muscle myotomes are more susceptible to mechanical damage during freezing than the muscle tissue of terrestrial animals. This is due in part to the orientation of the myotomes and to the relative weak connective structures that hold them together. Rapid freezing is also critical for maintaining the quality of animals frozen whole such as shrimp, lobster and molluscan shellfish. These animals are often frozen without eviscerating, so it is critical to freeze tissue rapidly with as little tissue damage as possible to limit digestive enzymes from being released into the flesh. Usually, after the fish has been frozen, it is protected with a water glaze to limit surface dehydration. Packaging materials that permit moisture retention and exclude light are preferred.

Freezing and on-board refrigeration has made it possible to expand commercial fisheries to new species that were not widely utilized until the late 1970's. The

TABLE 159.3
Practical Storage Life for Aquatic Foods (Months) (4,9)

development of a factory trawler fleet and growth of whitefish fisheries around the world for surimi, fillets, and fish blocks production would not have been possible without the ability to harvest tons of fish at a time and keep them in refrigerated seawater storage until the fish could be processed on board. Similarly, without recent developments in freezing technology it would not be possible to hold the millions of pounds of frozen processed product on board ship until it can be delivered hundreds of miles to shore, and from there to consumers.

A. Types of Freezing

Different freezing methods are employed in seafood production. Some of these are outlined in Table 159.4, with common temperature and air velocity parameters provided for freezing different food products. Most aquatic food products are blast frozen, or frozen under conditions in which product is packaged and placed upon shelves inside a chamber. Very cold air at high velocity is blown around the chamber by powerful fans near the ceiling. After the product is frozen, it is removed from the blast freezer and placed in a storage freezer.

Sometimes large fish, such as salmon, are frozen in a blast freezer without being packaged first. Glazing is also used to extend the shelf life of frozen whole, dressed fish, fillets, whole shrimp or molluscs. Glazing involves dipping or spraying water or an aqueous solution on the product after the surface has been frozen. Sometimes a cryoprotectant such as fructose, sucrose or sorbitol, an antioxidant such as ascorbic acid, or a thickening agent (*e.g.* alginate) are added to the glaze. Levels of glaze on whole fish can be as high as 9% by weight. The glaze sublimes during frozen storage, protecting the product from surface dehydration or freezer burn. The glaze also keeps oxygen from migrating into the food limiting lipid oxidation. The presence of a good glaze on seafood is positive factor, however to prevent economic fraud, seafood products are sold by weight after the glaze has been removed (or weight net of glaze).

TABLE 159.4
Freezing Methods for Different Muscle Food Products (9)

Product	Freezer Type	T	Air Velocity (m/s)
fish, bulk	air blast/batch	−30–−40	17
	air blast/continuous	−40	
fish	tunnel	−30	
	plate	−40–50	
fish	cryogenic nitrogen	−196	
	carbon dioxide	−78.5	

Adapted from Institut International du Froid, 1986 (9).

Contact plate freezers are commonly use for freezing products which can be marketed as uniform slabs such as blocks of fish fillets, fish mince, fish roe, and surimi. Plate freezing is used upon factory processors because it is compact, efficient, and has relatively low operating costs. In a contact plate freezer, the product is placed in a rigid pan between two large metal plates that contain circulating refrigerant. These plates are pressed down upon the product as it freezes. Plate freezing is *required* for products that must have uniform dimensions including fillet block, mince/block, or mince used for sandwich portions, fish sticks, or nuggets. Very uniform dimensions are required by the secondary manufacturer who cuts the blocks into portions of uniform size and weight. Plate frozen products are frozen in aluminum pans of very specific dimensions. These pans are lined with coated paperboard block liners folded to fit inside the freezer pan. The fish product is arranged inside the liner, and the lid of the liner folded over and closed. The product is packed by weight. These pans are placed into a contact plate freezer. Commercial freezers on ships can be 10–12 plates and contain dozen of blocks per layer. It takes approximately 2–2.5 hours to freeze a 7.7 kg block of fish in a commercial plate freezer (−28°F).

Cryogenic freezing or immersion freezing in liquid nitrogen or a carbon dioxide "snow" are popular methods for freezing high value items such as shrimp and molluscan shellfish. The freezing rate is extremely rapid, and for some products, this can cause the food to crack or split. The carbon dioxide forms a snow on the food, and then sublimes. Carbon dioxide is often preferred, since there is less thermal shock than with liquid nitrogen and less physical damage to the product. For seafood, the product is placed on a conveyor and passed through a carbon dioxide snow. For nitrogen freezing systems, the product is cooled with gaseous nitrogen before the liquid nitrogen is sprayed on it. After the product is frozen, it is packaged in plastic and allowed to equilibrate to the frozen storage temperature before it is transferred to a storage freezer. These products are generally glazed. Often vacuum packaging is used.

Individually quick frozen shrimp are commonly frozen in carbon dioxide snow in South American plants, and in spiral blast freezers in Asian facilities. Each type of freezing can produce an excellent product and freezing rate is rapid. Shrimp are glazed with a spray of water after freezing. After the glaze sets, the shrimp are packaged in plastic barrier film of various types, packaged in a cardboard master case and held in a storage freezer, preferably at –20°C although this not always possible.

Rapid freezing is critical for fish fillets or steaks to limit the formation of large intracellular ice crystals. Contact plate freezers would be used for frozen block, but tunnel freezer (blast freezer) operated as a batch or continuous system could also be used successfully. Chemical changes, specifically lipid oxidation, occur in fish tissue

during frozen storage. Even though the lipid content of "white fish" is less than 1%, the membrane lipids are highly susceptible to oxidation. This oxidation can lead to stale and rancid off-flavors. Gadoid fish including Atlantic and Pacific cod, hakes and haddock, contain high levels of trimethylamine oxide (TMAO). This compound is broken down by enzymes active during frozen storage that cause proteins in the muscle to cross-link and cause toughening. These enzymes are more active when the tissue has been damaged, which is another reason careful freezing is important. "Fishy" off flavors are a result of microbial decomposition occurring BEFORE the fish were frozen.

Frozen storage temperature must be carefully controlled to limit ice crystal growth and water migration in the fish. Wide fluctuations in storage temperature enhance the rate of deleterious chemical and biochemical reactions in the fish that lead to off flavors. For other products, poor frozen storage conditions would result in the liberation of proteolytic and lipolytic enzymes from the viscera which would cause loss of quality during storage and after the product is thawed.

B. Packaging

A wide variety of packaging materials are used for frozen aquatic food products. For frozen fish fillets, headed and gutted Pacific salmon, and frozen glazed crab, the product is loosely wrapped in plastic and placed inside a cardboard carton for shipment to distribution centers. Shrimp, individually quick frozen fillets, and breaded products, are commonly marketed in heat sealed plastic bags. Some large products, such as whole tuna, are not packaged at all. Certain traditional foods, including uni [sea urchin roe brined and treated with alum] and sujiko [brined, colored, whole skeins of salmon roe] are still marketed in small wooden boxes. Frozen Dungeness crab meat (muscle removed from cooked crab) and razor clams are packaged in cans with double seamed metal ends although there is a trend to package these products in plastic because of food safety concerns. People mistakenly believe that products in metal cans are shelf stable, which raises food safety concerns.

IX. CURED AND SALTED PRODUCTS

The addition of salt is the initial step in the production of cured, smoked, fermented and many dehydrated products. The purpose of curing is to reduce water activity through the addition of the salt itself and by the dehydrating effect the salt has by removing water from tissue being treated. After salt is added, products are placed on inclined or perforated surfaces to drain. This step removes water, and although is not enough to make a product shelf stable, will increase shelf life or, if drying is to follow, allow this step to be more efficiently conducted.

Salted aquatic foods are ancient products and still widely consumed today as specialty foods. In Japan, the most common salted fish are sardine, mackerel, salmon and roe, herring and roe, pollock and roe and squid. In China small pelagic fish, cuttlefish, shrimp, squid, jellyfish and molluscs are salted and dried. Marine fish of all types, most commonly cod, haddock, salmon, sardine, anchovies and herring are important products in Europe and North America and are cured and salted

Cured products are ready-to-eat raw foods. The most common are from salmon. Gravlax is made by adding spices, sugar, salt and herbs to salmon fillets and allowing these to cure for several days under refrigeration. In Japan, teijin is made by dry salting or brining salmon for no more than a few hours. Lox is made by dry salting or brining salmon for several minutes to a couple of hours, and then smoking the product for a short period of time at temperatures less than 90°F. These foods are not normally cooked prior to consumption. Because of the potential for parasite contamination in wild-harvested salmon, it is recommended that only frozen fish be used.

Fish roe products are another type of cured ready to eat foods (3). For a detailed description of roe products see Chapter 161 in this series. Production of roe products is still an art to some degree. Sturgeon roe is made by simply blending singled eggs with 4–5% finely ground salt by weight for a number of minutes at or somewhat below room temperature. The salted eggs are drained on a fine screen, during which time the eggs are carefully inspected and any defective eggs or connective tissue removed. After this, the product is packaged into cans that have slots in the side to allow fluid to drain from the container. The product is generally aged for at least 30 days prior to sale to develop oxidized flavor notes and a darker color, although there is a growing market for the highly desirable freshly salted eggs. Salted salmon roe or ikura were traditionally made using a dry cure method. But more common now is a process which carefully suspends singled out eggs in a saturated salt solution for two to less than ten minutes depending upon the species of eggs, degree of maturity, and desired final salt concentration. For sujiko, whole skeins are used. The skeins are soaked in saturated brine containing flavors, sodium nitrite (100 ppm) and hydrolyzed vegetable protein for about 20 minutes. After brining, the skeins are layered with fine salt in a plastic (formerly wood) container. Weights are placed upon these containers to compress the sujiko and to remove moisture. Barako is a similar product made by recovering broken salmon skeins from sujiko processing. Barako is sold as singled eggs and is not compressed.

Herring roe or kazunoko [*Clupea pallasii* (Pacific herring), *Clupea harengus* (Atlantic or Baltic herring)] are also a product in high demand in Asia, particularly in Japan. Kazunoko or "yellow diamond" roe is made by curing whole herring egg skeins and is commonly

prepared as sushi or as a garnish for rice dishes. The herring roe is not immediately removed from the fish. Instead, the fish are frozen, preferably by brine freezing, or a combination of brine freezing and blast or plate freezing, the objective being to preserve the natural shape and form of the roe sacs within the fish. The frozen herring is then shipped to processing plants where the kazunoko is produced. The freezing and frozen storage of the herring is part of the process of "conditioning" the herring making roe removal easier.

At the processing plant, the herring are thawed, tempered, or "slacked out" by placing the fish in fresh water that is exchanged several times during the 24-h thawing process. This helps to remove blood and other undesirable constituents from the fish. The skeins are then removed (or "popped") from the herring. While skein removal is commonly done by hand, automated systems are now used at many facilities both to sort the fish by gender and then to remove the egg skeins from the female fish. The skeins are sorted, brined, cured, and then packed in an approximately 5-gal plastic pails in 100% brine solution, which is topped off with a scoop (500 to 750 g) of loose salt. The product is then shipped and held under refrigerated temperatures of −4°C or lower. The brining process traditionally involves many steps in which the skeins are held in totes of brine of increasing strengths, finishing with a saturated brine solution. All in all, the brining process normally takes 5 to 7 days with daily changes of brine. A primary purpose of this process, in addition to curing, is to remove any discoloration in the skeins due to blood, enzymatic activity, or contaminants. In some instances, hydrogen peroxide is used by secondary processors to bleach discolorations. Following brining, skeins are sorted by quality and size. Most kazunoko is shipped to Japan where it is drained, inspected once again, and packaged for retail sale. Gift packs consisting of individual matched pairs of skeins sell for $10+ per pair (approx. 5 oz).

Individual brined herring eggs (capelin, cod, or tobiko also have the same application) are added to sea vegetable salads and to seafood salads containing, among other things, marine plants (sea vegetables), clams, limpets, or marinated octopus. Another product from herring roe is tarama, a mayonnaise-like condiment manufactured from emulsified fish eggs. Acceptable tarama can be produced from damaged skeins and from overly mature roe.

A most interesting herring roe product is kazunoko kombu or herring roe on kelp and is a garnish for a variety of dishes, most commonly soups, salads or side dishes. It can be very expensive, often over $100 per pound. For the highest quality kazunoko kombu, a uniform, dense layer of herring eggs of similar size and color covers both sides of a piece of kelp. Traditionally, kazunoko kombu is harvested when herring spawn. Schools of herring release their eggs simultaneously, and the eggs adhere to kelp until the fish larvae hatch. Kazunoko kombu is still harvested in the wild; however, most is now produced by harvesting live herring just prior to spawning and placing them into pens (called "pounds") in which cut kelp has been suspended. When the fish spawn, the eggs adhere to this kelp to a thickness of up to one-half inch per side (or an inch in total thickness). The fish are then released back to the wild and the egg-coated kelp is washed, trimmed, cut to market size, and packed in brine. Due to a shortage of natural kazunoko kombu, there have been several attempts at developing acceptable substitutes. One of the somewhat successful attempts at such uses a surimi-based paste as an adhesive in the highly labor-intensive operation of attaching a layer of herring eggs to pre-cut pieces of kelp. The coated kelp is then placed in a form under slight pressure and heat to set it and then packed in light brine.

Other aquatic plants are salted and used as food. Brown kelp (*Laminaria japonica*) is commonly washed, boiled, salted, dried, salted and repackaged. The largest market is China. Seasoned kelp is a popular snack in Taiwan and Japan prepared by cooking dried kelp in soy sauce, sugar, salt and spices. Wakame (*Undaria pinnatifida* and *U. peterseniana*) is a salted dehydrated brown seaweed reconstituted and added to miso soup (10).

Salted jelly fish is made with a multistep salting process by treating brine and alum in increasing concentrations with a final step in dry salt. Uni, from sea urchin gonadal tissues, is also made with salt and alum.

X. SMOKING

Smoking is a form of dehydration and is an ancient form of food preservation. Smoke imparts a flavor and color to the food but limited preservative effect. Fish with a higher fat content such as salmon, black cod or sablefish are the most popular smoked products in addition to specialty products such as cold smoked oysters. Fortunately, *Listeria monocytogenes* is somewhat sensitive to phenolic components in smoke. The shelf life of smoked product is similar to that of fresh product. Therefore, unless the smoked product has also been thermally processed (commercially sterile, canned or retort pouch), or dehydrated to a water activity low enough to inhibit pathogen growth (Aw≤0.85) it must be refrigerated (6).

Cold smoked products are ready-to-eat products that have not received a 'cook step' or pasteurization treatment. To cold smoke fish, cured fish is exposed to smoke at ≤ 90°F (6). Fish can also be cold smoked without brining. Product prepared in this fashion is held refrigerated and then broiled or grilled. It is a preparation that works especially well for halibut, black cod and salmon and is popular for restaurants.

A common smoking process is to treat fish fillets, steak or pieces of larger fish, or butterflied smaller fish

with dry salt or in a salt brine until a salt content of 1–3% is reached. Then the fish are drained and permitted to cure for several minutes or several hours depending upon the product. Curing allows intracellular fluids to drain from the fish, and permits further equilibration of salt within the muscle tissue. During curing, a pellicle or slightly hardened surface layer on the fish is formed from the migration of soluble proteins to the surface coupled with surface dehydration. After curing, the fish is exposed to smoke. The type of product will dictate the type of wood used, the heat, time and humidity of the smoking operation. With few exceptions, hard woods are used for smoking (*e.g.* oak, hickory, alder, maple, cherry, apple, mesquite). The key with cold smoking, is for the temperature remain low enough so that microbial growth is kept to a minimum. Smoking can take a couple of hours for lox to several days for traditional Indian smoked products, some of which are still made over fires in traditional drying sheds.

Cold smoked products are sometimes thermally processed in jars. Thin strips of cold smoked salmon, eel or lamprey are packed in jars with oil and then subjected to a commercial sterilization process.

Hot smoked products are cured and smoked as described above, then, in addition, receive a pasteurizing treatment. A heating cycle follows at the end of the smoking cycle. Depending upon the product, smoke may or may not be applied during this heating step. Hot smoked products are commonly vacuum packaged. Either hot or cold smoked product may also be canned or processed in retort pouches producing a shelf stable product.

XI. DEHYDRATION

Dried fish has historically been a critical item of commerce. Even today, as much as 25% of the world's fish harvest is dried. Access to cod fishing grounds was the cause of major international disputes throughout the 19th century. This is because dried salt cod (bacalao) was the major protein source for workers at sea, during the period of slave trading in the New World, and for the military in 16th–19th century Europe. Dried fish is light and easy to transport and did not decompose without refrigeration. Markets are still strong for dried cod in southern Europe, West Africa, Brazil and the Caribbean. Per capita consumption of dried fish is high in island states, Subsaharan Africa, and in nations with a high per capita fish consumption such as Portugal, where there has also been a historically large cod fishery.

Dehydrated product includes dried and flaked fish and are popular products in Asia. Flaked fish is usually reconstituted prior to use, primarily in soups. Dried bonito flakes form the base for popular condiments in Thailand and Japan. Dried fish (including shrimp, squid and cuttlefish) are often consumed as a snack in Asian communities, among Native Americans, and to a more limited degree in Africa and South America in areas where fish consumption is high.

Salted and dried fish are traditionally made by layering fish with dry salt at levels of 1:4 by weight of salt to fish, allowing the fish to cure and drain from anywhere from a couple of days to a few weeks. Then the fish are removed from the brine, the surface liquid removed, and placed on drying racks, often outside in the sun, until enough water is removed to make the product shelf stable.

Often, fish are strung through the tail or impaled on small wooden sticks to dry, commonly without being salted in advance. In earlier times, fish were split and placed upon rocks to dry in the sun and wind. Sun drying is still used today with major commercial operations for drying cod in the cold North Atlantic winds off the Lofoten Islands in Norway. Drying racks are up to sixty feet high. Similar operations for air drying fish are found in Newfoundland and Labrador. In Hong Kong and in other parts of Asia, small fish to large squid are commonly sun or air dried. In fact, the vast majority of dried fish products are still 'naturally' sun or air dried.

Even though this drying technology is simple it is not without sophistication. Multistage drying processes are conducted in facilities of simple construction. Among the Native American tribes along the Columbia River, salmon fillets are sun or air dried until a certain desired consistency is reached, then the fish are cut into strips, sometimes salted, and placed on dowels in drying racks. Drying, usually in combination with smoking, occurs over a number of days inside a drying chamber or shed. Ambient temperature and wind velocity control drying time.

Often times, dehydration is combined with other food preservation processes such as curing or salting. Jerkies are thin hard or somewhat pliable strips of fish made by a cold smoking fish treated with salt or salt-sugar mixtures.

Aquatic plants are often dehydrated. Nori or laver (*Enteromorpha* spp; *Ulva* spp., *Monostroma nitidum*) are green seaweeds sold in dried sheets that form the outer surface of sushi rolls. Small slices coat the surface of rice crackers and are included in dried seasonings for rice, soups and sauces. Nori is either mechanically or sun dried and is sometimes toasted. Dried or toasted nori is a component in seasoning pastes containing soy sauce and sugar.

Drying is a less important preservation method for fish in developed nations than in the past. Reconstitution and use of salt-preserved foods, such as salt cod or dried cuttlefish, in food preparation is involved and labor intensive. Many dried, salted foods have fallen out of favor in part because current meal preparation times are short – in the West averaging less than 15 minutes per meal! However, the increasing popularity of authentic Asian, Spanish and Caribbean cuisine are exposing more individuals to traditional salted and dried fish products, reintroducing these foods to many people.

All known mechanical drying methods have been used for fish products. The highest value are for freeze dried products such as small shrimp used in instant soups. Microwave drying technologies may replace freeze drying as a cost effective alternative to these methods are further developed. Fluidized bed drying makes a highly acceptable product as well. Flaked fish is prepared on drum dryers and by convective drying methods.

XII. FERMENTATION

Aquatic animal tissues are commonly fermented (9) at both low and higher salt contents. Lactic acid fermentation are utilized to some degree in the production of Asian fish sauces, fish balls and sausages. Fish sauce (from whole fish) or fish pastes (shrimp paste) are salty and highly flavored, and clearly an acquired taste for the Western palate – like single malt scotch and cigars. Fish sauce with specific flavor profiles, clarity and color are national and regional specialties in Thailand (nam-pla), Vietnam and Kampuchea (nuoc-mam), Indonesia (petis), Malaysia (budu), Philippines (patis), China (yu-lu) and Japan (shotturn). Traditionally, fish sauce is made by layering whole small fish with salt (20–40% by weight) in a ceramic crock with a perforated bottom. A weight is placed on top of the fish to remove air and to force the liquid produced during fermentation to drain off. The crock is held for several days at high ambient temperatures. To control fermentation temperature in certain regions, fermentation vessels may be buried in the ground, in this case, preparation of fish sauce may take a number of months. Fish sauce may be filtered or a certain amount of insoluble residue may remain in it. It may or may not be pasteurized. Common types of fish are sardines, anchovies, ambassids and shrimp. In Japan, fish sauce preparations may also contain soy sauce or wheat koji, small clams, or oysters to modify the flavor and aroma. Japanese fish sauces may also contain added sources of proteolytic enzymes to assist with the fermentation process.

Fish pastes can be made from the residue remaining after fish sauce production or by fermentation of fish and wheat bran by *Aspergillus oryzae*. Fish sauce residue is mixed with red rice and fermented producing the pink condiment, bagoong, popular in the Philippines. Similar products are made in southeast Asia by blending fish sauce residue with glutinous rice, or roasted rice and molasses (mam-cho).

Proteolytic fermentations using endogeneous microflora conducted at cold temperatures include fermented whole fish and fish viscera in Asia, and the stink fish and stink eggs of the Northwest US coast up through Alaska and into Siberia. Fermented organs (*e.g.* sea urchin gonad) or muscle (fermented squid) are popular foods in Japan (9). Fermented salmon belly flaps and viscera (the traditional lomi lomi in Hawaii) or fermented pyloric caeca are specialty items in Japanese and Filipino communities. These fermentations are generally conducted with little or no added salt. Among the Native people of the Pacific Northwest, Alaska and into Siberia, seal flippers, marine mammal muscle, and fish heads were traditionally packed into seal skins and buried in the ground for several months. Fermented seal flippers prepared by salting the flippers and packing them into barrels remains a popular food in the Pribilof Islands. Problems arose in these Native communities with the advent of plastic bags and central heating, when people began making these traditional foods indoors within a shorter period and at a higher temperature creating a risk for *Clostridium botulinum* intoxication. After this problem was discovered, practices were modified again to make the traditional foods safely. Stink eggs are another traditional food of the indigenous peoples of the Northwest. In one type of preparation, salmon eggs are fermented by placing them into a small cloth sack coated with flour to exclude air. After several days, the eggs become liquified producing a condiment.

Marine plants are incorporated as ingredients alcoholic beverage production in Japan.

XIII. THERMAL PROCESSING

By the mid 19th century, fish was being thermally processed in metal, lead soldered, and sealed cans. Thermal processing for aquatic foods includes retort pouches and more recently microwave sterilization. Canned tuna and salmon are still common, and new convenient forms of these products are making inroads into lunch markets. Canned tuna remains the most popular fish product by volume, consumed in the United States.

Improvements in the quality, availability and price of fresh and frozen fish products, along with cheaper poultry products, have negatively impacted the canned seafood market, particularly salmon, which is still widely consumed around the world and remains an important product for the Alaskan fishing industry. Producers of canned salmon are seeking new markets in the food service sector with retort pouch products, and with new market forms of canned salmon including seasoned products, canned smoked products, and skinless/boneless products and microwave processed shelf stable portions. The market for canned salmon is not expected to grow, with the possible exception of high-end pet foods. Likewise, the markets for other types of canned seafood products (clams, shrimp, tuna, anchovies, sardines, etc.) are expected to remain stable or to decline.

Recent innovations in commercial sterilization should create new markets for shelf stable aquatic foods. Salmon processed in a microwave retort with overpressure has properties similar to fresh steamed salmon. The dramatic improvement in quality is a result of the dramatically

reduced come-up time for the thermal process that reduces overheating at the surface of the container and resulting loss of texture and flavor. Similarly, dielectric processing using microwave (915 MHz) or radio frequency (27 MHz) energy shows similar promise for pasteurizing heat labile aquatic foods such as caviars and smoked fish that begin to thermally denature around 70°C.

XIV. SUMMARY

Aquatic food products are among the most varied and interesting food products we consume. Improvements in live haul and refrigerated transport have made year round availability of fresh aquatic food products a reality in world markets. Traditional dried, fermented and cured products are becoming popular in more markets as people become exposed to foods from other areas and regions. The aquatic environment, particularly aquaculture, will be the major source for increased sustainable production of protein foods as world population grows, making technical advances applicable in this area critical to food self sufficiency.

ACKNOWLEDGMENTS

We appreciate the support of the International Marketing Program for Agricultural Commodities and Trade (IMPACT) at Washington State University, National Fisheries Institute, and Aquaculture Idaho/Washington for this work and for development of aquatic food products technology.

CONTENTS

I. BACKGROUND

Surimi is composed of the myofibrillar proteins recovered by washing minced fish and was developed in the early 1960's as a source of fish muscle protein for neriseihin or kneaded seafood a popular food in Japan (1,2,3). Japan remains the primary market for surimi where various types of boiled, grilled or fried fish patties, cakes or balls constitute up to one-third of all seafood consumed. Pigott (3) describes the most common product forms as follows:

Kamaboko–washed fish flesh mixed with flavorants, possibly color (usually pink) and gelling agents; shaped, and steamed. It is commonly sliced and added to udon soup.

Chikuwa (broiled kamaboko) – is an open cylinder of kamaboko placed onto a skewer and broiled.

Satum-age (fried kamaboko) – kamaboko is shaped into different forms and sizes and fried. May or may not have other ingredients added.

In Western markets, surimi is most commonly recognized as the base material for production of imitation crab or kanibo. But because surimi is a protein gel, it can be used in all sorts of food products. The most common are breaded, broiled or fried surimi-containing hors d'oeuvres or entrée items. Surimi forms the base for flavored meat, seafood, or vegetable mousses, spread and dips. It can also be extruded into different shapes mimicking shrimp, scallops or lobster and vegetables such as mushrooms. Surimi has been used in low fat imitation cheeses and dairy desserts, fish sausages and fish-based hams. Ham and sausage kamaboko, the first analog products replacing pork with fish and adapting products which are part of Asian cuisines to Western tastes. Other objectives have been to reduce the fat or caloric content of the beef or pork products they imitate. Emulsions using surimi or washed or formed salmon mince or chunks, can also resemble ham or hard sausages. Reduced fat pepperoni and hard sausages have been made from fish, but are formulated most successfully when tallow or pork fat is added, defeating one of the major purpose for using fish as a base, since the level of saturated fat remains high.

Surimi can replace dairy emulsifiers and binding agents in foods where allergens are a concern. A novel application for surimi is the production of a kosher artificial black (sturgeon, lumpfish or paddlefish) caviar. A few of these foods have had limited commercial success, and hopefully more will follow.

Prior to the development of surimi, kamaboko was made from fresh fish in coastal communities in Japan including the conger eel, lizardfish and croaker with records for its production to the 12th century AD (2). Guild artisans produced surimi using a traditional labor intensive process involving a careful filleting of fish, removal of bone, skin, viscera, and the dark stomach lining. The fish was minced, washed several times with water to remove soluble proteins, salts, and lipids. Washing improves gel strength and elasticity, essential properties for high quality analog products (1). In the traditional process, the washed fish mince is drained and forced through a fine sieve. This last step removed any remaining bone and skin fragments. The resulting fish cake was ground with salt in a stone mortar to solubilize the myofibrillar proteins. Flavorings and starch are also blended into the fish muscle matrix forming a pliable dough, which is shaped into half cylinders upon a flat base consisting of a small piece of a native Sawara cypress making kamaboko. The wood contributes an aromatic flavor, and provides a cutting surface for the kamaboko after it is cooked. The kamaboko sets into a firm gel by cooking it in steam.

Recovery of the Japanese economy after World War II significantly increased kamaboko consumption, with production climbing to 268,000 tons in 1954, and to 408,000 tons by 1960 (2) and by 1965, there were over 40 shore-based kamaboko manufacturing plants in northern Japan (3). Accompanying this growth in demand was less availability of fish from in-shore grounds. Kamaboko requires relatively fresh fish and fish frozen at sea produces a less satisfactory product. Further, it was not economically feasible to produce any of the myriad of formulated consumer products, such as kamaboko or chikuwa, on board fishing vessels. A combination of these factors led to the development of the intermediate product, surimi.

In modern commercial operations, surimi is made by recovering the myofibrillar proteins by washing minced fish muscle, stabilizing the washed mince with a combination of cryoprotectants and then freezing it. Cryoprotectants are added to retain the functional properties of the muscle proteins during frozen storage. A typical cryoprotectant combination includes: 4–5% sucrose (granular cane sugar), 4–5% sorbitol (in powdered form), and a 0.3% blend of phosphate salts. These cryoprotectant blends are usually proprietary. Other additives may include calcium lactate, sodium bicarbonate, ascorbic acid, or antioxidants. With cryoprotectants, surimi can be stored frozen for a year or more at −20°F.

Other factors led to an increase in the demand for surimi analogs in the 1980's, most importantly a shortage of king crab which led to the development and commercial production of kanibo or imitation crab, which remains one of the most popular analog products on the world market in the form of "crab legs" and "crab meat" salad pieces or chunks is a popular product in the United States. "Crab legs" are made from small ropes or logs of texturized, colored, crab flavored surimi. Other "imitation" seafood products are much less common in US markets including imitation scallops, shrimp, lagnostino, and lobster.

Unfortunately, surimi production is one of the most inefficient uses of fish and one that comes with a high capital and operating cost. Yields have improved and can exceed 20% recovery on well run lines. The market is currently moving away from pollock surimi production, due to low market prices for surimi, although other species are becoming more common as a source of raw material. The demand for fillets and fish portions compete with surimi for raw material.

Fish that are not used for surimi production are used for individually quick frozen or shatter pack fish fillets (specifically deep-skinned fillets), fillet blocks, or minced fish blocks. Most at sea processing vessels have the capacity to make both surimi and fillet products. Many vessels also produce fishmeal from the meat that cannot be efficiently recovered as well as the skin, bone, viscera. The ratio of surimi to fillets manufactured will depend upon the market for the respective products. Currently, the market for fillets is stable and the price for surimi is low causing a bias toward fillet production.

II. SURIMI MANUFACTURE

Concurrent with development of offshore surimi production was the emergence of the Alaska pollock (*Theragra chalcogramma*) fishery. Alaska pollock is still the most common source of fish for surimi although other fish are commonly used. Alaska pollock could be harvested in large quantities with limited amounts of by-catch and could be purchased for a low price compared to other "white fish" such as Pacific cod (*Gadus macrocephalus*), and during part of the year provided a lucrative roe (mentaiko or mentiko) market. Alaska pollock is currently the most plentiful commercially harvested species in the world with an exploitable biomass estimated at over 6,800,000 metric tons and a target catch weight in most years exceeding one million metric tons. Surimi production is stable at roughly 200,000 metric tons per year. Surimi manufactured at sea on board a factory trawler is generally superior to that produced in shore-based facilities because the fish is fresher. The yield of surimi from at-sea processors also tends to be higher than for shore based plants because of the higher quality of fish. Shore based processors were established in the 1990's for political reasons tied to fishery allocations and not necessarily with the best interest of the fishers or the resource in mind.

To hopefully obtain better control over management of the fishery, the United States foreclosed foreign fishers from the North Pacific fishing grounds off the coast of Alaska in the late 1970's. The Fishery Conservation and Management Act (1976) and the International Fishery Conservation Act, extended the sovereignty of coastal nations over fish from 3 miles to 200 miles leading to the creation of a factory trawler fleet, that in the mid 1990's had over 60 vessels. In response, Japanese companies formed joint ventures with American companies to produce surimi and exert market control over the pollock resource. As part of this effort, U.S. subsidiaries were established to operate shore-based surimi processing plants in Alaska. The shore-based plants could be completely foreign controlled, whereas factory trawlers were required by law to have at least 75% US ownership.

To make matters worse, The Fishery Conservation and Management Act (1976) was amended in 1998, shifted a larger portion of the harvest to these foreign owned shore based processors. This significantly reduced the number of fish available to US owned at-sea processing vessels. This amendment was passed under the guise that a reallocation of fish would create more jobs in the local Alaskan economy; however, it has instead resulted in

the loss of much of the US fleet along with the high wage jobs they created. Currently less than half of the pollock surimi production occurs on at-sea processors, the reverse of the situation in 1997.

Pollock is currently harvested in the US in three to four seasons. In the first or "A" season, roe bearing pollock are harvested. The pollock roe (*mentaiko* or *mentiko)* is a very valuable product and is in high demand in Japan and Korea. During the "A" season in January–April, the muscle tissue is in relatively poor condition because the fish are spawning; therefore the surimi is also of a poorer quality. The pollock harvested in the "B" season during late summer, are not spawning and produce a higher quality surimi. The "C" season runs during the fall, and late in this harvest, some fish are beginning to spawn. A "D" season for early summer is also proposed during some seasons.

In a typical operation, Alaska pollock is trawl-caught and held on-board in refrigerated seawater (RSW) until they have progressed through rigor (Figure 160.1). The fish are then processed as soon as possible post-rigor but never longer than twenty-four hours after harvest. When surimi is to be manufactured at a shore based facility, the fish are held on-board in refrigerated seawater (RSW) at approx. 2°C, and delivered to the plant within 48 hours. Product held more than this will not make high quality surimi. The fish are off-loaded by pumps, and held at the plant in RSW until the fish pass through rigor, which takes around 5 hr.

Other fish species besides Alaska pollock are playing a more significant role in surimi production (see Table 160.1). The international demand for Alaska pollock has increased, both as a source for surimi and also as a relatively inexpensive source of fish fillets that can substitute for cod.

One species that has received particular attention in the United States is the Pacific whiting (*Merluccius productus*). This fish is commonly harvested in Washington, Oregon and British Columbia coastal waters. A relatively large biomass and low price, lack of competing uses and developed markets, and the proximity of the principal harvest, processing areas and markets, led to the utilization of Pacific whiting for surimi production. Recent Pacific whiting landings range between 310,000–350,000 metric tons. Management of the whiting fishery provides for separate in-shore and off-shore harvest allocations that, in turn, encouraged joint ventures by both U.S. fishing companies and Japanese firms with local shore processors in Oregon and Washington. In the Canadian whiting fishery, Canadian fishers harvest fish which are then processed on board foreign processing vessels or at on-shore facilities within 24 hr of harvest. For political reasons, US vessels are currently excluded from this fishery.

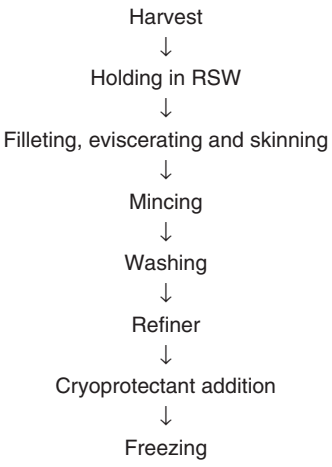

FIGURE 160.1 Outline of a Surimi Manufacturing Process.

The quality of Pacific whiting is affected by seasonal variations in muscle quality and in variations in pH as a result of spawning. A unique quality problem with Pacific whiting is an endogeneous protease produced in reaction to a muscle parasite (*Myxosporidian proteinas*). This parasite causes problems with proteolytic muscle disintegration reducing the gel-forming ability of myofibrillar proteins in whiting surimi. This protease is a cysteine cathepsin and weakens Pacific whiting surimi gel structure by hydrolyzing myosin, it is most active around 55°C (3). Fortunately, protease inhibitors (ca. 1% by weight) can be added to the minced whiting muscle in conjunction with the usual cryoprotectants (sucrose, sorbitol and phosphate salts) to maintain gel forming ability. Calcium lactate may also enhance the effectiveness of the inhibitors. Calcium salts, such as calcium lactate, enhance gel formation by accelerating myosin heavy chain crosslinking via cross-links between negatively charged groups on protein molecules. The most effective protease inhibitors include bovine blood plasma proteins, egg white, potato-based inhibitors (4,5) or whey added to a cryoprotectants blended at up to 1.5%. Recent concerns with "mad cow" disease (BSE) have resulted in the collapse of the blood plasma additive market. Allergen labeling requirements affect the attractiveness of egg white as an inhibitor. Together, these factors may create a demand for a new generation of surimi additives.

The production of surimi is highly mechanized and closely resembles the first few traditional steps in kamaboko manufacture. The yield of surimi can vary significantly from 14 to 30% of the original weight of the fish. A common process for surimi manufacture is outlined in Figure 160.1.

In the initial steps for surimi production, bones from fish fillets are removed mechanically in a "deboner." This is a perforated drum that minces the fish and removes any bones by forcing the tissue through 3–5 mm perforations. The muscle tissue passes through to the inside of the drum, and the bone and any remaining skin remains on the outside. This material may be recovered for pet food or fish meal production. Other types of meat-bone separators

TABLE 160.1
Some Fish Species Evaluated for Surimi Production

Atlantic croaker (*Micropogonias undulatus*)	White croaker (*Argyrosomus argentatus*)
New Zealand Hoki (*Macruronus novaezelandiae*)	Lizard fish (*Synodus* sp.)
Southern blue whiting (*Micromesistius australis*)	Antarctic whiting (*Merluccius australis*)
Pacific whiting (*Merluccius productus*)	Hake (*Merluccius merlussius*)
Atlantic cod (*Gadus morhua* L.)	Pacific cod (*Gadus macrocephalus*)
White hake (*Urophycis tenuis*)	Red hake (*Urophycis chuss*)
Arrowtooth flounder (*Atherestes stomias*)	Yellowfin sole (*Limada aspera*)
Pacific herring (*Clupea harengus pallasi*)	Capelin (*Mallotus villosus*)
Atlantic menhaden (*Brevoortia tyrannus*)	
Atlantic mackerel (*Scomber scombrus*)	Jack mackerel (*Trachurus murphyi*)
Sardine (*Sardina pilchardus*)	Sardine (*Sardinops melanosticus*)
Horse mackerel (*Trachurus japonicus*)	Bluefish (*Pomatomus saltatrix*)
Yellow striped trevally (*Selaroides leptolepis*)	Unicorn leatherjacket (*Alutera monoceros*)
Pink salmon (*Onchorhynchus gorbuscha*)	Chum salmon (*Onchorhynchus keta*)
Northern squawfish (*Ptychocheilus oregonensis*)	
Marlin (*Kakaira* sp.)	
Thresher shark (*Alopias pelagicus*)	Spotted shark (*Galeocerdo curier*)
Silvertip shark (*Carcharhinus albimarginatus*)	Silvertip shark (*Carcharhinus brachyurus*)
Hammerhead shark (*Sphyma lewini*)	Dogfish shark (*Squalus ancanthias*)
Milkfish (*Chanos chanos*)	Threadfin bream (*Nemipterus tolu*)
Sea bass (*Diplectrum fresum*)	Bacoco (*Pomadasys branicki*)
Weakfish or sea trout (*Cyanoscion nothus*)	Lisa (*Mugil cephalus*)
Ronco (*Micropropagon undulatus*)	

have also been used to a lesser degree including sieve type separators. Minced fish is composed of approximately 2/3 myofibrillar proteins and these proteins can form strong gels under the right conditions. In protein gels, the myofibrillar proteins are solubilized by blending, chopping or stirring salt into the minced muscle tissue.

Soluble muscle proteins (sarcoplasmic proteins) including enzymes and heme proteins, blood, and lipid are removed during the washing steps (4) and these must be removed during surimi production if a high quality gel is to be formed. Sarcoplasmic proteins and residual lipids impede gel formation and can accelerate protein denaturation during frozen storage. The washing step is conducted two to four times under agitation at 5–10°C. Typically, in shipboard operations, the fish mince is washed with 1.8 to 3.6 volumes of (5–10°C) water in a countercurrent two-step washing system. Water is removed from the washed minced fish by passing the mixture through rotating screens or through a decanting centrifuge. Having excess washing hydrates the meat and makes water removal difficult during dewatering steps and impedes gel formation as well. Salt (0.01–0.3%) may be added to the final wash to make water removal easier (3). The recovered minced tissue contains approximately 25% solids. The salt content must be lower than that required to solubilize actomyosin prematurely forming a protein gel. Sodium bicarbonate ($NaHCO_3$) may also be added to the rinse water to increase net recovery and to assist in the removal of unwanted constituents (6).

Refining is the final impurity removing stage of processing. A screw drive is used to force the washed mince through a cylindrical screen that has fine perforations. In a refiner, the washed fish mince is passed through a screw press achieving a final moisture content of 72–75%.

Yield is low in surimi processing with as much as one-third of the fish flesh lost during the washing steps. Typically, less than 25% of the "round" (whole, unevisceratedd) fish is recovered as surimi. Although much has been made of the potential to manufacture surimi from pollock frames and trim, this has yet to be successfully accomplished commercially. Almost all surimi is produced from the fillets, and the remainder of the fish muscle tissue is converted to fishmeal or discharged as waste (see Table 160.2). Recovery of additional solids by decanting wastewater streams and though secondary refining can increase overall recovery, but these steps must be conducted carefully if product quality is to be maintained.

Cryoprotectants are blended into the surimi to maintain the gel forming properties of the myofibrillar proteins during frozen storage. The cryoprotectants commonly added are: approximately 5% sorbitol, 4–5% sucrose, and 0–0.3% phosphate (generally in the form of a blend of tetrasodium pyrophosphate and sodium tripolyphosphate). High quality pollock surimi contains approximately 72–75% water, 18% protein, 4% sucrose, 4% sorbitol and 0.3% polyphosphates.

TABLE 160.2
Material Recovery in Surimi Production from Pollock (Data from (3))

Step	Yield
Whole fish	100%
Deheading and eviscerating	60%
Mechanical deboning	47%
Washing	45%
Refining	22%
Dewatering/screw press	20%
Mixing	24%
Extruding	24%

Sorbitol and sucrose act as cryoprotectants and stabilize the protein gel network in surimi during freezing. Sucrose inhibits ice crystal formation and water migration from proteins during frozen storage. Sorbitol and sucrose promote preferential hydration of protein molecules and effectively increase the surface of area of the protein. Other monosaccharides used include glucose, lactose and fructose. Initially 10% sucrose was used as a cryoprotectant, however this produced surimi that was too sweet for Western palates and resulted in the formation of brown off colors during frozen storage from Maillard reactions. Sorbitol, which has a bland flavor, was substituted for half of the sucrose, and found to be effective.The level of sucrose and sorbitol vary depending upon the type and condition of fish and the desired flavor characteristics of the finished product.

Gelling properties of surimi are improved by adding phosphate salts. Phosphates partially decouple actin myosin complexes formed during rigor. By adding phosphate, the gel forming ability and functional properties of a gel approach that of pre-rigor tissue. Phosphate addition can counteract loss of gel strength resulting from starch addition during the surimi analog process. Phosphates also increase moisture retention and increases the ability of a protein to reabsorb liquid when the surimi is thawed or tempered. Phosphate will increase the pH slightly, which will also lead to improved gel forming ability, gel strength and cohesiveness due to an increase in water holding capacity at a higher pH. Phosphate will also sequester magnesium, iron and zinc ions that interfere with gel formation. It can also sequester calcium, and this may or may not impact gel-forming ability. Polyphosphates added at 0.5% provide the greatest gel strength, but 0.3% is optimal for gel strength and flavor (3,6) with sodium tripolyphosphate (STP) and trisodium pyrophosphate (TSPP) used in combination (4).

Sodium bicarbonate ($NaHCO_3$) is also used in the leaching steps of darker fleshed fish to aid in the removal of solubles and lipids in herring surimi and as cryoprotectant in pollock and whiting surimi. Antioxidants have been added to maintain protein functionality during frozen storage, the most common being ascorbic acid which may promote disulfide bond formation.

Normally, surimi is extruded into plastic bags (often 17 b) and frozen in contact plate freezers for 2.5 to 3.0 hours, with a target temperature of −20°C. After freezing, the surimi may be packed two bags to a case and transferred to a storage freezer.

III. ANALOG MANUFACTURE

A common formulation for a gelled fish product will have approximately 60% surimi. However, by adding certain starches imitation crab analogs containing as little as 33% surimi can be commercially produced. A protein content of 11% will provide a strong gel suitable for most analog products. To make an imitation seafood product from surimi, the surimi is tempered to slightly less than 0°C, blended with salt and other additives, including flavors and colorants; formed, extruded, or texturized by multiple folding or the use of spinnerets; and heat set, and packaged, generally under vacuum. These products are ready to eat. As a safety precaution, almost all analog products produced for sale in the United States, are pasteurized and are held either refrigerated or frozen. A common process is outlined in Figure 160.2.

Surimi is tempered, or taken from a frozen state to a condition where it is pliable, under controlled conditions until it can be easily mixed in a silent cutter. This is a large bowl shaped device with moving blades which chop the protein gel into pieces and incorporate salt and other additives before the surimi mix is extruded to form myofibrillar protein gels, similar to what occurs in sausage manufacture.

The texture and flavor of the surimi-based product is affected by the quantity and type of salts added, and the pH of the surimi. Therefore, tempered surimi is combined with salt to solubilize actomyosin. Starch is an extender

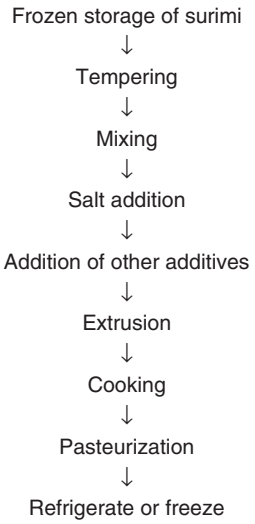

FIGURE 160.2 Surimi analog production.

for surimi and reduces formulation cost. More importantly however, starch can strengthens the gel, and participates in gel formation as a dispersed phase. Egg white also increases gel strength and gel elasticity. Egg white can improve color and appearance of the surimi-based product after extrusion. Flavors, flavor potentiators, colorants and additional phosphate, sweeteners, mirin (Japanese rice vinegar) and antioxidants such as ascorbic acid (Vitamin C) may be added depending upon the desired product traits. After addition of various components, the surimi gel is transformed into a thick paste or protein gel that is subsequently heat set. When heat set, this results in the formation of a three-dimensional, continuous structural matrix.

Salt (NaCl) solubilizes actomyosin. Complete solubilization is required to make a resilient surimi gel. Salt binding to myofibrillar proteins creates electrostatic repulsive forces between protein molecules, loosens the structure of a protein network and permits greater water binding. The optimal salt content varies with the fish species used. Generally, 2.5–3% salt provides optimal gel strength, however 2–2.5% produces products with a more acceptable flavor. The preference for salt content is product and market dependent. Higher concentrations of salt reduce the thermal stability of fish proteins allowing them to gel at lower temperatures. Very high levels of salt decrease gel strength due to protein precipitation, a phenomenon known as "salting out." Freeze denaturation of the proteins in surimi during frozen storage will reduce protein solubility and increase the amount of salt required to solubilize actomyosin during analog manufacture.

The minimum concentration of salt for extracting actomyosin from fish muscle is pH dependent. At pH 7.0, approximately 2% salt is needed. Salt solubilizes myofibrillar protein forming a thick sol or paste. The presence of the chloride ion may shift the isoelectric pH to a lower value increasing protein solubility at the existing pH.

In surimi starch modify texture and improve gel strength of low quality surimi. Adding starch can reduce formulation cost by increasing water retention in the surimi product. It can also bind water, improve adhesion and stabilize the surimi gel. Adding excess starch makes surimi based gels brittle. Up to 20% starch can be added without adverse affects on gel strength.

The mechanism for interaction between starch and protein in surimi gels is not well understood. Swollen starch granules are dispersed within the protein gel matrix. Starch granules swell but complete gelatinization does not normally occur. The surimi gels set at temperatures below the starch gelatinization temperature. Potato and wheat starches are commonly used. Potato starch has a low gelatinization temperature and produces high strength surimi gels. Pre-gelatinized tapioca starch and thin boiling starch produce surimi with reduced gel strength (3).

Some surimi analog products contain egg white. Egg white modifies the rubbery texture of surimi caused by the addition of starch. It also provides the surimi with a whiter and glossier appearance. Egg white makes the partially heat-set analog more elastic and stretchable, this is an advantage for "ropelike" products like imitation crab legs. The amount of egg white added depends upon the fish species used and the quality of the fish used.

Egg white added at 10% produces a gel with a high yield stress, gels containing up to 20% are softer, and greater than 20% there is a decrease in gel strength and gels become brittle. Egg white contributes to the structure of surimi analog gels by filling interstitial spaces in the fish protein network.

Because egg white is an allergen, it must appear on the label of surimi analog products. Class II food recalls of analog products have been initiated in the United States because of failure of companies to list egg white on the ingredient statement.

Carotenoproteins in crab turn orange-red when crab is cooked. This is the reason a colorant is used on the surface of kanibo [imitation crab]. A natural or artificial color is added to surimi paste and applied to the outside surface of ropes of crab leg analog following extrusion.

Flavors are added as liquid concentrates, pastes, or free flowing powders to the surimi mix during blending. Natural and artificial flavors are used. Crab meat extract and extracts from shell and processing by-products have been used. Crab-like flavors derived from non-shellfish sources have also been used to produce a kosher imitation crab.

The level of salt, level and type of phosphate, and level of sugar and sorbitol have an impact on the flavor of surimi analogs. Hydrolyzed protein, dipeptides, or amino acids added to provide meaty, sweet or slightly bitter flavor to analog products. Monosodium glutamate (MSG) may be added as a flavor enhancer. Nucleotides are also added as flavor modifiers, commonly guanosine (0.0035%) and inosine monophoshate (0.01%). Nucleotides enhance flavor potentiating properties of MSG.

Heat setting occurs in 3 stages represented by distinct textural changes. At 40°C, the setting is attributed to hydrophilic interaction of protein molecules. At 60°C, the gel weakens somewhat due to action of endogeneous proteases. Intermolecular and intramolecular protein bonding occurs around 80°C increasing gel strength.

For the production of crab meat analogs, the surimi paste containing the desired additives (with the exception of red colorants) is sheeted in a thin layer and then heat set. After this first heat set, the sheet is scored with a device that looks like a large comb. The sheet is not cut completely through. This scoring forms long thin strips that resemble crab muscle fibers. Several of these strips are rolled together to form "muscle fiber bundles." These are set and then a portion of the outside surface is colored red with a blend of surimi and food coloring. The ropes

are then cut into logs (approx. 4 inches in length), or into small cylinders or diagonal cut product for salad chunks.

A second extrusion process involves extruding spaghetti thin strips of a surimi containing mixture into an acid bath. This sets the surimi and when this material is cut into small pieces and reformed, has the texture and mouthfeel of muscle fibers. This product is commonly mixed with salad chunks for use in seafood salads.

Kamaboko is formed into half-rolls, surface dyed, and heat set. Other products, such as chikuwa (which look like a huge fish ziti or rigatoni) are extruded and cooked.

Surimi texture is affected by how the product is heated and by the heating rate. Cooked surimi based analogs are more stable in the frozen state than surimi. Surimi based products pass through three stages of gel formation during conventional heat processing. The conventional isothermal method of producing analogs is divided into three stages of gel formation. These three stages are treated as separate unit operations called: forming, heat-setting and cooking. The first stages of gel formation occur as the surimi is initially heated. The gel increases in strength up to 13°C. In the range from 13°C to approximately 30°C, few changes in gel properties are observed. A second heat set occurs between 30–40°C and a final cook between 50–90°C during which time the maximum gel strength is realized.

Imitation crab products are commonly vacuum packaged in plastic or nylon packaging. The products are pasteurized inside the package in a hot water bath. This is a food safety precaution because surimi analogs are ready to eat foods. In addition to killing vegetative cells of bacterial pathogens, pasteurization reduces the number of spoilage flora leading to an extended refrigerated shelf life.

Surimi-based products are distributed as refrigerated or frozen foods. For frozen product, individual packages are frozen in a blast freezer, packaged into cases and held in frozen storage, preferably at −20°C. Surimi-based products have a shelf life of approximately 1 year under these conditions. Quality changes, which occur to the product during frozen storage, include flavor changes resulting from oxidation of lipids and lipid soluble constituents, toughening, and loss of product integrity and product texture.

The gel-forming ability of fish is affected by the frozen storage treatment as well as the fish species, freshness, and biological conditions of the fish prior to harvest. Poor frozen storage can encourage enzymatic lipid oxidation, cause protein denaturation and negatively impact gel formation.

CONTENTS

I. INTRODUCTION

Fish roe products are popular traditional foods, often of very high value, with growing domestic and international markets. Caviars are the salt-cured and preserved eggs of finfish or aquatic invertebrates. Fish eggs are commonly called "roe," particularly when they are present in skeins. Roe products are usually refrigerated or frozen although some are shelf stable, as a result of thermal processing, pickling, salting or dehydration. Roe are sometimes consumed along with other tissue in a single dish for example whole scallops in the shell, shrimp or lobster with coral (or roe), rock sole with roe, and she crab soup.

Caviars are generally made after the eggs have been singled out by screening or otherwise separated from any supporting connective tissue. The eggs are then brined and cured, and sometimes flavored and/or colored. The most widely recognized and valued caviar is made from sturgeon harvested from the Caspian Sea region. Only sturgeon caviar can be labeled in the U.S. simply as "caviar." Caviar from other fish or aquatic animal species must be identified with a qualifying term including the common name of the fish used. For example, caviar from salmon (or ikura) must be labeled "salmon caviar."

II. PROCESSING ROE INTO CAVIAR

Roe products are to be made from wholesome, undamaged eggs, have a proper color and glossiness, texture, a desirable mouth feel, and their characteristic flavor with limited fishy, bitter, or oxidized flavor notes. The preferred mouth feel varies with species. In the case of ikura or salmon roe, a distinct fracture or "pop" when the egg is broken with the teeth or palate, a smooth, honey-like mouth feel is desired, while with sturgeon caviar a buttery texture that tends to melt in the mouth is desirable.

Often hundreds or thousands of individual eggs are enveloped within ovarian membranes and these skeins or whole ovaries can be processed into products such as sujiko. More commonly, the individual eggs are separately recovered, brined and cured. Pastes or spread are common products made by blending eggs with butter, mayonnaise or salad dressing bases, lemon juice or soy or miso based sauces. Roe can be dehydrated. Dried mullet roe is one such food possessing an odd rubbery texture. Technically, caviar should only be used to describe fish eggs that are separated from the connective tissue of the ovaries and then salted and cured.

Roe, regardless of the type, must be an optimal level of maturity to produce caviar. Immature roe tend to be bitter (*e.g*., herring, salmon) and may not take up salt uniformly. If salt uptake is not uniform, the product can readily spoil during storage since psychotropic spoilage micro flora, specifically certain types of lactic acid bacteria can grow within the lower salt pockets of the stored product. Overly mature roe may be soft, lose its elasticity, and may not form a plump, full egg after brining. Overly mature salmonid roes develop tough, rubbery outer shells, while the sturgeons become soft when overly mature. Also, the flavor and consistency of the lipid moieties and proteins change with maturity making the mouth feel of caviar prepared from overly mature roe less desirable.

III. RECOVERY AND YIELD OF ROE

Recovery of roe from whole fish can vary a great deal and is dependent upon the species, method of reproduction, stage of maturity, availability of appropriate feed, the level of stress and various environmental elements. For a female pink salmon, the yield of eggs is approximately 15%, and for a gravid sturgeon as high as 25%. Normally salmon roe is measured as the percent recovered from the entire harvest including both males and females or bucks and hens as they are referred to in trade. For midseason (mid- spawning) pink salmon runs recoveries are as low as 3% (range 3 to 10%, average 6%) (6). Mature roe herring are purchased by the ton on a basis of 10% roe recovery. A herring harvest testing out higher than 10% would receive a premium and one of less than 10%, a reduction in the final price. A more detailed comparison of egg yields for a number of species may be derived from the values presented in Table 161.1.

IV. STURGEON CAVIAR

More than 20 species of sturgeon are harvested for caviar. All are important sources of high quality and expensive sturgeon caviar. The most famous are the caviars produced from the Caspian white or beluga (*Huso huso*), Osetra (or Osietr or Ossietre) (*Acipenser sturi* or *A. guldenstadti* (1), Sevruga (*A. stellatus* or *sevru*), and Chinese or Kaluga sturgeons (*Huso dauricus, A. dauricus* or *A. mantschuricus.* Other important sources of caviar are the Russian sturgeon (*A. gueldenstaedti*), Amur River sturgeon (*A. schrenki*), ship sturgeon (*A. nudiventris*), and Siberian sturgeon (*A. baerii dauricus,* or *A. mantschuricus*) (2). Depending upon the species and environmental conditions, it can take 15 to 20 years for a female fish in the wild to become sexually mature and suitable for caviar production. A single one-ton Beluga sturgeon can produce 350 pounds of caviar worth hundreds of thousands of dollars on the wholesale market (10).

Prices for premium Caspian Sea beluga caviar have always been high, and through 2003 prices of US$700/100 g with prices of US$150–400/100 g for osetra and sevruga caviars depending upon quality common in high end retail markets around the world. Prices for the world's most expensive and extremely rare white or gold colored "Almas" or diamond Beluga caviar from fish, possibly 100 years old or more, was US$2,330/100 g in 2002. Almas caviar is traditionally sold in 24 karat gold tins. It is unclear whether Almas caviar is still available in the marketplace. Current prices of all forms of sturgeon caviar have skyrocketed following new CITES restrictions placed upon trade in beluga caviar in 2005. Current prices

TABLE 161.1
Egg Yield and Size for Fish Roe

Species	Yield (Ave % wt)	Diameter (mm)
White Fish		
Whitefish (*Coregonus* sp.)	14	0.9–1.4
Cod (*Gadus morhua*)		1.3–1.4
Alaska or walleye pollock (*Theragra chalcogramma*)	14	1.3–1.5
Herring (*Clupea harengus*)	18	0.9–1.5
Haddock (*Melanogrammus aeglefinus*)		1.2–1.4
Whiting (*Merlangus merlangus*)		1.0–1.1
Saithe (*Pollachius virens*)		0.9–1.1
Capelin (*Mallotus vilosus*)		1.0–1.2
Carp (*Cyprinus* sp.)	20	0.8–1.6
Sand eel (*Ammodytes lancea*)		~0.3
Pike (*Esox* sp.)		2.5–2.8
Flounder (*Psuedopluronectes* sp.)		0.8–1.2
Lumpfish (*Cyclopterus lumpus*)	23	2–5
Tobiko (*Cheilopogon furcatus*)		<2
Salmon		
Chum (*Onchorynchus keta*)	8–13	4–5
Pink (*Onchorynchus gorbuscha)*	7–11	3.5–5
Coho (*Onchorynchus kisutch)*	7–12	3.5–4
Sockeye (*Onchorynchus nerka)*	6–8	4–4.5
Chinook (*Onchorynchus tshawytscha)*	10	6–7
Sturgeon		
Cultured beluga (*Huso huso*)	25 (max)	
White sturgeon (*Acipenser transmontanus*)	20	<2.2–>2.5 mm

Data from: (6)(15).

(March 2005) for sturgeon caviar at Caviar House, Heathrow Airport, London, UK were as follows:

Osetra: US$220–635/100 g
Sevruga: US$250–400/100 g
Beluga: US$612–665/100 g

Despite a strong demand for sturgeon caviar, supplies of wild harvested product have been decreasing. Over the last few decades, sturgeon (*Huso* spp.) harvest from the Caspian Sea has dwindled, and currently production cannot keep up with consumer demand. Naturally occurring populations of *Acipenser* sp. in Europe and Central and Eastern Asia have also decreased in recent years, resulting in part from political instability in Iran and new states formed from the republics of the former Soviet Union. Because of this, cultured fish species particularly *Acispenser* have received increased attention as sources of black caviar. Sturgeon culture is currently employed to restore natural runs, enhance natural run through hatcheries, or by production of adult animals in culture facilities for meat and roe. These efforts will hopefully ensure that sturgeon fisheries remain viable or become viable again. Currently there are culture operations for *Huso* and *Acispenser* sp. in the nations surrounding the Caspian Sea, Eastern Europe, China, North and South America. However, in addition to CITES, the US Department of Fish and Wildlife has taken the short-sighted position of barring sale of beluga caviar in the US, effectively stopping culture efforts of *Huso* sp. in the United States, because the agency is concerned that it will not be able to differentiate whether or not caviar is from these culture operations or from wild harvested product.

Regulation of caviar production is nothing new, with the fishery highly regulated for centuries. Russia and Iran are the largest producers of black caviar in what have been historically tightly controlled politicized fisheries. The Russian government has regulated production of black caviar since 1675 when Tsar Alexi prohibited Cossacks from direct marketing their caviar to foreigners (4). Many individuals associated with caviar production were executed who objected to Soviet control of the industry in the early 1920s. Fortunately, the Soviet Union was able to maintained reasonable control of caviar harvest and production, maintaining product quality and supporting close monitoring of fishing effort to protect fish stocks during this era. But after the break up of the Soviet Union, management of the fishery fell apart.

Iran is the other major producer of sturgeon caviar. Their territorial waters do not appear to have suffered to the same extent from poaching and boot leg production as areas under the control of the former USSR republics including Russia. Sturgeon caviar is a subject of Persian lore back to biblical times, but the fishery was not highly regulated until 1893. In 1893, the Lianozov brothers managed to secure a fishing concession from the Persian government to harvest sturgeon and process the roe into caviar under a quality control system similar to that in place in Russia. The Soviets seized the Lianozov caviar operations in 1925, ignoring the fact that the operations were in Iran, not the USSR, creating a series of conflicts with Reza Shah Pahlavi who took umbrage at this incursion. By 1927, the Persians signed an agreement with the USSR government and caviar operations recommenced (4). The ouster of Mohamed Reza Shah Pahlavi in 1979 precipitated over 20 years of political chaos in Iran including an eight year war with Iraq that following directly upon the heels of the Islamic Revolution. Governmental control of caviar production in Iran deteriorated after the Revolution along with programs to protect the fishery. Fortunately, the situation has improved in recent years. Iran continues to be a major producer of caviar with well established markets in Europe and recently in the U.S. markets following a two decade trade embargo.

Unlike Iran, the current situation in the former Soviet Union is grim. The construction of dams on the Volga River and the devastation to the fishery caused by virtually uncontrolled poaching after the breakup of the USSR has brought the Caspian sturgeon fishery to the point of collapse with extinction of the beluga, osetra and sevruga

sturgeon becoming a very real threat. Projections are that 90% of the beluga sturgeon population has been lost in the past 20 years. In late 2001 only 28 beluga sturgeon were found over an entire Caspian Sea collection area with over 85% of the fish harvested being immature suggesting a highly depleted population (5).

Although there are several well intended efforts to restore the depleted runs, the generally poor economic conditions in the effected countries has resulted in a reduction of funding to maintain sturgeon hatcheries in Russia and the former Soviet republics, and this has made matters worse. Demands for the surrounding range states to cooperate in setting realistic quotas and for conducting comprehensive surveys of sturgeon stocks have fallen on deaf ears. Recent harvest quotas were largely arbitrary and do not reflect fishing pressure on the Caspian Sea stocks (5).

The situation with poached sturgeon has become so desperate that Russia has considered establishing a governmental monopoly on sturgeon harvest as a means to control poaching to some extent and maintain a viable fishery. Predictions are that illegal fishing generates $2 to $4 billion dollars a year in Russia and the former Soviet republics (Anon, 2001). Interpol has been involved in assessments of illegal trade in sturgeon although currently available data on illegal harvesting, trade and enforcement is very limited, citing the "Paris Agreement" CITES SC45 Doc 12.2 (5).

Control of the fishery is difficult. For example, the Dagestani Coast Guard confiscated 64 tons of fish and 184 kg of caviar from poachers in 2000 and 10 tons of sturgeon through April 2001. In response, a crowd of at least 300 poachers stormed a coast guard station in Izberbash, Dagestan, to forcibly retrieve their confiscated boats and fishing nets in a well-organized attack that local officials described as part of the ongoing war with the local "caviar mafia" (6). Poachers used their wives and children as human shields in this attack. The seizure was a result of a newly instituted Russian restriction on sturgeon fishing and the caviar trade. More problems are sure to follow in light of new fishing restrictions. Mature and immature sturgeon are commonly available in bazaars and for sale on the street, with most of this harvest unregulated.

As a result of the threat to the fishery, international organizations have called for measures from severe restrictions to the complete prohibition of import/export sales of caviar from Caspian Sea species. The UN's Convention on International Trade in Endangered Species (CITES) and Russia, Kazakhstan, Turkmenistan and Azerbaijan reached agreement in January 2002 to severely restrict production of caviar from their waters (7). Regardless, much bootlegged product remains on the market.

The US imports roughly 80% of all beluga caviar (5) and there have been numerous incidents of caviar being smuggled into the U.S. in recent years. In 2000, the U.S. Fish and Wildlife Service seized one ton of illegal imported product through its enforcement powers under the Endangered Species Act, destroyed it, and fined the importers over 10 million dollars. Misbranded and adulterated products are also common in the US market. Decomposed, adulterated, and misbranded osetra, kaluga, sevruga, and beluga caviars have made their way to U.S. markets, and, when detected, have been seized.

In 2002, the US Fish and Wildlife Service proposed a ban on beluga caviar imports into the United States stating that: "Despite the CITES listing, beluga sturgeon populations have continued to decline, and the population structure is increasingly skewed towards sub-adult fish, with a critical lack of spawning-age adult female fish." The US Fish and Wildlife Service proposed to list the species as endangered[1] due to "...loss of habitat throughout historic spawning areas due to dam construction and river-modification projects, over-harvest, widespread poaching and illegal trade, and pollution, [which] imperil the continued existence of this species."

The net effect of the turmoil in the Caspian Sea fishery has been an increase in aquaculture or farmed produced sturgeon caviar. The product is accepted as a responsible way to continue the production of this delicacy and to protect the remaining wild stocks. Although captive breeding programs for sturgeon in Russia began in the 1930s, development was much later in other countries. There are currently commercial aquaculture operations for sturgeon in Germany, Hungary, Romania, Italy, France, Spain, Portugal, Israel, Chile, Argentina, Russia, China, Iran, the Czech Republic, Uruguay and the United States. France and the Czech Republic each produce roughly 10 tons of caviar annually, with French production expected to double in the next 2 years (6). Most of these operations rely upon primary species such as beluga while commercial hybrids of the beluga include the bester, a cross between a female beluga sturgeon and a male sterlet (*Acipenser ruthenus,* also listed as *Acerpensiformes ruthenus*) are also cultured. There are also emerging commercial aquaculture operations of the single strain sterlet (*Acipenser ruthenus*) in Hungary, Poland, other European countries, and Florida directed toward meeting the international demand for gold caviar.

[1]An endangered species is any species which is in danger of extinction throughout all or a significant portion of its range (16 U.S.C. 1532(6)). Factors which support listing the beluga sturgeon as endangered include: (1) loss of 85–90% of its historic spawning habitat through dams, river channelization etc., (2) over fishing, (3) disease causing tumors, reproductive abnormalities and large fish kills throughout their range, (4) inadequacy of existing regulations. For example, arbitrary catch limits, no maximum size limits which would protect spawning fish, poor control of by-catch mortality, insufficient penalties for poaching and illegal trading, and (5) an additional problem is lack of genetic diversity in hatchery stock in which fewer than 10 adult females may provide the base for regional hatchery operations for any given year class. 67 Fed Reg. 49657-49660.ecting sturgeon li.

Commercial harvesting of sturgeon in North America appears to have started about 1750 in New Jersey, however, the production of caviar did not enjoy much attention until the mid-1800's. Initially starting on the Atlantic coast using Atlantic sturgeon (*Acipenser oxyrhynchus*), the production expanded to the Pacific coast from California to British Columbia where the white sturgeon (*Acipenser transmontanus*) was most common. The industry was virtually eliminated in just 50 years by overharvesting. US caviar production is currently seeing a significant revival primarily due to the farming of white sturgeon primarily in California and Idaho.

The most common source of black caviar in North America is the white sturgeon (*Acipenser transmontanus*). This is also the most common sturgeon found on the North American continent. However, the production of caviar from the native wild stock is not normally permitted due to the near extinction of certain sturgeon species and subspecies in some North American watersheds. Therefore, almost all commercial production of sturgeon for either caviar or meat is from cultured sturgeon. Captive breeding programs for white sturgeon along with federal, state, and tribal management projects for wild stocks in the Snake, Columbia, and Missouri River systems should reverse a decline in wild fisheries stocks. In the Pacific Northwest, Native American tribes, along with US Fish and Wildlife, are the primary leaders in sturgeon restoration efforts. The Nez Perce, Kalisbell, and Yakama Nations have wild white sturgeon broodstock in captivity and are developing fishery enhancement programs for the sturgeon. Some of the tribal organizations are expanding their restoration efforts to include production and growout facilities for fish suitable for caviar production. By coupling restoration efforts with production, there is a greater likelihood that programs will remain viable because they would become financially self-sustaining.

U.S. culture of sturgeon began in earnest in the late 1970s. In 1979, the U.S. began an intensive aquaculture program for white sturgeon as part of the Aquaculture and Fisheries Program at the University of California, Davis (8). For this program, wild female brood stocks were harvested and their eggs surgically removed. The eggs were fertilized and the first hatchlings produced in 1980. After this first success, commercial aquaculture firms began raising sturgeon for caviar from *A. transmontanus* possible between 6 to 10 years of age (8); other sources indicate 8 to 9 years (9). Dozens of sturgeon farms have been started in California (10) and Idaho. Southern states, including South Carolina, Florida and Louisiana, began evaluating programs for culturing Atlantic and Gulf sturgeons during the 1980s with current production and pilot operations in place. Cultured sturgeon are harvested at 1.5 to 6 years for meat production and 7 to 10 years for caviar. The Gulf of Mexico sturgeon (*Acipenseroxyrinchus* desotoi) a subspecies of the Atlantic sturgeon distributed from the Mississippi River to Tampa Bay, was commercially harvested for caviar in small quantities in inland Florida (12). As with other North American sturgeons, culture programs have been established for the Gulf sturgeon.

Unfortunately, determining the sex of even mature sturgeon can be relatively difficult. Currently, the most practical method of sex determination requires a small incision in the upper part of the fish's abdomen and a visual examination of the gonadal tissue. Male fish are generally diverted to harvest for meat and the female fish are returned to growout facilities where they remain until they have reached sexual maturity. At maturity, female fish may weigh from 40 to 80 kg. Premium caviar from farm-raised sturgeon is valued at a price equal to that of imported osetra or sevruga with the lowest prices around $36.00 per ounce (3) and production in California farms projected at 30,000 pounds annually.

A. Processing Sturgeon Roe

Preferably, black caviar processing begins with the removal of the roe immediately after the fish has been killed. Wild sturgeon are generally harvested by seining and are transported alive to the processing facility. In some instances, the roe is removed from the sturgeon on board the harvest vessel. It is not necessary to kill the fish however to take the roe. Russian technologists long ago discovered that as much as two thirds of the roe can be removed by Cesarean section and after a short recovery period the fish can be returned to the wild or to the aquaculture tanks (6), thus roe can be harvested again from these fish during later spawning cycles. There are many instances in which roe has been successfully harvested over ten times from the same Beluga female and Sternin reported that eggs were taken from a single bester seven times over a period of 15 years (11).

Processing caviar from cultured sturgeon begins when the fish are removed from the growout tank and transported immediately to the processing room where they are stunned and the roe is immediately removed. Bleeding the fish prior to roe recovery improves quality. The roe is then normally controlled in lots which identify the individual fish from which the roe was harvested. The roe is kept on ice and then processed as rapidly as possible under sanitary conditions in a cool environment. The total processing time from extraction to primary packing is normally less than 2½ hours.

Following extraction, the first step in caviar production is the separation of the individual eggs from the connective tissue. This is normally accomplished by rubbing the skein on single stainless steel screen over a stainless steel bowl. The opening dimensions of the screen are approximately equal to the size of the eggs being separated. Traditionalists in Russia still prefer linen thread screens. Nylon has also been used with success. In contrast to singling out of salmon eggs where two or even

three layers of screens are used, only a single screen is commonly used for sturgeon eggs.

The singled eggs are then inspected, picked over, and briefly washed in a chilled, mild saline solution (ca. 3%) to remove extraneous debris. This rinsing step should not be more than 15–20 seconds or the quality and the shelf life of the end product may be reduced. The eggs should be briefly drained following the rinsing.

The eggs are then placed in a stainless steel bowl, weighed and 3–5% by weight of fine, non-iodized salt, is added and blended by hand. They are then immediately spread out in a 2–5 cm thick layer on a stainless steel, fine mesh, and screened rack for curing. The curing step is very brief and need not be more that 5–15 minutes. From curing the caviar is placed in two-part, specially coated, tins for aging and sale. The tins are slightly overfilled and the top placed on and pressed down to gently compress the caviar so as to drive out any trapped air. A broad rubber ban is placed about the connecting segment of the can and cans are placed in refrigerated storage, initially on their sides, for continued draining and curing. This step takes approximately 28 days for the caviar to develop a mild and distinctly oxidized flavor favored by caviar aficionados. It should be noted, however, that many Americans prefer the flavor of the caviar present immediately after the initial 15 minute curing which leads us to another subject. Just what is good caviar?

Salinity (total salt) of 3 to 3.5% is achieved in the final product after the excess fluids are drained off (11). The final salt concentration will vary depending upon egg maturity, freshness, brining temperature, and brining time. Salting affects the physical characteristics of the egg and increases the hardness of the egg sheath. Egg sheath assays show that the hardness doubles after brining and curing.

Sturgeon caviar can also be pressed (pausnaya). Small or damaged eggs may also be lightly salted and compacted into a product that resembles a thick marmalade and is used as a spread. Damaged eggs are also added to butter or soft cheese and can be incorporated into sauces or pâtés.

Fine caviar has much akin with fine wine and individual preference can be very different. Superb caviar to one person may not be so to another. In general, however, the best caviar should not taste salty, fishy or musty. It should have a mild flavor described by some as being slightly "nutty." The texture should be similar to that of butter and should almost melt in one's mouth. High quality caviar should have no detectable membrane or residual shell material present and a pleasant aftertaste. There should be no metallic or other off-flavors.

Caviar also tends to readily absorb off-flavors, particularly from contact with certain metals. Traditionally, therefore, it is consumed with an ivory, mother of pearl or horn spoon and served in glass or porcelain bowls. Caviar should be stored in the refrigerator, tightly closed in the jar or specially coated metal tin in which it was purchased. Some individuals like to place the container inside of a sealed plastic bag as well.

A few additional notes on processing; for maximum quality and storage stability, sturgeon roe should be handled using exemplary sanitation practices and processed at as low a temperature as possible. The processing, curing and storage areas should be as clean as an operating theater and the temperature of the area kept well below 50°F while processing. The eggs should not be allowed to come in contact with metals other than stainless steel. The water used in the processing should be as aseptic as possible and not contain chemicals that will impart any off-flavors. Only non-iodized salt should be used and salt that has not been coated so as to reduce caking. Kosher-style salt seems to work quite well.

The flesh of harvested sturgeon is first reduced to what is referred in the seafood industry as a "bullet." A bullet is formed by removing the fins, scutes (the armored plates on the sides of the fish), gills, blood, intestines and the spinal cord from the fish. The bullet is commonly processed further into fillets, steaks, roasts, and hot or cold smoked meat products. The skin can be tanned into rather durable leather.

B. Paddlefish Caviar

Caviar from the sturgeon's poor cousin, the paddlefish, is showing significant growth in the Southeastern and Western US as a source of black caviar. In North America, paddlefish (*Polyodon spathula*), the shovel-nose catfish (*Hemisorubim platyrhynchos*) in addition to fresh water sturgeons (*Acipenser* sp.) are harvested from wild stocks for black caviar production. Paddlefish are found mainly in the Mississippi–Missouri River systems, reaching as far north as Minneapolis and St. Paul, Minnesota; as far east as Pittsburgh, Pennsylvania; and as far south as New Orleans, Louisiana.

Their roe is processed in a similar manner as sturgeon roe and the quality of these products can be very high, although the products are generally less expensive than sturgeon caviar, ranging between $7 to $15 per ounce (3). However, wholesale prices of U.S. domestic paddlefish caviar (2002) reached these levels with retail sales prices being in the range of $20–35/oz. Restriction on sturgeon caviar should cause prices for these products to increase. Domestic production of North America paddlefish roe is roughly 60,000 pounds. The commercial culture of paddlefish is viable. The fish are raised both for their meat and roe. The meat is commonly hot smoked. Paddlefish feed on plankton, and this has led to a unique method of polyculture for these fish in the U.S. Paddlefish can be placed at a relatively low density in catfish ponds where they feed on the natural algal blooms and on blooms resulting from the breakdown of uneaten feed and fecal material. This type of polyculture has the potential to reduce the problem with benthic off-flavors in catfish

resulting from consumption of geosmin containing algae. The paddlefish must large enough before introduction into ponds to discourage predation by the catfish.

The roe from paddlefish harvested from recreational fisheries in Montana are sold by non-profit civic organizations and the government to commercial processors and the derived funds are used to support local fisheries and wildlife programs.

V. OTHER FISH ROE PRODUCTS

The increased popularity of sushi, coupled with a heightened interest in haute, international, and fusion cuisines, has spurred the development of expanded markets and new products from fish and fish roe. Important quality parameters for roe are a small sized egg (generally); a mild flavor and an appropriate mouth feel including a good "pop." The most marketable roe products can withstand distribution and handling procedures, frozen storage, and have a reasonable shelf life under refrigeration. Fish from many species can be colored or flavored to match popular products such as black caviar or tobiko, which are in short supply. Data for size and yield of various fish roe are presented in Table 161.1.

A. Catfish Roe

Channel catfish (*Ictalurus punctatus*) has been evaluated as a black caviar substitute (13). Catfish roe from *Ictalurus sp.* and *Clarius* sp. resembles that of paddlefish or sterle and ranges in color from dark charcoal to gray and rarely to a light gold. The eggs have a greater variation in average diameter than do most other species and many are of a smaller size. The eggs also tend to be much more difficult to separate at earlier stages of maturity, however, can be made in to an excellent spread that has a number of gourmet applications.

B. Salmon Roe

"Red" or salmon caviars, called "ikura" in Russia and Japan are popular around the world. Ikura is the style of salmon caviar where individual eggs are separated from connective tissue and cured. Other forms of salmon roe preparations include marinated roe, smoked and flavored roe products, barako, and sujiko. Sujiko are salted and flavored whole skeins. The majority of salmon caviar is produced from Pacific salmon, with chum salmon (*Oncorhynchus keta)* and pink salmon (*O. gorbuscha*) being the most popular. Salmon caviar is also produced from the other Pacific salmon: coho (*O. kisutch*), sockeye or red (*O. nerka*), and king or Chinook (*O. tshawytscha*). Both the largest volume and value is from chum salmon with ikura production at 2000 to 3000 MT per year. Salmon eggs are a major source of income for Alaskan harvesters and processors; the price paid for chum and pink salmon is often so low as not to warrant harvest or processing, however, the roe always has value. It is against the law in North America to simply harvest the roe and not to utilize the remainder of the carcass, a process known as "roe stripping;" however, some jurisdictions have permitted the practice in times of severe economic depression. The practice is not as harmful to the salmon runs as one might think at first glance, as these salmon are at the termination of their life cycle and spawn but once and then die. The harvest size is calculated to not adversely impact future runs. Still the practice of discarding the carcasses should be avoided and some use should be found for the fish.

Atlantic salmon (*Salmon salar*) and Arctic char (*Salvelinus alpinus*) are used to a lesser degree for caviar production (6). The Pacific masu or cherry salmon (*O. masou* masou) is a minor source of ikura, restricted to small regions of Japan and Korea (11).

Returns of salmon are cyclic with a peak in the late 1990's followed by a collapse in 2000, putting the valuable roe in incredibly short supply. Chum salmon returns for the 2001 harvest season were similarly grim. Harvests increased in 2002 and 2003, but prices were somewhat depressed due to a poor economy and near deflationary conditions in important East Asian markets. The market potential for 2004 was brighter, due to a stronger economy, and to the resurgence in interest in wild harvested salmon resulting from a number of unjustified food scares tied to cultured salmon in 2003 and 2004. High protein low carbohydrate fat diets spurred a trend for greater salmon consumption and bolstered prices for wild salmon. This trend is expected to continue through 2005.

Most of the salmon roe harvested in Alaska is exported, primarily to Japan, Korea, China and Western Europe although the US domestic market is growing. Some is processed into ikura in Alaskan facilities, but a large quantity of the "green" or unprocessed roe is simply packed in bulk, frozen, and then exported.

Farmed Atlantic salmon (*Salmo salar*), coho salmon (*O. kisutch*), rainbow trout (*O. mykiss* formerly *Salmo gairdneri*), and its ocean run variant steelhead trout (also *O. mykiss* and referred to as salmon trout) are available in large quantities, exceeding 1 billion pounds per year. Due to the current glut of salmon on the world market, Atlantic salmon culturists in Norway and Finland are holding fish to sexual maturity, harvesting the roe, and producing a very high quality salmon caviar. The market for the product is growing, particularly in Europe and in South America. Salmon trout is already a popular source of red caviar in Europe where much of the product is from cultured fish. There have been some complaints in Japanese ikura markets that roe from cultured fish have an "aquaculture" smell, but that the appearance, color and sheen are excellent (6). Any legitimate issues surrounding the flavor of the aquacultured product can be addressed by altering fish diet. If there continues to be an oversupply of

salmon on the world market this will lead to even a greater proportions of the harvest being directed toward the production of roe products.

1. Processing Salmon Roe-Sujiko

Eggs from salmonid fish are much larger than sturgeon roe, for chum, the eggs range from 4 to 5 mm diameter to as large as 7 mm for Chinook salmon (Table 161.1) and are generally processed with less added salt. Salmon roe have a less "fishy" flavor and oxidized flavor than many sturgeon caviars (6) because salmon roe products are not aged.

Salmon roe are most commonly processed into cured, individual eggs (ikura) or as whole egg skeins (sujiko). Sujiko is prepared by brining whole roe skeins for approximately 20 min in a solution of salt, nitrites, polyphosphates, and other additives and seasonings. After brining, the skeins are sorted by quality and size, and then alternately layered with fine salt in plastic or wooden containers (most commonly containing 5 kg of the finished product). The curing process involves compressing the skeins under a weight for 3 to 5 days at temperatures below 50°F (11°C). The freshly brined product contains approximately 20 ppm nitrite and after curing, the finished product should have no more than 5 ppm, which is the maximum concentration allowed for import into Japan. At this time, this is not an approved use of sodium nitrite in the United States, therefore, all product thus processed in the U.S. must be exported.

Sockeye or red salmon is the primary species used for sujiko production, although chum and pink salmon are also used in large quantities. The early summer run of sockeye salmon in Bristol Bay constitutes the largest single supply of sujiko, and every effort is made to speedily process and ship it to Japan each summer for the Japanese summer festival of Obon at which sujiko is traditionally consumed. A byproduct of sujiko production is "barako," or singled-out eggs from broken or rejected skeins of sujiko. To make barako, the broken skeins are removed following the sujiko brining process, and the eggs are simply singled by mechanically separating them from the skein membrane using a screen.

2. Processing Salmon Roe-Ikura

a. Separation of eggs from skein material

The process for separating the eggs from each other and from skein material is called screening. Screening is normally a manual, laborious, and time-consuming process. Using the conventional method, the roe is rinsed with 3% salt brine. Then the individual eggs are removed from the skein by mechanically forcing the eggs gently through specially designed three tiers of nylon or stainless steel screens. Enzyme-based processes for removing the connective tissue surrounding the eggs for ikura production decreases hand labor and may increase recovery.

b. Enzyme processes for egg recovery

Enzyme preparations for roe recovery include high concentrations of collagenase. The enzymatic process mimics the release of collagenases and other activities by the female fish to dissolve the connective tissue surrounding mature roe when the eggs are released into the water column for fertilization. Recovery of a high yield of good quality eggs varies greatly with enzyme treatments. Proteolytic enzyme mixtures for removing the membranous egg skein material from the individual eggs have been developed for salmon roe.

c. Brining and curing processes for ikura

Brining and curing fish eggs is still an art and requires a great deal of skill. Salmon caviar usually contains 3 to 4% total salt for "malasol" or lower salt caviar. Higher salt products in the range of 4 to 6% are also common and are becoming a regulatory requirement in some markets due to concerns about *Clostridium botulinum* growth. Products with a salt content (2.8 to 3.5% salt) are becoming more popular as consumer preferences change, but these products tend to have a shorter storage life and must be prepared with this consideration in mind.

For ikura, the separated eggs are agitated in brine (for saturated brine the egg/brine ratio is usually 1:3 (v/v) or less). The eggs are brined, generally 2 to 6 minutes between <8 to 12°C, until the desired salt content is reached. The shell of the egg becomes fairly firm after brining. The best process control for ikura manufacture is achieved using saturated brine. Salt uptake of the egg varies between species of salmon. Salt uptake also depends upon the condition and degree of maturity of the eggs and often is affected by whether the fish are "early" or "late" run. Salt uptake varies with eggs in a given lot by 0.5% or more (26). Salt uptake is also faster in frozen or enzyme treated roe, compared to fresh roe, assuming that roe are of the same quality initially and consistent salt uptake is difficult to control (6).

After brining the roe is cured. During the curing process for ikura, the roe is placed on inclined stainless steel screens or in perforated plastic baskets, allowing the excess salt brine to drain off. Salmon roe is cured at refrigeration temperatures for at least 30 min and up to 12 h. This allows excess surface and cellular fluid to be released from the eggs and drained off. Also, the curing permits the salt concentration within the egg to equilibrate and the eggs sheath to harden slightly. Efforts to speed up the curing process by the using fans, etc. results in a product of lower quality.

3. Processing Salmon Roe, Marinated Roes and Other Products

Once the predominant salmon roe product in Japan, the popularity of sujiko is decreasing and being replaced by

lightly salted ikura and flavored/marinated salmon roes. Marinated roe constitutes up to 80% of some Japanese ikura markets (6). These are prepared by taking singled out green roe and marinating them in a solution of garlic, mirin or Japanese sweet rice wine vinegar, soyu (soy sauce), sugar, or other seasonings. The product may be prepared in a commercial food processing plant or in the home or restaurant just a short time before serving. Roe treated in this fashion is used in a number of dishes, including sushi, in sushi-rice combinations such as domboro, or in a number of other Asian or Pan-Asian preparations. The popularity of marinated roes and ikura is also increasing in Europe, North America, China, and other Asian countries.

In Europe and North America, ikura or "red caviar" is commonly consumed as a hors d' oeuvre. It is also added to cream or white sauces in pasta dishes, as a garnish on seafood salads, fish or poultry entrees, and served as a condiment with egg dishes. The traditional wild salmon caviar markets in Europe have been in Germany, Spain, France, and Scandinavian countries. New growth markets are in Eastern Europe and in the Commonwealth of Independent States (former Soviet republics). Western chefs have began to discover many uses for ikura and other roes and the caviars are increasingly found on the menus of white tablecloth restaurants

Traditional Pacific Northwest Native American and Native Alaskan salmon roe products include compacted and dried whole skeins (salmon egg cheese) or "stink eggs." Stink eggs are produced by covering the skeins in animal skins and burying them in the ground, allowing them to ferment under anaerobic conditions and reasonably cool temperatures. Other preparations involve holding salmon eggs in flour coated cloth sacks at temperatures somewhat below ambient for a period of time sufficient to obtain the desired flavor development. Eggs are also dried or smoked and used in soups.

C. Lumpfish Roe

Lumpfish (*Cyclopterus lumpus*) roe is an extremely popular, moderately priced 'red' or 'black' caviar and in much the same fashion as more expensive caviar products. Flavor should be mild and somewhat salty, but with no strong fishy flavor notes.

In its natural state, lumpfish roe is a small 2- to 5-mm egg and ranges in color from gray-white for the immature roe, to purple to red (mature roe), to reddish-orange for overly mature roe (14). The eggs are dyed black or red. Female lumpfish release approximately 100,000 eggs as a sticky mass that attaches to rocks or benthic organisms in the ocean environment during spawning. The male guards the nest of eggs until hatching (10). Lumpfish roe can survive pasteurization better than other caviar products and can also be produced at a high enough salt content and a low enough water activity to make a shelf stable food commonly found in supermarkets. Gum tragacanth may be added to reduce the water activity. Sodium benzoate is commonly added to inhibit mold growth during refrigerated storage.

1. Processing of Lumpfish Caviar

Lumpfish roe is mechanically separated out and the resultant caviar salted to 3 to 5% salinity and packed immediately, or salted to 10 to 14% and then delivered for reprocessing, desalting, and repacking for later retail sale (11,14). Salt levels of 5.8 to >11% may be found (14). After addition of the dry salt, the eggs stick together and must be mixed until uniform dispersion is formed from the eggs and the brine created from expressed intracellular fluid. The eggs are drained and cured. Curing is important for achieving the desired viscosity of the inner fluids of the egg.

An alternative process involves rinsing roe recovered by a mechanical screening process in 5% salt to remove blood spots, ovarian membrane, and other foreign material. At this stage, the product can be stored at 0 to 3°C in vacuum sealed packages for curing at a later date.

Lumpfish caviar is dyed as part of or after the curing process. Most lumpfish is dyed black using coal tar based dyes but 10 to 15% of the world's production is dyed red. Commonly for each 100 g of roe, 0.4–0.5 g of a black dye, 5g salt and 22 ml water are added and held at 4 to 7°C for 1 h. The caviar is then rinsed with an acidified brine (20 g salt, 5.2 g 8% acetic acid, 0.12 g citric acid (per 100 ml)), drained for 30 min, and then vacuum packaged and refrigerated (6,14).

D. Tobiko or Flying Fish Roe

A popular caviar used in sushi preparations is flying fish roe or tobiko [*Cheilopogon furcatus* (spot fin flying fish)]. This is a small, crisp, golden orange roe with an egg size of 2 mm or less. It is sometimes flavored with chili. Wasabi (Japanese horseradish) tobiko is a popular condiment where tobiko is mixed with wasabi and dyed a light spring green. Sometimes tobiko is dyed red. As with salmon caviar or ikura, tobiko may also be flavored with Japanese rice wine vinegar (mirin), a fermented soybean paste (miso), soyu, or other seasonings. In these forms, it is generally served with rice or sushi. Caribbean Islanders commonly fry flying fish, and make a pie from this fish which also includes the roe.

Because tobiko is in short supply, faux tobiko is often prepared from the mature or immature herring roe (*Clupea* sp.), from the eggs of small capelin (*Mallotus villosus*), smelt (*Spirinchus lancerolatus)*, and other fish that have small, bland, light colored roe. For making faux tobiko from immature herring roe, whole herring roe skeins are brined, then graded. The salt content is reduced

by rinsing or soaking the skeins in weak saline solutions or water. Various colorants or flavors can be added at this point. The individual eggs are recovered by rubbing the skeins on a plastic or metal screen.

E. Whitefish Roe and Similar Products

Other fish with roe of small size sold commercially are mullet (*Mugil cephalus*) smelt, and the roe from various white fish including: Atlantic whitefish (*Coregonus huntsmani*), Lake whitefish (*Coregonus clupeaformis*), Mountain or Rocky Mountain (golden)whitefish (*Prosopium williamsoni*). Other fish with small light colored roe used in similar applications as tobiko or lumpfish are the: lavaret (*Coregonus lavaretus*); roach (*Rutilus rutilus*); perch (*Perca fluviatilis*); Pacific herring (*Clupea pallasii*), Atlantic or Baltic herring (*Clupea harengus*), smelt (*Spirinchus lancerolatus*), and burbot (*Lota lota*). There is also a limited roe fishery for the Pacific sardine (*Sardinops caerulea*) (16)(17). Most of these roes are brined, cured, flavored and/or seasoned, and sometimes smoked.

A special note should be made regarding smelt roe or "masago" which is experiencing an increased market again as a substitute for tobiko and similar small size, mid-priced caviars. This roe is commonly subjected to a number of flavored or seasoned variants including green tea, wasabi, chili oil, teriyaki, and combinations thereof.

Another small roe is vendace (*Coregonus albula*) the eggs of which are tiny and pink, and green or unprocessed vendace roe is sometimes consumed as a paste or spread with no salt added. Roe products are consumed in Central and South America from the hake (*Merluccius hubssi* and *M. antarcticus*), mullet (*Mugil cephalus*), orange roughy (*Hoplostethus atlanticus*), and white fish (*Coregonus albula*) (17,18).

F. Cod Roe

Atlantic cod (*Gadus morhua*) roe has long been used for a variety of products by fishers throughout its population range. The skeins may be simply breaded and fried or used in soups. A very popular product in Scandinavian homes consists of a blend of cod eggs and cream cheese or another soft cheese, with or without additional seasonings or herbs, which is served as a pâté or spread. The cheese based products are commonly sold in tubes and may not require refrigeration. Cod roes are also consumed alone or blended with butter. Sometimes roe is a component of meat spreads. Additional uses include the use of cod roe as a condiment in poultry or egg-based dishes, pasta dishes or salads. Other small white fish roe may also be treated in a similar manner and have become more common in areas where cod are scarce.

Salted cod roe [*Gadus macrocephalus* (Pacific cod), *G. morhua* (Atlantic cod)] are sometimes flavored with sugar, treated with nitrite, and smoked. Oil, potato flour, and other ingredients may also be added to salted cod roe. Salted roe may be aged for several months before sale.

Pacific cod roe (*Gadus macrocephalus*) or "tarako" is prepared in a similar fashion as pollock roe (*Theragra chalcogramma*) (see below), including spicy roe preparations. Alaska pollock roe has replaced cod roe in many product lines due to erratic availability and the market preference for a consistently small sized egg. Commonly now, most tarako will be made from pollock roe.

G. Shad Roe

An unusual product, shad roe (*Alosa sapidissima*) is harvested from this anadromous member of the herring family. Colonists transplanted the fish from the rivers originating in the Great Lake region and Northeastern US rivers to the Sacramento River in 1871 and the Columbia River in 1876. Shad now range from Cook Inlet, Alaska, to the US/Mexican border. Because the runs happen within a very short period, it has been difficult to develop a successful commercial fishery in the Columbia basin, although there is a great deal of interest in removing this introduced species from the Western watersheds. Shad roe can be eaten fresh; it is also frozen, and thermally processed in oval metal cans resembling large sardine cans. Commercial harvest is primarily in the West with recreational fisheries in the eastern United States. Shad is a popular spring dish in East Coast markets. Shad are harvested with roe during spring runs, with the fillets prepared separately, and then dressed with the sautéed roe. Shad roe is also breaded and fried, used as a spread or pâté, or incorporated into egg or meat-based entrees.

H. Mullet Roe

Mullet (*Mugil cephalus*) roe (karasumi) is consumed either as a salted product similar to ikura or salted and dried (similar to sujiko). Dried mullet roe has a yellowish red color and a rubbery chewy mouth feel due to the large quantity of wax esters, which runs as high as 60 to 70% of the extracted oil (19). Making mullet roe involves coating the roe with dry salt for 4 to 5 h, removing the salt, compressing the roe during the curing process, and air drying the compressed roe until 30% of the original product weight is lost. Mullet roe is also served as a pickled food ("Botargo") in Italy and other Mediterranean countries (19,20).

I. Orange Roughy Roe

Another roe with a high concentration of wax esters is the orange roughy (*Hoplostethus atlanticus*) (21). Orange roughy lipids have become a suitable replacement for sperm whale (*Physter macrocephalus* and *P. catadon*) oil or jojoba oil for industrial applications. Sale of the roe is not common. Applications are similar to tobiko.

J. Herring Roe or Kazunoko

Herring [*Clupea pallasii* (Pacific herring), *Clupea harengus* (Atlantic or Baltic herring)] are also a product in high demand in Asia, particularly in Japan. Kazunoko or "yellow diamond" roe is cured whole herring egg skeins, and kazunoko kombu is herring roe on kelp. Herring produce small, creamy white to yellow eggs (1.3 to 1.5 mm diameter) (15) in skeins about 8 cm long and 3 cm in width. The highest value kazunoko is a perfectly matched pair of skeins. A perfect pair of skeins has no surface blemishes or discolorations, large veins, nicks, or other visual defects, with both skeins of nearly identical size containing eggs of a consistent degree of maturity and a uniform, natural color. Herring harvesting methods are critical for good product quality. The skeins are vascularized, and the more the fish struggles during harvest, the greater the likelihood that the skeins will become bruised and discolored (6).

The herring roe seine fishery in Sitka Sound, Alaska, has the distinction of being one of the shortest fisheries in the world. Generally, the fishery is open for a few days at best. Among the shortest openings was the 1986 season, with the first opening of only 3 h and 10 min, and the second opening, held about a week later, of 2.5 h long (10). Several seiners may join forces to hire aircraft to spot schools of herring. Meanwhile, fisheries biologists sample the herring and permit an opening only when the fish reach the exact, desired degree of maturity and an average roe content of 10% by weight. Biologists signal the start of the opening by radio. State-commissioned aircraft then fly over the harvest area determining the number of successful catches. When the target allowable catch has been reached, the fishery is closed, again signaled by radio.

The herring roe is not immediately removed from the fish. Instead, the fish are frozen, preferably by brine freezing, or a combination of brine freezing and blast or plate freezing, the objective being to preserve the natural shape and form of the roe sacs within the fish. The frozen herring is then shipped to processing plants where the kazunoko is produced. The freezing and frozen storage of the herring is part of the process of "conditioning" the herring to make removal of roe from the fish easier.

At the processing plant, the herring are thawed, tempered, or "slacked out" by placing the fish in fresh water that is exchanged several times during the 24-h thawing process. This helps to remove blood and other undesirable constituents from the fish. The skeins are then removed (or "popped") from the herring. While skein removal is commonly done by hand, automated systems are now used at many facilities both to sort the fish by gender and then to remove the egg skeins from the female fish.

The skeins are sorted, brined, cured, and then packed in approximately 5-gal plastic pails in 100% brine solution, which is topped off with a scoop (500 to 750 g) of loose salt. The product is then shipped and held under refrigerated temperatures of –4°C or lower. The brining process traditionally involves many steps in which the skeins are held in totes of brine of increasing strengths, finishing with a saturated brine solution.

All in all, the brining process normally takes 5 to 7 days with daily changes of brine. A primary purpose of this process, in addition to curing, is to remove any discoloration in the skeins due to blood, enzymatic activity, or other contaminants. In some instances, hydrogen peroxide is used as a bleach to remove discolorations. Following brining, the skeins are sorted by quality and size. Specialized automated weighing machines are used in some instances.

Most kazunoko is shipped to Japan where it is drained, inspected once again, and then packaged for sale. Often individual matched pairs of skeins are packaged in gift packs that sell at retail for $10 or more per pair (approx. 5 oz). Kazunoko is commonly prepared as sushi or for dombori.

Individual herring eggs (capelin, cod, or tobiko can also be used) are added to sea vegetable salads and to seafood salads containing, among other things, marine plants (sea vegetables), clams, limpets, or marinated octopus. Another product from herring roe is tarama, a mayonnaise-like product manufactured from emulsified fish eggs that is used as a condiment or salad dressing. Acceptable tarama can be produced from damaged skeins and from overly mature roe.

A most interesting herring roe product is kazunoko kombu or herring roe on kelp. Kazunoko kombu is used in a variety of dishes, most commonly soups, and can be very expensive, oftentimes over $100 per pound. For the highest quality kazunoko kombu, a uniform, dense layer of herring eggs of similar size and color covers both sides of a piece of kelp.

Traditionally, kazunoko kombu has been harvested when herring spawn. Schools of herring release their eggs simultaneously, and the eggs adhere to kelp until the fish larvae hatch. Kazunoko kombu is still harvested in the wild; however, most is now produced by harvesting live herring just prior to spawning and placing them into pens (called "pounds") into which cut kelp has been suspended. When the fish spawn, the eggs adhere to this kelp to a thickness of up to one-half inch per side (or an inch in total thickness). The fish are then released back to the wild and the egg-coated kelp is washed, trimmed, cut to market size, and packed in brine. The finished product is commonly used in soups, salads, or as a side dish.

Due to a shortage of natural kazunoko kombu, there have been several attempts at developing acceptable substitutes. One of the more innovative attempts uses a surimi-based paste as an adhesive in the highly labor-intensive operation of attaching a layer of herring eggs to pre-cut pieces of kelp. The coated kelp is then placed in a

form under slight pressure and heat to set the product, which is then packed in light brine.

K. Pollock Roe or Mentaiko

Another roe product popular in the Japanese/Korean markets is mentaiko (also spelled mentiko). Mentaiko is the Japanese name for Alaska or walleye pollock roe (*Theragra chalcogramma*). The most valuable form of mentiko is whole, matched pairs of skeins, defect free and preferably with the oviduct intact. Mentaiko is brined and cured. It may be dyed (mostly red) and/or flavored.

There are literally dozens of grades of mentiko, depending on the type and degree of the defect (Table 161.2).

Other defectives include: hemorrhages or bruising, crushed roe skeins, large veins or unattractive veining, fracture of the oviduct connection between the two skeins, paired skeins of non-uniform size, and skeins that are not uniform in color or no longer connected together. Contact with sea water can reduce the quality of the roe, resulting in a two-tone discoloration on a roe sack. Sea water can also toughen or impart a rubbery texture to the skin surrounding the roe sac.

Tarako is the term used for smaller salted roe sacs. Although the literal translation of the Japanese word "tarako" is salted cod roe, most tarako is actually produced from pollock roe. This is a popular food item and served as a topping for rice or rice balls (musubi). Pollock roe is a component in ready-to-serve sauces for noodles or spaghetti marketed to children and young adults using Digimon cartoon characters.

Lower-grade pollock roe is commonly seasoned with salt, sugar, monosodium glutamate, garlic and other spices, sesame, chili or other flavored oils, soyu (soy sauce), or sake. Sodium nitrate may be added for products destined for export from the U.S. The product is called "spicy roe" or "mentai" and is marketed as a condiment in Korean markets.

Karashi mentaiko incorporates ground cayenne or flaked chili pepper. Mentaiko may also be treated with sodium nitrite and ascorbic acid and/or nicotinic acid to produce a product with a pink coloration. In some cases, fresh roe may be treated with a solution containing salt and 25% ethanol at pH 4.0 to 4.2, and brined in solution containing salt, nitrite, and antioxidants (22).

Pollock roe may also be used as an ingredient in salad dressings, in pastes or spreads, and in preparations where single eggs (barako) are desirable. Dehydrated tarako or mentaiko are used in seasonings in soups and sauces. Popular 'Hello Kitty' characters have been used in marketing campaigns for dry mix preparations and condiments containing pollock roe.

TABLE 161.2
Typical Alaska Pollock Roe Grades

Name	Description
Mako	No defects
Kireko	Defective, generally; broken skeins, skeins with cuts or tears
Aoko	Blue green discoloration from contact with bile
Kuroko	Dark colored roe
Iroko	Orange stains from contact with digestive fluids
Gamako	Immature
Mizuko	Overly mature
Yawoko	Soft

L. Hake Roe

Roe skeins from the Southern Atlantic hakes (*Merluccius hubbsi* and other species) are boiled in water and seasoned and are a traditional food in Uruguay served during the autumn (18).

M. Rock Sole Roe

Rock sole (*Lepidopsetta bilineata*) with roe is a unique, high risk winter fishery in the North Pacific often under severe weather conditions. In 2001, the catcher-processor vessel F/V *Arctic Rose* was lost at sea with all hands while participating in this fishery. Fish may be frozen whole and shipped in this form, headed, and sliced diagonally in strips (kirimi) containing both flesh and roe, or the roe may be removed and processed separately on-board. The roe is quite valuable.

N. Sea Urchin Roe (Uni)

The gonadal tissue of invertebrates, specifically the sea urchin is a popular food in Asian and Mediterranean cuisine. Both roe and milt from sea urchins are consumed. Several species of sea urchin are commercially harvested primarily by divers, including the highly valuable green urchin (*Strongylocentrotus pulcheriius*), the red sea urchin (*S. franciscanus*), and purple urchin (*S. intermedius*). *Pseudocentratus depressus* and *Heliocidaris crassispina* are used for fermented uni (23) as are lower grades of the *Strongylocentrotus* spp. Sea urchins are cultured in the Mediterranean, Ireland, China, and Japan and more recently in the US. Wild harvested animals may also be held in raceways and fed a high-nutrient diet. Proper husbandry and nutrition can increase yield 40% or more in gonadal tissue production.

Sea urchin may be consumed raw, but is more commonly steamed, baked, or sautéed. Uni, a preparation for sushi, is brined sea urchin gonadal tissues treated with alum. It may also be colored ranging from mustard yellow to bright orange. Color and condition are important for determining grades of uni, and a bright orange product is the most desirable.

The salted gonadal tissue from the sea urchin may also be fermented, producing a paste (neri uni). Also, a

more watery preparation, mizu uni, is prepared using a dry cure process. Doro uni is made by washing the gonadal tissue with dilute alcohol, draining it, then mixing it with salt.

O. Sea Cucumber Roe

Fresh and dried gonadal tissue from the sea cucumber (*Stichopu* spp.) is also consumed (10). The gonads can sell for 50 times the price paid for sea cucumber muscle tissue in China. Culture of this organism in China and elsewhere in Asia, and experimental efforts in North America are currently underway.

P. Roe from Crustaceans

Roe or "coral" from gravid female shrimp, lobster, and crab are popular delicacies in European and Asian cuisines. The roe from these crustacea are incorporated into traditional preparations of boiled or steamed lobster or crab. Stir-fried or deep fried dishes and soups are also common. She-crab soup, available as a canned product in many countries, is an example of a product where gravid female animals are targeted.

VI. CHEMICAL COMPOSITION OF CAVIAR PRODUCTS

The chemical composition of caviar varies from species to species, with the condition and maturity of the eggs, within and between runs or harvest areas, and from year to year. Caviar composition also differs slightly due to the variation between eggs within a single skein. This is because the degree of the maturity of the eggs suitable for caviar is greatest in the anterior end of the skein, with the eggs becoming more immature as you progress from the head to the tail of the fish.

The caloric content of caviar is between 370 and 320 calories/100 g and can vary with the quality and fat content (6). Salmon caviar products are highly digestible and have been used traditionally in Russia to aid the recovery of surgical patients and to treat rickets in children. Black caviar (osetra) has 251 to 282 kcal/100 g, with other varieties having a somewhat lower caloric content (220 to 255 kcal/100 g) (6). Caviar has formed the basis for fat diets over the years. Caviar is a recent addition to salon hair care products and cosmetics because of alleged benefits from the protein, lipid conditioners and vitamin content.

Fish roe are also a rich source of vitamins. Salmon eggs contain 50 to 3000 IU/g vitamin A, 5 to 25 IU/g vitamin D, 10 to 80 IU/100 g vitamins B1, B2, and B12 and 10 to 30 IU/100 g vitamin C. The vitamin content of catfish roe includes: vitamin A −2 mg/100 g, vitamin C −0.26 mg/100 g, vitamin D −0.2 mg/100 g, vitamin E −0.1 mg/100 g (13). Mineral nutrients include calcium, iron, magnesium, manganese, phosphorus, potassium, copper, and zinc (13)(24).

A. Proximate Composition of Fish Roe

Like poultry eggs, fish roe have high concentrations of lipid and protein. In general fish roe products are high in protein (16 to 30%). Crude lipid content can vary from less than 5 to 20% with an average value for salmon of around 10%. The lipid content of fish roe can double on a dry weight basis as the roe matures. After the roe is brined, the percentage of moisture decreases, the protein content increases because water is removed during the brining process. The ash content increases because of the added salt, and the lipid content increases proportionately as moisture is removed during brining and curing.

Like poultry eggs, the distribution of macronutrients within individual eggs is not uniform. For example, the interior fluid of coho salmon (*O. kisutch*) eggs constitutes 98% of the volume of the egg and is primarily a clear to translucent protein solution. A waxy low-density lipid fraction and oil droplets constitute the remaining volume. For chum salmon (*O. keta*) the volume of the oil droplet comprises up to 10% of the volume of the individual egg with lipids in the mature roe constituting about 13.5% of the wet weight of the egg.

The protein quality of fish roe is high with methionine/cystine or typtophan/tyrosine being the limiting amino acid. Table 161.3 shows the proximate composition of the unprocessed roe several roe producing aquatic animals along with data for muscle tissue and processed products.

B. Lipid Composition of Fish Roe and Fish Roe Products

Lipid composition and fatty acid profiles have been used to evaluate caviar quality and to determine the species of origin. With few exceptions, the predominant lipid components in fish roe are triglycerides and phospholipids. Also, lipid classes and the ratio of different lipid classes have been evaluated as a basis for objective quality assessment traits. In fish with a total lipid content of 10 to 15%, the majority of the lipid (ca. 70%) is polar lipid (15). For example, Baltic herring (*Clupea harengus*) and roach (*Rutilus rutilus*) have polar lipid contents of 75 to 90% (17). Table 161.4 provides compositional information for lipids for selected roe products and muscle tissue.

For fish with a high level of polar lipids, phospholipids may serve as an energy source rather than triglycerides, being more easily mobilized in the eggs. The requirement for alternative sources of energy for the egg is influenced by different species dependent incubation periods for individual fish. Fish from the same order or family can have widely differing ratios of triglycerides to phospholipids in the roe, for example chum salmon

TABLE 161.3
Proximate Composition of Roe, Roe Products, and Muscle Tissue (Average Values)

Data from (6).

(*O. keta*) vs. steelhead (or sea) trout (*O. mykiss*) and cod (*Gadus* sp.) vs. hake (*Merluccius* sp.).

Diet can affect the lipid profile of caviar products. For example, cultured Gulf sturgeon roe (*Acipenser oxyrinchus* desotoi) has a different fatty acid composition than that of the wild Gulf sturgeon (12). The cultured sturgeon had a higher ω-3 fatty acid content (13.8 to 30.2) than wild caught sturgeon (8.86 to 15.5) and a different lipid profile generally, but these conclusions are based upon very limited data.

A high relative proportion of neutral lipids are often used to define roe ripeness (6),(17),(20),(21),(25). The higher lipid content, in general, of the Salmonidae roe compared with Clupeidae roe may be a result of differences in energy needs for the fertilized eggs (17), even though the muscle tissue of the Clupeidae is among the food fish with the highest muscle fat content. The lipid content of the roe from either Salmonidae or Clupeidae does not vary greatly with the degree of maturation or from year to year (17). For whitefish (*Corengonus albula*) (total lipid: 6.6 to 9.8%, 14% salt), there are proportionately greater triacylglycerols (66%) content compared with phospholipids (31%). Lecithin is the major phospholipid (90%). These products contain high cholesterol, 1.3 to 1.6% of total lipid (6).

Certain roes have an unusual lipid profile. Sand eel (*Ammodytes lancea*) and capelin (*Mallotus vilosus*) roe have high total lipid contents and a higher percentage of neutral lipid, over 75%. Capelin and sand eel also have high concentrations of steryl esters at a level that exceeds the free sterol content (15). These two fish have longer incubation times, roughly twice as long as many other

Northern marine fish, and the high neutral lipid content serves as an energy reserve for embryonic and early larval development. Levels of wax esters and steryl esters are high in mackerel (*Scomber japonicus*) and in mullet (*Mugil cephalus*) (20). The role of wax esters and steryl esters is unclear, but these may be used to determine the degree of maturity for some types of roe. Wax and steryl esters may play a role in buoyancy, permeability control, serve as insulation, or as an energy reserve for the eggs during incubation (17). These esters may also serve as a fatty acid reserve for modifying structural lipids after the fertilization of the eggs has occurred.

C. Cholesterol Content of Fish Roes

The cholesterol content of roe is about one-fourth of that of chicken eggs. The cholesterol content of vertebrate fish roe ranges from 200 to 500 mg/100 g. Some fish such as smelt, kahawai, and channel catfish are higher with cholesterol values 550 to 640 mg/100 g (Table 161.3). The cholesterol content of the roe is substantially higher than muscle tissue, generally by a factor of 10 for finfish but less for invertebrates (Table 161.3). Salmonid roes contain variable amounts of cholesterol (Table 161.3).

VII. GRADING AND QUALITY ATTRIBUTES OF ROE PRODUCTS

Upon completion of the curing process, caviars are graded and packaged. Grading can be a very labor-intensive process. During grading, any crushed or broken eggs are removed, along with "bullets," which are bitter, dark, undeveloped eggs. The amount of effort spent grading a product is proportionate to the final product quality and to the overall value of the product.

Roe may be graded according to flavor. Salmon eggs from sockeye, coho, or Chinook have a slightly bitter taste, a main reason the popularity of these roes is lower than for pink and chum salmon eggs, which tend to be sweeter. Salmon from stocks with longer migration patterns may tend to produce roe with higher lipid content a smoother mouth feel and a richer flavor profile. High quality product from early salmon runs have high value as these are the first new products of the season. Sensory properties of roe from different regional fisheries, *e.g.,* Hokkaido, Eastern Russia, and Alaska are different, although there have been no systematic studies to substantiate these variations. Little effort has been made to take advantage of these differences between strains for wild harvested products, or to investigate how to improve flavor and texture profiles for roe from culture operations. This will provide opportunities for market differentiation.

Taste is a primary consideration for grading products. With sturgeon, eggs may have a grassy or muddy aftertaste (11). The taste of the roe is dependent upon proper processing, the fish's feed, water conditions, maturity, harvest area, or culture practices and characteristics of the individual species. There is research currently underway investigating how the incorporation of vitamin E into sturgeon diets may to improve the flavor stability of black caviar. The flavor/taste of the eggs may change, be masked, or disappear after salting.

Color of roe is also critical to grade. There are color standards for many species of fish. This is particularly important for salmon, as the color ranges from light orange to a bright reddish orange. Because the color of roe can vary widely within a single lot from the same species, product is sorted to match. Consistent color for ikura in the Japanese market is very important to a high price, so both sujiko and ikura are matched in retail units whenever possible.

The color of sturgeon eggs is also highly variable, ranging in shades of gray (light to dark), black, yellowish gray, brownish gray, greenish gray, and even a dark golden color (11). Eggs from other fish species are pale shades of gray, yellow, pink, green, or brown. Depending upon the product, some roe are colored and sold as an imitation of the roe of another species (*e.g*., dyed herring roe for flying fish roe (tobiko); lumpfish roe for "black" sturgeon or paddlefish caviar). Regardless, the highest quality product involves uniform coloration.

Some caviar products are also graded by size. Sturgeon eggs, due to their high value, are typically size graded. Sturgeon eggs have three sizes: small (diameter $<$2.2 mm), medium (diameter = 2.2 to 2.5 mm), and large (diameter $>$2.5 mm). High-quality ikura (salmon caviar) may also be graded by egg size. Generally, larger fish produce larger eggs. The size of salmonid eggs varies: 3 to 5 mm diameter and larger for chum salmon, 3 mm or larger for pink, sockeye, and coho roe, and 6 to 8 mm for Chinook roe. Maturity, feed quality and nutritional status affect egg size.

Shell or sheath toughness is another factor considered when grading roe products. Manual or mechanical tests, which squeeze the egg until it breaks, test for product toughness. This process works best with larger eggs that come from salmon and sturgeon because their outer membranes are not as strong as smaller eggs from herring or carp. Toughness provides an indication of maturity although many factors can be involved. In salmon and most other species, soft eggs are an indication of immaturity. The situation for sturgeon is not so simple, with changes in egg texture varying less dramatically as the egg matures. Eggs from all fish will become soft as a result of enzymic degradation or microbial decomposition. Frozen eggs also tend to be softer than fresh ones.

Controlled proteolysis is an important feature for flavor development in roe products such as tarako and karasumi from pollock or cod roe and for traditional products made

from salmon roe. Sturgeon caviar is commonly aged under refrigeration for a month or more prior to retail sale for flavor and color development. Sturgeon caviar darkens and develops an oxidized paint-like and somewhat fishy flavor during aging which is desirable is some markets. Changes during aging result from endogenous and most likely microbial enzymes in the caviar under microaerophilic conditions. Psychrotropic lactic acid bacteria may be involved in flavor development as well as a souring form of decomposition. A new market for unaged sturgeon caviar is being developed. This product should be popular with the US market and others that prefer a mild flavored product. Production of unaged product is now possible as a result of a wider availability roe from the controlled harvest of cultured sturgeon.

VIII. PACKAGING ROE PRODUCTS

Vegetable oil (olive or cottonseed for sturgeon caviar) or glycerol is sometimes added to the packaged eggs to give a bright, shiny appearance and to prevent the eggs from sticking together. Salmon caviar is commonly packaged in plastic containers often with double bottoms, with the layer closest to the product perforated, to allow for draining, curing and drying. Traditional cotton lined wooden boxes (500 g to 3 kilo) are still popular in the Japanese market although plastic is replacing it due to food safety considerations. After curing, the packaged roe is compressed to remove additional water and reduce the water activity somewhat. This also removes entrained air and reduces spoilage from lipid oxidation and microbial growth. Traditional dehydration methods for caviar exposed the product to airborne bacteria; other methods sometimes used are centrifugation or drying with controlled currents of clean air (6). Modified atmosphere packaging and/or vacuum packaging are becoming more popular. Some products are pasteurized. Ikura has a shelf life of approximately 5 days at refrigeration temperatures, but can be stored for a year at −20°F.

Sturgeon caviar is often packaged into 2-part metal tins of 1.8 kilos (4 lb) that have a slot for drainage along one side wall. Lids are placed onto containers that have been overfilled by 10–15% and pressed down. The tins are laid on their sides to allow fluid to drain from the product during curing. After 2 h, the tins are placed under weight to further compress the caviar and remove excess liquid and air. Finally, a thick rubber band is placed around the circumference of the tin to secure the lid. Product is aged for a number of months at super chilled conditions of –2–8°C. For retail sale, the caviar is repackaged into smaller containers generally glass jars (1, 2, and 4 oz) with screw cap, crimp seal, or press-on vacuum closures. Retail tins up to 100 g and wholesale tins of up to 1 kg are also sold. Caviar is also packaged in crystal and in gold plated containers. Interestingly, an American, Harry Dolbro developed the familiar two part metal can plus rubber band packaging system for aging black caviar around 1900. He also developed the concept of marketing caviar in small 2 and 4 oz glass jars. Prior to this, the standard packaging for black caviar was a 135 pound wooden keg (4).

After the caviar is packaged, it is stored at −2 to −3°C. Depending upon the microbial load of the product, the shelf life can be several months. Frozen storage of a year or more is also possible. Addition of a variety of preservatives, including borate (unfortunately not permitted in US), antioxidants, chlorous acid, and nisin can extend shelf life. Unapproved compounds including formaldehyde have been added to improve storage stability. New processes are currently being evaluated to extend product shelf life and enhance product safety including various combined technologies (e.g. antimicrobials and mild heating), dielectric thermal processing methods, and cryogenic freezing. High hydrostatic pressure processes are most likely not feasible for pasteurizing caviar product, as the roe become elastic and loose translucency at pressures above 45 KPSI.

Lumpfish roe is generally packed in 10.5-kg plastic barrels. Iceland and Canada are the major producers of lumpfish caviar (6). Icelandic companies process a large percentage of the green roe into ready-to-eat lumpfish caviar products. The most common product forms are dyed cured roe packaged in 50- and 100-g glass jars with screw- or lug-type closures.

Alaska pollock roe (mentaiko) is sold in several different forms. The highest quality is defect-free matched skeins in which both ovaries are of uniform size with the oviduct intact, with no bruises, no prominent dark veins, no discolorations, and no cuts. Intact skeins of pollock roe, which include defects, are of lower value. Retail packages can be as small as a single vacuum-packaged pack containing a set of matched skeins.

Other product forms include 4, 8, and 16 oz plastic trays (traditionally black in color with a clear lid), 500 g or larger boxes of skeins, nicely arranged, or marinated products sold in glass jars. Sometimes mentiko is packaged in flat 100-g (3.5 oz) cans for retail sale.

Broken skeins of mentaiko are of the lowest value. This product is shipped frozen in bulk primarily to Japan or Korea. It may be marinated in salt or highly spiced with hot chili ("spicy roe"). In addition to pollock, spicy roe can be made from either pollock, cod, capelin, herring, mullet, whiting, Southern blue whiting (*Micromesistius australis*), hoki (*Macruronus novaezelandiae*), flying fish, or sometimes lumpfish roe. Spicy roe is usually packaged in small 30–250 g glass or plastic containers for retail sale.

IX. FOOD SAFETY ISSUES ASSOCIATED WITH ROE PRODUCTS

Salted fish roe products are often ready to eat. However, roe are heat labile and can only be heated to a temperature of 70°C without the eggs becoming dull or loosing color

(6)(11)(27). Irreversible protein denaturation occurs between 70 to 80°C. Some caviar can be pasteurized, but this is not yet a widely used practice and the pasteurized product is not of as high a perceived quality as unpasteurized. Refrigerated caviar products are often packaged in the same way as pasteurized products (*e.g.*, in glass jars), and the possibility of inadvertent or unintentional thermal abuse is a risk and can occur if products are either not adequately labeled or label instructions are ignored by the retailer or consumer. Market requirements for time temperature indicators may improve this situation.

The United States Food and Drug Administration requirement for roe products call for a combination of refrigerated temperature and either a pH at or below 4.6, a water phase salt content at or above 3.5% or a water activity at or below 0.97. The water phase salt content at or above 3.5% is actually a value identified for cured and smoked foods, and FDA guidance (28) actually recommends 5% for caviar products despite a lack of scientific justification for this higher value. Only the combination of refrigerated temperature and the 0.97 water activity value appears to be practical for caviars if one wishes to retain the flavor and textural and other qualitative attributes associated with these highly valued products. All products we have tested with a water phase salt content of at least 3.5% have also met the water activity requirement of 0.97. The purpose of these measures is to protect the product against *Clostridium botulinum* growth.

The salt concentration and storage temperature are the factors relied on to preserve and make caviar safe, yet salt concentration varies widely among caviar products of the same type (Table 161.4). Adjusting pH is not an appropriate preventive measure for *Clostridium botulinum* or *Listeria monocytogenes* growth as suitable products cannot be made at pH $<$ 4.6. The pH of roe falls between 5.7 to 6.5 (6) and can decrease up to 0.5 unit during refrigerated storage. The pH of lumpfish caviar ranges from 4.8 to 5.9 (6)(14). At least for lumpfish caviar, products with a higher pH had greater acceptability, appearance, and flavor. A compilation of salt, pH, and water activity values for different caviar products are provided in Table 161.5.

Because caviar is a ready-to-eat product, the lack of suitable preservatives for caviars for most markets is a safety concern. Borax (0.l3%) and boracic acid (0.1%), urotropin(e) (0.1%), sorbic acid ($<$0.1%), sodium benzoate ($<$0.1%) and formic acid ($<$0.05%) may be added

TABLE 161.5
Salt Content, Water Activity and pH for Various Roe Products

Product	Storage Conditions	N[1]	Salt (% wt)	Water Activity	pH
Lumpfish	Refrigerated	4	6.33[2]	0.96	5.6
		2	7.74[2]	0.95	5.7
		4	6.81[2]	0.96	5.6

[2] Salt concentration in brine. Other values are % weight in the edible portion.

to sturgeon caviars. Formaldehyde is also found in some non-North American products. Nisin (<0.1%) is also a permitted additive in Russia. Recent research indicates that nisin in combination with a mild heat treatment is effective in both inactivating listeria and in preventing its outgrowth in sturgeon caviar (27).

Adulterated and misbranded products containing unapproved preservatives and color additive are routinely imported into the U.S. Borax is particularly problematic as it can mask decomposition. Adulterated and misbranded salmon caviar is somewhat less common, however, salmon roe product containing nitrate/nitrite can be found at retail.

The salt content and storage temperature of caviar are key preventive measures for producing a safe caviar product. In general, salt content alone may not be high enough to inhibit the germination of *C. botulinum* spores. *Clostridium botulinum* type E can grow at 4.5 to 6% salt and at temperatures of 3.3°C (28). Water phase salt concentrations of 10% will inhibit *C. botulinum* germination for low acid foods held at room temperature. It is unlikely that type E would germinate and grow in caviar products with a aw<0.97. Somewhat disconcerting are results from inoculated pack studies chum salmon ikura with *Clostridium sporogenes* (PA 3679) spores showing that at a water phase salt concentration of >13% with 200 ppm potassium nitrate, spores may still germinate and grow.

Pasteurization processes could improve caviar product safety. Pasteurization is the destruction of pathogenic vegetative cells. Thermal pasteurization processes have been used to extend the shelf life. Batch pasteurization in steam or water bath of air tight containers or vacuum packaged containers of caviar have been attempted with limited success. Because protein denaturation occurs in caviars between 70 to 80°C, long pasteurization times at 50 to 70°C are feasible, but cause loss of product quality. Within this range of temperature, the fish egg proteins do not undergo substantial coagulation and the appearance of the product remains visually the same. However, as a result of pasteurization, salmon caviar becomes slightly paler and soft, and immature salmon eggs lose their shape. At 56 to 60°C, only slight changes in pink salmon caviar color are noticeable (11). At 71°C, all the eggs appear dull; at 72°C, the egg yolk is completely coagulated and the caviar converts into a chewy, boiled egg mass. Conventional thermal pasteurization of sturgeon and whitefish caviar should be conducted at temperatures less than 65°C. For salmon and sturgeon, process temperatures up to 70°C can be used (27).

Development of a high temperature-short time pasteurization using radiofrequency pasteurization (27 MHz) shows great promise. Pasteurization extends the shelf life of the caviar, and allows short term storage at refrigeration temperatures (2 to 3 weeks). The D values of *Listeria* spp. for roe are within the range for meat and egg products. The D60°C value for *L. innocua* is 10 min for chum salmon (*Oncorhychus keta*) caviar (0.5% salt), 4.8 min for 2.5% salt. The D60°C for white sturgeon caviar (*Acipenser transmontanus*) (approx. 3% salt) range from 10 to 19 min.

X. CONCLUSION

The roe of literally hundreds of aquatic animals are used for food. Most of these roe products are brined or cured. Some are flavored or colored. The appearance, flavor and texture are all important sensory characteristics for these foods. Roe products are most commonly used in relatively small quantities as a hors d' oeuvres, as a condiment, a garnish, or as an ingredient. They are often associated with ethnic or gourmet foods and may be served with rice or in preparations with other aquatic foods, meat products or eggs.

Despite the importance of these products in international commerce, there is relatively little technical information available about the chemical composition, product quality, and food safety attributes of roe products in the scientific literature. As a result, all too often regulatory agencies have promulgated regulations or guidelines that are contrary to the consumer desired attributes of these products and which may not contribute to increased food safety. It would appear that increased education about and research on these products is warranted.

CONTENTS

I. INTRODUCTION

Heat transfer is one of the most important unit operations in the food industry; it is the cheapest and most efficient method of preservation. Almost all processes include supplying or removing heat by physical, chemical or biological methods. The objective of food heat treatment is the destruction of microbial populations and enzyme inactivation in order to prevent spoilage and proliferation of pathogens and spoilage microorganisms. Sanitation is ensured after heating; practically all microorganisms are destroyed or irreversibly damaged by heat (1). Process conditions – time and temperature – are the decisive applied factors according to the expected shelf life of the product, although heating also causes changes in physicochemical and biological food characteristics (2). Therefore, in order to ensure thermal processing efficiency several variables must be considered such as microbial survival rate and physicochemical composition and structure.

Heat processing also aims enzyme destruction. Intrinsic and extrinsic parameters leading to microbial destruction are practically the same to those involved in enzyme inactivation as microbial death is due to destruction of at least one enzymatic system resulting from denaturation of the protein moiety (3). Most foods, particularly meats, are consumed after heating as chemical constituents react improving sensory and nutritional characteristics. Conversely to microorganisms and enzymes, heat processing aims the least nutrient destruction (4). Even though, the same factors destroying or inhibiting microbial growth also accelerate nutrient loss. Therefore thermal processing of foods must reach a compromise between sanitation and quality.

II. THERMAL PROPERTIES OF FOODS

In order to calculate thermal processing efficiency, the following information is necessary:

- Thermal resistance of a given microorganism, as calculation basis (z- and F- values) (5).
- Temperature profile of the product. Thermal processing includes two transport phenomena: heat transfer where heat flows proportionally to the driving force and inverse of the resistance to flow; mass transfer within the food material and resulting from reactions among food component (lipids, proteins, minerals, etc.) (6).

In any food, thermal properties are determined by heat distribution within the product. These are mainly related to transference (thermal conductivity and specific heat) and physical properties (density and geometry) (7). Thermal conductivity in a food material depends on the thermal flow rate through the product. Heat is defined as energy transferred as a result of temperature gradients, the larger the temperature difference the higher the flow rate. In solid foods temperature difference between the product surface and the center determines the heating rate.

Heat penetration depends on the transfer mechanisms within the foods. Food heating depends on the surface heat transfer coefficient; physical properties of the food and container, if any; temperature difference between the heating medium; and food initial temperature and container size (8). However, food thermal processing assumes that heat transfer in the surface is very high; therefore resistance is only due to the food composition and structure. Knowing the type and extent of the driving forces involved transport parameters can be calculated (9).

The main mechanisms involved in heat transfer in food processing are conduction and convection. Conduction is transmitted within a solid due to vibrations of adjacent molecules. In meat canning, conduction occurs in meat chunks or in gelled canned pastes, such as luncheon meat. Heat transference rate through a uniform material depends on the area (A) and temperature gradient (ΔT) but inverse to the thickness of the material (L); it also depends on the thermal conductivity of the canned food and tin (k) (7). Fourier's law indicates this relationship

$$q = k\,(A\Delta T/L)$$

In meats, k is very low (1.89 kJ/h m°K) as compared to stainless steel (59.47 kJ/h m°K) (10). This makes conduction in food materials very inefficient.

Convection heating is mostly related to fluids, such as soups, brine, milk, etc., as a result of movement of differential densities when the fluid is heated or cooled. Convection can be accelerated if stirring is applied reducing the temperature difference. In this mechanism, heating depends on the area of transference (A), temperature difference (ΔT) and a constant, h, which depends on flow properties, type of surface and flow rate. For boiling water h = 1898 to 25308 kJ/h m°K, whereas for air h = 3.16 to 31.63 kJ/h m°K (11). Convection is based on Newton's law:

$$q = h\,A\Delta T$$

Canned foods with low viscosity or with small particles, such as soups or sausages in brine, have higher transfer coefficients as heat penetration follows a convection mechanism increased by can rotation. The mechanism can change from convection to conduction during heating of heat-induced gels, such as luncheon meats. As convection rate is higher than conduction, heating rate varies during processing (6).

Conductivity in meats depends on the direction in which heat is transferred. Pérez and Calvelo (12) reported that thermal conductivity in lean beef at 78.5% humidity and 0°C, applying thermal flow perpendicular to the meat fiber, is 0.411 kcal/m h°K, whereas under the same conditions, in lean beef at 75% humidity, if the flow is parallel, conductivity is 0.422 kcal/m h°K.

Heat transfer also depends on characteristics of the heating medium (Table 162.1). High coefficients mean high heat transference rates to the product surface. According to these figures, free convection in a smokehouse has the lowest transference rate; forced convection with a fan significantly increased heat transference rates.

III. THERMAL PROCESSES

Heat transfer principles can be applied to any material, including foods. However every thermal process has a specific aim, its severity varies accordingly. Hurdle effects are the result of particular event interactions (13). In order to alter food quality to a minimum extent, only necessary hurdles to obtain a microbiologically safe food with considerably extended shelf life must be applied. Therefore severity of heat treatments also depends on intrinsic microbial controls such as low pH, presence of bacteriostatic compounds, application further preservation methods such as refrigeration, etc. Because heat processing may alter food quality attributes, it is advisable it is as mild as possible, without

TABLE 162.1
Heat Transfer Coefficients of Heating Media (11)

Heating Medium	Coefficient (kcal/h m² °K)
Free convection in gases	2.5–25
Forced convection in gases	10–100
Forced convection in water	500–5000
Boiling water	1500–20000
Condensing steam	5000–15000

compromising quality or sanitation. If other antimicrobial hurdles are present, they must be taken into consideration.

There are four heating processes applied to food materials, based on temperature increase:

A. Scalding

It is generally applied to tissues before freezing, drying or canning. Conditions depend on the subsequent process. If scalding is applied before canning, the objective is to remove gases from tissues, to increase tissue temperature and to provide initial cleaning (14). When applied to meats, scalding usually results in volume reduction. Scalding temperatures are around 65°C (15).

B. Cooking

It is applied to improve sensory characteristics of the food material, although it also destroys a number of microorganisms and inactivates some enzymes. In meat processing "cooking" implies several heating methods: oven cooking, roasting, frying, boiling, steaming and grilling. How heat is applied to meats depends on the method. Oven cooking, roasting and grilling are carried out with dry heat and high temperature (around 100°C), whereas boiling and steaming are applied in water. Frying temperatures are above 200°C (8). Cooking is also a preservation method, if recontamination is prevented. In addition to enzyme destruction and reduction of microbial populations, cooking also destroys toxins present in the meat or from microbial origin and improves digestibility. However, it also promotes adverse changes such as nutrient depletion (5).

C. Pasteurization

In most cases, the aim of pasteurization is to destroy pathogens. Vegetative cells may survive, therefore a further preservation method, such as refrigeration, addition of antimicrobials, packaging or fermentation must be applied. Pasteurization time-temperature relationship depends on specific thermal resistance of a given strain and on food heat sensibility (14). Pasteurization temperatures are 140 to 150°C for 1 to 45 seconds, or 70 to 73°C for 15 to 20 seconds (8). Optimization of a pasteurization process depends on relative destruction rate of a given microorganisms without considerable altering quality factors.

Vegetative cells are destroyed at temperatures slightly higher than their maximum growth temperature, whereas spores can survive at much higher temperatures. Processing conditions vary depending on the microbial growth interval; pasteurization applies temperatures higher than those where microbial growing can occur (16). Meat products are generally pasteurized in water baths. The packed product is placed in stainless steel tanks and heated with water; cooling is carried out with cold water. Continuous pasteurization equipment consists in a long tank; the product is transported through the water in a conveyor (5).

D. Sterilization

A sterile product does not contain any viable microorganisms therefore the shelf life of sterilized foods is considerably extended even without the application of additional preservation methods. Because sterilization temperatures are above maximum to allow bacterial growth, this process destroys vegetative cells but not spores; sterilization process calculations are based on spore survival. However food sterilization in not practically achieved as, strictly speaking, sterility is the destruction of all spores or vegetative cells that can grow in normal storage conditions (5). Therefore, although pathogens are destroyed some non-pathogens may be inactivated preventing them to growth and reproduce. This is called commercial sterilization and depends on the type of food; storage conditions after heat treatment; cell or spore resistance; heat transfer characteristics of the food, container and heating medium; and initial microbial load. Time-temperature relationship of the sterilization process depends on the thermal resistance of a given microorganism, taken as indicator. *Clostridium botulinum* and *Clostridium sporgenes* are indicators for meat products (16).

Sterilized foods are packed in hermetically sealed containers in order to prevent recontamination. Under these circumstances aerobes do not grow and spores of strict anaerobes are less heat resistant than those of anaerobe (17). Even though, in some foods such as cured canned meats oxygen is not completely removed from the product. Spoilage due to anaerobe growth, such as *Bacillus subtilis* and *Bacillus mycoides* may occur. In this situation, in addition of moderate heat processing other preservation methods are necessary, such as curing or smoking (18).

IV. THERMAL PROCESSING OF MEATS

Basically, meat is subjected to two types of thermal treatment: cooking and canning.

A. Cooking

Meat cooking is carried out in forced convection ovens in batch and continuous operations. Convection and conduction are the dominant heat transfer mechanisms (8). Conduction is the main heat transfer mechanism within the product, starting from the product surface inwards in a transient state as temperature changes with time in any point within the product. Convection occurs from the heating medium to the product surface due to mixing of the heating medium. In free convection, fluid movement is due to density gradient resulting from temperature variation. Force convection is promoted when the fluid is moved using any

device, such as a fan (14). Convection from the heating medium to the product surface, and conduction from the product surface to the inner part of the food occur at the same time, for example, meat batters, stuffed in water permeable casing, or cuts such as ham, ribs or loins in stockings cooked in a forced convection oven (19).

Process variables in forced convection are cooking time, air velocity and relative humidity (dry bulb-wet bulb temperature) (5). If the heat transference coefficient to the product surface is small, convection from the heating medium to the product surface is the limitant force whereas if the coefficient is high the limitant is the conduction within the product (10).

Cooking can be also considered as a pasteurization process, as it is carried out at temperatures below 100°C. Meat in batch operations are manually placed and removed to and from the oven. Small ovens can process 180 kg of boneless ham; large ovens up to 25,000 kg. In a continuous operation the product is automatically transported in a conveyor through one or several cooking zones and through a cooling area (20).

A variation in meat oven cooking is smoking. It implies two processes taking place at the same time; with the exception of cold smoking where the aim is to impart flavor and to add preservative compounds such as phenols, the main process is cooking, smoking being a secondary procedure.

B. Canning

The basic purposes in canning are:

(a) All microorganisms (cells and spores) feasible to grow and produce toxins must be eliminated. Canned meat, to be safe from the public health point of view, must be free of *Cl. botulinum* the most dangerous agent producing a fairly heat-stable toxin (16).
(b) Spoilage microorganisms must be reduced to a safe limit.

Thermal processing is carried out in two ways: aseptic processing where the food is heated at conditions of commercial sterilization and placed in sterile containers which are subsequently sealed; and canning where the food is placed in the container, then sealed and finally sterilized. Process conditions are the same for both cases (21).

From the commercial point of view, any canned food is sterile if it is free of spoilage microorganism such as *Bacillus stearothermophilus* or *Clostridium perfringens* (commercially sterile). Spore-forming thermophiles such as *Cl. sporogenes* must be considered only when storage temperatures are high, as 40°C is their maximum growing temperature. However, *Clostridium thermosacaroliticum* spores, a spoilage bacterium, can survive at temperatures as high as 450°C. Heat treatment eliminating *Cl. botulinum* and *Cl. sporogenes* renders heat-stable foods with considerably long shelf life (22). Processing conditions to destroy vegetative cells are shown in Table 162.2.

Commercial sterilization consists in four stages: food preparation, can filling, can closing and sealing, and thermal processing (24). At industrial level it is carried out in batch and continuous operations, both are based on the heat transfer principles described before. The batch or retort method consists in loading the retort, closing and heating with vapor. The temperature is controlled throughout the process depending on calculated processing conditions. Pressure difference is also controlled to avoid deformation of large cans or lid blowing. The heat transfer mechanism is convection. Heating medium in continuous retorts is also vapor; as the cans are continuously moving in this process the heat transference rate is higher. In some systems cans are fed into the continuous retort through a pressure lock, moving along the system in a U-shaped conveyor where heating and cooling are applied (5).

V. TIME-TEMPERATURE PROFILE CALCULATION

As mentioned before, thermal process conditions are calculated on the basis of several considerations such as composition of the food material, expected shelf life, transportation and storage conditions, initial microbial load and specific present microflora, among others.

As thermal processing is aimed to destruction of microbial population responsible of spoilage or a health hazard, process calculation must take into consideration how the food material will be handled. Microbial associations in refrigerated meats consists of Gram negative, rod shaped, non-fermentative psychrotrophs of genus *Pseudomonas, Alcaligens, Flavobacterium, Shewella* and *Moraxella* (23). This association changes during curing, becoming dominant Gram positive microorganisms of genus *Micrococcus, Lactobacillus, Carnobacterium* and *Brochothrix* (25). Table 162.3 shows the growth interval of several microorganisms associated with meat spoilage.

TABLE 162.2
Processing Conditions to Destroy Vegetative Cells (8, 10, 15, 16)

Microorganism	Z-Value (°F)	D_{250} Value (min)
B. stearothermophilus	12.6	4.0
B subtilis	13.3 to 23.4	0.48 to 0.76
B. cereus	17.5	0.0065
B. megaterium	15.8	0.04
Clostridium sporogens	23.4	0.15
Cl. botulinum	17.8	0.21
Cl. thermosaccharolyticum	16–22	3.0 to 4.0

TABLE 162.3
Microorganisms Associated to Meat Spoilage (26)

Microorganism	Growth Interval
Psychorphiles	−5 to 35°C
Pseudomonas sp.	
Achromobacter	
Mesophiles	15 to 45°C
E. coli	
Bacillus subtilis	
Facultative thermophiles	24 to 54°C
Streptococcus thermophilus	
Clostridium perfringens	
Thermophiles	45 to 75°C
Clostridum thermosaccharolyticum	
Bacillus stearothermophilus	

TABLE 162.4
Pathogens Associated to Meats (8, 10, 14, 21)

Microorganism	Lethality (min)
Clostridium botulinum	$D_{65°C} = 0.1$
Vibrio sp.	$D_{70°C} = 0.3$
Aeromonas hydrophila	$D_{55°C} = 0.17$
Listeria monocytogens	$D_{60°C} = 1.9$
Salmonella sp.	$D_{60°C} = 0.2$
E.coli 0157:H7	$D_{60°C} = 4$
Staphylococcus aureus	$D_{60°C} = 0.4$

Several inactivation parameters have been developed as mathematical tools to obtain a time-temperature relationship necessary to achieve a successful treatment.

(a) D- and z-values. If a microbial population is subjected to temperatures slightly above those for its maximum growth temperature, vegetative cells or spores are destroyed due to the inactivation of enzymes present in the microorganisms. The destruction follows the exponential equation:

$$-(dc/dt) = kc$$

That is, cell concentration decreases (dc) with time (dt) in a direct proportion of cell concentration (c). In other words, 90% of the microorganisms are destroyed in a given time interval if constant temperature is applied. The time interval is different for each microorganism, and is called decimal reduction time (D). It represents the minutes necessary to destroy 90% of a given microbial population at constant temperature. Table 162.4 shows D values for some pathogens possibly associated to meats.

Therefore it is possible to compare thermal destruction of different microbial populations. D values are expressed at a given temperature ($D_{120°C}$). For example when heating at 110°C, 90% of the population of *Cl. sporogenes* (i.e. from 10^5 to 10^4) is reduced if heating is maintained for 10 min ($D_{110°C} = 10$ min). If the same population is heated at 115°C, the time necessary to reduce the population one logarithmic cycle at 115°C is 3 minutes ($D_{115°C} = 3$ min), and at 120°C it requires only 1 min ($D_{120°C} = 1$ min) (20).

Heat resistance for a given microorganism is given by z-values, indicating the temperature required decreasing D-values in 1/10.

(b) F-values. Calculation, evaluation and comparison of different heat treatments are achieved by the so-called F-value. This value represents the extent of thermal death of microorganisms and severity of the treatment in order to predict the product's shelf life. The practical importance of F-values is that the individual effect of each part of the process is additive. As it is impossible to rise the temperature in the container to 120°C in every point at the same time F = 1 concept is applied. It is the lethality effect of heating at 120°C for 1 min. F-values increase, depending on the severity of heat treatment required for given meat. F_s is the sum of all F-values in every parts of the container.

According to the F-value concept, each temperature above 100°C has a given lethal effect; it increases with temperature's increment. For instance, heating must be applied during certain time and temperature in order to have similar heat damage: 100 min at 101°C, 10 min at 110°C, 1 min at 120°C or 0.1 min at 130°C (8). Thermal treatments therefore depend on a time-temperature relationship. Increasing the temperature for 10°C, the time necessary to achieve the same thermal effect is 1/10. Heat treatments are also calculated taking into consideration the survival of spores from two of the most damaging bacteria in meat products: *Cl. botulinum* and *Cl. sporogenes*.

However, as heating is not homogenous in the entire can geometry, calculations are always done considering the temperature rise at the cold point (where heating is the slowest). In this point, the sum of all lethal effects is F_c. The position of the cold point is determined by the type of food material, therefore by its main heat transfer mechanisms, and to a certain extent by the agitation of the cans in the retort.

In conduction heating, the cold point is located in the geometrical center of the container. For viscous meat, with cans rotating during the heating cycle, the cold point is close to the geometric center. Rotation in this case does not substantially increase the heating rate.

In static heating of liquid or semisolid products, such as meat pieces in brine, where the leading heat transference mechanism is convection, the cold point is on the

vertical axis, one-third from the can bottom end (10). F_c is always lower than F_s due to the fact that heat effect in the center is always lower than in the rest of the container. When a thermal process is calculated for the first time, the cold point is located experimentally, using thermocouples (Figure 162.1).

A simple method to calculate the lethal effects during the heating and cooling phases consists of measuring with thermocouples the temperature at the cold point, and to calculate the corresponding F-values.

The relationship between D and F, taking into account the amount of cells before and after heat processing is:

$$F = D (\log a - \log b)$$

where a = initial cell load; b = final cell load.

It is assumed that low acid foods, as are most meat products, are heated at a temperature that assures total absence *Cl. botulinum* spores, and are microbial safe. In this case, spore counts must be reduced from 10^{12} to 10^{0} (24), that is, reducing the count 12 log cycles or 12D. This means that heating must be enough to find only 1 *Cl. botulinum* spore in 10^{12} cans, i.e. one spore per gram of meat or $1/10^{12}$. *Cl. botulinum* types A and B are reference microorganisms for D values at 120°C and 0.21 min., as follows:

$$F = 0.21 (\log 1 - \log 10^{-12})$$

$$F = 2.52$$

For *Cl. botulinum*, $D_{121°C} = 0.21$ min and z = 10°C. In order to reduce an assumed number of *Cl. botulinum* cells 12 log cycles, heat must be 12 times higher during 0.21 min, that is 2.52 min at 120°C. Heat processing of food around F = 2.5 is called "botulinum cook."
Lethality is calculated by the equation:

$$(\log t - \log F) / (\log 10) = (250 - T) / Z$$

where log 10 = 1; therefore log (t/F) = (250 − T) / Z.
The destruction rate per minute of a given microorganism at a temperature T in the process corresponds to the time, t, needed for the destruction of microorganism at that temperature. For every minute, lethality can be calculated at a given temperature, obtaining a curve. The area under the curve represents the total lethality of the process.

Another way to calculate the lethality necessary in a given process is by adding all F-values during the heating and cooling phases; this gives F_{total}, the sum of all F values.

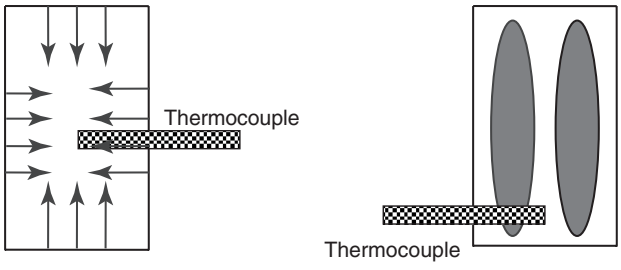

FIGURE 162.1 Location of cold point in conduction (left) and convection (right) mechanisms.

VI. EFFECT ON MEAT QUALITY

Quality improvement or deterioration of heat-treated foods depends on three factors:

- Type and amount of microorganisms in the food. Insufficient heat treatment may results in microbial survival and presence of metabolites such as gas, acid or off-odors and flavors. Inadequate cooling after heat treatment in processes such as canning encourages thermophile growth (26). Recontamination can also occur from microorganisms in cooling water lacking of suitable sanitary conditions.
- Chemical reactions of food components with one another or with the packaging material (27) can result in can or thermoformed package blowing.
- Physical alterations due to inadequate equipment or process operation, such as rapid increase in retort pressure, insufficient vacuum in packages or excessive package or can filling of the processing equipment.

Heat treatment severe enough to destroy *Cl. botulinum* or *Cl. prefringens* ensures the production of a stable food without the need of applying further special storage conditions. However, as severe heating can alter sensory characteristics, it is necessary to achieve a compromise between preservation and alteration of sensory attributes. Heat treatment can also improve sensory characteristics of meat, such as texture due to alteration of the muscle fibers, and flavor due to generation of aroma-related compounds (23).

VII. EFFECT OF MEAT PHYSICOCHEMICAL CHARACTERISTICS ON MICROBIAL GROWTH

Thermal properties in foods are altered due to changes in chemical components, such as protein denaturation, fat melting and water evaporation. Thermal conductivity in a meat batter is related to water content and increases with temperature and humidity. Carbohydrate, protein and fat protect microorganisms against thermal destruction due to their low heat transfer coefficients (28).

On the other hand, microbial resistance to destruction can be increased by physiochemical characteristics of the food material such as water, fat, carbohydrate, and protein and salt content; pH; and presence of inhibitory compounds. Quality and sanitary risks depend on microbial access to the food, a function of microbial characteristics of the contaminant strain; food intrinsic antimicrobial attributes; storage extrinsic conditions in particular temperature, oxygen availability and time; and microbial interactions (29). Physicochemical attributes that must be also considered when thermal processing is applied are:

A. Water Activity and Redox Potential

It is directly related to microbial growth. Dry meat products do not require further heat processing. Limiting a_w for *Cl. botulinum* is 0.97 for psychrothrophic species and 0.95 for mesophiles (30). There is also a correlation between a_w and redox potential. Raw meat has a redox potential around –50 mV; it changes after heating, for example, sausages have potential from +20 to –100 mV, depending on the degree of grinding and ingredients added. Vacuum and addition of reducing agents can further decrease the redox potential (21).

B. Oxygen Tension

It is particularly important for strict anaerobes such as *Clostridium* sp. or microaerobes as lactic acid bacteria. Canning cured meat, where some oxygen remain in the product, implies applying mild heat treatment conditions although other preservation methods such as curing or refrigeration are used. In this situation spoilage may occur due to the presence of aerobes such as *Bacillus subtilis* or *Bacillus mycoides*. Carbon dioxide addition displaces oxygen; together with low temperature storage carbon dioxide reduces Gram negative bacterial growth (32).

C. pH

Meat and meat products, with the exception of fermented meats, are a low acid food (>4.5). In this case, heat treatment must be more severe as potential pathogens or spoilage microorganism can grow in this environment. In most cases *Cl. botulinum* grows and produces toxins at pH close to neutrality (8,16).

It is a determinant factor for several inactivation processes; generally highly acidic (pH , 3.7) or acid (pH 3.7 to 4.5) foods do not represent a sanitary risk. Growth of Cl. botulinum does not occur at pH # 4.5. Only foods with moderate acidity (pH . 4.5) may present a risk due to Cl. botulinum growth; at this pH level it produces toxins and heat-resistant spores. This anaerobe can be present in canned foods, where low acidity and absence of oxygen are suitable to growth and produce toxins. Its spores are heat resistant; that destruction is the calculation criteria for thermal processing of low-acidity foods, such as meats. A and B are the most heat-resistant toxins but are destroyed heating at 100°C for 10 min. Preventing conditions leading to toxin and/or spore presence in the food is the process calculation criteria (33). In low acidic foods such as most meat products, processing is based on inactivation of *B. stearothermophilus*, spores, 20 times more resistant than *Cl. botulinum* spores and responsible, when germinating, of producing sour taste and gas.

D. Temperature

Meat storage of meats at 0–4°C promotes the growth of *Pseudomonas* and *Acinetobacter* spp.; at 20–25°C *Micrococcus* grows in addition to the previous two microorganisms; at 25–40°C there is a dominance of *Enterobacter, Clostridium* and *Bacillus* spp.; above 40°C *Clostridium* y *Bacillus* spp. proliferate (17).

E. Antimicrobial Agents

Such as added benzoate and sorbate, or chemical components of the food (organic acids, lysoszyme, medium length chain fatty acids) (34,35,36).

F. Physical Structure

Physical structures are at the same time a barrier and a way to migrate to the internal part of a food. Microbial growth starts initially in the food surface; this is particularly true with meats, where microbial contamination starts in the carcass or cut surface, finding its way to the inner part of the muscle through the perimysium. However, when meat is cut or minced, microbial population is rapidly distributed throughout the food (32).

G. Food Composition

As foods in general, and particularly meats, have more than one constituent (oil/water emulsions, protein gels, collagen casings, connective tissue, muscle fibers) heterogeneity must be considered (37,38). It promotes different habitats due to a variety of physical structures and chemical compositions that influence growth and colonization of specific microbial populations. Meat smoking establishes a concentration of phenol and other compounds, at the same time a humidity gradient is established from the sausage center outwards promoting different microbial ecologies throughout the product. Heat processing must be calculated to reduce a given microbial type and counts in the food section where microbes are most protected (16).

VIII. MICROWAVE HEATING

It is based in alignment of water dipoles when exposed to an electric field. As the microwaves change the direction of the electric field at rate around 5×10^9 per second, water dipole alignment also changes causing friction and producing thermal energy. The same direct heating, microbial inactivation is the result of enzyme destruction. However, the microwave may cause overheating of some areas due to excessive energy absorption as a result of food heterogeneity (8). Microwaves frequency is between 300 Mhz and 300 Ghz, wavelengths between 1 mm and 1 m, although domestic and industrial microwaves are between 915 Mhz and 2450 Mhz (11). At present, microwave heating is applied to meat and meat products only for cooking purposes.

CONTENTS

I. INTRODUCTION

Meat freezing is a necessity that has emerged and grown with the opening of world level markets. Meat industry, in its quest to become more competitive, has found itself constrained to establish marketing channels at a long distance and for extended periods. Even though refrigeration is one of the most commonly used preservation methods, it is insufficient to cover such needs. Therefore, freezing becomes a solution in spite of its high cost compared to refrigeration and a decrease of the price of thus preserved meat, which results in a paradox.

The primary need required for a meat processor is to have and to be acquainted with an equipment adapted in cost function and quality production. However, such need cannot always be covered due to the fact that the election criteria employed in its selection is based on company's capacity or facility to acquire such equipment. Nearly 80% of the water contained in fresh meat submitted to a −5°C (23°F) freezing temperature is actually frozen; but it will rise to nearly 90% if it is frozen at −30°C (−22°F) (1).

The different types of equipment that have been utilized for the freezing of meat and processed products are presented in this chapter. Freezing equipment is classified according to its heat transference system (air, contact, immersion); its operation procedures (batch, continuous or in line) and by product handling presentation (before or after packaging).

II. FREEZING EQUIPMENT

There are three basic red meat freezing methods applied at commercial level: freezing by air, freezing by immersion in a coolant medium and freezing by contact. The type of equipment will depend on the method utilized. References for different types of equipment and their utilization on meat are shown in Table 163.1.

A. Freezing by Air

Such a freezing method is quite common; air is the refrigerating medium in it. Its particular compatibility with food even before packaging is one of its multiple advantages, and regardless of form or product dimension, it can be perfectly adapted to the processor requirements (3). This last issue turns into a very important matter in meat freezing because of large bulks handled in certain cases (meat carcasses or large product boxes intended for ulterior transformation) (4). While freezing, cold air presents a low specific heat (1 kJ/kg°C) requiring just a small amount of energy to increase its temperature, which should be reflected in a low heat transference coefficient (25 to 35 $W/m^2°C$) that is translated in a lack of heat transference in an air-product interphase. Air freezing devices are determined to be regularly voluminous due to these air properties (5).

Ventilation is an important factor in air freezing, because as the air speed increases, the amount of heat relinquished by the food by time unit increases as well, due to an increase of heat transfer coefficient. Therefore, to absorb the heat being relinquished by a product while freezing, great amounts of air must be handled. The energy cost required by a ventilator determines the practical limitations which indicate air maximum speed. It is interesting to analyze if this energy cost has an impact in the process, considering that this cost rises due to an increase on air speed

TABLE 163.1
Equipment Utilized in Freezing of Meat

Freezing Method	Equipment	Application	Reference
By air	Chamber with plates	Meat carcass, cuts (with or without packaging)	(3) (4) (7) (11)
By air	Tunnel continuous	Meat carcass, cuts (with or without packaging)	(3) (9) (11)
Immersion	Liquid nitrogen	Meat in pieces, fish and chicken	(3) (6) (9) (11)
Cryogenic	Nitrogen atomizer	Meat, fish and fruits	(8) (9) (11)
Contact	Horizontal plates	Meat cuts (packaged)	(3) (11)
Contact	Vertical plates	Meat cuts (packaged)	(3) (11)

upon third potency approximately. In practice, frozen air will normally be expelled at −30°C if the fluid being frozen by the air (cryogenic fluid) reaches a −40°C temperature. In order for the air to reach a −40°C temperature it would be necessary to duplicate the freezer energy consumption so the freezer can lower its temperature (5).

Regarding red meat freezing by air, it can be carried on by utilizing some of the following procedures:

a) Cold storage room. There is no standard design equipment. They are chambers built specifically according to volume of the meat to be frozen (cuts or carcasses) and presentation (with or without package). Basically, they are rooms designed to operate at low temperature levels. Airflow within chambers can be controlled in them, but not the air flowing over the product (6). It is worth mentioning that due to air effect a product tends to dehydrate on its surface, which results in a mass loss and turns into an economical loss, especially if the meat has not been properly packaged.
   Beef carcasses can be frozen in forced air freezers, which are usually refrigerated from 16 to 48 hours before freezing at temperatures from −10 to −30°C and air velocities from 1 to 3.5 m/s. At temperatures lower than bovine carcasses (−30°C to −40°C) pork can also be frozen with no previous refrigeration and so can lamb carcasses (without refrigeration) at −20°C at a speed from 0.5 to 1 m/s for 12 to 18 hours. Regarding meat cuts freezing, either for processing or separate selling, the most common form is by using individual packaging or grouped by muscle type placed in 15 cm width boxes. Temperatures of −30°C and air velocities of 12 m/s are the conditions utilized (5).
b) Tunnel type: These are chambers equipped with vaporizers and ventilators, where cold air circulates through the products located on trays or in boxes from 20 to 30 kg. Such boxes and trays are prepared on stationary shelves or on cars that travel through the tunnel, either isolated or in series, separated enough so the air can freely circulate. As red meat freezes, it is suspended over transporters or rails (6)(7). Cold air flows perpendicularly to a product movement, providing air in the tunnel in continuous sections. This represents an advantage of having only one-way in and out for its unloading. Having a perpendicular cold air direction allows a heat exchange reduction between the air within and outside the tunnel. Another advantage is that thermal conditions to keep humidity level high in each section can be controlled avoiding evaporation and preventing dehydration on a product surface, which leads to burn by freezing. Thermal transportation in this type of freezing depends on dimensions and product form. A tunnel freezing equipment turns very flexible and adaptable to products of all dimensions and forms, packaged or not (4)(8).

B. Freezing by Immersion

A direct contact between the food or the container that holds the product and the coolant is established in this type of freezer. The methods to freeze can be either by submerging the food in a cold liquid or spraying the liquid on it, using brines and syrups as well as calcium chloride, ethylenglycol, propylenglycol and alcohol among others (6). This method has been in practice since the beginning of the freezing process. In freezing by direct immersion, coolants selection becomes limited, especially when the food is not covered by package. Thus the coolant must fulfill some characteristics, such as non-toxic, certain purity, free of coloring, flavors and strange odors, etc. Also, when it comes to packaged foods, it is also important that the coolant does not contain toxic products or substances that could corrode the container (9). Nowadays, this freezing method is employed in irregular form products such as meat, fish and chicken (4).

C. Cryogenic Freezers

In cryogenic freezing a direct contact between the coolant and the food takes place. It has been proven to be a good conservation method. In this equipment the coolant is not provided by a static cooling system, but it is a consequence

of the change phase from a heat-transmitting agent. Such agent can be a sublimatory solid (solid carbon dioxide) or a cryogenic liquid (a liquefied gas with an extremely low boiling point) such as liquid nitrogen at −195°C and carbon dioxide at −78°C (5)(10).

The liquid carbon dioxide under pressure is employed to reinforce conventional freezing lines by cold air or to provide a total refrigerating medium in a freezing room. A mixture of cold carbon dioxide and carbonic snow (solid) is produced when this liquid atomizes, which can establish contact with the food to freeze. Since liquid nitrogen boiling point is −196°C (at atmospheric pressure), freezing velocities are extremely fast. This provides a quality hardly reached by any other freezing method known. High heat transference coefficients between a solid and a coolant fluid can be obtained by using liquid nitrogen. Irregular formed products can be frozen as easy as rectangular blocks, as they can equally be frozen individually (Individually Quick Frozen, IQF). A frozen food production by this method offers an advantage, since it allows the consumer to acquire individual portions from a package, storing the rest until needed (3)(11).

Nitrogen is the most important cryogenic liquid used in freezing by immersion. It is employed for meat cuts, fish fillets, seafood, fruits, etc. The employment of this cryogenic liquid is common in freezing equipment through tunnels. A reference to several types of equipment used appears on Table 163.1.

The most commonly used equipment for this type of freezing is the one where a product enters from one side of the tunnel and nitrogen is sprayed from the other; when it vaporizes, cold nitrogen gas runs through the tunnel until reaching the product. The gas lowers product temperature before the sprayed nitrogen gets to it. Once in contact with the spray, its superficial temperature goes down to a value close to nitrogen temperature (−195°C). The product passes to an equilibrium zone where cold surface temperature as well as the hottest core temperature are equaled in order to reach uniform temperatures. Finally, water spraying is applied to induce the cold stored within the product to form a thin frost layer, which will protect it from storage dehydration. Immersion freezing equipment is more commonly used to freeze packaged white meat (chicken and turkey) than for red meats.

Generally, compared to any other method, liquid nitrogen freezing causes less losses by freezing dehydration and thawing drainage. This can represent up to 5% of the weight from some foods. If analyzed, this freezing process though expensive in some cases can prove profitable considering the quality and volume obtained; for instance, a large scale beef patties production. An advantage of this type of equipment is that its installation expenses are lower than others; approximately 30% less compared to any freezing system of the same capacity. Weight loss by the product dehydration is reduced (8).

D. Freezing by Contact

Freezing by contact includes methods in which food or food containers are in contact with a surface cooled by a refrigerant. When this method is utilized, the food or container is not in direct contact with the coolant (5)(12). Generally, it requires a flat surface or an almost flat surface to be in contact with the refrigerated plates for solids or packaged products. Thus, a contact between these plates and 1 or 2 surfaces from the food or food container can be established (9). A good operation from this type of equipment is achieved if the heat transmission coefficient between food and coolant is high and uniform. This is possible if there is a deep contact from the food to the package material, that is if the vessel material is completely full of food. Aluminum compounds employed for plates manufacture has improved freezers plates capacity significantly (3).

Contact equipment freezing time periods are shorter than for air freezing systems; for instance, cardboard boxes with 27 kg of meat are frozen from 14 to 16 hours instead of 20 to 24 hours in a freezing tunnel (13).

Freezing by contact can be made with equipment that operates with plates provided in a horizontal or vertical way. In both cases such devices assure a good thermal transmission in a short freezing period, assuming that the product itself is a good heat conductor. The advantage of this transfer is reduced when product thickness increases; this procedure is more frequently applied to a thickness that does not surpass 5 or 6 cm, limiting its use to meat cuts packaged over trays (4)(6). Although it is possible to place solid foods over an ice block or dry ice, it is rarely done at a commercial level. What is actually done is placing the food over plates, trays, transporting bands or even more cold walls frozen by a circulating coolant so that the food is kept in contact with a cold wall but indirectly in contact with the coolant. A more detailed description of equipment provided with horizontal and vertical plates is presented next (4)(10)(14).

a) Horizontal plates: In this case, a product is placed on trays or metallic tables, which can be accomplished manually or automatically. Automatic operation is carried out by doing the following: The battery from the plates can be moved upward or downward in an elevating system; at a load carrier level plates are separated and the packages accumulated on the conveyor are pushed among the plates, unloading simultaneously frozen packages on the opposite side. The operation is repeated until all the frozen packages have been replaced; the two plates are adjusted again afterwards, the set goes back up and a new cycle begins.
b) Vertical plates: They are mainly used for products in blocks from 10 to 15 kg, such as entire

fish or meat cuts. This equipment contains a set of cooled plates, which at intervals form the compartments where the product is placed. The frozen blocks are unloaded sideways, upwards or downwards.

Certain freezing processes by indirect contact must not be mistaken with direct immersion. In order to distinguish one from the other, a direct contact from the food or its vessel with its coolant must be apparent. It will be a direct immersion freezing if a slice of meat or a slice of meat covered by a film is submerged in a brine bath or if it is sprayed with it. If the same meat is placed in a metallic bucket and immersed, the food and its package are being frozen by indirect contact.

III. EQUIPMENT SELECTION

A wide range of equipment to freeze foods is available in the market. Thus, there is a long list of characteristics that must be fulfilled in order to select a method and freezing equipment. Until now a final selection has depended basically on the cost-benefit analysis that it represents. However, there are many factors affecting the adoption of a correct cooling installation and it is difficult to make the right decision. Among the main factors are (6)(7)(15):

a) An appropriate size or capacity for the production.
b) Space requirements.
c) Cost and benefits for equipment installation and maintenance.
d) Quantity of products and presentations that can be frozen.
e) Cooling power (Q) required.
f) Operation temperature from the cooling fluid (T∞).
g) Heat transmission coefficient (h) achieved for freezing operation (Table 163.2).
h) Energy recovered as well as freezing as part of the process in line.
i) Feasibility and method comparison regarding evaporation losses.

TABLE 163.2
Heat Transfer Coefficient of the Surface Layer According to Freezing Method

Freezing Method	Heat Transfer Coefficient W/(m²°K)
By Airflow	
Static	6–9
Air at 3 m/s	18
Air at 5 m/s	25–30
By Immersion	
In freon	500
In liquid nitrogen	1500
By Direct Contact	
Plates	100

Adapted from (8)(15).

Furthermore, some inherent characteristics must be considered:

1) Process: Damage to the product, hygiene, and safety (6).
2) Product: Composition (humidity, w), thermal conductivity (λ), specific heat (C), specific weight (ρ) and geometry (5)(12).

The equipment selection definitely depends also on the size of the company in a sense that a smaller company will give more credit to a direct cost–benefit analysis along with characteristics of the freezing product to freeze. On the other hand, in a medium size company, besides these factors, the listed points before must be analyzed and prioritized according to the expected benefits. In big size companies, these factors are completely taken into account and include some more of their own as to effort, personnel, machinery and storage time saving policies. However, all these factors become obsolete if an inventory of the freezers is not done. Good Handling Practice, which is using the right procedures or systems for in and out product control (Just On Time, In and Out frozen products, etc.). It is common to hear that "freezing is useless because it decreases products quality with its usage" when problems arise, which is not completely accurate. Therefore, it is important to train the commercail user on the equipment, operating conditions and products to freeze.

IV. CONCLUSIONS

The different types of equipment utilized in meat freezing were described in this chapter. Regarding carcass freezing and boxed meat, the use of air remains the most commonly used method at commercial level, especially because it represents a lower cost concerning the volumes handled. It is also worth emphasizing that the utilization of contact freezing and the use of cryogenic agents offer greater advantages based on the ultimate quality of the product being frozen. Therefore, its usage is still limited to cut meats, where the operation cost is covered by the sale of the product. In conclusion, a meat freezing equipment selection must be very carefully carried on and consider not only cost-benefit, but also priority factors according to company size and policies.

164 Dry-Cured Ham

Fidel Toldrá
Instituto de Agroquímica y Tecnología de Alimentos (CSIC)

CONTENTS

I. INTRODUCTION

The origin of dry-cured ham is lost in ancient times, when humans used salting as a useful preservation tool for times of scarcity. The evolution of this product has followed a traditional route over the centuries, with oral transmission of the techniques involved from generation to generation but it was produced very empirically, with a rather limited knowledge of the process technology (1,2). In the last decades of the 20th century, rapid advances in the scientific knowledge of the chemistry, biochemistry, and microbiology involved in the process were made (3); this knowledge prompted successful developments in technology and significant progress in quality standardization (4).

The wide variety of processing technologies (with important variations in the conditions for drying, ripening, smoking, etc.) as well as the important influence of the hams used as raw material (genetic type, feed, rearing system, etc.) make for important variations in quality, especially in sensory characteristics. Main types of hams and the most important processing technologies are described in this chapter.

II. TYPES OF PRODUCTS

Some of the most important and well-known hams are listed in Table 164.1. Iberian hams are produced in the

TABLE 164.1
Main Characteristics of Dry-Cured Hams World-Wide

Dry-Cured Ham	Country of Origin	Approx. Length of Process (Months)	Smoking
Iberian	Spain	24–36	No
Serrano	Spain	9–18	No
Bayonne	France	9–12	No
Corsican	France	24	No
Parma	Italy	12–18	No
San Danielle	Italy	9–18	No
Katenschinken	Germany	3–5	Yes
Westphalia	Germany	3–5	Yes
Country-Style	U.S.	3–9	Yes
Sauna	Finland	2–4	Yes
Ching Hua	China	3–6	Yes
Yunnan	China	3–6	Yes

Source: Ref. 3.

southwest region of Spain by a long process that usually takes 2–3 years and gives an unique typical flavor. Hams originate from autochthonous heavy pigs (around 150 kg live weight), grown in extensive system and fattened with acorns (2). Similarly, Corsican hams take a long time (18 months) to produce in Corsica (France) and are made from autochthonous heavy pigs grown in extensive system and fattened with chestnuts, although the output is restricted due to the low number of pigs.

Hams from certain crossbreeds of white pigs constitute the raw material for Spanish Serrano, Italian San Danielle, and French Bayonne dry-cured hams. These pigs are slaughtered at 110 kg live weight whereas those used for Italian Parma hams are heavier (150 kg live weight). Dry-cured hams may receive different labels in the European Union (EU) area, such as Protected Designation of Origin, Protected Geographical Indication, or Traditional Speciality Guaranteed, depending on the specific region and particular regulations (e.g., type of crossbreeds, type of feed, slaughter age, processing technology). These hams are controlled by consortiums, such as the Parma Consortium or the Serrano Foundation, that verify the fulfillment of the specific requirements. All these hams can be eaten and require no further smoking or cooking (5).

Country-style ham is produced in the United States, particularly in Kentucky and Virginia. Hams are salted, dried for at least 70 days or even longer for better flavor development, and then smoked. The traditional German Westphalian ham, the German cold smoked ham (Katenschinken), and the Finnish ''sauna'' hams are dry-salted, left for a few weeks in vats or wooden barrels, and then smoked (6). Hams are also produced in other areas such as China, where typical hams like Ching Hua or Yunnan enjoy great acceptance (7).

III. PROCESSING TECHNOLOGY

Traditionally, pigs were reared at home and slaughtered by the end of November or early December so that hams could be salted and then left for salt diffusion during the coldest months. During the spring and summer, hams were ripened and dried, becoming ready for consumption by autumn (almost one year of total process). The production sites were usually located in the mountains, with cool and dry weather conditions favoring this process. The windows of the rooms were opened or closed depending on visual and tactile assessment by an experienced operator. Of course, this method was transmitted from fathers to sons, but the subjective assessment resulted in a great variability in the final quality. Today, most modern factories use computer-controlled drying chambers that allow a full control of air speed, temperature, and relative humidity. The final quality depends on the length of the process because time is needed for the enzymatic and chemical development of flavor, as will be discussed later. In general, the process is as schematized in Figure 164.1 and consists of the following stages.

A. Reception

Pork legs are classified when they arrive at the factory in order to facilitate their correct processing. This classification depends on the particular area but is usually based on ham weight, pH, and fat thickness (3). The composition of fatty acids in the fat mainly depends on the animals's feed (8) and, to a minor degree on the crossbreed used (9) but is of extreme importance for correct flavor development. Depending on the composition of certain polyunsaturated fatty acids, hams may develop an adequate flavor or may experience undesirable oxidation and develop rancid off-flavors. Fat may be controlled through the iodine index (as an indicator of unsaturation) and the acid index (as an indicator of freshness).

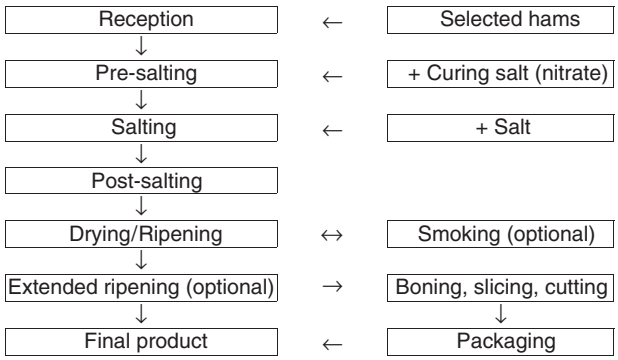

FIGURE 164.1 Process flow diagram for the processing of dry-cured hams.

The exudative hams, with a condition known as pale, soft, and exudative (PSE), have a low water-binding capacity and may sustain important weight losses, substantially higher than normal hams (10). In addition, PSE hams have a pale color and a wetted surface that facilitates the dissolution and penetration of the added salt but, on the other hand, results in an excessive salt uptake and unpleasant salty taste. Other groups of hams, those having high ultimate pH and known as dark firm, and dry (DFD), must be rejected in order to avoid microbial contamination.

Although the modern meat industry uses standard pigs, hams produced from older pigs usually are of better quality due to the higher amount of myoglobin (improved color) and different enzyme profile (better flavor profile) (11,12).

The skin is partially removed, leaving an area where salt will penetrate and water will evaporate. Hams are then registered to facilitate traceability, subjected to pressing rollers for bleeding, and left for 1 or 2 days under refrigerated storage (2–4°C) to reach a uniform temperature. Frozen hams are allowed to thaw until a temperature of about 4°C is reached inside the ham.

B. Presalting

This is a short stage during which nitrate is added to the hams in the form of a curing salt (sodium chloride with a small amount of potassium nitrate in order to get a final nitrate concentration of 150 mg kg^{-1} inside the ham) for a few minutes within a rotary drum (i.e., Spanish Serrano hams). The curing salt may be directly applied in the salting stage (i.e., for French and country-style hams). Nitrate and/or nitrite are used as protective agents against botulism (13) and slowly diffuse throughout the entire ham. Nitrate is reduced to nitrite by the action of nitrate reductase, a bacterial enzyme present in the natural flora (i.e., *Micrococcaceae*) of ham. This reduction is slow due to the low bacterial counts. Further formation of nitric oxide is achieved at slightly acid pH, as found into the ham and favored by curing adjuncts, such as ascorbic or erythorbic acids, that act as reducing substances. The maximum amount allowed in the European Union is 150 ppm potassium nitrate or 300 ppm for combination of potassium nitrate + sodium nitrite, and in the United States 156 ppm sodium nitrite (1/4 ounce per 100 pounds of meat). In some cases, the use of nitrate and/or nitrite is banned (i.e., Italian Parma ham).

C. Salting

Salt inhibits the growth of spoilage microorganisms by reducing the a_w; it also imparts a characteristic salty taste and increases the solubility of myofibrillar proteins. The main objective of the salting stage is to supply the necessary amount of salt to the outer surface of the hams. Absorbed salt is then slowly diffused through the whole piece during the postsalting stage. The amount of salt may be tightly controlled, on a weight basis, allowing time enough for its penetration into the piece (exact salt supply). So, hams are weighed one by one and the exact amount of salt per kilogram of ham is added on the lean surface. For instance, Parma hams receive 20–30 g medium-grain salt per kilogram on the lean surface and 10–20 g of wet salt per kilogram on the skin (14). Then, salt is hand-rubbed and left to be absorbed into the ham (14–21 days, depending on size).

In other cases, the amount of salt is undetermined but time of salting is strictly controlled. Hams are entirely surrounded by rough sea salt or refined mineral salt and then placed by layers into stainless steel bins with holes for the elimination of drippings. Salt may be rubbed onto the lean surface, and the hams are placed on shelves. This stage may last up to 13 days under refrigeration with 3–4% weight losses. In some cases, hams are salted again. Once the salting stage is finished, the excess salt is removed by brushing and water rinsing.

D. Post-salting or Resting

The main objective of this stage is to achieve salt equalization through the entire piece. Salt and nitrate must diffuse through the whole ham piece as shown in Figure 164.2. The required time may vary between 40 and 60 days, depending on many variables such as the size of the ham, pH, amount of fat, and conditions in the chamber. The relative humidity in the chamber is progressively reduced with time, and the typical weight losses are around 4–6%.

E. Smoking

The use of smoke is one of the oldest preservation technologies, and it is used for short term processed hams like American country-style or German Westphalia ham. The use of smoking is typical in areas where drying was originally more dificult (i.e., Northern countries) and gives a particular flavor and color to the hams. The smoke compounds also protect hams against molds or yeasts growth due to their bactericidal effects (15).

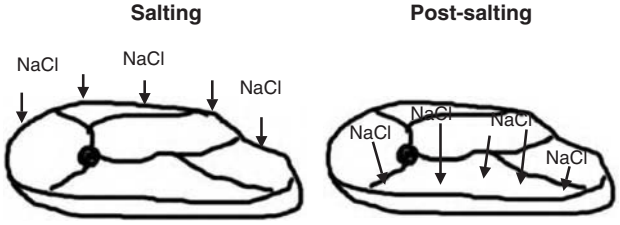

FIGURE 164.2 Scheme showing the uptake of salt and nitrate during the salting and then its diffusion during the post-salting stage.

F. Ripening-Drying

Hams are placed into modern computer-controlled drying chambers; some may contain up to 30,000 hams per chamber. Temperature, relative humidity, and air speed must be as homogeneous as possible and are carefully controlled and registered. Each type of ham has a specific set of variables along time of processing. For instance, Spanish hams are subjected to a progressive slow increase in temperature whereas French hams are heated to 22–26°C just after the post-salting stage. In all cases, these conditions allow the action of the endogenous enzymes, as will be described later. The length of the process depends on the type of ham (pH, size, amount of intramuscular fat, etc.) and drying conditions. Water is slowly diffused towards the outer part of the ham, specially the lean, for further evaporation once it reaches the ham surface as shown in Figure 164.3. The final expected weight loss (around 32–36%) is usually achieved within 6 to 9 months. Then, hams are covered with a layer of lard to avoid further dehydration and prevent any growth of molds and/or yeasts on the outer surface. Hams quality is monitored through a sniff test consisting of the insertion of a small probe in a specific area of the ham prone to spoilage and immediately smelled by an expert for detection of any off-flavor (14). The rapid development of commercial electronic noses and probes to get an objective assessment of flavor quality has led to their increased use for quality classification of hams (15).

G. Extended Ripening

Hams of high quality are further ripened in cellars for several months under mild conditions in order to get a full, rich flavor development. This is the case with Iberian hams, which may undergo 24 to 30 months of total processing time.

H. Final Product

Hams may be sold either as an entire piece (usually those of higher quality) or boned. Commercial distribution of sliced ham in vacuum-packages or under controlled atmosphere is increasing very fast (17). Boned hams are usually vacuum-packaged and distributed through retailers for final cutting into pieces or slices (see a slice in Figure 164.4). Hams are sliced by retailers or directly by consumers at home.

IV. MICROBIAL EVOLUTION

The increased concentration of salt and progressive reduction in water activity constitute limiting factors for microbial growth (18). In fact, low bacterial counts have been found inside the hams (19). Some species of the Kocuria family with nitrate reductase activity are present in ham. Some microorganisms, such as *P. pentosaceus* and *S. xylosus*, which are present in the natural flora of ham, have been studied for their enzyme activity but no significant endoprotease activity was detected, only a minor exopeptidase activity (16) although *S. xylosus* also showed an important nitrate reductase activity. The enzyme profile of some lactic acid bacteria has been also studied, because they could be used as microbial starters to accelerate the process. In fact, *L. sakei*, *L. curvatus*, *L. casei*, and *L. plantarum* have shown good endo- and exo-proteolytic activity against myofibrillar and sarcoplasmic proteins (21–24).

Molds can grow and develop on the outer surface of the ham due to the humidity and temperature conditions in the curing chambers when no precautions are taken. The most common mold is Penicillium (25), but some yeasts, mainly *Candida zeylanoides* in early stages and *Debaryomices hansenii*, also may grow (26). The isolated molds (around 75%) have shown good antimicrobial activity against *Staphylococcus aureus* and are able to inhibit its growth (25).

V. PHYSICAL AND CHEMICAL CHANGES DURING THE PROCESS

Main chemical changes are the result of changes in composition due to water loss and salt penetration as shown in Figures 164.2 and 164.3. The diffusion of water through

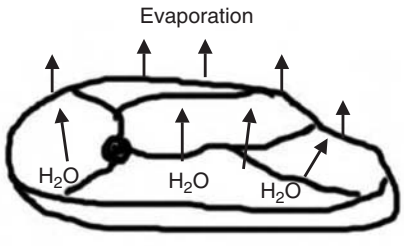

FIGURE 164.3 Scheme showing the diffusion of water towards the outer lean areas and then its evaporation once it reaches the surface.

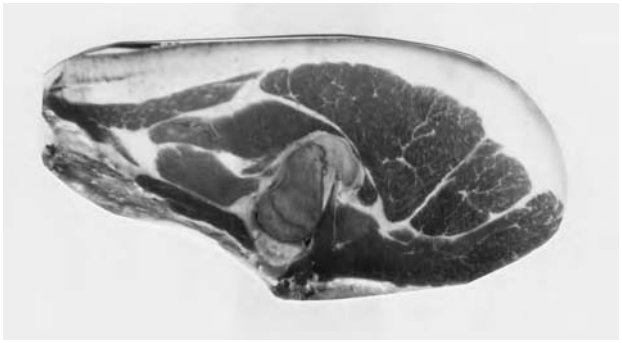

FIGURE 164.4 Cross-section of a typical dry-cured ham.

the ham and its evaporation when reaching the surface is a slow and difficult process. Both rates must be equilibrated to achieve adequate drying and, in this sense, it is very important to have the water sorption isotherms to predict the required time for drying. Diffusion of salt is also very slow and is affected by many variables such as temperature, size of the ham, pH, amount of moisture, and intramuscular fat. It takes around 3–4 months to get full salt equalization through the entire piece, although the salt profile may change a little depending on the particular moisture content in each muscle. pH increases from initial values of around 5.6–5.8 to values near 6.4 toward the end of the process. PSE hams have a pH evolution similar to normal ones (10,27). This evolution constitutes a narrow range where all the enzymes and chemical reactions operate (28). However, even slight variation in pH might affect the action of muscle enzymes; for example, more intense proteolysis has been reported in low-pH hams (29).

VI. BIOCHEMICAL CHANGES DURING THE PROCESS

Many biochemical changes have been reported during the processing of dry-cured ham, most of them bring a consequence of enzymatic reactions. Some of these changes are restricted to the beginning of the process; such is the case with nucleotide breakdown reactions or the glycolysis-related enzymes and subsequent generation of lactic acid. Proteolysis and lipolysis constitute two of the most important enzymatic phenomena, responsible for the generation of compounds with direct influence on taste and aroma.

A. PROTEOLYSIS

Proteolysis consists of the progressive degradation and breakdown of major meat proteins (sarcoplasmic and myofibrillar proteins) and the subsequent generation of peptides and free amino acids. The result is a weakening of the myofibrillar network and generation of taste compounds; but its extent depends on many factors. One of the most important is the activity of endogenous muscle enzymes, which depends on the original crossbreeds (9,30) and the age of the pigs (11,12). Main muscle enzymes involved in these phenomena and their main properties are listed in Table 164.2. These enzymes show a great stability in long dry-curing processes like hams (19,31). Other important factors are related to the processing technology: for instance, the temperature and time of ripening will determine the major or minor action of the enzymes, and the amount of added salt, which is a known inhibitor of cathepsins and other proteases, will also regulate the enzyme action (32–35). Excessive softness in ham has been correlated with high cathepsin B activity and low salt content (36,37).

Great amounts of small peptides, in the range of 2700 to 4500 Da or even below 2700 Da, are generated during the process (38–40) although this generation may be depressed by the level of salt that inhibits muscle peptidases (41). Some of these peptides give characteristic tastes (38). Recently, several tri- and dipeptides have been isolated in flavorful fractions and sequenced (42). Final generation of free amino acids by endogenous muscle aminopeptidases is very important, reaching impressive amounts as high as several hundreds of milligrams per 100 g of ham (43–46).

B. Lipolysis

Lipolysis consists of the breakdown of triacylglycerols by lipases and phospholipids by phospholipases, resulting in the generation of free fatty acids. These fatty acids may contribute directly to taste and indirectly to the generation of aroma compounds through further oxidation reactions. The relative amounts of released fatty acids will depend on the initial composition in fatty acids of both triacylglycerols and phospholipids. Fatty acid composition is strongly affected by dietary fat (56,57) and slightly affected by cross-breeding (58–60). Main lipolytic enzymes located in muscle and adipose tissue and involved in these phenomena are listed in Table 164.3. These enzymes show good stability through the full process (61–63). Although their activity also depends on pH, salt concetration, and water activity, the conditions found in the hams favor their action (64). The generation rate of free fatty acids in the muscle, especially oleic, linoleic, estearic, and palmitic acids, increases for up to 10 months during the process (65). Most of these fatty acids proceed from phospholipids degradation (3). After this time, a reverse trend is observed due to further oxidative reactions (62,66). In the case of adipose tissue, the rate of generation, especially of oleic, palmitic, linoleic, stearic, palmitoleic, and myristic acids, is also high up to 6 months (63). In the same way, a decrease in 14% of the triacylglycerols is observed (67).

C. Oxidation

The generated mono- and polyunsaturated fatty acids are susceptible to further oxidative reactions, giving rise to volatile compounds. The beginning of lipid oxidation is correlated to an adequate flavor development (68). In contrast, an excess of oxidation may lead to off-flavors. In fact, the generation of the characteristic aroma of dry-cured meat products correlates with the beginning of lipid oxidation. Free-radical formation is catalyzed by muscle oxidative enzymes, like peroxidases and cyclooxygenases, external light, heating, and the presence of moisture and/or metallic cations. The next step in oxidation is the formation of peroxide radicals (propagation), by reaction of free radicals with oxygen. The formed hydroxyperoxides (primary oxidation products) are flavorless but very reactive, giving secondary oxidation products that contribute to flavor (69). Oxidation is finished when free radicals react with each other. Main products from lipid oxidation (70–72) are aliphatic hydrocarbons (poor contribution to flavor), alcohols (high odor threshold), aldehydes (low odor threshold), and ketones. The last two groups are related to the aroma of dry-cured ham in French-type hams (73) and Spanish hams (74,75). Alcohols may interact with free carboxylic fatty acids, giving esters, especially when nitrate is not used, as in Parma ham, in which esters are generated in greater amounts and are well correlated with its aged odor (76).

VII. DEVELOPMENT OF SENSORY CHARACTERISTICS

A. Color

The color of dry-cured ham mainly depends on the concentration of its natural pigment myoglobin, which depends on the type of muscle and the age of the animal (77,78). So, myoglobin concentration is higher in muscles with oxidative pattern and in older animals. The typical bright-red color is due to nitrosomyoglobin, a compound formed after reaction of nitric oxide with myoglobin. About 10–40% of total myoglobin is transformed into nitrosomyoglobin (79). Those hams without added nitrate present a pinky-red color. Some surface colors on smoked hams may result from the pyrolytic decomposition of wood.

TABLE 164.3
Lipolytic Muscle and Adipose Tissue Enzymes and Main Properties

Enzyme	Main Action	Main Substrate	Opt. pH	Opt. Temp (°C)	Stability	Effect of Salt	References
Muscle							
Acid lipase	Lipase	Triacylglycerols	5.0	37	Months	Activation	61,62

Acid esterase	Esterase	Triacylglycerols	5.0	60	Years	"	62,63
Neutral esterase	"	"	7.5	45	Years	"	62,63

B. Texture

The texture of dry-cured hams depends on several factors, such as the extent of drying (loss of moisture), the extent of proteolysis (degree of myofibrillar protein breakdown), and the content of connective tissue (80). In fact, major structural proteins such as titin, nebulin, and troponin T are fully degraded whereas myosin heavy chain and α-actinin are partly proteolyzed (31,81). Some small fragments (150, 85, 40 and 14.4 Kda) appear as a consequence of proteolysis (1,28). The content of intramuscular fat also exerts a positive influence on some texture and appearance traits (82).

C. Flavor

1. Generation of Taste Compounds

Taste is closely related to the enzymatic breakdown of proteins and peptides into smaller peptides and free amino acids as summarized in Table 164.4. Glutamic and aspartic acids impart an acid taste and sodium salts give ham salty and umami tastes. Bitter taste is mainly associated with aromatic amino acids such as phenylalanine, tryptophane, and tyrosine; sweet taste with alanine, serine, proline, glycine, and hydroxyproline (38). The generation of all these free amino acids is extremely important in dry-cured ham (40,43,45) and is somehow affected by levels of salt (45,83). For instance, lysine and tyrosine are well correlated to an improvement in the aged taste of Parma ham (76), although in other cases, such as in French-type dry-cured ham, only a small effect on flavor development has been reported (73). An excess of proteolysis (proteolysis index higher than 29–30%) is undesirable because it may give a bitter or metallic aftertaste (76,84). Some sourness may be expected from the generation of free fatty acids if they are not followed by further reactions like oxidation. Specific tastes for dry-cured ham have been found after fractionation by gel filtration chromatography in several fractions with low molecular mass, below 2700 Da, accompanied by some nucleotides and a few compounds from protein-lipid interaction (38). Some of these tasty peptides, mainly di- and tripeptides, have been successfully purified and sequenced (42). Free amino acids may also serve as a source of volatile compounds during further ripening (85) or when the ham is heated, like the country-style ham (86).

2. Generation of Aroma Compounds

Aroma development in dry-cured ham is a very complex process involving numerous reactions such as chemical or enzymatic oxidation of unsaturated fatty acids and further interactions with proteins, peptides, and free amino acids (71,89). In fact, more than 200 volatile compounds have been reported in dry-cured hams (70,74,90–92) as summarized in Table 164.5. Some volatile compounds, such as 2-methyl propanal, 2-methyl butanal, and 3-methyl butanal, arise from Strecker degradation of the amino acids valine, isoleucine, and leucine, respectively. Some pyrazines formed through Maillard reactions between sugars and free amino acids, although in low amounts, also impart some characteristic aromas like nutty, green, earthy, and so forth. Final flavor depends on the mixture of characteristic aromas and odor thresholds for each compound, although, in general, ketones, esters, aromatic hydrocarbons, and pyrazines are correlated with pleasant aroma of ham (93). Some correlations have been found between some volatile compounds and specific characteristics of the process. For instance, the correlation of aged flavor of Parma ham with short-chain methyl-branched aldehydes, esters, and alcohols (76,94); hexanal, 3-methyl butanal, and dimethyl disulfide with short drying

TABLE 164.4
Main Groups of Non-Volatile Compounds Generated during the Processing of Dry-Cured Ham

Groups Non-Volatile Compounds	Main Origin	Characteristic Taste
Tri- and di-peptides	Proteolysis of proteins and larger peptides	Different tastes depending on amino acid composition
Phenylalanine, tyrosine, tryptophane, leucine, valine and isoleucine	Proteolysis of proteins and peptides	Bitter taste, may be strong when high concentration of these amino acids from intense proteolysis
Alanine, serine, proline, glycine and hydroxyproline	"	Sweet taste that depends on the reached concentrations
Sodium glutamate and aspartate	"	Umami taste
Inosine monophosphate	ATP degradation	Slight taste enhancement
Glutamic and aspartic acids	Proteolysis of proteins and peptides	Slight sour taste
Lactic acid	Postmortem glycolysis	Slight sour taste
Free fatty acids	Lipolysis of triacylglycerols and phospholipids	Very slight sour taste
Inorganic compounds	Salt, mainly NaCl, added during salting	Strong salty taste

Source: Refs. 3, 38, 42, 87, 88.

TABLE 164.5
Main Groups of Volatile Compounds Generated during the Processing of Dry-Cured Ham

Groups Volatile Compounds	Main Origin	General Characteristic Aromas
Aliphatic hydrocarbons	Autooxidation of lipids	Alkane, crackers
Aldehydes	Oxidation of free fatty acids	Green, pungent, fatty
Branched aldehydes	Strecker degradation of amino acids	Roasted cocoa, cheesy-green
Alcohols	Oxidative decomposition of lipids	Medicinal, onion, green, alcoholic
Ketones	β-keto acid decarboxylation or fatty acid ß-oxidation	Buttery, floral, fruity
Esters	Interaction of free carboxylic acids and alcohols	Fruity
Nitrogen compounds	Maillard reaction of amino acids with carbohydrates	Meaty, nutty, toasted nuts
Sulfur compounds	Sulfur containing amino acids	Dirty socks
Furans	Reaction of sulfur containing amino acids with carbohydrates	Ham-like, fishy

Source: Ref. 3.

processes (74); or methyl-branched aldehydes, secondary alcohols, methyl ketones, ethyl esters, and dimethyl trisulfide with nutty, cheesy, and salty descriptors (95).

VIII. ACCELERATED PROCESSING OF DRY-CURED HAMS

Many attempts have been made to accelerate the process, especially in country-style hams. Most of them try to accelerate the penetration and diffusion of salt into the hams, such as by boning and skinning of hams (96–98), mechanical tenderization through blade penetration prior to dry cure (99), tumbling in a revolving drum with bafles (100), or the direct use of nitric oxide instead of nitrate or nitrite (101). In other cases, more intense biochemical changes through papain injection (102), microbial inoculation (103), or membrane disruption by prefreezing and thawing of hams (104,105). Other attempts for reduction of the salting time have consisted on the substitution of the salting stage by using simultaneous brine thawing-salting method, that can be even further accelerated by performing vacuum impregnation (106). Future developments will include the addition of microorganisms with a determined enzyme profile or just a purified enzyme, microencapsulated in lyposomes or rubbed onto the outer surface of the hams, with specific roles to reinforce the action of the endogenous enzymes during the process.

165 Poultry Carcass Evaluation

M. Lourdes Pérez-Chabela and Alfonso Totosaus
Biotechnology Department, Universidad Autónoma Metropolitana-Iztapalapa

CONTENTS

I. INTRODUCTION

The low relative price of poultry meat and shifting consumer preferences have expanded poultry meat share of global meat output. In 2001, broad-based output gains were realized in most regions with that of developing countries growing by 3 percent. Global per capita consumption inched up slightly, from 11.2 to 11.3 kilograms/caput. While consumers in developing countries increased their intake slightly to 7.7 kg in 2001, shifting meat consumption preferences in the European Community, a region that accounts for only 13 percent of global consumption but accounted for almost 30 percent of the consumption gains in 2001, pushed up the average intake in developed countries from 24.1 to 24.8 kilograms/caput. Consumer preferences for poultry prompted global poultry trade to increase 4 percent in 2001 to 7.6 million tones, pushing up poultry's share of global meat trade to 44 percent. Asia, mainly China, is one of the largest poultry markets, resulted from lower domestic prices, as excess supplies built up due to Avian Flu problems that limited exports (1).

II. SLAUGHTER

Slaughter begins with the bird catching and preparation to transport from the poultry yard to the slaughterhouse. Since transport could be a very traumatic experience for any animal, many troubles could result from this operation. Main welfare problems in poultry (broiler, turkey and duck) industries are leg disorders, overstocking, underfeeding and cannibalism, inadequate bird inspection, catching and transport, and stunning. Although deaths during transport are low, congestive heart failure (CHF) has been related to 47% of bird's deaths, appeared to stress associated with loading and transport that precipitate the heart attack in broilers with CHF. In its severe form, CFH leads to ascites (water belly), and ascitic birds are not fit for human consumption. Another cause of death

is a different kind of traumas (Table 165.1), which account for about 35% of the total deaths (2).

In the slaughterhouse process line, the birds are unloaded and hanged from the legs in hooks. The conventional method of poultry processing involves shackling live birds and use electrical stunning using a multiple bird water bath stunner or directly to neck prior to bleeding. Generally the electric shock is between 100 to 500 volts. Alternatively, another novel method of killing poultry is by using gas mixtures, named controlled atmosphere stunning, using 90% of inert gases in air or a mixture of 30% carbon dioxide and 60% inert gases in air (3). Immediately the neck is sectioned for the bleeding, followed by an automatic plucking. The carcasses are washed and ready for the first inspection (4). Depending on the line process design, there are two ways to make the evisceration. In the first, generally an incision in the abdomen is made to retire intestines and the crop, gizzard, liver and heart are extracted and examined. Evisceration process is modified when the plant has a general inspection, where after the abdominal incision the liver and heart are exposed for inspection. Figure 165.1 is a check-point diagram of the general poultry process industry from the reception to process line. An automatic on-line inspection system developed in the Agricultural Research Service, where the system quickly diagnoses all physical or nonmicrobial, biological conditions that cause an inspector to remove a chicken from the processing line (5).

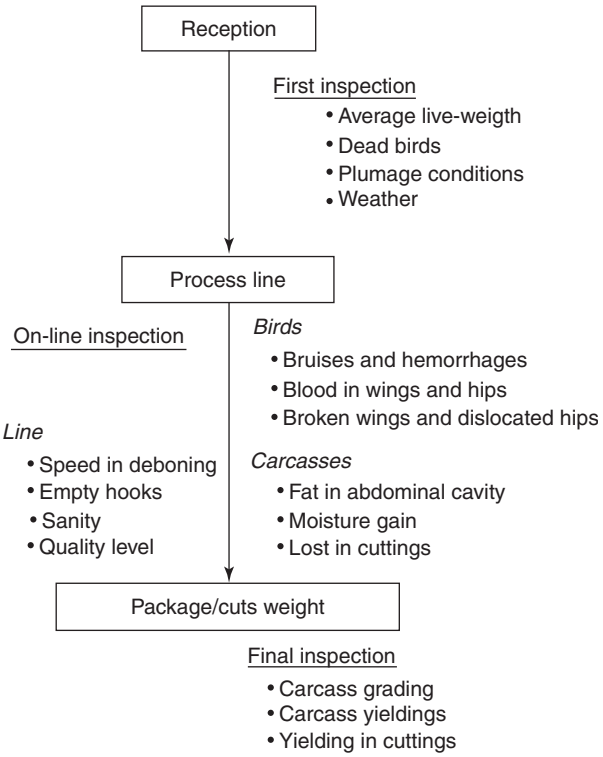

FIGURE 165.1 Check point by area in poultry processing.

III. MAIN FACTORS AFFECTING CARCASS QUALITY

A. Microbial Contamination

An important problem in poultry meat is the higher microbial contamination. Each carcass could contain bacteria from poultry yards, skin, pens and cross-fecal contamination during process, and microbial population in live birds can be as high as 10^4 cfu/cm^2 (6). To eliminate fecal contamination, the poultry processors employ interior and exterior washers. Fecal material could be difficult to remove, especially in two areas: wing and below the fat deposits. Many methods for poultry carcass decontamination have been suggested, as irradiation, electromagnetic waves, microwaves (7), but washing is the most common practice, including some chemical agents such as clorhexidine digluconate (8). Many studies have been made to reduce poultry carcass pathogens, such as *Salmonella* (9) *Salmonella enteritidis* (10) and *Escherichia coli* (11).

TABLE 165.1
Main Causes of Trauma that Cause Poultry Death

Dislocated or broken hip	76%
Liver or internal hemorrhages	14%
Head trauma	8%
Others	2%

B. Color

Some of the poultry muscles are white and others red due to myoglobin concentration. Because of different muscle activity, the oxygen demand will be different. Red and pink color and the blood in carcasses are the main problems in poultry plants. These colors are due to conditions before the slaughter and punches during birds handling. The stress due to heat and excitation can produce an abnormal red color and a high myoglobin concentration (12). Heat-shortening turkey meat is less red probably because the haem pigments are denatured by the high temperature-acid conditions, and this type of pale meat in turkey is similar to pale, soft, exhudative meat in pork (2). The handling and bleeding could cause bruises. There are two important forms of ante-mortem bruising in poultry: breast bruising and red wingtip, caused mainly by inadequate transport conditions (2). Figure 165.2 shows the location of common bruises.

C. Texture

Poultry breast muscle is an important eating quality criterion. The major factors affecting texture are the rate of

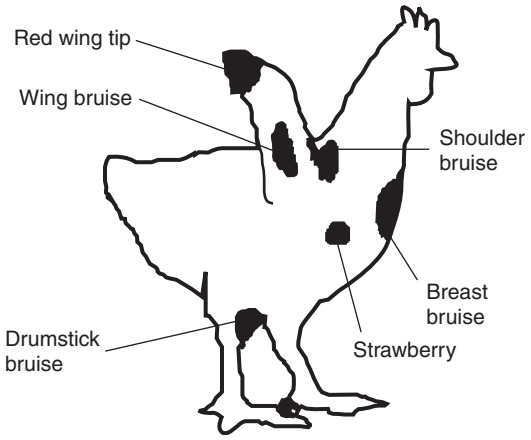

FIGURE 165.2 Location of common sites of bruising in poultry carcasses.

rigor development, rate of carcass chilling and filleting time. Stunning methods can affect texture mainly by altering the time course of rigor development and the extent of muscle contraction and relaxation occurring during early post-mortem (3).

If the birds are stressed before slaughter and this causes depletion of their muscle glycogen, the meat is likely to be more tender. On the other hand, if the birds struggle and flap their wings excessively just before slaughter, this will cause a build-up of lactic acid in the breast muscle and the meat is likely to be tough. In this last case the muscle glycogen is not depleted and becomes acidic whilst it is still hot. Meat toughness increases as the lactic acid content in the muscle at the time of slaughter increases. The increase toughness is due to more extensive muscle contraction during rigor development, and this effect is temperature dependent: the higher the temperature as the muscle goes into rigor, the stronger will be the contraction, named heat shortening. Breast meat is more prone to heat shortening than thigh meat. In turkeys, hot shortening is likely to be paler as well as having a lower water-holding capacity. In general, toughness in heat-shortened poultry meat does not resolve when the meat is left to age for 48 hours (2).

D. Poultry Carcass Electric Stimulation

An electric current applied three minutes after the plucking and cooling resulted in the ATP fall and pH reduction, increasing the meat tenderness (13). Electrical stimulation by breast contact has been commercially implemented in poultry plants, but there was difficulty in maintaining contact between the bird and the metal rub bar. When the birds contracted due to the stimulation, they pushed off of the bar, losing contact with the electrical current and decreasing the tenderizing effect. Using electrically stimulating carcasses at the neck in a saline bath could reduce the aging time, decreasing the costs (14).

IV. CARCASS EVALUATION METHODS

The objective of the estimation of carcass composition is to determine the edible part of the carcass. The differences among poultry carcasses have been of great economic significance for the meat industry. The most valuable carcasses are those that meet the highest quality standards and highest yields. To evaluate quality and yield is required to estimate and measure some characteristics of the carcass. Poultry can be commercialized in carcass or pieces. Figure 165.3 shows the main cuts for poultry.

A. Ante-mortem Methods

1. Ultrasound

The same equipment employed to monitored gestation, can be employed to determine the carcass composition. The images are received in real time and some measurement can be made to determine fat and muscular tissue. This can be made in live animals or birds and carcasses (15,16).

2. Live Weight

The live weight without the gastrointestinal content gives the empty body weight used for the carcass yielding. Poultry producers influence on carcass composition looking for a higher muscle proportion together with a convenient fat proportion and minimum bone (17). Table 165.2 show the carcass yielding of some poultry species (17,18,19,20). As observed, broilers and capons had the highest carcass yielding (up 90%) as compared with the other species. Geese and turkey had similar yielding (80–87%), followed by ducks. Ostrich had the lowest yielding, probably due to its bigger size and weight with more viscera content.

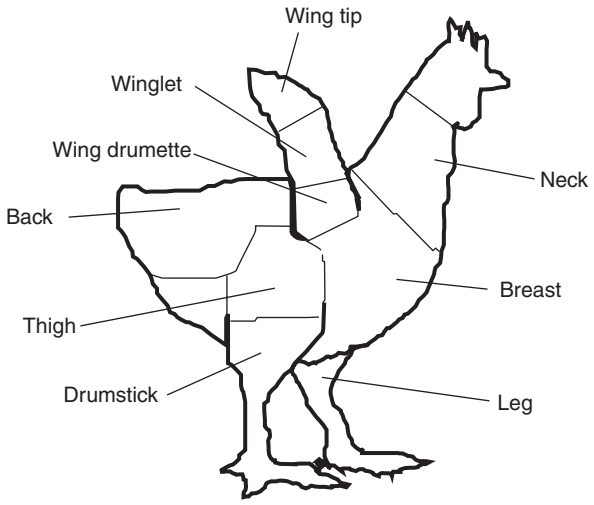

FIGURE 165.3 Main cuts in poultry carcass.

TABLE 165.2
Carcass Yielding for Some Poultry Species

	Live Weight (kg)	Hot Dressed (kg)	Yielding (%)
Broiler	1.92	1.71	88.89
Capons	3.92	3.51	89.66
Turkey	8.28	7.61	91.85
Pekin duck	2.57	2.18	85.09
Roaster	3.69	3.29	89.02
Geese	5.48	4.77	87.06
Ostrich	80.00	48.00	60.00
Duck	2.32	1.75	75.46

B. Post-mortem Methods

1. Electric Conductivity

The electric conductivity in the meat will be different as a function of the fat content. The higher the fat content the lower electric conductivity, because the fat and water content are inversely proportional. A fatty muscle has less water. These results are used to determine the fat, water and protein muscle composition. Total body electrical conductivity (TOBEC) is a technique that relies upon the differences in electrical conductivity and dielectric properties of the fat free and fat tissues to estimate body composition. The instrumentation used is an adaptation of the commercial device developed for determination of lean tissue in meat and live animals (21). The oscillating field with induces an electrical current in any conductive material placed within the coil. The actual measurement consists of the difference between the coil impedance when empty and that when the subject is inserted (22).

2. Optical Fibers

Fiber-optic light guides can be used for spectrophotometry within the carcass. But for illuminating and receiving apertures locates behind the cutting tip of the probe, light guides are restricted in their minimum radius of curvature and require a relatively thick shaft. A thick probe is difficult to push into the carcass. A beam splitter can be used to both illuminate and gather light from meat (23).

3. Multispectral Images

Recently, real-time multispectral image processing algorithms were developed for on-line poultry carcass inspection. The classification accuracy using dual wavelength spectral images was much higher than single wavelength spectral images in identifying unwholesome poultry carcasses. The classification accuracy was 91.1% for wholesome and 83.3% for unwholesome carcasses (24). In the system, which has been tested in commercial process poultry plants, when a chicken carcass on a hook dangling from a moving chain passes through a light beam, the interruption triggers a scan with a light probe from about an inch away. The reflected light is analyzed by a computer using Agricultural Research System-developed "Automated Poultry Inspector" software to identify variations in external skin color and texture and tissue composition, which are clues to problems (5).

V. INTERNATIONAL LEGISLATION ON POULTRY CARCASS GRADING

Generally speaking, quality refers to the appearance of carcass or meat and has become more important in determining consumer acceptability and retail price. Some of the more commons carcass and meat quality defects are: red wingtips or feather tracks, engorged wing veins, hemorrhagic wing veins or shoulders, in breast or/and legs, and dislocated or broken pectoral, wing or leg bones. The commercial significance of these defects varies according to market outlet. However, the prevalence of appearance defects can also lead to downgrading and loss of value of fresh carcasses (3). Normally, the categories are reduced to three, being the flesh in breast and thighs, ending of the breastbone, number of broken bones in carcass, exposed flesh, etc. (19). Figure 165.4 despite the main classification of poultry carcasses.

A. United States of America

In the United States, there are Standards for Quality of Ready-to-Cook Poultry (25), with three quality gradings: *A*, *B* and *C*. In the A Quality the carcass or part is free of deformities that detract from its appearance or that affect the normal distribution of flesh. Slight deformities may be present, with a well-developed layer of fat in the skin. The carcass or part shall have a clean appearance, especially

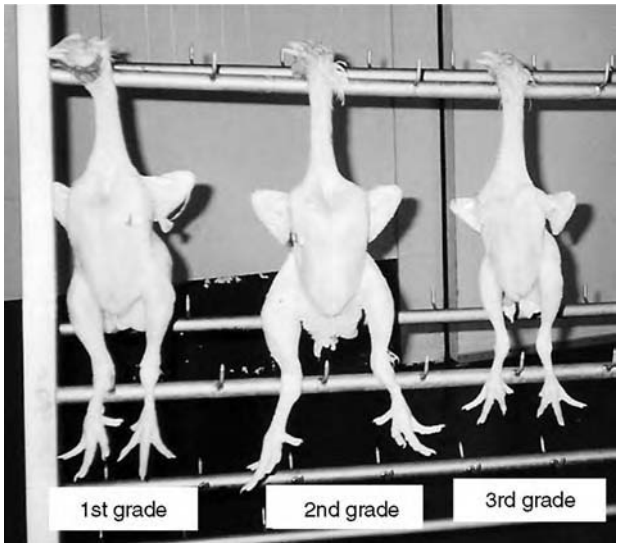

FIGURE 165.4 Poultry carcass grading or classification.

on the breast and legs. For all parts, trimming of the skin along the edge is allowed, provided that at least 75 percent of the normal skin cover associated with the part remains attached, and further provided that the remaining skin uniformly covers the outer surface in a manner that does not detract from the appearance of the parts, and is free of broken bones and free of disjointed bones. Discolorations that do not detract from the appearance of the product are allowed. Evidence of incomplete bleeding is not permitted. In the B Quality the carcass or part may have moderate deformities, such as a dented, curved, or crooked breast, crooked back or misshapen legs or wings, which do not materially affect the distribution of flesh or the appearance of the carcass or part. Any parts may be disjointed, but are free of broken bones, two disjointed bones, or one disjointed bone and no protruding broken bones. Discolorations are limited to moderately shaded areas and the carcass or part is free of serious defects. Evidence of incomplete bleeding shall be no more than slight. The skin and flesh shall have a sound appearance, but may lack brightness. The carcass or part may have a few pockmarks due to drying of the inner layer of skin. Carcasses that do not meet the requirements for A or B quality may be of C quality if the flesh is substantially intact. Both wings may be removed or neatly trimmed. Trimming of the breast and legs is permitted, but not to the extent that the normal meat yields is materially affected. The back may be trimmed in an area not wider than the base of the tail and extending from the tail to the area between the hip joints.

B. Canada

In Canada there are three grades of poultry carcasses: *Canada A*, *Utility* and *C* (26). The carcass of the grade Canada A is not deformed except for a slightly crooked keel bone that does not interfere with the normal placement of the meat. In the case of poultry, other than a turkey, the breast, thighs and back show evidence of fat cover. In the case of a turkey, the carcass has deposits of fat in the main feather tract on each side of the breast as indicated by a pronounced thickening at the center of each such area. The carcass has no prominent discolorations and no broken or dislocated bones; and does not have more than 3 cm of exposed flesh at the posterior end of the keel bone. Canada Utility carcass is not missing more than the wings, one leg including the thigh or both drumsticks, the tail, small areas of flesh, and skin not exceeding an area equivalent to one half of the area of the breast; where no flesh has been removed, the carcass breast has sufficient fullness of flesh on both sides of the keel bone to prevent a sharp falling away of flesh from the anterior to the posterior end and the keel bone does not project more than 3 mm beyond the flesh with a minimum fat cover to prevent the flesh from appearing prominently through the skin. The carcass has no dislocated bones other than in the wings or legs; and has no broken bones. In poultry carcass Canada C the wings or any part of them has been removed elsewhere than at a joint; and only a part of the drumsticks has been removed. Mature chicken may be graded as C if the carcass weighs more than 1.8 kg and the carcass breast has not sufficient fullness of flesh on both sides of the keel bone to prevent an extremely sharp falling away of flesh from the anterior to the posterior end, with prominent discolorations.

C. Mexico

In Mexico poultry carcasses are classified in three categories: *First* or *Mexico-Extra*, *Second* or *Mexico-1*, and Out of classification (27). The first category is defined by a well-developed musculature without deformations and a uniform fat distribution, besides no bruises or broken wings present, and an average weight of 1.950 kg including viscera and feet. The second are carcasses with a moderate musculature and enough fat to cover the muscle in breast, leg and thigh. This category allows two articulations separated in the wings, but with no severe damages. The minimum weight is 1.750 kg including viscera, head and feet. Finally, the carcasses out of classification are: a) those dead before slaughter; b) birds out of the Sanitary Legislation; c) birds with fracture, mutilations, hemorrhages, exposed flesh, out of the limits; d) pigmented with forbidden substances; e) present the incorporation of substances for weight gain; and f) pigmented birds by immersion. The approved and graded poultry carcasses can be commercialized in fresh or frozen. The main poultry in Mexico is consumed fresh.

Nonetheless, Mexican poultry grading for the international trades shall be similar to the described above. Poultry eligible for export under NAFTA rules would likely be processed in existing facilities and would represent a small percentage of Mexico's total production, besides U.S.-origin poultry carcasses and parts or products of poultry carcasses that are shipped to Mexico for processing and then returned to the United States (28).

D. European Community

The European Community (29) established regulations applied to the commercialization of poultry in the community territory, grading in two categories in agreement with carcass conformation and aspect. Poultry meat is included in Category *A* or *B* in agreement to carcass conformation and parts aspect. The category A is divided in *A1* and *A2*, taking in account the state of the carcass and fat cover, damage or contusions. Poultry carcass are commercialized in fresh, freeze or ultra freezing. To be classified into grade *A* or *B*, carcasses shall meet the following standards: carcass or part shall have to be intact, with a clean appearance,

without foreign material or blood. Some little protruding feathers and hairs are permitted on breast, thigh and back. Discrete discoloration or contusions are permitted as well. Wing tips can be missing. Fresh carcass shall have no evidence or previous freezing. Freezing and ultra freezing carcass have to be free of frozen burns, accepting little or discrete burns but not in breast or thighs. In the A category there are three classifications depending on the carcass weight: A or European chicken, no heads, no legs, ready to cook (1.0–1.1 kg); B or big chicken (1.8–2.2 kg) and C or small chicken (1 kg). A fourth grading of residue carcasses is not commercialized.

166 Canned Poultry Products: Turkey Ham

Edith Ponce-Alquicira
Departamento de Biotecnología, Universidad Autónoma Metropolitana-Iztapalapa

CONTENTS

I. BACKGROUND INFORMATION

A. Canning as a Preservation Food System

Canning is the technique of preserving food in airtight containers through the use of an extensive heat treatment that inactivates enzymes and kills microorganisms responsible for deterioration during storage. The airtight packaging protects the food from recontamination following sterilization, thus permitting storage at room temperature for many months without spoilage. In general canned meat products may be described as a convenience food, because they offer several advantages as they contain little or no additives, retain most of the nutritive value of raw materials, are ready-to-eat, shelf-stable, and easy to consume and handle [29].

This process is the basis of a large segment of the commercial food industry, a position that probably will continue despite the development of other means of preserving food. However, the food canning industry needs to renew itself continuously, in order to keep consumers' attention; especially nowadays, when market globalization politics

provide new opportunities for process and trade a great range of products from all over the world. Therefore, canners most offer safe and nutritive products; but also, use attractive containers, with opening features, heating instructions using microwave, several size serving portions, etc. In addition, the use of friendly environmental packaging materials that provide the same stability and safety of those conventional metal cans may be more attractive for consumers who demand healthy foods [23].

Developments in thermal processing involve new packaging materials as flexible retotable pouch and plastic containers. Addtionally, control systems for retorts are becoming more advanced, permitting real-time calculation of process lethality, and optimization of temperature and time required without excessive heating [8].

B. Poultry Meat

Poultry refers to any domesticated avian species, and poultry products can range from whole carcasses, cut-up carcasses, portions, boneless meat, or any further processed meat. Poultry production and consumption all over the world have increased considerably during the last years as it is shown in Table 166.1 with data obtained from U. S. Department of Foreign Agricultural Services [30]. Several variables influence buying decisions and eating patterns in short or long-term bases, including ethnic or religious traditions, diet and health concerns, as well as price and availability. Recently, consumer attitude about eating meat has been greatly influenced in relation to the saturated fat and cholesterol intake and their contribution to arteriosclerosis and heart attack. Additionally, recent outbreaks of Bovine spongiform encephalopathy (BSE) or foot-and-mouth disease have modified consumers' attitude against red meats [19].

Processed meats, including canning products now contain less fat (under 25% or lower), where poultry, especially chicken and turkey are popular as an alternative to manufacture healthy low fat meat products. U.S. trade projections (Figure 166.1) show an increasing demand for fresh poultry and processed poultry products, over other meat species such as pork or beef. This may be explained as poultry meat posseses a "plain" flavor easy to adapt to most recipes and it is an excellent choice to develop low-calorie products with the advantage of being a low cost protein source. Although, the presence of Avian Influenza and Sudden Acute Respiratory Syndrome (SARS) outbreaks in 2003 joined with stricter quarantine and sanitary requirements with a zero tolerance for salmonella and *E. coli* have had a stagnant effect on the poultry trade market all over the world.

All meat and meat products, including poultry must be subjected to inspection and declared suitable for human consumption; most countries have national laws and regulate inspections with specific requirements for conditions in which animals are reared, transported, slaughtered, and how products are prepared, distributed and sold. In the United States, poultry and poultry products are subject to the Poultry Products Inspection Act, which is enforced by the FDA Food Safety and Inspection Service. In Mexico, SAGARPA (Secretary of agriculture and rural development) dictates all regulations for food processing and distribution [30].

C. Types of Commercial Canned Poultry Products

Canned poultry products include a wide variety of products such as reformed and emulsion type products, or puree and soups formulated with chicken and turkey cubes. But most of them claim to be low fat products. Examples are cured breast of turkey, ham turkey, chunky chicken, chicken & vegetables, Vienna sausages, chicken soup, and chilorio (Mexican spiced poultry) that are shown in Figure 166.2.

1. Formed Products

Formed poultry products are boneless and uniform in composition; examples are hams, loaf and restructured products. They may be produced from sectioned muscle pieces or from grounded or chopped meat and shaped into a specific portion and size. Texture varies according to the initial material; for example, hams are primarily produced from intact muscles and have more a "whole-muscle" texture, while restructured products have a smaller particle size as they are produced from grounded or chopped meat.

Formed products are prepared from defatted whole muscle pieces bounded together after marinating, tumbling and cooking. Proteins form a network between meat pieces during heating to form a continuous body. Non-meat binders can be used to enhance cohesivity between meat pieces to obtain a whole meat-like texture; such as soy protein, casein or hydrocolloids, among others [26].

FIGURE 166.2 Variety of canned poultry products (includes sausages, soups, ham, pâté, chilorio, etc.).

2. Emulsified Products

Emulsified or comminuted poultry products include frankfurters, bologna or loaf items, and are usually prepared from chilled or frozen mechanically deboned poultry or turkey. Meat is homogenized in a cutter bowl with iced water, salt, cure, alkaline phosphates, starch, sodium erythorbate, milk or soy proteins, starch, gums and spices; to an end temperature of 15°C to avoid melting of fat that might result in fat caps or fatting-out after heating. Batter is then vacuum encased and cooked and after peeling, sausages are canned [26].

D. Composition and Physicochemical Properties of Meat

The process of canning begins with the selection of high-quality raw materials, where skeletal muscle is the main constituent. Turkey meat contains 75% moisture, 23% protein, 1.2% lipids and 1% minerals. Table 166.2 shows the principal skeletal muscle proteins, which are classified according to their solubility and location as: sarcoplasmic, myofibrillar and stroma fractions [17]. The myofibrillar or salt soluble fraction comprises more than 20 distinct proteins and represents about 60% of the total poultry

TABLE 166.2
Main Poultry Skeletal Muscle Proteins [17]

Protein Fractions	Content (% of total protein)

Reticulin	0.5

muscle protein. Myofibrillar proteins can be divided into three groups based on their function as: contractile (responsible of muscle contraction), regulatory (involved in regulation of contraction) and cytoskeletal proteins (responsible of myofibril integrity). The contractile proteins, myosin and actin have a large influence in muscle functionality; these proteins are usually forming the actomyosin complex in *post-rigor*, and contribute to functionality for comminuted and formed processed poultry products. The ratio of actin to myosin, as well as the ratio of free myosin to actomyosin, also influences the functional properties of poultry meat [17,23].

Sarcoplasmic proteins play a minor role in meat protein functionality, although myoglobin and other water-soluble compounds may have a great influence in color. Myoglobin consists of a heme group bound to the histidyl (His^{93}) residue of a single polypeptide chain as shown in Figure 166.3 [4]. The amount of myoglobin varies within species, age, and muscle fiber distribution; for instance, dark muscles in turkey thigh are mainly comprised of red fibers which containing more myoglobin than light breast muscles. White turkey meat contains from 0.1 to 0.4 mg of myoglobin/g, whereas dark meat ranges 0.6 to 2 mg/g. Moreover, mechanically deboned turkey (MDT) contains some bone marrow and will have higher pigment levels than manually deboned meat [12,26].

Stroma proteins are related to meat tenderness; collagen is the major stroma protein present in flesh and in poultry skin. When present in a high concentration in the

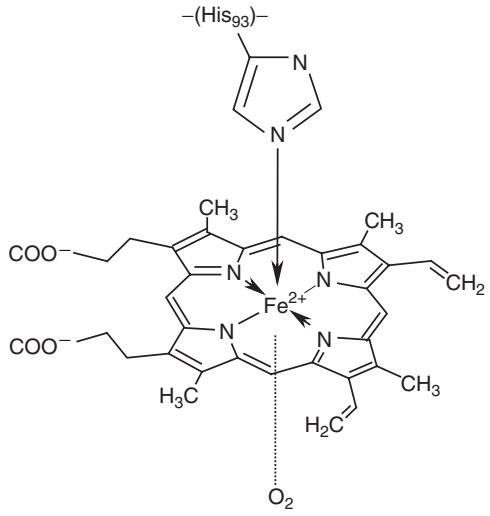

FIGURE 166.3 Myoglobin heme group bound to a histidyl (His_{93}) residue of the peptide chain and oxygen. (Adapted from Belitz and Grosch, 1999.)

poultry product formulation, collagen shrinkage may reduce functionality of myofibrillar proteins, reducing binding between meat pieces in formed products, and may reduce fat and water retention in comminuted products, especially when cooked at high temperatures [17,26].

Meat functionality is based on the physicochemical properties of proteins and determines its behavior during processing, storage and consumption. Poultry meat

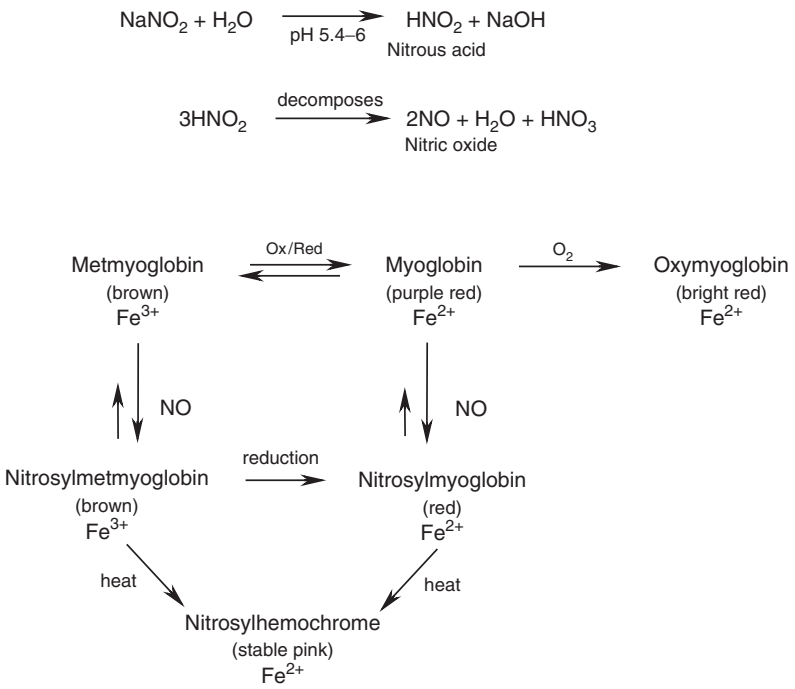

FIGURE 166.4 Reaction pathway leading to the formation of nitric oxide (NO) and nitrosylhemochrome pigment. (Adapted from Pearson and Gillett, 1999, and Smith and Acton, 2001.)

functionality is based on three types of molecular interactions as: protein hydration and water holding capacity (WHC), depending on protein-water interactions; while cohesivity and gelation are based on protein-protein interactions, and emulsifying is based on protein surface related properties. All these interactions are affected by intrinsic and extrinsic factors such as the type of protein, distribution of hydrophobic and hydrophilic groups on the protein surface, charge, and molecular flexibility. Extrinsic factors include pH value, salt concentration, phosphate salts, temperature, and integrity of meat, processing and addition of other non-meat additives [17].

The amount of total myofibrillar protein, the ratio of moisture to total protein, and the physicochemical condition (PSE or DFD) determine the functional properties of raw materials. Lean poultry meat contains 19 to 23% protein, while mechanically deboned poultry without skin has 14 to 16% protein and with skin 11 to 12% protein. Therefore, both poultry product formulation and processing must be designed in order to improve protein functionality and the final product quality [10].

1. Water Holding Capacity

Water holding capacity is the ability of meat to retain or absorb added water in the presence of an external force; this functional property is based on protein-water interactions. Water is held by muscle proteins, and physically entrapped within the muscle structure in the inter-filament spaces of myofibrils. Factors such as pH, salt concentration, process, and temperature influence the protein-water binding and the quality of the poultry meat product network [10,17].

Protein-water interactions are highly related to the state post-mortem. At the isoelectric point (pH ~ 5.1), myofibrillar proteins have no net charge and tend to aggregate. However, as the pH increases during resolution of rigor mortis, proteins become more negatively charged, with an increase in repulsive forces between myofibrils that leads to swelling, allowing more water to interact with proteins, and therefore, protein solubility and water holding capacity increase as proteins become more negatively charged.

Addition of salt up to 0.6 M (2–3.5%) NaCl reduces electrostatic interactions between proteins increasing protein extractability, solubility and water binding in both breast and tight muscle. In addition, alkaline phosphates in combination with salt and mechanical work increase pH and myofibrillar protein extraction and solubilization. Additionally, chopping or tumbling disrupts the muscle allowing the muscle fibers to absorb water and swell. However over-chopping or tumbling can lead to an excessive disintegration of muscle fibers and can induce protein denaturation, as it is also associated with an increase in temperature and excessive shearing. Denatured proteins as in PSE muscle form aggregates that have low water affinity and reduced emulsification and foaming abilities [17,23].

2. Cohesivity

During cooking muscle proteins denature and form a continuous cross-linked gel network, stabilized by a series of protein–protein interactions, such as electrostatic and hydrophobic interactions, hydrogen and disulfide bonds. Muscle protein gelation involves a series of steps. First, when muscle proteins are heated up to a critical temperature they unfold; in a second step, unfolded molecules aggregate to form an increasing viscous solution, then when the gelling point is reached, molecules aggregate into a continuous gel. Myofibrillar proteins form irreversible strong gels that are responsible for the textural and sensory properties, as well as the cooking yields of poultry products. Nevertheless, connective and sarcoplasmic proteins may interfere with the ability of myofibrillar proteins to form a gel [10,14].

3. Emulsifying

Poultry comminuted products such as sausages may be referred to as emulsions, as the fat tissue is comminuted and dispersed in small particles into a continuous salt/protein/water matrix. The stability of this system is influenced by pH value, ionic strength, melting range of the lipid, soluble protein content, and by temperature of processing.

Soluble and extracted meat proteins form a monomolecular film around the fat globules, proteins rearrange where polar regions are oriented towards the water phase, while non-polar regions align towards the fat droplets to minimize free energy [15,26].

Meat proteins show different emulsifying responses that decrease in the following order: myosin > actomyosin > sarcoplasmic proteins > actin. The hydrophobic heads of the myosin dip into the fat globules, while the tails interact with actomyosin in the continuous phase. Actomyosin binds water and contributes to stabilization of emulsion because of its viscous, elastic and cohesive properties. Comminuting is necessary to extract proteins, disrupt fat and to form an emulsion; also, concentration of protein must be sufficient to form continuous and stable film around the fat globules. During the emulsification stage, poultry batter temperature and chopping times should be monitored to avoid melting of the fat globules. Stable emulsions require at least 45% myofibrillar protein in the formulation with a maximum of 30% sarcoplasmic and connective proteins should be limited to less than 25% of total protein [15].

II. RAW MATERIALS PREPARATION

Canned turkey ham is a boneless-formed product, made from cured meat pieces bound together into a specific shape in a sealed container, and heat processed. This

TABLE 166.3
Basic Curing Brine Formula [23]

Component	%
Salt	2
Phosphate	0.5
Sucrose	0.5
Carrageenan	0.3
Sodium nitrite	156 ppm
Sodium erythorbate	450 ppm

product retains most of the nutritional value of raw materials, is ready-to-eat, shelf-stable, and convenient for consumers [15]. Process for the manufacture of canned turkey ham involves several stages such as meat conditioning, brine injection, vacuum tumbling, can filling, exhaustion, closing and sterilization [23].

Turkey ham may be prepared from boneless breast, legs, thighs, desinewed drumsticks, and MDT with or without skin. These raw materials may be chilled or frozen but without off-color, off-odor, or apparent microbial growth. The internal temperature of fresh cuts should not be above 4.4°C, while frozen materials should be below −18°C when received. Frozen cuts must be kept packaged during thawing to prevent dehydration, and to avoid the risk of microbial contamination until reaching −3.3 to −2.2°C. Turkey meat can be sliced, cubed or ground, according to the desired final texture, but up to 33% of the meat may be finely comminuted to provide good binding that resembles a whole "meat-like" texture and good water retention. Nevertheless, temperature must be kept below 10°C during these operations to avoid the risk of microbial growth [15,26,27].

III. CURING AND BRINE INJECTION

Meat is usually cured by injection of brine under pressure using a multineedle system, which facilitates and accelerates incorporation of the curing solution (see Table 166.3) [21]. Salt improves flavor, and in conjunction with phosphates extracts myofibrillar proteins producing a sticky surface that will bind meat chunks during thermal processing. Sodium chloride increases protein negative charge as well as protein repulsion, allowing more water to bind within the muscle fibers. On the other hand, alkaline phosphates increase pH and ionic strength allowing protein to uncoil exposing hydrophilic sites; therefore phosphates act in a synergistic way with sodium chloride to increase WHC and protein extraction [9,15,27].

Sodium nitrite is a multifunctional ingredient. It prevents the outgrowth of the anaerobic spore former *Clostridium botulinum*, which grows under anaerobic conditions as those created during canning. Some spores can survive normal heat processes and generate vegetative cells that produce lethal toxins [9,31]. The antibacterial properties of nitrite are based of the reaction of nitric oxide with SH groups to form nitroso thiols (R-S-NO), and by depriving anaerobic spore formers from available iron compounds with a key role in biochemical mechanisms [24]. Nitrite is also responsible for the development of the distinctive color and flavor of cured processed meats. Nitric oxide derived from sodium nitrite reacts with the heme iron of myoglobin and metmyoglobin to form nitrosylmyoglobin and the heat-stable pink nitrosylhemochrome after cooking [27] (see Figures 166.3 and 166.4). Although, color intensity depends on the myoglobin content of the raw material [4,11,21]. Nitrite also contributes to the flavor stability preventing warmed-over-flavors by complexing the heme iron, which could promote lipid oxidation reactions [31]. It has been reported that the non-heme iron is a potent prooxidant and it is released during heat processing as a result of porphyring breakdown, thus heating accelerates the release of iron from the heme complex [4]. Legal limits of initial nitrite levels are 200 ppm and 156 ppm for pasteurized and sterile canned hams, respectively; with residual levels of 100 and 120 ppm[6]. Finally, the addition of reducing agents such as sodium erythorbate accelerates curing, promotes formation of nitrosylhemochrome, and contributes to the flavor and color stability [15,21,31] (Figure 166.5).

IV. VACUUM TUMBLING

Injection followed by non-continuous tumbling cycles maximizes the quality of the product, as it permits a uniform distribution and absorption of curing ingredients, and extraction of salt-soluble proteins [15,16,21]. A vacuum tumbler consists of a large rotating tank with paddles

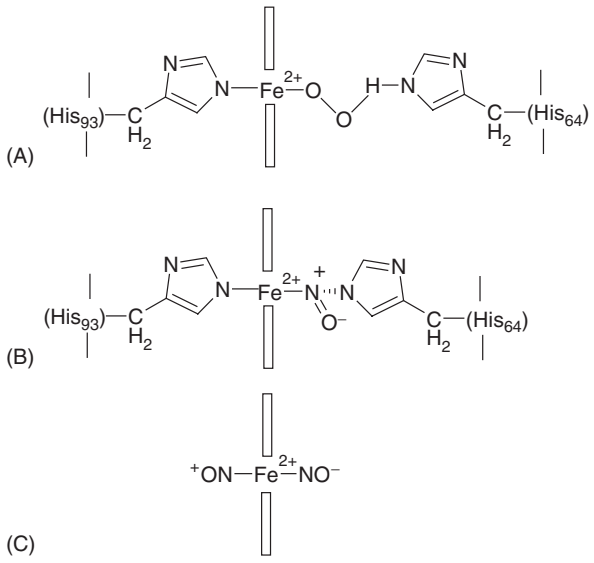

FIGURE 166.5 Heme ligands of (A) oxi-myoglobin, (B) Nitrosylmyoglobin and (C) Nitrosylhemocrome. (Adapted from Larousse and Brown 1997.)

inside, and jacketed walls to cool the product while tumbling. The temperature should be kept between 4 and 8°C, and the rotation rate between 3 and 15 rpm; a higher speed can cause cell breakdown and temperature increase thus reducing the quality of the final product. Vacuum tumbling has the advantage of speeding up the brine uptake, and avoiding formation of air bubbles within the product [9,16,21].

V. CONTAINER FILLING

Containers should be clean and washed before filling, the cured meat mix is then transferred into appropriate containers using an automatic vacuum filler as well as pressed to ensure elimination of air pockets [13,16,29]. Selection of the appropriate container is vital to maintain stability and organoleptic properties and avoid damage during transportation, storage and distribution. Packaging materials include metal, glass, and laminated containers. Semi-rigid containers made of nylon, surlyn, and other ethylene/vinilacetate copolymers are used for cook-in products that receive a pasteurizing treatments [29].

A. Metal Cans

Containers for poultry canning can be made in a variety of forms that include flat rectangles, tall and thin, squat, pot, pot-bellied, wasp-waist, parallelepiped, twisted, embossed, etc. Bodies may be fabricated from steel or aluminium with protunding or flush end seams, preprinted or bright. These materials are cheap and provide excellent barrier properties against gases, water vapor, light and odors. Additionally, they can be used in on-line filing processes, have high mechanical resistance and excellent thermal conductivity, are suitable for sterile products, and can be hermetically sealed and recycled. Metal cans have some disadvantages, for instance, shipping empty cans takes up a lot of space. Also during storage cans must be protected from moisture and/or humidity (if not lacquered or coated), and cans may be considered old fashioned by the modern consumer because they are not suitable for use in the microwave oven [6,29].

Metal containers usually have an internal and sometimes external enamel coating to avoid corrosion during storage, and prevent interaction of the can with the food product; while the external coating provide both decorative and protective function. Coating materials include natural oleoresins or synthetic products, such as epoxy, phenolic, acrylic and polyester lacquers and coatings. Synthetic resins have better performance and are available in a wide range of materials and specially designed for use in different foods. In addition, a release agent is applied to facilitate product removal after opening [21,29]. Coatings should impart no odor or flavor to the food, must be non-toxic and protect the can and contents during the required shelf-life; must not flake of the plate during can manufacture or storage, be easy to apply and quickly cured, and resist all temperatures encountered during processing and storage [29].

1. Fabrication

Cans are fabricated into the three-piece can or into the two piece can. The three-piece can is composed of a body and two ends. The body is usually cylindrical (but can be rectangular, pear-shaped and oblong) and after it is formed, the two edges are brought together and sealed. The ends are made of tinplate, one end is applied by the can manufacturer, and called the manufacturer's end, whereas the other is prepared by the canner and called the canner's end. Round and no round two-piece containers are made from a precut aluminum alloy or steel sheet by stamping out in a cupping press, or by combination of stamping and deep drawing. Ends or covers are made from aluminum alloy, tinplate or tin-free steel (TFS), coated on both sides [29].

Application of ends is critical, as the end provides mechanical resistance to support the internal pressure differentials during thermal processing and cooling. It is also a barrier against all type of contamination and ensures food safety throughout storage. Sealing forms a double seam into three operations. First, the can body and the cover are brought together and clamped on a seaming chuck by a load applied vertically to the base plate; the end curl is tucked under the can flange and interlocks it. In a second operation, the interlocked layers of metal are compressed and the seaming compound is squeezed into voids to complete the hermetical seal [29].

B. Glass Jars

Glass jars are used less often for meat products because of their fragility. They consist of a glass body, and a metal lid. In households, glass jars with glass lids are often used. The seaming panel of the metal lid has a lining of synthetic material. Glass lids are fitted by means of a rubber ring.

C. Retort Pouches

The retort pouches are flexible lightweight and easily disposable laminated containers for preserving foods. Heat-resistant plastic pouches, which are closed by clip, are usually made of polyester (PETP) and used ready-to-eat dishes. Laminated films made of polyester/polyethylene (PETP/PE) or polyamide/polyethylene (PA/PE) are relatively rigid containers, which are used for filling with pieces of cured ham or other kinds of prepared meat. While, round containers formed out of a laminate of aluminium foil and polyethylene (PE) or polypropylene (PP) are widely used for small portions, as PE or PP permit the

heat-sealing of these containers, which can then even be subjected to intensive heat treatment. Retort pouches offer some advantages over other typical food containers used in canning, because they are easy to handle and the thermal process is faster and therefore produces less flavor and texture changes. Also the consumer can easily heat the pouch in boiling water before eating and save shelf space [6,8,18].

VI. EXHAUSTION AND CLOSING

Once containers have been properly filled and pressed, they are sealed under mechanical vacuum, or by using steam to create a vacuum while the product is cooled. Air evacuation from the headspace as well as from the bulk of the turkey ham is necessary to achieve good heat penetration; also to minimize alterations in color, flavor and texture during processing and storage. Afterwards, the exterior of the container should be cleaned and closure must be checked prior to sterilization [16,21,29].

VII. STERILIZATION

Canned foods are preserved by application of a heat treatment, which inactivates enzymes, pathogens, and microorganisms that cause deterioration during storage. Turkey canned ham is considered as a commercially sterile food, because the sterilization step ensures that the product is free from viable microorganisms capable of reproducing in the food under normal no refrigerated condition of storage and commercialization. Sealed cans protect the product from recontamination after sterilization, allowing storage at room temperature for several months without spoilage [21]. Canning includes two steps; first, the product is heated in a retort to high temperature for enough time to destroy spoilage and pathogenic microorganisms, followed by a rapid cooling to room temperature, where additional microbe destruction is achieved [9,31]. Most non-spore-forming organisms are heat labile; but some spores can survive even after heating to 120°C; however, addition of salt and nitrite decreases the thermoresistance of microorganisms [9].

A. Thermal Destruction of Microorganisms

Thermal destruction of bacteria is expressed in terms of its exposure to a specific temperature for a period of time, at higher temperatures, shorter periods of time are required to get the same destruction. However, the amount of microbial destruction within the food matrix depends on several factors such as the number and kind of microorganisms and the growth conditions of the microorganisms of concern. As well as, composition, viscosity, moisture, and pH of the food, presence of preservatives; as well as can size and shape, among others. Thus, successful sterilization requires knowledge of the rate of heat penetration at the coolest point, since heating is not homogeneous throughout the entire can due to its geometry [24]. For example, food in small container is heated more rapidly than in a large container; also the center of a solid product or near the end in a liquid caned food may be the coldest point within the food matrix. There are several mathematical relationships that describe the thermal destruction of microorganisms, and the rate at which a food is heated, and the temperature of the coldest point. The number of microorganisms destroyed by the thermal process can be estimated by incorporating the destruction rate of the microorganism of concern into the heat transfer model for a food system. However, not all food systems are easily modeled. Therefore, actual time-temperature measurements can be used to establish the amount of microbial destruction during the process. In addition, microbial destruction can also be measured by inoculation of an indicator organism and then measuring the remaining population after the thermal process [2].

The rate of inactivation of microorganisms increases in a logarithmic rate with increasing temperature and tends to follow a first order rate reaction. The D-value is the time in minutes during which the number of a specific microbial population exposed to a specific temperature is reduced by 90% or 1 log. It is expressed as D_T = t min, where T is the temperature and t is the time for 1 log reduction of the microbial population. In addition the F-value represents the amount of time in minutes required to completely destroy a given number of microorganisms at a reference temperature (121.1°C for spores and 60°C for cells) [24].

Several authors [2,16,21] indicate that changes in microbial populations as a function of time can be described by the following equation (166.1); while equation (166.2) describes a first–order kinetic model, if k is the slope of the natural logarithm of survivors at any time for the microbial population, then equation (166.2) can be integrated into equation (166.3) to describe the reduction of microbial populations:

$$\log [N/No] = -t/D_T \quad (166.1)$$

where:
N = microbial population at any time, t
No = initial microbial population
D_T = decimal reduction time required for a 1−log cycle reduction in the microbial population.

$$dN/dt = -kN \quad (166.2)$$

$$\ln [N/No] = -kt \quad (166.3)$$

Consequently, the decimal D-values and the constant k can be correlated by equation (166.4):

$$k = 2.303/D_T \quad (166.4)$$

TABLE 166.4
Thermal Resistant Parameters for Some Microorganisms Having Public Health Significance [2]

Microorganism	D (min)	k (1/min)	Z (°C)	Temperature (°C)
S. typhimurium	2.13–2.67	0.86–1.08		57
E. coli O157:H7	4.1–6.4	0.36–0.56		57.2
E. coli O157:H8	0.26–0.47	4.9–8.86	5.3	62.8
C. jejuni	0.62–2.25	1.0–3.72		55–56
L. monocytogenes	1.6–16.7	0.14–1.44		60
S. aureus	2.5	0.921		60
Bac. cereus	1.5–36.2	0.064–1.535	6.7–10.1	95
Clo. perfringens	6.6	0.349		104.4
Clo. botulinum B	1.19–2.0	1.152–1.935	7.7–11.3	110
Clo. botulinum E	6.8–13	0.177–0.339	9.78	74
Clo. botulinum 62A	1.79	1.287	8.5	110
Bac. subtilis	32.8	0.0702	8.74	88

D = decimal reduction time, k = rate constant, Z = thermal resistant constant.

Both parameters k and D-values describe the microbial population reduction only at a constant and specific temperature. In order to measure the influence of temperature, the thermal resistant constant (Z-value) must be incorporated in the thermal death time curve (log F vs. T) or thermal resistance curve (log D vs. T) as shows equation (166.5) and (166.6), respectively:

$$\log [D/D_R] = -(T - T_R) / Z \qquad (166.5)$$

$$\log [F/F_R] = -(T - T_R) / Z \qquad (166.6)$$

The thermal death time (TDT) involves graphical integration of time-temperature data at the coolest heating point during thermal processing, and measures the microbial death rate in relation to temperature. Thus the Z-values indicate the number of degrees the temperature must be increased to decrease the microbial population by one log cycle, and measure the microbial heat resistance; Table 166.4 shows the thermal kinetic parameters for some microorganisms having public health significance, where it can be seen that spore-forming microorganisms have the largest D and Z-values.

The rate of inactivation of microorganisms increases in a logarithmic rate with increasing temperature. Thus D and F values will decrease logarithmically with increase in temperature. Z is the change in temperature that accompanies a 10-fold change in the time for inactivation. The z value is calculated by plotting log (D) against temperature and increasing the temperature of a thermal process by the z value results in a 10-fold reduction in the time required to obtain the lethality of the original process. Conversely reducing the process temperature by the z value necessitates a 10-fold increase in the processing time to achieve the original lethality [2].

Commercial sterilization ensures destruction of microorganisms growing in the product under normal storage conditions. The low acid or high pH foods require a severe heat treatment to guarantee microbial destruction to an F value ≥ 3 [9,21]. The heat treatment for this type of food is based on the total destruction of *Clostridium botulinum* type A or B spores (the most heat resistant spores of a pathogen) by applying the 12-D concept or "botulinum cook." This refers to the heat process necessary to reduce the number of surviving spores of *Cl. botulinum* from 10^{12} to 10^{0}, i.e., to reduce the number of surviving spores by 12 log cycles. Canned turkey ham falls in the category of low-acid foods as it has a pH higher than 4.8. The reference temperature for canned low-acid foods for measuring the destruction of *Cl. botulinum* is 121°C; at this temperature the destruction time for 12 log cycles is designated as F_0. The high acid or low pH-food (pH $\leq$ 4.6) requires lower heat treatments, since *Clo. botulinum* cannot germinate and outgrow at this low pH [5,9,13,16,26].

Heat penetration tests are performed to determine appropiate heating parameters to design thermal processes. Determinations of the coldest point known as point of lowest lethality within the container and runs to measure temperature in the coolest spot at various time intervals allow the establisment of a thermal process. An accepted practice for heat penetration testing is to use an exaggeration or worst case approach by using data collected from the slowest heating container with the largest heating rate index (f_h-value) and the corresponding lag factor (j_h-value) or to conduct the test on samples that reflect the most adverse operating conditions; however, data varies with the number of test containers and test runs. Some authors have suggested the use of statistical approaches to reduce variations in heating parameters when designing processes, using an univariate and a

bivariate statistical method that also enable to estimate the minimum number of heat penetration measurements to give reliable values to calculate safe thermal processes [28].

B. Texture and Flavor Changes during the Thermal Process

During cooking the extracted muscle proteins denature and form a continuous cross-linked network, which is stabilized by electrostatic and hydrophobic interactions, hydrogen and disulfide bonds, giving rise to the characteristic product texture. Myofibrillar proteins are mainly responsible for meat binding and textural properties, as well as the product yield [21,26]. Nevertheless, stroma and sarcoplasmic proteins may interfere. In particular, collagen, a major stroma protein present in flesh and skin, diminishes WHC and binding when it is present at high concentrations due to shrinkage and conversion into gelatin during cooking [9,26,27].

Heating also promotes changes in flavor, since uncooked meat has little aroma and blood-like taste. During cooking, lipids and water soluble non-volatile precursors and/or their breakdown products generate a large number of intermediates and volatiles that contribute to flavor [7,20]. The main reactions that take place during heating are the Maillard reaction, thermal degradation of lipids, and degradation of thiamine, that lead to a complex mixture of chemicals, such as aldehydes, ketones and sulfur compounds that provide the meaty, toasted, roasted, fatty, fruity and sulfurous meat aroma [1,3,25].

VIII. FINISHED PRODUCT

Canned poultry products can suffer several alterations due to chemical, enzymic and microbial activity which diminish the quality. Production of H_2, CO_2, browning and corrosion of cans are due to chemical reactions; while liquefaction and discoloration are due to enzymic reactions. Improper processing and handling, as well as storage at elevated temperatures are the main factors associated to spoilage of canned products. Alteration can take place before heat treatment due to microbial growth, chemical reactions with the container and physical alterations when there is a delay prior to heat processing [26]. Therefore, it is recommended that heat processing must be applied within 20 minutes of can closure. Spoilage is usually associated with defects and mechanical damage as improper pressure control during retorting and cooling operations may stress the seam, resulting in poor seam integrity and subsequent spoilage. Therefore, quality control of the finished product involves: pH determination of the product, gas analysis of can headspace, microbiological testing, and complete external can examination for any leakage, pinholes, dents, buckling, and general exterior conditions [18].

A. Microbial Spoilage

Depending upon the thermal treatment, microbial cells and spores can be sublethally injured or dead. The sublethally injured cells and spores are capable of repair and can multiply [24]. Canned products can have spores of thermophilic bacteria organisms (such as *Bacillus stearothermophilus*, *Bac. coagulans*, *Clo. thermosaccharolyticum*), but if stored at 30°C or below, the spores do not germinate to cause spoilage; but if the cans are stored under temperature-abused conditions to 40°C or higher, the spores germinate, multiply and spoil the product. Microbial spoilage is generally due to germination and growth of thermophilic spore-forming bacteria, because of inadequate cooling after heating or high storage temperature. On the other hand, growth of survival mesophilic microorganisms is associated with an inappropriate heat treatment and microbial contamination from outside [24].

Insufficient thermal treatment or insufficient cooling allows the survival of thermophilic spores that can germinate when cans are temperature abused at 40°C even for a short period; once germinated, some can outgrow and multiply at temperatures as low as 30°C and generate acid with or without gas [13,16]. Germination and growth of the facultative anaerobic *Bac. stearothermophilus* is accompanied by acid without gas due to fermentation of carbohydrates;

while the growth of the anaerobic *Clo. thermosaccharolyticum* produces H_2 and CO_2 gas and swelling of cans. The sulfide stinker spoilage is caused by the Gram-negative anaerobic sporeformer *Desulfotomaculum nigrificans* which is characterized by flat container but darkened product with the odor of rotten eggs due to production of H_2S from the sulfur containing amino acids that dissolve in the liquid and reacts with iron to form the black color iron sulfide. Spoilage can be either from the breakdown of carbohydrates or proteins. *Clostridium spp*., *Clo. butyricum* and *Clo. pasteurianum*, ferment carbohydrates to produce volatile acids and H_2 and CO_2 gas causing swelling of cans. Proteolytic microorganisms such as *Clo. sporogenes*, *Clo. Putrefaciens* or *Clo. botulinum* metabolize proteins and produce H_2S, mercaptans, indol, skatole, ammonia, CO_2 and H_2 [24].

Proper sterilization process ensures the destruction of bacteria; however gas and other microbial metabolites can remain in the can. Additional microbial contamination can take place after thermal processing due to improper sealing, or in damaged and leaky containers or because the use of poor sanitary quality water during the cooling-down stage. Those conditions will allow different types of microorganism to get inside from the environment after heating. They can grow in the food and cause different types of spoilage depending upon the microbial types, care must be taken because contamination with pathogens will make the product unsafe. Therefore, cans that undergo abnormally high pressure or excessive filling can suffer physical deformation, and must be discarded to avoid the risk of leak [13].

B. Corrosion

Corrosion of metal containers can be both internal and external, it can be initiated during the can manufacture or at any point during processing. External corrosion is evident by formation of a reddish-brown ferric oxide, and may be induced by corrosive water conditions or by poor conditions during storage or shipment. Internal corrosion is not visible until it produces leakages or swelling of the container. This phenomenon is associated with elevated oxygen levels in the headspace and aggressive foods. Bubbles or loose flaps in the internal coating may occur followed by corrosion at the point of detachment, if the base metal is exposed, then the corrosion will be more extensive. The presence on nitrites also may induce internal corrosion [16].

IX. APPLICATION OF PROCESSING PRINCIPLES

167 Processed Poultry Products: Nugget and Pâté

Alfonso Totosaus and M. Lourdes Pérez-Chabela
Biotechnology Department, Universidad Autónoma Metropolitana-Iztapalapa

CONTENTS

I. POULTRY NUGGETS

A. Background Information

Poultry nuggets are restructured meat products made from poultry meat or mechanical recovered meat (MRM) where the frying process will reduce product humidity and develop color and texture, but with a considerable increase in fat content. Nuggets are usually small (bite-size) and are covered or breaded with a mixture of flour and spices to give characteristic flavors, color, and a crispy texture. Nuggets are preformed with a precooking step and then fried. Frying is considered one of the oldest cooking methods in existence, especially in countries where oil plays an important role (1). The kind of oil used depends on cultural traditions and the kind of crops in the region, such as olives in Mediterranean countries, corn or soy oil in the United States,

and peanut or canola oil in Asian countries. The immersion frying process is also called deep-fat drying (2). During frying many chemical reactions occur from heat and mass transfer. Breading nuggets with batter improves texture due to starch gelatinization and results in a unique color from Maillard reaction compounds formed during the crust layer formation. Figure 167.1 shows the general flow chart and Table 167.1 describes the principal steps of the process.

B. Raw Materials Preparation

Poultry meat is chopped to liberate myofibrillar proteins that will act as "glue" to bind meat pieces. The addition of a binder enhances and improves nugget texture, and breading is the most common practice. Binders can also be another protein, such as egg white. A great variety of ingredients can be added for a specific or ethnic flavor. Oil temperature must be hot enough to maintain a constant heat transfer during the frying process. Temperatures around 130–150°C are recommended. The cleanliness of oil is important because impurities may accumulate on parts of the nugget or its cover. In addition, air and water escaping from the food during frying can cause many chemical alterations.

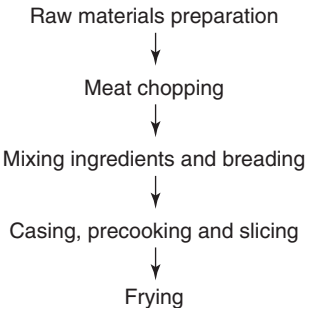

FIGURE 167.1 Flow chart for poultry nuggets elaboration.

TABLE 167.1
Processing Steps and Application Principles of Poultry Nuggets Elaboration

	Stages of Processing	Application Principles
1.	Raw materials preparation	Oil preheating

3.	Mixing ingredients and breading	Poultry nuggets batter homogenization Flour addition
4.	Casing, precooking and slicing	Mechanical entrapment to give form Moderate heat treatment Slicing
5.	Frying	Cooking process Microbial population reduction Color and texture development

C. Processing Stage 1: Meat Chopping

Functional properties of meat myofibrillar proteins, mainly myosin, are responsible for many meat products sensory characteristics. In poultry nuggets, myofibrillar proteins act like emulsifying agents mainly to bind the meat pieces in a restructured product. Egg white proteins have the same function. The binding and gelling capacity will give form to the nuggets in the precooking stage. Using MRM implies the use of another protein or flour to give form to the nugget.

D. Processing Stage 2: Mixing Ingredients and Breading

The homogeneous mixture of the ingredients is important for the distribution of proteins that will form matrix-entrapping water, fat, and other components. This protein matrix is different than in an emulsified meat product, where the proteins act like emulsifiers stabilizing the fat droplets in the water-protein-salt system. The fat content in this kind of batter is low. So, proteins have the function of holding together the small pieces of meat. Flavor ingredients must be well distributed in order to have a quality product.

The breading will contribute to nuggets yield and help to develop crispy texture and characteristic color. Breading is composed of wheat flour, corn flour, or whole-wheat flour or a combination of two or three of these flours. Other ingredients may be used to provide the needed adhesion and functional properties and to produce the desired appearance, color, texture, crispness, and flavor, with a great increase in product yield. Breading for chicken nuggets is recommended not to exceed 30 percent by weight.

E. Processing Stage 3: Casing, Precooking and Slicing

A preforming stage, where proteins will form a restructured gel, is an important step before applying the cover ingredients or breading. The homogeneous batter is put into casings of the desired diameter and cooked until it reaches an internal temperature of 58°C. After cooling, the product is cut into slices with a height of 1–1.5 cm. The height and size of the nugget are important due to the heat necessary to reach the center of the nugget without producing an overheating of the cover ingredients, resulting in an extra golden color.

F. Processing Stage 6: Frying

The result of deep fat frying produces food with a different structure and properties: textural changes, attractive

and tasty surface, crust, increased palatability and browning reactions. During deep fat frying, the fat is continuously or repeatedly used at a high temperature. Oxidative transformations usually accompany and probably precede the thermal transformation of the frying medium. The fried food absorbs this heated fat and contributes considerably to the fat ingested by consumers (3).

During frying the oil undergoes many reactions, resulting in oxidative and hydrolytic degradation. The oil is exposed to molecular tension and changes due to the energy applied to heat the oil (4). In the frying process the high temperature employed (180°C) promotes fatty acid hydrolysis and many oxidative reactions take place. Oxidative reactions, polymerization and hydrolysis occur rapidly during frying, depending on process conditions like temperature, time and aeration (5). The complex series of reactions include those such as oxidation, polymerization, hydrolysis, isomerization, and cyclization (6).

G. Finished Product

Fried foods absorb a considerable quantity of oil. The oil imparts a great part of the flavor, odor and color properties. The oil flavor is given to the food. The quantity of oil absorbed depends on food composition (humidity, porosity and surface exposed to the frying oil). Fat or oil quantity has an effect on nuggets quality during storage. Higher fat content increases the flavor, but the product tends to be softer with storage time (7). Absorption of fat during frying should be kept to a minimum because fat-soaked foods are less palatable and carry more calories. Keeping the contact time and the surface of the food exposed to the fat at a minimum reduces absorption (8).

H. Application of Processing Principles

The main applications during poultry nuggets process are heat and mass transfer during frying. During immersion frying of foods, there are two distinct modes of heat transfer – conduction and convection. Conductive heat transfer, under unsteady-state conditions, occurs within a solid food. The rate of heat transfer is influenced by the thermal diffusivity, thermal conductivity, specific heat and density. Convective heat transfer occurs between a solid food and the surrounding oil. The surface interactions between the oil and the food material are complicated because of the vigorous movement of water vapor bubbles escaping from the food into the oil. In addition, the water vapor bubbles entrapped on the underside of the food material prevent efficient heat transfer between the bottom side of the food and the oil. The amount of water bubbles escaping food material decreases with longer frying times as a result of the decrease in the remaining moisture of material. During frying the temperatures inside a food material are restricted to values below the boiling point of liquid. Since the liquid present in foods is mostly water with some solutes, the boiling point of the liquid inside a food is slightly elevated above the boiling point of the water. As the frying process proceeds, more water evaporates from the outer regions of a food material. Consequently, the temperature of the dried regions begins to rise above the boiling point (2).

Deep-fat frying has long been a means of food preparation for achieving desired texture and flavor attributes of a variety of food products. The breading enhances the texture, flavor, and appearance of the food. It acts as a moisture barrier to diffusion of water vapor from inside and thereby contributes to juicy meat during the holding of the product. In some products, it acts as the major carrier of the seasoning and thus the flavor system. The physicochemical phenomenon of heat-induced texture of breading (denaturation of protein and gelatinization of starch) is the combined effect of several multiple-order chemical reactions. However, such reactions can be modeled as a pseudo first-order reaction affecting breading texture, strength, water-holding capacity, etc. The texture of the breading in a piece of chicken will largely be dependent on the temperature history, pressure during frying and the specific ingredient included, such as type of flour, browning agent, protein content, and other functional agents. It is well known that using positive pressure during frying imparts a softer texture to the breading, while using atmospheric pressure results in a crispy texture (9).

Figure 167.2 shows the principal process pathways during frying and the main alteration caused in oil during frying. On the left side, the four sequential distinct processes that take place during frying are described (10). During the first step, lasting a few seconds, Initial Heating, the surface of the food heats to a temperature equal to the boiling point of oil. The mode of heat transfer between the oil and nugget in the first seconds is by natural convection, and no

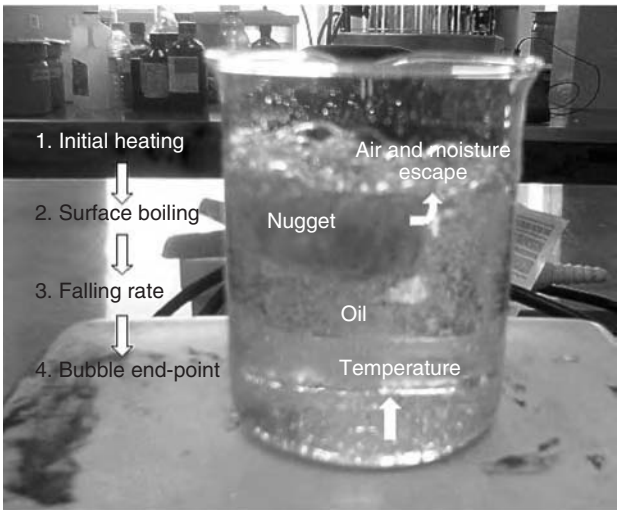

FIGURE 167.2 Distinct stages during frying process.

vaporization of water occurs from the food surface. Second step is Surface Boiling, when the surface boiling state due to the vaporization process starts. Here, the convective heat transfer changes to a forced convection because the presence of turbulence in surrounding oil. The crust or dry region begins to form at the surface of the food. The Falling Rate is the stage during which more internal moisture leaves the food, and the internal core temperature rises to the boiling point. Additionally, several physicochemical changes (e.g., starch gelatinization and cooking) take place in the internal core region. The thickness of crust layer increases and after sufficient time and more removal of moisture, the vapor transfer at the surface decreases. Finally, during the Bubble End-Point stage, after a considerable period of time, the rate of moisture removal diminishes and no more bubbles are seen escaping from nuggets surface. As the frying process proceeds, the thickness of crust layer increases. As food material undergoes frying, several important changes take place in the surrounding oil. These reactions cause the formation of a great number of decomposition products, both volatile and non-volatile. The rate of deterioration of the heated fat is greatly influenced by its degree of unsaturation, the conditions of frying, the nature of the fried food and the presence of chemicals that minimize darkening and polymerization during prolonged heating. The significance of the unsaturation and distribution of fatty acids in the triacylglycerol molecule as well as the effect of antioxidants, silicon and phytosterols on the stability of heated oils is discussed in terms of the mechanism proposed for antioxidant activity (6). The alterations that frying oil can undergo are due mainly to three factors: air, temperature and moisture. Air and moisture are produced when the food surface begins to boil, reflecting the moisture escaping by the increase in internal core temperature. Oxygen and humidity condensation accumulates in oil during successive frying, producing oxidative and hydrolytic alterations. Oxidative alterations produce fatty acids, monoglycerides, diglycerides and glycerol. Hydrolytic alterations produce oxidized monomers, oxidative dimmers and polymers, non-polar dimmers and polymers and volatile compounds (hydrocarbons, aldehydes, ketones, alcohols, acids, etc.). The compounds that can be formed during frying by thermal alteration are cyclic monomers, dimmers and polymers (11).

The heat transferred from oil into a food causes several chemical and physical changes such as starch gelatinization, protein denaturation, water vaporization, and crust formation (color and flavor development). Mass transfer during frying is characterized by the movement of oil into the food and the movement of water in the form of vapor from the food into oil. Frying oil becomes contaminated with component of food materials leaching into oil, water vapor condensing in oil. thermal breakdown of oil, and oxygen absorbed at the oil-air interface. These contaminants reduce oil surface tension acting like surfactants. When the level of surfactants increase the wetting of food surface by the oil is also increased, influencing the heat and mass transfer processes. The surfactants entering the food with the oil are suspected to influence the moisture pickup by the food during subsequent storage, hence reducing its shelf life (2).

II. POULTRY PÂTÉ

A. Background Information

Liver from poultry and mammals is the most widely used organ, resulting in many styles of processed meats such as liver sausage and paste (12). Pâté or liver sausage is a ready-to-eat cooked sausage, with the special feature that the meat batter can be worked at relatively high temperature. In meat batters, the temperature is important in order to maintain the integrity of the solubilized protein-salt-water matrix. The muscle proteins (myosin, mainly) must be liberated and activated during meat chopping and the addition of ice and sodium chloride. The fat must be dispersed in the batter with the cutter, to induce protein matrix gelation, entrapping fat and water. This results in juiciness and textural attributes in sausages. In liver pâté, the amount of lean meat is low as compared with sausage formulation (15% versus 50–60% in the average sausages). The meat added must be precooked. This reduces the protein functionality and makes the product less thermostable, where fat can be released or color and flavor affected by excessive heat. Thus, liver proteins act like the main emulsifying agent in pâté elaboration. In the same way, fat is an important part in the formulation (47–50%), and higher as compared with the fat amount in sausages (10–15%, depending on formulation). Also, fat in pâté has different functions that in regular sausage, where the juiciness, flavor, and texture are affected by fat. In pâté, the fat is responsible for the product spreadability. That is, certain type of protein must be added to the formulation to improve emulsification. Normally, milk protein is added (1–2%) to do this and enhance flavor.

Heat treatment is the other important process in pâté production. Heat is applied to: form the protein gel matrix, destroy microbial population, extend shelf life, and make the product safe for consumption. Heat transfer is usually achieved by conduction in water or by steam in autoclaves. Two important criteria in this step: the internal temperature in the pâté or the heating effect (F value) necessary to destroy the microbial population. Figure 167.3 shows the general flow chart and Table 167.2 describes the principal steps of the process.

B. Raw materials Preparation

Fresh poultry liver is used for pâté formation, because old livers lose emulsifying capacity. Livers must be clean, with no fat or vessel. They can be chopped or cut in half-inch cubes and frozen if not used in the next 24 hours. Lean meat cut in one inch cubes is parboiled in salt (one third of

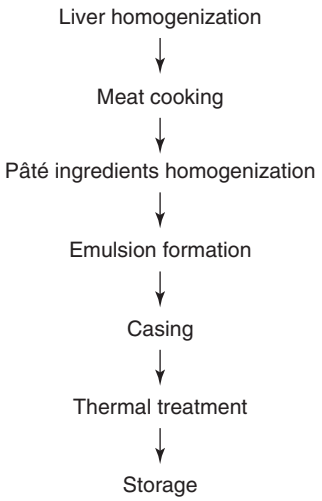

FIGURE 167.3 Flow chart for poultry pâté elaboration.

TABLE 167.2
Processing Steps and Application Principles of Poultry Pâté Elaboration

	Stages of Processing	Application Principles

2.	Ingredients homogenization	Particle size reduction (protein liberation)
		Homogenization
3.	Emulsion	Fat globules dispersion
		Homogenization
4.	Casing	Mechanical entrapment to give form
		Heat transfer
5.	Thermal treatment	Microbial population reduction
		Fat and water entrapment in the gelled protein-water matrix
6.	Packaging	Extend shelf life

the total weight), not exceeding 80°C for 30–60 minutes. The broth is left to settle and concentrated by boiling, clarifying and kept at 60°C until addition to batter (13).

C. Processing Stage 1: Ingredient Homogenization

1. Liver Homogenization

Raw livers are comminuted in the cutter with half of the salt to obtain a uniform mass. The cooked meat is added and roughly disintegrated using the lower cutter speed. The percentage of liver in the formulation has a direct influence on the emulsion stability. The higher the amount of liver, the more stable emulsions will be formed, with a constant fat content (14).

2. Pâté Ingredients Homogenization

After the meat is cooked and the fat scalded (>65°C) they are placed together in the cutter and homogenized at low speed. The speed is then increased, adding the rest of the salt. If milk proteins are used, half is added at the beginning and the rest at the end of the operation (13).

D. Processing Stage 2: Emulsion

1. Emulsion Formation

Hot broth is added gradually during homogenization to maintain the mixture at a constant temperature of 58–60°C, with a final temperature reaching 45°C. When the batter is thoroughly homogenized, the homogenized liver (step IV-1) is added and well distributed. The sausage emulsion is then ready. In order to improve flavor, spices such as onion can be added. If desired, the raw pâté or liver sausage mass may be passed through an emulsifying mill (13). Liver proteins will act like an emulsifying agent. Proteins are adsorbed at the fat/water interface, reducing interfacial tension to prevent fat globule coalescence. The parameters that influence meat batter formation and stability are: chopping time (fat globule size), protein concentration (emulsifying agent concentration) and mixing speed (energy input and batter heating). The last factor, i.e., temperature is the most important factor to control during emulsification (15).

2. Emulsion Temperature

The temperature of meat ingredients used in processing is a decisive factor in pâté production. Fat and lean meat must be heated >5°C to melt fat and denature proteins. Raw livers should be added when the meat-fat-broth mixture falls <60°C in order to avoid liver protein denaturation, but >45°C to ensure that the fat is melted (13). The final fat content in the pâté has an important effect on the texture, slicing, spreading and color. Products with a high fat percentage have a fine texture and are more spreadable but with less stability in the emulsion (16).

On the other hand, high fat content meat products, e.g., poultry pâté, have other problems. For example, fat not completely entrapped in the protein matrix tends to move outside the product as water. If so, liquids and melted fat occupy the empty air spaces, improving heat transfer. Furthermore, the pate surface will be affected by the presence of fat and liquids (17).

E. Processing Stage 3: Packing (Casing)

1. Casing

Molded meat products can be processed in the same mold or casing. Heat and energy are transferred first to the casing and then to the batter. Air is an excellent insulator,

and if air bubbles are present in the batter inside the casing, the heat transfer will be interrupted provoking temperature differentials in the same product and extending the heat treatment due to the low efficiency of heat transfer. If the pâté batter is in a water impermeable casing, humidity losses will cause an important reduction in final volume (17).

F. Processing Stage 4: Thermal Treatment

Thermal process can be reviewed in standard literature. We are interested in its effect on poultry pâté and meat products. Thermal treatment is crucial in killing or reducing pathogens. If so, an evaluation and a recording of cooking temperatures become an important part of any food safety program, including the Hazard Analysis Critical Control Points (HACCP) requirements and should be regulated (17). The shelf life of cooked meat products is achieved through reducing growth of, or inactivating, microorganisms by a thermal process. Heat or thermal treatment is done by submerging the products in cooking vats or pressure cookers that contain hot water or steam or a mixture. It can be performed under pressure in retorts or autoclaves in order to reach temperatures above 100°C (sterilization). In contrast, temperatures up to 100°C can be achieved in vats (pasteurization). A certain amount of microorganisms resist the moderate heat treatment and the resulting pasteurized products must consequently be stored under controlled low temperatures to retard microbial spoilage (18).

The intensity of thermal treatment can be defined in physical terms. The term widely used under practical conditions is the F-value, with which the lethal effect on microbial population can be defined. The thermal death time for different microorganisms calculated at 121°C and expressed in minutes is used as the reference value. For example, the thermal death time for spores of *Clostridium botulinum* at 121°C is 2.45 minutes, or, a F-value of 2.45 is needed to inactivate the spores in the product at 121°C. This pathogenic microorganism is the most resistant and serves as reference for low pH foodstuffs (18).

1. Organoleptic, Physical and Microbial Aspects of Thermal Treatment

The intensity of heat treatments has not only decisive impact on the inactivation of microorganisms, but also on the organoleptic quality of the final product. There are products that undergo intensive temperature treatment without significant losses in quality. On the other hand, some products may deteriorate considerably in taste and consistency after heat treatment. One objective of heat treatment is to destroy microorganisms. Since some resist moderate heat treatment, the resulting pasteurized products must be stored under controlled temperatures. Proper preventive measures must be taken to avoid protein denaturation or fat release due to emulsion destabilization from excessive heat application.

2. Internal Temperature

A uniform batter is necessary to obtain the same internal temperature. When variations in composition are present in the product, final temperature will be affected. Final internal temperature only can be obtained if all the product or casing is at the same temperature. Casing surface will receive the same heat quantity at the same rate in different points if the heat is applied uniformly on the casing surface (17).

3. F Value

By measuring the temperature of the product periodically during thermal treatment, the final F-value can be determined. It is obvious that during thermal treatment the product temperature will rise. The temperature taken in the center of the container or casing after each minute of heat treatment corresponds to a certain F-value. These partial F-values are added up and the sum is the overall F-value of the product. The exact F-value is of special importance to the meat producer because it ensures appropriate thermal treatment of the product, thus avoiding undercooking. It also enables the product storage time to be determined (18).

G. Processing Stage 5: Packaging

Handling after processing is considered the primary cause of contamination in cooked meat and poultry products. Quantitative information that the processing plan meets the specific lethality performance standard for each product is necessary in order to implement a zero tolerance presence of pathogens in this kind of product. In poultry pâté the advantage is that the casing in which the batter is cooked is also the final package.

Storage time and temperature, apart from the packaging method, greatly affects the shelf life of meat products. The purpose of packaging is primarily to protect foodstuffs during the distribution process, including storage and transport, from contamination by dust, microorganisms, mold, yeast, toxic substances or those influences affecting smell and taste or causing loss of moisture. Packaging should help to prevent spoilage, weight loss and enhance consumer acceptability (18). Therefore, the type of material for the casings must be chosen correctly to comply with the specification in order to avoid oxygen intake and humidity loss.

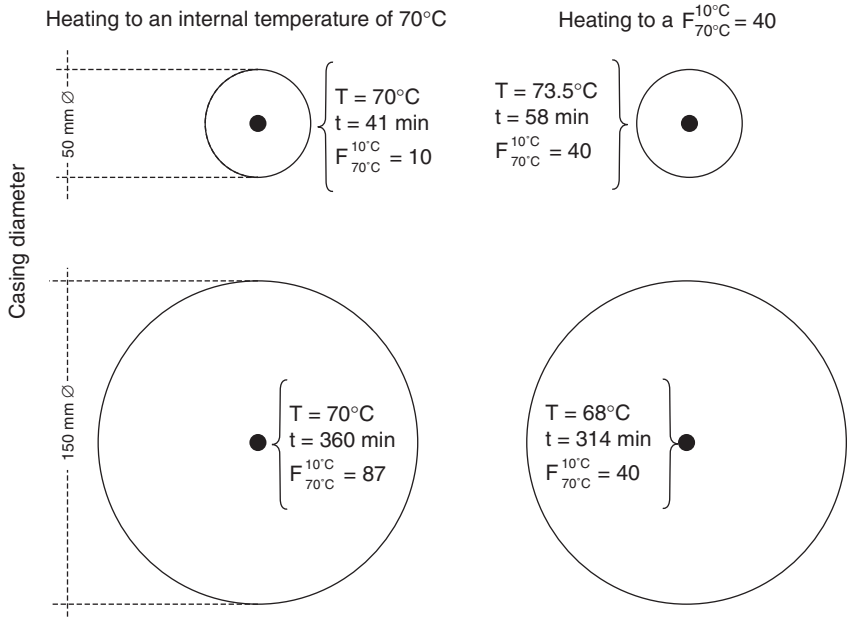

FIGURE 167.4 Comparison between internal temperature heating and $F^{10°C}_{70°C} = 40$ thermal treatment for different casing diameters of pâté sausages.

H. Finished Product

Factors that limit shelf life can be intrinsic, i.e., pH value and water activity (aw), and extrinsic, i.e., oxygen, microorganism, temperature, light and humidity loss (18).

Intrinsic parameters, pH and aw are controlled in the correct selection and managing of raw materials before and after process, together with a correct heat treatment (for both microbial reduction and gel formation). The other parameters should be controlled after the poultry pâté is finished and packed in the casing. The storage temperature for the pâté (1–4°C) is important to prevent microorganism spoilage and fat rancidity or protein denaturation.

The finished product shelf life is the reflection of the quality of the raw materials and the handling of the product during all the process steps, and the right storage conditions to guarantee a high quality poultry pâté.

I. Application of Processing Principles

Emulsion formation and heat treatment are considered the most important aspects of the manufacture of pâté or liver sausage. This means:

1. Form the protein matrix entrapping fat and water.
2. Ensure a physicochemical, microbiological and sensory stable shelf life.

Heat is necessary to destroy microbial population (denoted by F value) (19). The temperature in the foodstuff may be inadequate if one considers data for thermal treatments above or below 100°C, because:

- The prediction of the overall heating effect cannot be done, due to dependence on the food dimension (diameter and length), the cooking temperature magnitude and the cooking time.
- Maintaining a determined internal temperature for a given time cannot be done.
- The microorganisms destruction is not lineal, but exponential. Thus, the microbial count reduction depends on the applied temperature and time.
- Changes in sensory (color, flavor, texture) and other parameters (fat separation, cooking loss, protein coagulation) also depend on time and temperature.

If so, some advantages in the use of F values on the internal temperature are the following:

- The lethal effect on microorganisms can be significant with different food or casing sizes.
- Unnecessary alterations by cooking are not produced due to higher casing capacities or size of the containers.
- A comparison between different heating temperatures can be done by referring to heat alterations (fat losses, weight loss, sensory attributes).

F value has many advantages:

- F values can compare the lethal effect reached with different temperatures
- In new product development, the reference values are available from similar products and bibliographic references
- A comparison between different sizes and shapes can be done
- Different heating procedures can be compared

F value in the meat industry is employed only in sterilized products. To improve the heat treatment, the use of $F_{70°C}^{10°C}$ is recommended. Comparing casing sizes (i.e., 50 and 150 mm ∅), different F values are obtained if we use a heating temperature of 75°C until reach 70°C in the geometric center, or, we apply an $F_{70°C}^{10°C} = 40$ (Reichert, 1988). For 50 mm ∅ casings, takes 41 minutes to reach an internal temperature of 70°C, and only a $F_{70°C}^{10°C} = 10$ was reached. In contrast, if a $F_{70°C}^{10°C} = 40$ is applied, the internal temperature reach 73.5°C in 58 minutes, ensuring a higher microorganisms destruction. In casing of higher diameter (150 mm), the excessive heat is more important due to sensory changes in final product. It takes 360 minutes to obtain an internal temperature of 70°C, with a $F_{70°C}^{10°C} = 87$. Using a $F_{70°C}^{10°C} = 40$, the internal temperature only reach 68°C in 314 minutes. Heating to the same internal temperature provokes a higher lethal effect in higher casing sizes, causing more heat damage with loss of the quality. A heating effect of $F_{70°C}^{10°C} = 40$ should be enough in many cases. Try to reach a given internal temperature, the F value could be not enough and a short shelf life will be expected if the microbial population is not low. Instead, if a given F value is followed during thermal treatment, unnecessary alteration by the heat can only be justified if the contamination of the raw materials is high (19) (Figure 167.4).

ACKNOWLEDGMENT

168 Extruded Snacks

Mian N. Riaz
Head-Extrusion Technology Program, Food Protein R&D Center, Texas A&M University

CONTENTS

I. BACKGROUND

American Heritage dictionary defines snack as "hurried or light meal" or "food eaten between meals." Traditional snack foods appeal to consumers on a number of levels. Snacks can be considered a treat or reward. Snack foods have always been a significant part of modern life, and they represent a distinct and constantly widening and changing group of food items, whose sales in 2002 was over $22 billion (1), and per-capita snack consumption was 22 pounds. According to a rough working estimate, annual worldwide sales including US is $30–35 billion.

Designing snack foods today can be a complex process to meet changing consumers' taste and expectation, e.g. "good for your health," "rich source of soy protein," "offering a unique flavor" and the elusive search for something unique that also appeals to a wide variety of people. Most snack manufacturers use some form of existing technology as the basis for creating snack products, but incorporate variation that increase the resulting snack's health image appeal by lowering fat and calories or adding nutrients (2). This can be accomplished by using extrusion technology.

II. WHAT IS EXTRUSION?

Food extrusion is a process in which a food material is forced to flow, under one or more varieties of conditions of mixing, heating and shear, through a die which is designed to form and/or puff-dry the ingredients (3). The food extruders can be visualized as a high temperature short time (HTST) device that can transform a variety of raw ingredients into intermediate and finished products. During extrusion, the cooking temperature could be as high as 180–190°C, but residence time is usually 20–40

seconds (depends on types of extruders and speed of the shaft). For this reason the extrusion process could be called as HTST process. It is very important to understand the extrusion terminology, since each manufacture likes to use their own terminology based on their equipment. Extrusion technology provides several different advantages over the traditional methods of food and feed processing. Some of the advantages based on Smith (4) and Riaz (5) with modification include the following.

Extrusion technology provides the opportunity to process a variety of food products by just changing a minor ingredient and processing condition on the same machine. Several different shapes, texture, color, and appearances can be processed by minor changes in the hardware and processing conditions. Extrusion process is energy efficient, and low cost compared to other processes. Presently, most of the extruders are available with automation, which can increase the productivity. Since extrusion process is considered HTST the product quality is much better than other processes, since cooking is done in a very short time and less destruction takes place to the heat sensitive ingredients. It is very easy to scale up the extrusion process for larger installation.

III. DIFFERENT TYPES OF EXTRUDERS

Food or snack extruders are generally divided into two major categories: single screw and twin screw. Single screw extruders can further be divided to different classification (6):

1. Low shear forming extruder;
2. Low shear cooking;
3. Medium shear cooking; and
4. High shear cooking.

Whereas twin screw extruders can be divided into four different categories (7):

1. Co-rotating intermeshing,
2. Co-rotating non-intermeshing,
3. Counter-rotating intermeshing, and
4. Counter-rotating non-intermeshing.

In the past the most common extruders in the snack food production have been the single screw extruders. Still most of the expanded snack is made from single screw extruders because of the economic point of view. Many common snack food such as fried or baked are corn-based and produced by single screw extruders. However, with the new and complex ingredients, different snack shapes and color, the twin-screw extruders have begun to take the place of single screw extruders. Snack products like half products or third generation snacks, may require more advanced extruders like twin screw.

IV. SNACK CONSUMPTION PATTERNS

The snack food market is constantly changing relative to product types, and although most snacks are not primarily consumed for their nutrients, many snacks are made with nutrition in mind. The snack food industry is experiencing extraordinary changes from the consumers point of view. Consumers want snacks to not only taste good, but also smell good, feel good, and look good. Snacks should give the consumer a homemade/fresh feel. Some of the snacks are developed with a special theme in mind like world soccer. These snack pellets are soccer ball shaped, which upon frying or microwaving become soccer balls.

Snacking overall is on the rise in the US owing to an increasingly hectic lifestyle with more time spent at work. Currently more than two-thirds of US women work outside the home and the number of two income families in the US has doubled over the last 20 years. Snacking is increasing from factors such as increases in one-person households, and more school age children obtaining their own meals and refreshments, a highly mobile population, and availability of snack foods in vending machines and convenience markets. Snacking now provides approximately 30 percent of many American's daily calories (8). Various products that were once consumed mainly on impulse, are becoming accepted as side-dish items, for example, corn chips or potato chips served in place of mashed potatoes. The established position of snack foods in the diet is demonstrated by the continuous growth in sales.

In the last ten years, changes in life-style and eating patterns have led to a gradual increase in demand for snack foods. The pattern of snacking in different countries can be affected by several factors such as the lifestyle in each area, the economic climate, rival foods and public receptiveness of current views on nutritional matters. Snacks can provide an increased dietary intake of essential amino acids and other nutrients for developing countries.

V. TYPES OF SNACK FOODS

Although it is not possible to discuss all types of snack foods available in the market in this article, only extruded snacks (expanded and pellets snacks) will be discussed in detail. A broad variety of snacks made by different processes are available in the market. These include potato chips, tortilla chips, corn chips, ready-to-eat popcorn, extruded snacks, pretzels, snack nuts, meat snacks, pork rinds, party mix, multi-grain chips, granola products, variety packs etc. Most recently we have seen a variety of health snacks made with soy protein. These soy-based snacks contain 6.25 grams of soy protein per serving to qualify for the health claim of the Food and Drug Administration. On the same lines, snacking on soy nuts

is becoming very popular among the health conscious consumers. Nowadays, we can find soy nuts with different flavors in most grocery stores. Snacks with different spices and flavors are becoming very popular with US consumers. There is a substantial growth in ethnic snacks from Mexico and India in the markets. Snacks from India are mostly fried lentils, chickpeas, and similar types of pulses with different flavors (mostly with chilli powder) are entering the US market.

Each snack processor may use a specific unit operation and somewhat different technologies to produce unique snacks. There are many ways to classify the snacks. Snack manufacturers use three main terms to identify the snacks:

1. First generation snacks: In this category all the natural products used for snacking, nuts, potato chips and popped popcorn are included;
2. Second generation snack: Majority of the snacks fall in this category. All the single ingredient snacks, simple shaped products like corn tortilla chips and puffed corn curls and all directly expanded snacks are included in this category;
3. Third generation snacks also called half-products or pellets: In this category, multi ingredients formed snacks and pellets, made by extrusion cooking are included.

VI. PRODUCTION OF SNACKS

It is not possible to discuss every snacks manufacturing procedure in detail. Only major snacks manufactured using extrusion technology will be discussed here.

VII. EXTRUDED SNACKS

This category has the greatest potential for growth among the snack foods. The snacks can be made to produce innovations that capture the consumer imagination. Some of the examples are three dimensional snacks, a variety of animals, cartoon, and alphabet shapes etc. Producing a successful snack is a fine balance between the consumer's needs, like tastes and interests vs. a manufacturer's production abilities, economics and quality control. Raw material cost plays an important role in the finished product's selling price. Therefore, it is an advantage to use the lowest cost raw material to produce a successful snack.

VIII. COMMON INGREDIENTS USED FOR EXTRUDED SNACKS

Presently, snack products are being made from a variety of ingredients. However, the selection of the ingredients was limited by the equipment availability. By the introduction of extrusion process, other processing equipment and better knowledge of extrusion technology have led to more diverse and complex formulations for snack foods. The most common source of ingredient is corn, wheat, rice, potato, tapioca, and oats. This is not an inclusive list and one should not limit his/her snack food formulation based on these ingredients. There are several other sources of ingredients for snack food all over the world. A major ingredient in snack food formulation is starch. In its natural form, the starch is insoluble, tasteless, and unsuited for human use. To make it digestible and acceptable it must be cooked.

IX. CEREAL SOURCES

Almost any cereal can be extruded, but if expansion is a major objective, the numbers of functional cereals are limited to degermed corn/grits and rice. Cereals that have high amounts of lipids, are more difficult to expand due to dough slippage within the extruder barrel. This type of cereal usually requires high moisture and high temperature before significant puffing will occur. In general, starches with 5–20% amylose content will significantly improve expansion as well as texture of the snack foods. The most common cereals used in snack food formulations are described below (9).

A. Corn

Extruded snacks are a growing segment of the corn-based market. Corn (also called maize) is a primary ingredient for corn collets and many pellet products. For most corn-based extruded snacks, dry-milled corn meal is used. Large quantities of corn meal are used in puffed extruded snack production and some is used in corn chips. Cornmeal, corn grits, corn flour and corn cones are all a different form of dry-milled dent corn, and in general vary only in particle size distribution. Selection of the granulation depends upon the type of snack and type of extruder. For example, for fine texture and cell structure, or softer bite, a fine granulation of corn meal should be used. Whereas for crunchy texture with a slightly large cell structure snacks, more coarse granulation of corn meal is desired. Similarly, a twin screw extruder can handle fine as well as coarse granulation corn flour, while collect extruders require coarse granulation. Mostly, degermed corn is used in extruded snacks because it expands better than a whole corn. Yellow and white corns are most commonly used in snack foods. Corn starch granules are medium in size (5–20 μm) and have very good expansion characteristics. Protein content of corn ranges from 6–10%. Snack food formulations with corn have a definite flavor. Corn starch is usually cooked at a medium to higher temperature during extrusion. The function of the starch in snack foods is to achieve various textural attributes and characteristics. These attributes can be changed by changing the amylose/amylopectin ratio in the starch.

Today, we can find corn starches with high amylose or high amylopectin in the market. High-amylose corn starches are used when crunchiness and strength is required in the snack. To increase the expansion of the snack, high amylopectin corn starches (waxy starch) can be used. Waxy corn contains very little amylose, whereas the normal corn contains approximately 25–35% amylose. Under high shear and high temperature cooking, a cross-linked waxy corn starch is recommended in snack foods, since it exhibit an improved property of resistance to amylopectin breakdown.

B. Wheat

In general, wheat can be classified into two types: hard and soft. Hard wheat is higher in protein, produces a stronger flour, and is better for bread making. On the other hand, soft wheat is lower in protein and yields a weaker flour, which is better for cake making. In the snack food industry, wheat flour is used in formulation for making baked and fried snacks, flavored crackers, snack cakes, pretzels, bread, and the like. Semolina (coarse particle) usually produced from hard wheat milling, is also used in snack food formulation. The semolina product had an expansion ratio and bulk density about the same as corn meal. Snack foods with all-semolina will produce a very crispy texture. Wheat starch granules are fairly large (20–40 μm) as compared to other cereal grain starches. In wheat, amylose and amylopectin are found within a narrow range of 20–25% amylose. It gives good expansion during extrusion cooking. Wheat is relatively high (8–15%) in protein than other cereals. Sometimes it is difficult to expand due to the presence of gluten. In extruded snacks, wheat gluten provides nutritional value, crispness and desired texture. In general, 1–2% wheat gluten is used in snack foods. Hard wheat is commonly used in bread roll, pretzels, fabricated or pellet type snacks. Wheat varieties with a lower gluten level, will give more tender expanded product than semolina, or hard varieties. Snack products made with wheat usually have mild flavor and white to off white color. It needs medium to low cooking temperature during extrusion cooking. Milling by-products (bran) can be used with soy protein and some other ingredients to produce expanded snack foods of high nutritional and fiber value. The use of wheat in snack foods formulation is limited because of cost.

C. Rice

Rice is one of the largest crops grown in the world. Four types of rice are produced in the United States: long, medium, short and waxy grain. In the US, rice ingredients are not commonly used in snack food formulation. In Japan, most of the snacks are made with rice or rice flour. One major reason is the cost of the rice as compared to the other snack food ingredients. Broken rice can be used as ingredients in expanded or puffed snack products, since rice has good expansion qualities. Rice starch granules are the smallest (2–8 μm) of all grain starches and it digests very easily. Its functional properties are very different from corn or wheat starches. The primary difference is in amylose-to-amylopectin ratio in the starch. Flours from different rice varieties have major differences in physical and chemical properties, which can affect the snack cell structure and expansion. For example, long grain rice flour can increase the crispiness in snack foods, whereas waxy rice flour can reduce chip hardness and at the same time can provide a melt-in-the-mouth texture usually achieved with extra fat. Rice is commonly used as a carrier product for other flavor, since it is bland in flavor. Rice requires the highest temperature during extrusion to cook a snack. Selection of the rice starch in the snack foods formulation will depend upon the amylose content of the common rice varieties. Long grains have 22–23%, medium grain 15–19%, and waxy grain $<1\%$ amylose (10). This difference in amylose-to amylopectin ratio greatly affects the gelatinization temperature of rice flour. The protein content of rice ranges from 6–8%. Rice flour could be used for texture improvement in multi-grain snack foods. Rice flour can be mixed with masa flour, potato flakes, or bean flakes. Chips made with 100% rice flour absorb 20–30% less oil during frying. In a formulation where rice and potato blend is used, the potato flavor and texture remains distinctive even though it is mixed with the less costly rice blend. A mixture of bean flake and rice flour produce a distinct visual appearance of the beans while creating a well-blended bean flavor with no bitter aftertaste.

D. Oats

In general, oats are marketed as rolled oats or as an ingredient for breakfast cereal. Oats have not been used in grain-based snacks as wheat and corn. Recent discoveries that oat bran can reduce serum cholesterol level in humans have boosted the market for oats in the snack food industry. The major problem with oats is high oil content (7–9%) and lipase enzyme. Before using oats in the snack food formulation, it is desirable to inactivate the lipase. Otherwise lipase will catalyze the hydrolysis of oil, which would lead to the production of bitter tasting free fatty acid. Oat starch granules are comparatively small (2–12 μm) in size as compared to other starches. Amylose content of oats varies from 16–27%. Oat starch has a very strong flavor and it gives light brown color to the product. It requires a relatively low gelatinization temperature, but a higher amount of energy input for cooking because of higher amounts of oil content. Oats contain high levels of fiber. Snacks extruded with oat starch expand poorly. For this reason, it has only found its way into product at low level. By using longer barrel extruders with preconditioner, a higher level of oats can be used in snack foods. Among the snacks that have

traditionally included oats in their formulation are cookies and granola. With new technologies and more interest in oats due to health claims, oat-based snack products may be popular in the future.

E. Barley

Barley is used in small quantities in some snack food formulations. It has a mild flavor and nutritionally it is almost the same as wheat, except it contains considerably more fiber. Barley starch granules are medium to large in size as compared to other cereals. A reasonable amount of expansion can be obtained during extrusion of snack foods using barley starch. It gives light brown to gold color to the product. Snack food formulation containing barley starch needs a low cooking temperature during extrusion. Barley fiber can be used in healthy snack foods, as a fiber supplement. Sometimes, manufacturers use barley in multi-grain snack foods in order to add one extra cereal on the label.

X. OTHER CEREAL SOURCES

Cereal such as rye, sorghum, millet, amaranth, and triticale have been used in snack foods. Presently, these cereals are not major ingredients in the snack food formulation.

A. Tuber Sources

Roots and tubers belong to the class of foods that basically provide energy in the human diet in the form of carbohydrates. According to a recent FAO estimate, virtually every country in the world grows some species of root crop. Potato and tapioca (also call cassava) are two main tuber crops used for extruded snack foods.

B. Potato

Different forms of potatoes (granules, flakes, flours and starches) are used in snack food formulations. Potato starch is often used in snacks to provide extra expansion. Potato starch has a wide range of sizes with some larger granules (60–100 μm) than the other cereals. This starch contains 20–25% amylose and has very low oil contents. Potato starch develops high viscosity during extrusion cooking. It has an excellent swelling and binding power. In snack food it has a definite flavor and it gives gold to light brown color to the product. It requires low cooking temperature since its granules breakdown easily. Potato flour is the major ingredient for two common snack products, i.e., direct expanded snack (product looks like French fries) and fabricated chips.

C. Tapioca

Tapioca (cassava) is a basic source of low calories or a supplement to cereal. In general, tapioca starch is used in third generation snack foods formulation. Tapioca starch grains vary in shape, and size from 5–35 μm. The amylose content is about 17%. Good quality starch should have a pH of 4.7–5.3, a moisture content of 10–13.5% and should be uniformly white in color. Tapioca starch develops very high viscosity and it is an excellent binder. It has a bland flavor and requires moderate cooking temperature during extrusion cooking.

XI. EXPANDED SNACKS

The majority of extruded snacks are in this category. This group is also referred to as "collet" or "second generation snacks." In general, expanded snacks are made on high-hear extruders. These are high-fiber, high-protein, and low calorie snacks. Some examples are corn curls, onion rings, three dimensional snacks, and potato sticks. These types of snacks can be seasoned with a variety of different flavors, oils, salt, sugars, etc. The quality of an expansion-cooked product depends upon the conditions of operation of the extruder and the main raw material used in the formulation. Several other factors can influence the degree of puffing of snacks during extrusion, i.e., amount of moisture in the feed material, dough residence time in the extruder barrel, and cereal particle size.

A. Fried Collets

These are the most familiar extruded snacks in the market. A special die arrangement gives the product a twisted puffed shape. These collets are made on collet extruders. The product is then fried in vegetable oil, and coated with cheese and some other flavor. During frying the moisture level reduces from 8% to 1–2% in this product. The most common material used for fried collet is corn meal. Typical corn meal specifications are given in Table 168.1. Some other cereal grains can also be used for this type of product.

B. Baked Collets

Baked collets are another example of the expanded extruded snacks. This includes products such as baked corn curls,

onion rings and potato sticks. Baked collets can be made with different cereal grains and tuber flours. Protein, fibers, cellulose, and bran can be blended with cereal grain up to 20% to make healthy snacks (11). Potato sticks usually made by mixing potato flour with corn or rice flour. A typical formulation for baked snacks is given in Table 168.2.

XII. THIRD-GENERATION SNACKS

Third generation snacks (3G), also referred to as "half products" or pellets provide an alternative to fully prepared puffed snack foods. Third generation snacks, or half products are extrusion cooked, and formed at low pressure to prevent expansion, and then dried to a final moisture content of about 10% to form a glassy pellet. In developing third generation snacks, "half" of the process is completed to prepare "pellets" which are shelf-stable for periods of up to a year without refrigeration, provided they are properly packed to retain their moisture. Many types of proteins and protein enrichments may be added to third generation snack type recipes such as meats (whole fresh shrimp, fresh chicken, beef, etc.), dairy products (cheese, yoghurt, milk solids) and legume proteins (soy, pea, bean). Up to 30 to 35% levels may be added and still maintain high quality final products (12). Several minor ingredients have very useful effects on the texture, quality and flavor of the final products. Salt is very useful in assisting with uniform moisture migration throughout the third generation pellet after drying during the moisture equilibration period. Baking soda will give special flavor and textural attributes to the finished products after frying, puffing or microwaving. Oils or emulsifiers reduce stickiness during cutting and other processing steps (13). Drying is very critical in the production of good quality third generation snacks. Proper drying will reduce the moisture content of the pellet to approximately 12 percent. Temperatures of 70–95°C and retention times of one to three hours are required. These products are economical to run and have built-in-marketability due to their highbulk density. Third generation snacks can be prepared in homes or restaurants. Unlike typical snack foods, half-products do not yet contain oil that can oxidize to give off-flavor to the products. These pellets can be shipped from a central manufacturing distribution point, held until needed for the market, and then puffed, flavored and packed fresh and locally. New variations of the third generation snacks expand using infrared heating, hot air, or microwaving. The use of hot air systems reduces the oil uptake that occurs in frying and allows a controlled addition of oil to be made as required for flavoring. With consumer concerns about fats and oils, a half product

snack that expands using hot air offers snack food manufacturers an oil free snack with perceived health benefits. Elimination of frying oils reduces calories and allows a marketing opening for snacks with a "lite" image. Typical flow diagrams for the production of third generation snacks are shown in Figures 168.1 and 168.2.

With the multidimensional snack system, a wide range of raw ingredients can be used to blend together to make an excellent formulation for many types of third generation snacks. The extruder feed must contain a high level of starch to maximize expansion of the collet during exposure to hot oil or air. Levels of 60% or less total starch in the formula give only slight expansion in the puffing step and yield a final product with a crunchy, hard texture. Wheat, corn and tubers are widely grown crops in developing and industrialized countries, and they are cheaper and more available in the market than the other cereal crops. Several formulations for third generation snacks are given in Table 168.3.

XIII. CO-EXTRUDED SNACKS

This is a relatively new technology introduced in 1984 for the snack food industry. In this process two different materials are extruded from one die. The two materials can come from two extruders or from one extruder and one pump. This process can produce a snack with two

different flavors, or two textures or two colors. The most common snack produced by co-extrusion is a cereal-based outer tube with a cheese filling inside. There are three basic types of co-extruded snacks in the market: cereal-based tubes with cereal-based fillings, cereal-based tubes with fat-based fillings, and cereal-based tubes with water-based filling. The shelf life of these snacks is limited, because of migration of moisture and/or oil from the filling to the outer shell. A typical formulation of co-extruded snacks is given in Table 168.4 (14).

In conclusion, snacks can be processed by a variety of different methods and techniques. Several new raw materials containing nutraceutical and functional properties are being introduced in the market every day for snack food products. Snacks can be made with a combination of different raw materials containing different properties. The role of snacks in a healthy lifestyle is only starting to be developed. The recognition of snacks as healthful will increase as industry changes products from merely good taste to nutritious.

169 Coating Snack Foods

Sheryl Barringer
Department of Food Science and Technology, The Ohio State University

CONTENTS

I. THE SNACK FOOD INDUSTRY

The snack food industry includes everything from chips to confections, from salty to sweet. In the United States, sales of savory snack foods reached $21.8 billion in 2001, according to the Snack Food Association's State of the Industry report. If cookies, crackers and snack bars are included, sales top $34 billion. Potato chips, America's favorite salty snack, accounted for $6 billion of those sales. Overall, the snack market ranks third in total dollar sales in supermarkets, which comes to around 22 pounds per person, per year. Snack foods are sold everywhere from retailers to prisons. They're eaten at every mealtime, and in between, from breakfast pretzels to midnight chips, and they're popular in every demographic age group from the cradle to the grave (1).

Much of the success of snack foods is due to the coatings that are applied. Coatings are added to a variety of foods because they add novelty, give an attractive appearance, define the product shape, improve taste, increase shelf life, protect ingredients, prevent migration of core constituents, create texture, or maintain structural integrity. Coatings are especially important in the snack food industry where the snack base (which frequently consists of items such as corn chips, popcorn, and extruded corn starch) often has an unattractive appearance and tastes bland, mealy, sticky, dusty or dry. The secret to the popularity of these snacks is coatings which give an appealing color and flavor.

For most snacks, it is the way they are coated that produces their pleasant mouth sensations and taste profile (2). The majority of flavored snack products are flavored topically, that is, the seasoning is applied onto the surface of the product. Some flavorings are incorporated into the main body of the snack, but the high temperatures involved in baking, frying or extruding drive out most of the volatile flavor compounds, making it necessary to apply the bulk of the flavors to the surface of the product.

II. ADHESION OF THE SEASONING

Since most seasonings are applied on the surface of the product, it is critical that the seasoning adhere to the surface for the entire shelf life of the snack. For fried snacks, seasonings are typically applied as a powder. The snack goes straight from the fryer to the coating line so that the product is still hot and the surface of the snack is still wet with oil when the seasoning is applied. Thus, no additional tack agent is required. The temperature of the snack has only a small effect on the adherence of the seasoning. Comparing potato chips at 300 and 100°F, the adherence decreased from 81 to 68% (3).

Alternatively, oil can be applied directly as a tack agent (Figure 169.1). The dry product is sprayed with oil, then seasoning is applied and adheres to the oil. Other tack agents include water, sugar water and hydrocolloids. For these solutions, a final drying step is required, which may be undesirable with dry snack foods because of the increased expense from the additional processing step.

Some products, such as fried corn chips, absorb most of the surface oil after frying, so they require a secondary spray

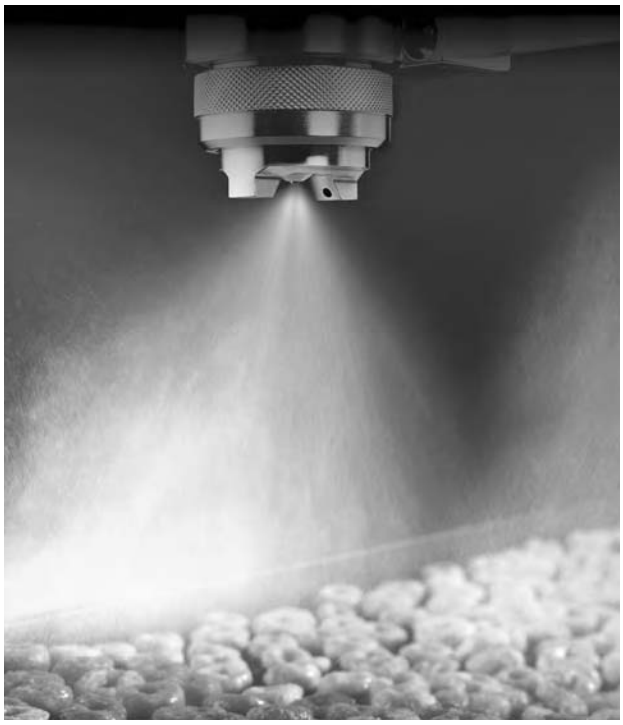

FIGURE 169.1 Application of liquids onto the surface of foods. (Photo courtesy of Spraying Systems Co.)

FIGURE 169.2 Over the belt seasoner. (Photo courtesy of FMC Food Technologies/Allen Systems PPM.)

of oil after the powder is applied, to hold the seasoning to the surface. A top coating of oil is also added to low or no fat snacks, to add palatability. Without the surface oil, these products are unpleasantly dry in the mouth.

III. COATING APPLICATION METHODS

Coatings can be applied to snacks on a conveyor belt or inside a tumble drum, in coating pans or by enrobing. Each method has its own advantages and disadvantages, and produces different coating characteristics.

In a conveyor belt system, the seasoning is dispensed over the belt, so that only one side of the snack is coated, unless there is a device to flip the pieces over. In some foods, such as potato chips, the chips are layered two or three layers deep, so that more seasoning lands on the top layers. One study found that adherence dropped from 60% on the top layer to 30% on the middle layer and 10% on the bottom layer (3). Thus, a conveyor belt system may not produce snacks that are as evenly coated as other methods, but requires much less space. In some factories there is not enough ceiling height to allow for tumble drums to be installed, and so conveyor belts are used instead. In addition, some companies use conveyor belts because they want to apply seasoning to only one side of the snack, such as for crackers. If the snacks are only one layer deep and one-sided coating is desired, this method can give very even coating. However, more waste is typically produced because the food does not cover the entire surface of the belt, unless a waste recovery system is used. An example of a seasoner that can be placed over a conveyor belt is shown in Figure 169.2.

Many foods are coated in a tumble drum because the tumbling action mixes the product as the seasoning is being applied, producing even coating on both sides. Tumble drums are horizontal cylinders with one end raised so that product flows from one end to the other. Flights are set inside the drum which lift the product, causing the product layers to be rearranged as they move down the drum. As the layers of product slide over each other there is some transfer of seasoning, producing more even distribution of powder. Spray nozzles and dispensing tubes can be installed inside the drum, so that the snack may be sprayed with oil in one section, then coated with powder in the next. Popcorn being salted in a tumble drum is shown in Figure 169.3.

Another method is coating pans, which are a slow, batch process, but have become highly automated. The panning process consists of building up successive layers of coating on a core material. The core is commonly a nut, dried fruit or candy, and the layers of coating are most commonly sugar or chocolate. The product is tumbled in a smooth pan which comes in different shapes. The round, or apple shape is the least effective shape for coating because it doesn't move the product from the front to the back of the bowl. The doughnut shape is for coating nuts with sugar (Figure 169.4, left). The pear shaped bowls move product around the most effectively and are the work horse of the coating industry (Figure 169.4, right). Coating is sprayed

FIGURE 169.3 Popcorn being coated with salt in a tumble drum.

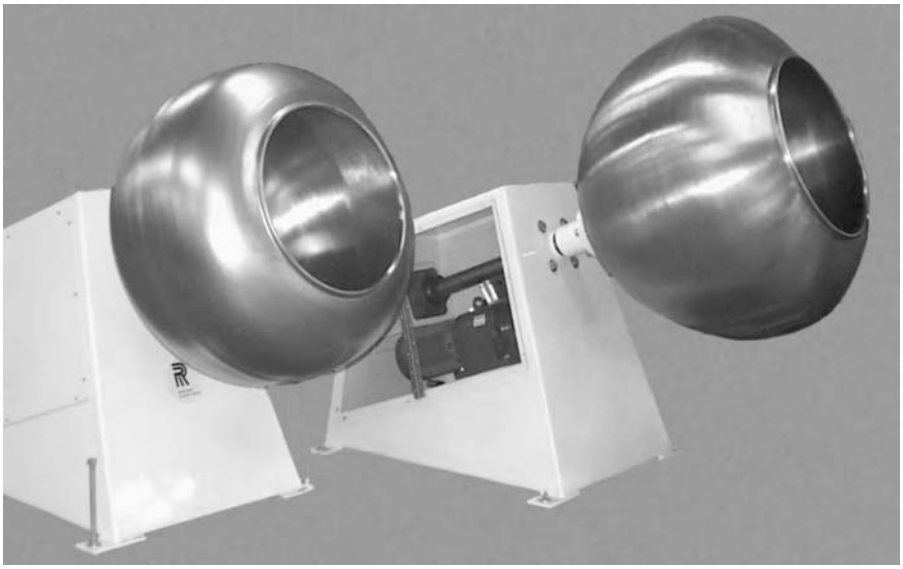

FIGURE 169.4 Donut shaped (left) and pear shaped (right) coating pans. (Photo courtesy of Royce Metal Products Limited, Toronto Canada.)

onto the core material then dried with forced air, and the process repeated until the desired number of layers has been built up. This is popular for approximately round, evenly coated snacks, such as yogurt covered peanuts. These products have smooth surfaces caused by the polishing action of the pan. If a rough surface is required, this can be produced by spraying on maltodextrin to produce a bumpy surface.

Enrobers work by dipping, pouring or spraying a liquid coating onto a core material (Figure 169.5). Products that are dipped may be individually dipped, such as caramel apples, or carried between two belts to keep the product submerged as it is carried through the coating. Other products are coated by passing underneath a curtain of molten coating, especially for chocolate. With a curtain, a pan

FIGURE 169.5 An enrober. (Photo courtesy of Macintyre Chocolate Systems/Ladco.)

beneath the curtain catches the excess coating and recirculates it to the top. Air knives are used to remove excess coating and control the thickness of the coating. This is followed by a shaker to remove further coating. Disks, wires or rollers are used to apply a final decoration on the top of the product (Figure 169.6). A pre-bottomer may be used with a curtain system, especially for chocolate coatings. In a pre-bottomer, the core material is passed through the coating on a conveyor belt, then passed over a cooling plate to set the coating, before proceeding through the curtain.

A subset of enrobing is battering. Batters are produced from flour, starch, sugar, fat and water, with some flavorings added in, though the majority of the flavor is usually applied as an oil slurry onto the outside of the batter. If a smooth surface on the batter is desired, the product is tumbled in a coating drum with smooth walls to produce the desired surface smoothness (2).

An even smoother coating can be produced by spraying on a hydrocolloid solution. Gum arabic is common, as well as modified starch. Once dried, the coating has a glossy, crunchy surface. The solution itself has a bland or starchy flavor, so flavorings are sometimes added into the coating solution to produce a more desirable flavor.

IV. POWDER COATING

Powdered seasonings can be dispensed from several different types of distributors. Powdered seasoning can be applied by gravity feed out of a tube, pneumatically conveyed by forced air or centrifugally applied by spinning cones or disks. Many systems are gravity fed due to the simplicity of the design. In a seasoning tube, the seasoning is conveyed down the tube along the flights of a rotating screw (Figure 169.7). Seasoning may be dispensed only out of the end of the seasoning tube, or the tube may have small openings along its length, allowing seasoning to fall out over the whole length of the tube. The curtain of seasoning produced by the powder falling out of holes along the length of the tube can be seen in Figure 169.3. Another gravity fed device is a roll salter, which employs a slotted roller to dispense salt or seasoning over unseasoned snacks on a conveyor. Systems using air currents or centrifugal force to dispense the powder are especially useful for cohesive powders that tend to clump and produce erratic feed rates in gravity fed systems.

Snack manufacturers put 30–50% more seasoning than actually needed onto a product because of the expected waste (4). Also, to produce more even coating, flavorings are often diluted with a bulking agent so that excess powder can be added to the coating system (5). During processing, the extra coating falls off and leaves the food with a more uniform coating than would be possible if only the desired amount was applied to the food initially. A recycling system is installed under some coating systems to capture the powder that falls off, remove the fines and clumps and reuse the rest of the seasoning.

V. LIQUID COATING

Sometimes oil or other liquid coatings are applied to the surface of a product (Figure 169.8). Oil-soluble flavors and colors may be dissolved in oil and applied directly to

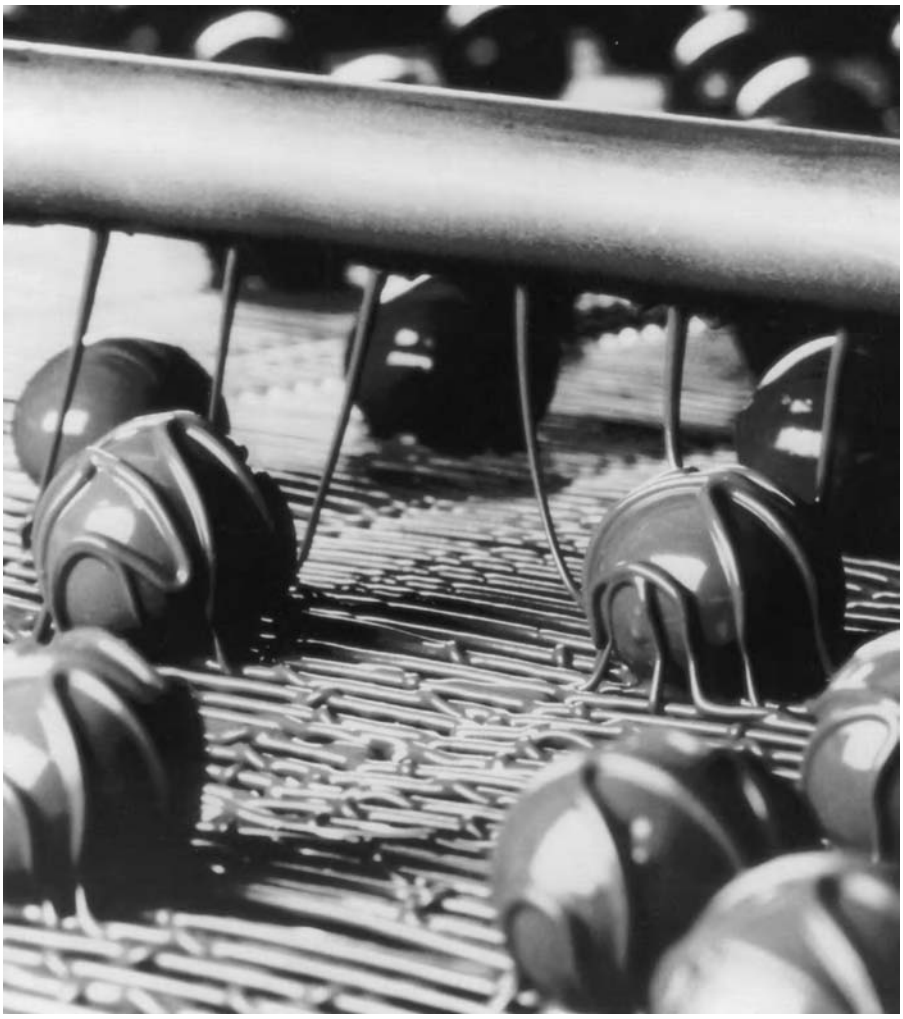

FIGURE 169.6 Adding the final decoration. (Photo courtesy of APV Baker.)

FIGURE 169.7 A screw-type seasoning dispenser. (Photo courtesy of Spray Dynamics, Inc.)

the surface of the product. Sugar solutions are also commonly sprayed onto the surface, especially for breakfast cereals. When applying sugar, solutions of 80% sugar are often made so that less water needs to be removed from the final product. The solution needs to be kept heated to keep the sugar in solution since it is above the saturation point at room temperature. For snacks that are not fried or have a dry surface, an oil slurry can be used to apply seasonings. The powder is suspended in oil in a ratio of 80:20, oil to powder (2). The slurry is sprayed onto the product, applying the seasoning and tack agent at the same time.

FIGURE 169.8 Spraying of oil onto the surface of bread. (Photo courtesy of Spraying Systems Co.)

The biggest challenge with liquid application is to produce an even spray pattern across the surface of the

conveyor belt or within a tumble drum. Nozzles have been designed to produce circular, donut, fan and other spray patterns in an attempt to produce more uniform application. In comparison to powder application, liquid application is usually very even and the amount of liquid delivered is very reproducible.

VI. ELECTROSTATIC COATING

The basis of electrostatic coating is that by charging the seasoning powder as it is dispensed, it is attracted to the food product, which is grounded through contact with the conveyor belt or tumble drum underneath it. The charged particles tend to separate and distribute themselves evenly as they coat the food item because of repulsion between the particles. Electrostatic attraction has been claimed to produce a more homogeneous coating even on difficult shapes, reduce seasoning fall off and make it possible to lower the oil content by up to 20% because of improved adherence (6). The charged powder coats not only the surface of the work piece facing the coating source, but also the more difficult, hidden regions, due to the wrap around effect of the space-charged field (7). The attraction of the charged coating particles towards a ground also reduces dust that would otherwise be produced (8). The use of electrostatics has been shown to increase transfer efficiency an average of 68% and decrease dust 65% (9). A labeled example of an electrostatic system is shown in Figure 169.9.

A comparison of an electrostatic salter with a mechanical salter found that the electrostatic salter maintains uniform spacing of particles during dispensing by inducing a negative static charge on their surfaces, causing the particles to mutually repel each other and producing a more even distribution of salt (10). Other foods that are electrostatically coated include seasoning corn and tortilla chips (4), putting salt onto crackers and pretzels (11), and flavors onto confections (12). Liquid smoke applied to meat electrostatically improves flavor uniformity and decreases waste (13). The bactericide added to control pathogens on the meat surface can be reduced by as much as 90% using electrostatic coating because electrostatics improves coating evenness and eliminates overspray (14).

In the flavor industry, some flavor houses perceive electrostatic application as a reduction in revenue, however some producers have experienced an increase in market share and thus require more flavor to meet the demand (15).

VII. SALT

The most common snack food seasoning is salt. Typically, salt is the first flavor variety sold and if the product is successful, line extensions are developed using other seasonings. But even with other seasonings, salt is added to accentuate the flavor. The Snack Food Association recommends a salt level of 1.75% plus or minus 0.25% for salted potato chips. Between 1.5% and 1.7%, the saltiness curve is ascending, so small differences in concentration can make a larger difference in saltiness (16). There is a plateau region between 1.7% and 2.5% where additional salt adds very little to the intensity of taste.

Most salt in the food industry is produced by thermal evaporation of artificial salt brines. Salt is available in different shapes. Purified brine is evaporated in a vacuum pan to produce a concentric or cubic form of crystalline salt, which is then screened into different size fractions (Figure 169.10, top). A second salt shape is dendritic salt. Dendritic salt is a porous variation of the cubic crystal. Its crystal formation is interrupted by sodium ferrocyanide, also known as yellow prussiate of soda (YPS). Low levels of YPS added to the brine prevent normal crystallization. The crystals form as aggregates of attached cubes,

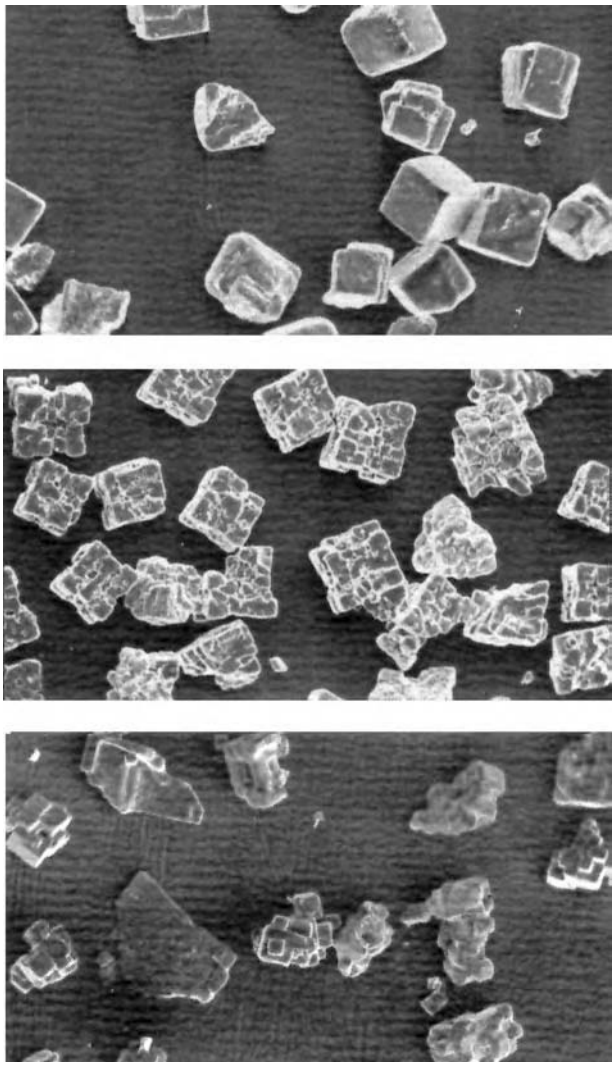

FIGURE 169.10 Cube (top), dendritic (middle) and grainer (bottom) salt. (Photo courtesy of Morton Salt Co.)

providing a porous structure with large surface area and good adherence (Figure 169.10, middle). A third type of salt is produced by evaporating salt in the grainer, or modified Alberger process (16,17). Due to evaporation at the surface of the brine, the uppermost layer of the brine becomes saturated before the lower, causing the crystal nuclei to be produced entirely at the surface. The crystals are held there by surface tension but, being heavier than the brine, are partially immersed into it. Because crystallization proceeds at the surface, the crystals grow laterally, causing them to sink more deeply. The result is a hollow quadrilateral pyramid, floating inverted, with thin sides and a relatively heavy bottom point (Figure 169.10, bottom).

Salt is also available in a range of sizes. Size can be determined by laser diffraction, but it is most commonly sold based on sieve size. Generally, the percent retained in each sieve of a series of sieves is reported, though in some cases a single sieve size is reported. When a single sieve size is reported, it is the sieve that stops at least 50% of the salt. The sieve size is the number of wires per square inch, thus the larger the sieve size, the smaller the salt. Salt is available from coarse or pretzel salt at a 20 sieve size, down to extra fine with a 325 sieve. Flour salt, originally developed to mirror the size of wheat flour, is about 70 mesh. The size is adjusted to match the size of the powder it is blended with. The size can be reduced by grinding rolls or screening out the smallest size fractions. If the salt is formed with grinding rolls, it no longer has a regular form (18).

The size of the salt affects a number of factors. The taste perception of salt is affected by the size of the salt crystals. Small salts dissolve quickly because they have a large surface area to weight ratio, creating an intense salty sensation, but then disappear quickly. Larger salt particles provide a longer lasting salty perception because they dissolve more slowly (16). Fat decreases the intensity of saltiness, so in snacks with a large amount of surface fat, small particles of salt are enrobed in fat, losing their intensity. For that reason, large salt is typically used for potato chips and high fat snacks (16). Dry snacks with less than 30% oil, such as tortilla chips, work best with a small particle size flour salt because the small salt has better adherence, more uniform distribution and high solubility.

Size also affects salt's flow characteristics. The ability of the salt to flow is crucial to produce an even, reproducible coating on snacks. Flowability is improved by low humidity in the environment, a free flowing structure such as for cubic salt, and the use of anti-caking agents, such as tricalcium phosphate (TCP). Smaller salts can be more evenly applied, though this size benefit may be offset because smaller salts are more cohesive and will clump readily unless an anticaking agent is used.

It is important that the size and density of the salt be the same as the other ingredients in a mixed seasoning blend to minimize stratification during handling. The density of salt can be decreased by the addition of sodium ferrocyanide to interrupt the crystal structure and produce a more porous structure. Also, the more irregular the shape and the more porous the structure, the lower the bulk density. Since salt is denser than most food powders, the goal is typically to reduce the salt's bulk density and match its size to the other powders.

The solubility of salt is important in some food systems because it determines how rapidly the salt will dissolve in the food system. When high solubility is desired, a porous structure, such as in dendritic salt, will be more soluble. The irregular surfaces found in Alberger and pulverized salt also make them go into solution more rapidly than cube salt. In some cases, a lower solubility is desired. For example, large, rock salt is frequently added to pretzels for visual appeal. However, the partially dissolved salt raises the local heat capacity, creating a weak spot in the dough. This is not a problem for large pretzels, but for small, thin pretzels, flake salt is used instead because it is

less soluble, causes less of an increase in heat capacity and therefore is less likely to cause blisters (16).

Once the salt reaches the snack, it must adhere to be of any value. Flakes give better adhesion than cubes because of their larger surface area. For crackers especially, adhesion can be difficult because of their smooth surface. Crackers are frequently oiled then flaked or dendritic salt is applied because they have the best adherence to the smooth cracker surface.

VIII. OTHER FLAVORS

The most popular flavors for salty snacks are cheese, BBQ, sour cream and onion, and ranch (5). Typical seasoning levels are 8–10%, depending on the seasoning and snack base (3). These flavors are complex, and change over the years as consumer preference changes. The flavor base frequently combines cheese, tomato, onion and garlic. Monosodium glutamate, yeast extracts, disodium inosinate and disodium guanylate can be added to accentuate savory, salty flavors. Botanical extracts may also be added to boost savory notes, as well as acting as antioxidants. Maltol is a sweetness enhancer, but it also enhances and modifies savory flavors, adds mouthfeel, increases creaminess and dairy notes and decreases bitterness. At low levels, salt enhances sweetness as well as rounding out flavors. Fillers such as maltodextrin, whey powder, wheat flour, or corn flour are also used to add bulk (5). Finally, a free flow or anticaking agent such as silicon dioxide or tricalcium phosphate is used to prevent clumping.

Anticaking agents are frequently added because of the hydrophobic nature of many food powders. These are very small powders that are added to another powder to inhibit its tendency to cake, improving the flowability (19). Most anticaking agents are insoluble in water but many of them can absorb considerable amounts of water as a result of their large surface area. The host particles are coated with a layer of these anticaking particles and are physically separated. Thus the points of contact are between anticaking particles, which are chosen primarily for their low attractivity. This prevents the rest of the powder from clumping.

Another problem with flavors is their tendency to lose intensity quickly during storage. Flavors deteriorate on snacks primarily because of oxygen and ultraviolet rays. To minimize loss, snacks can be packed in nitrogen flushed, aluminum foil laminate bags. Greater than 2% moisture in potato chips also accelerates oxidation of both the flavors and the oils. Flavors can be encapsulated to extend shelf life but this is not common due to the cost.

IX. POWDER PROPERTIES

The effect of size and shape on taste, adherence and flowability has already been mentioned in the section on salt. The increased flavor intensity as the particle size decreases is used in a number of applications, such as powdered sugar on donuts (20).

In a typical gravity fed tumble drum application, the most efficient coating is produced by small, free flowing powders (21). Larger particles are more likely to be unevenly distributed, and are more likely to fall off of the product. Free flowing powders produce a more reproducible flow rate and are evenly distributed across the surface of the product. If the powder is cohesive or ambient humidity gets too high, spices clump, and uniformity in application suffers. Many flavor powders are very hygroscopic and agglomerate easily. Thus the addition of anticaking agents is important to keep powders free flowing. The smaller the powder, the more cohesive it is (22), thus anticaking agents are especially important for small powders. In a pneumatically fed conveyor belt system, free flowing powders are still the most efficient, but efficiency increases as particle size increases. This is because smaller particles are more likely to be lost off the conveyor belt unless a powder recovery system is used.

CONTENTS

I. INTRODUCTION

Vegetables are increasingly recognized for their values in human diet. A commercial vegetable business is an important sector of the agricultural industry. Several important fresh vegetable commodities (e.g., potatoes, tomatoes, sweet corn, peppers – red and green, onions, lettuce, cabbage, and cucurbits) are currently important in the international market. Production and consumption of processed vegetables are also increasing in the world market.

Vegetables are highly perishable fresh food material. Water loss and post-harvest decay account for most of their losses. The post-harvest technology for treatment and storage of vegetables is critical to minimize wastage and to obtain the maximum benefits from the harvested crops.

Post-harvest technologies include harvesting, handling, maturity, low temperature storage and environmental control (controlled/modified and hypobaric storage), irradiation, use of chemicals and fungicides, packaging techniques and processing of fresh vegetables into suitable products with improved storage characteristics, etc.

II. CLASSIFICATION

Vegetables grown for their leaves or stems are cabbage, kohlrabi, collards, asparagus, rhubarb, salad crops and all leafy greens or potherbs. Vegetables used for their fruits include tomatoes, melons, eggplant, okra, peppers, beans and peas; and those grown for their flower parts include cauliflower and broccoli. Vegetables grown for their underground portions (roots, tubers, bulbs, and corms) are potatoes, sweet potatoes yams, taro, cassava, beets, carrots, parsnips, radishes, turnips, onions and garlic. Crops within a family may vary widely in their physiological characteristics, growth conditions, and requirements for cultural practices. Potatoes and eggplant, for example, belong to the same family, *Solanaceae*, but their requirements are very different. However, other crops in this family, such as tomatoes, eggplant and peppers have similar requirements. While only a few vegetables belong to the class Monocotyledonneae (e.g. sweet corn, onion, garlic, or taro), most other vegetables belong to the class Dicotyledonneae (two seed leaves), including crucifers, peas and beans, and cucurbits. All crops belong to the *Solanaceae* or *nightshade* family.

III. PRODUCTION

With the continuous increase in demand, the world vegetable production has been largely expanded in the past two decades (1). Total acreage of land used for vegetable production was about 47 million ha in 2002, which was 74% increase from 1982. Meanwhile, yield per ha has also increased by 26% within the same time scale, with the adoption of improved management practices, such as, new varieties, optimized fertilization, irrigation, and weed management. Both expansion of land acreage and increases of yield per ha have contributed to the substantial increase of the total production.

The present annual world production of vegetables is close to 800 million metric tones, 2.2 times of what it was in 1982 (1). China is the largest producer of vegetables in the world, accounting for about 47% of the total vegetable and melon production, followed by India (10%), United States (5%), and Turkey (3%). China and India together produce more than half of the world total production.

The production of several vegetable crops in the less-developed countries includes roots and tubers (the cassava, potato, sweet potato, yam and aroid root), which form the majority of the total vegetables produced in the tropical countries providing staple food for over 500 million people. The comparison of total agricultural area covered by the vegetable production, of average yield and import and export figures in the developing and developed countries clearly indicates that there is a great scope to increase the vegetable production by improvements in pre and post-harvest technology. Although the total vegetable area of the developing countries in the world is about six times larger than that of the well developed countries, the mean yield per hectare is only one half. Export of vegetables by developing countries is low and there is a lack of uniformity in the quality of vegetables.

The high production of vegetables in most developing countries is mainly due to the increase in area under cultivation. Owing to poor harvesting, handling, processing and marketing of these perishables, high post harvest losses occur in tropical and subtropical countries, which vary widely according to commodity and areas.

IV. PHYSIOLOGY OF VEGETABLE

A. Seed Storage and Germination

Most vegetable crop growth and development begins with seeds. Physiological aspects of seeds related to storage, germination, quality and enhancements are practically important. Seeds are stored at low water content and they have unique characteristics that permit them to withstand desiccation. The period of storing time from harvesting to sowing can vary from a few months to several years. Two major environmental factors influencing seed storage are seed moisture content and temperature.

Moisture content is determined by the storage relative humidity and by seed characteristics. Seed components determine the water binding status in seed tissues, which governs the types of reactions, enzymatic or non-enzymatic, that may occur during the storage. Since the variation of components in seeds from different vegetables, the water binding status in seeds can be variable, and is classified into three types. Type 1, water is bound tightly and interacts very strongly with charged groups of proteins (2). Type 2, water is less tightly bound and condenses over the hydrophilic sites of macro-molecules (3). Type 3, water is bound with very small energy and forms a bridge over hydrophobic moieties (2).

Temperature has a direct and significant influence on longevity of storage. The rate of seed deterioration increases with increases in temperature at a given relative humidity.

Seed aging (e.g., loss of germination) during storage for a particular species maintained under a given moisture content and temperature can be predicted by using the Ellis and Roberts equation as follows (4):

$$v = K_i - p/\{10\exp[K_E - (C_w \times \log m) - (C_H \times t) - (C_q \times t^2)]\}$$

where v is the probit of the germinability (%) after a storage period of p days; K_i represents the probit of the initial germinability; K_E, C_w, C_H, and C_q are species-specific constants; m is the seed moisture content expressed on a fresh weight basis; and t is the storage temperature (°C). The storability of vegetable seeds varies largely amongst the species.

Seed germination is the transition period between the resting and the growing stages of the plant. Germination

starts with water uptake, of which the process can be explained using the terminology of water potential, the sum of the matric, osmotic and pressure potential. Water uptake in vegetable seeds can be classified as a three-phase pattern, 1) the initial rapid uptake phase, 2) a lag phase, and 3) a second increase in moisture content. Phase I is known as imbibition which is a physical process that happens in both living and dead seeds (5). The water uptake during this phase proceeds very rapidly (such as tomato seeds are fully imbited in a period of 4–8 hours), and is caused by cell wall components and proteins, which form the negative matric potential. With the process of imbibition, the seeds swell due to the expansion of hydrophilic compounds, such as proteins, pectic substances, and cellulose (6). During phase II, the osmotic and pressure potentials regulate the total water potential, because the matric potential is very small. During this phase, enzymes and membranes are functional in the fully hydrated cells as seed advances to the completion of germination. The duration of phase II is largely species dependent and is influenced by the environmental conditions, especially temperature. There is little water uptake in phase II. Phase III of water uptake starts with visible germination. In this phase the seed coat is ruptured by the emerging radicle which forms the root system. Radicle growth is caused by cell elongation, and then followed by shoot growth. Consequently, the seed becomes a seedling and meanwhile losses its ability to withstand desiccation. Drying seeds during phase I and II is not injurious to the viability of the seed, while drying seeds after visible germination will result in death of the radicle.

Factors affecting seed germination include water, oxygen, temperature, and seed quality. While plant population is not a factor, seed vigor is important for yield potential in many vegetable crops, especially those harvested in the vegetative or early reproductive stages.

B. Transplanting

Transplanting is a practice which is often used with small-seeded vegetable crops, particularly those which are slow or difficult to germinate, or need special germination conditions**.** In the areas where growing season is short transplanting technique is also often used. Factors controlling the growth rate of seedlings and transplant size include the size of container cell, above ground space among individuals, supply of water and mineral nutrients, light quality, growth-retardant chemicals, day-night temperature differences and transplant pruning.

The growth rate of seedlings is proportionate to the volume of the container cell. Big container size means that loosely spaced individuals have more total light available which is richer in far-red light than do individuals close to each other. Seedling plants develop elongated stems and petioles when illuminated with light having relatively high amounts in the far-red (725 nm) compared to the red (650 nm) part of spectrum. The more growing space available to the plant, the larger it becomes, and the more rapidly it attains particular stage of growth. Sufficient supply of both macro- and micro-nutrients (N, P, K, Ca, Mg, S, B, Mn, Cu, Zn, Mo, Fe, Cl) is necessary for satisfactory growth of plants in transplant containers. Stem extension is favored with higher day temperature relative to night temperature. Removal of leaves from transplants in early days would reduce moisture loss from the plants in the field and result in more rapid establishment.

Satisfied transplants expected are the seedlings which are capable of withstanding stress during transplanting and of hastening the recovery of active growth in the field. Many researchers have found that early yield of tomatoes is enhanced by producing seedlings in large rather than small containers. However, for production systems in which earliness is not important, such as production for processing tomatoes, transplants grown in small cell volume can give satisfactory yields.

C. Development, Growth and Yield Formation

In general, the entire period of plant development and growth can include two stages, vegetative stage and reproductive stage. Sowing is the start of the development and growth processes, after which plants emerge, grow, develop with or without transplanting. Vegetables may be harvested in the vegetative (such as cabbage and lettuce) or reproductive phase (such as tomatoes and green pepper). After transplanting growth phase or the equivalent phase if directly seeded, the plants will experience the exponential growth phase and the linear growth phase. If the vegetables are grown for reproductive organs, the plants will continue to experience fruit growth phase (flower bud differentiation, anthesis, fertilization, concentrated or continuous fruiting) and grain filling phase. All the physiological processes and consequently the formation of harvesting yield are affected individually and/or interactively by a number of variables, including soil factors and climatic conditions.

1. Soil Factors

Major soil variables affecting vegetable growth and development are nutrients, moisture, aeration and temperature.

Nitrogen is the essential component for amino acids, proteins, and enzymes or co-enzymes. Nitrogen deficiency generally reduces photosynthesis and limits plant growth. In the early stages of nitrogen deficiency, carbohydrates accumulate in leaves and in the root system. The reduction of photosynthetic rate caused by nitrogen deficiency is not apparent until later, so the plants temporarily have a surplus of carbohydrates, which may be available to continue root growth. Induced nitrogen deficiency can cause increases in levels of ABA, which consequently leads to the reduced expansion of leaves. In general, nitrogen

deficiency has relatively larger effect on vegetative growth than on reproductive growth.

The most essential function of phosphorus in plants is in energy storage and transfer. An adequate supply of phosphorus at the early stage in plant life is important in the development of its reproductive parts. A large quantity of phosphorus is found in seed and fruit, and is considered essential for seed formation. A good supply of phosphorus is also associated with increased root growth, greater straw strength, enhanced resistance to disease and other adverse environmental conditions and early maturity of crops.

Potassium, not like nitrogen, phosphorus and most other nutrients, forms no coordinated compounds in the plant. Instead it exists solely as K^+, either in solution or bound to negative charges on tissue surface through radicals. Potassium is involved in activation of 80% of enzymes in plants. Potassium provides much of the osmotic "pull" that draws water into plant roots and maintains plant turgor, which is essential to the proper functioning of photosynthetic and metabolic processes. Potassium deficiency causes plant lodging due to the weaken straw, increases in crop damage by bacterial and fungal diseases, insect and mite infestation, and nematode and virus infection.

In general, the reaction of the plant to deficiencies of particular nutrients will depend on the specific effects that those nutrients have on shoot growth, the rate of photosynthesis, the export of assimilates and their on-time proper distribution. There are interactions among nutrients which can be either positive or negative. For instance, excessive phosphorus uptake may reduce zinc uptake and thus cause zinc deficiency. Increased nitrogen uptake can increase crop phosphorus demand accordingly.

Soil moisture content is another important soil factor influencing vegetable growth and yield formation. Excessive water supply reduces soil aeration and respiration rate of crop roots which consequently decreases water and nutrient uptake, while shortage of soil water decreases nutrient availability to crops and leads to the development of deep-rooting systems.

2. Climatic Conditions

Typical factors of climatic conditions affecting plant growth and development are temperature, precipitation (both quantity and temporal distribution), radiation and CO_2 concentration.

a. Temperature and radiation

Both production and partitioning of assimilates are influenced by light quality and intensity. The photosynthetic active radiation is from 400 to 700 nm. When a plant is transferred to a low light condition, growth of the shoots closest to the light source is relatively less decreased than root growth. Meanwhile, leaves become thinner to maximize the capacity for light interception per unit plant biomass. Partitioning of assimilates for some plants can be affected by light quality. Storage of root-bearing crops by exposing to far-red light enhances stem growth.

It has been long certain that a given genotype of any annual crop has its own definite optimal requirements of temperature and light, called photoperiod. The plant can not proceed at an economically desirable rate to flower formation, flowering and the production of seeds, if the photoperiod is not reached. All crops of tropical or subtropical origin are essentially short-day plants, whereas the majority of crops temperate or Mediterranean in origin are long-day plants. In addition, many species of crops also include genotypes which are intensive to photoperiod, named day-neutral plants.

b. Precipitation

The quantity, intensity, and seasonal distribution of rainfall in a certain area are directly related to the timely supply of soil water to the growth and development of vegetable crops. In order to meet the crop demand for maximized crop production, irrigation is often required when possible. In addition to springer irrigation, drip irrigation or fertigation has been widely used to increase the water use efficiency and to minimize the adverse effects of agricultural chemicals and nutrients on surface and ground water quality.

c. CO_2 concentration

Carbon is a main component of plant biomass, making up 40–45% of total dry matter. Plants adsorb CO_2 mainly from atmosphere, with a small amount from the soil solution, and form carbohydrates through photosynthesis. Increase of CO_2 concentration in the atmosphere enhances the reactions of photosynthesis and consequently the crop yield. Fertilization of CO_2 has been largely used in vegetable production under controlled environment, such as greenhouse.

V. COMPOSITION AND NUTRITIONAL VALUE OF VEGETABLES

Leafy vegetables (or edible leaves) form the second important category of vegetables. They are the most important sources of essential minerals, vitamins and dietary fiber for the regulation of digestive tract. The third important category of vegetable, "fruit-type vegetables," including tomato, eggplant, pumpkin, squash, gourd, also provides protein, vitamins, and minerals, apart from their greatest value in adding variety to the human diet. The immature or green grain legumes (peas and beans) are the most important sources of protein. With some crop types, in addition to their pods, leaves, flowers and sprouted dried seeds are also utilized.

The nutritional value of vegetables as a food source of essential minerals, vitamins, dietary fiber, and as a source of many health-promoting compounds has been well recognized. Vegetables not only supply fair amounts of carbohydrates, proteins and energy, but also play an important

role in human nutrition in supplying certain constituents. Dietary fiber and secondary metabolism constituents in vegetables are increasingly realized for their health benefits in recent years. The possible beneficial effects of crude fiber and secondary metabolism constituents derived from vegetables on human health are being examined by extensive research *in vivo* and *in vitro* trials.

Vegetables are fair suppliers of calcium, phosphorus, and iron for the needs of human body. Leafy greens are rich sources of calcium (or calcium oxalate), phosphorus and iron. Vitamin C is an important constituent from vegetables. Human's dietary vitamin C is obtained mostly from vegetables. Some vegetables are rich sources of vitamin A, thiamin, niacin and folic acid. Vitamin A (beta-carotene) is essential for the normal functioning of the visual processes and structure of the eye. Vegetables do not contain an active vitamin A compound, retinol, but certain carotenoids such as beta-carotene are converted by man to active retinol in the body. The carrot, sweet potato, and spinach are rich in vitamin A. Carbohydrates in vegetables is in the form of cellulose, hemicellulose, pectic substance and lignin. The human body lacks some enzymes like cellulose, hemicellulase and pectinase. The epidemiological evidence shows that dietary fiber is critically important to cure several diseases of human body. Most vegetables, especially the leafy vegetables, such as celery, cabbage, spinach and lettuce, contain a high percentage of cellulose (fiber). Vegetables also supply protein, lipid, organic acids, and volatiles giving a characteristic flavor or aroma to the produce.

While cucurbits are generally low in carbohydrates, starchy vegetables such as potatoes, sweet potatoes, taro and cassava are high in carbohydrates. Most vegetables contain about 2% protein and some, such as dried seeds of beans, peas and lentils, are rich sources of proteins. The lipids comprise less than 1% of most vegetables and are associated with protective cuticular layers on the surface of the produce and with cell membranes. Spinach, legumes, potatoes and tomatoes contain a relatively higher proportion of citric acid; and melons, broccoli, carrots, celery, lettuce and onions are rich in malic acid.

Another special group of components in vegetables that needs to be pointed out is the toxicants, which are defined as the incidence of adverse effects in humans or in animals. The range of toxicants in vegetables is large, but mainly including lectins, glycoalkaloids, *S*-methylcysteine sulfoxide (SMCO), isoflavones, glucosinolates, nitrate, furanocoumarins and oxalates.

Glucosinolates are thioglucosides which are widely distributed in vegetables, particularly among members of the cruciferae. Over 100 different glucosinolates have been identified. They all share a common structure, being composed of a thioglucose group attached to an R-group. The R-group can be within a wide range. In cabbage, for instance, the main glucosinolates are sinigrin, progoitrin and glucobrassicin. These three glucosinolates also predominate in a variety of other brassica vegetables, including broccoli, cauliflower, etc. In addition, brassica vegetables also contain a non-protein sulfur amino acid in the form of SMCO. Contents of SMCO in brassica vegetables can be very different. For instance, concentrations of SMCO are 14, 18, 19, and 68 mg/100g fresh weight in cauliflower, cabbage, broccoli, and Brussels sprouts, respectively (7). Highest levels of SMCO are generally found in the young leaves and growing shoots, but increases have also been observed as the brassica crop reaches maturity.

TABLE 170.1
Concentrations of Nitrate in Some Vegetables (*Source*: Lyons et al. 1994)

Vegetable	Nitrate-N (mg/kg fresh weight)
Cabbage	70–370
Lettuce	65–330
Parsley	10–330
Beetroot	290–650
Radish	145–790
Broccoli	30–85
Brussels sprout	10–15
Cauliflower	40–75
Celery	295

Vegetables are almost the greatest source of nitrate in the human diet, accounting for 76% of the total intake (8). Concentrations of nitrate in vegetables vary very widely, because of the physiological variation of each species, soil nitrogen status, fertilization rate and timing, as well as the effects from environmental factors (temperature and precipitation). Levels of nitrate tend to be negatively correlated with light intensity and temperature. A summary of data relating to nitrate contents of different vegetables is presented in Table 170.1. Based on the nitrate concentrations, various vegetables can be grouped into three categories: 1) high in nitrate content, including celery, lettuce and beetroot; 2) medium in nitrate content, including spinach, cabbage and potatoes; and 3) low in nitrate content, mainly including tomatoes.

Lectins are present in the seeds of a variety of plants, including kidney beans (*Phaseolus vulgaris*), lima bean (*Phaseolus lunatus*) and jack bean (*Canavalia ensiformis*).

Although the above components have been believed to be toxic, it has been reported that moderate intakes of some of them may be beneficial in the prevention of cancers, such as SMCO and isoflavones.

VI. POST-HARVEST TECHNOLOGY – HARVESTING, STORAGE AND TRANSPORTATION

The post harvest technology includes different commodity treatments, such as the use of physical (low and high

temperatures, modified atmosphere, correct humidity, magnetic fields, preservation by ionizing radiations, good sanitation and development of wound barriers) and chemical (waxes, fungicides, growth regulators, etc.) methods, improvements in packaging techniques, and processing of vegetables into durable products. The vegetables are harvested, packed, transported, prepared for market and ripened and stored or sold in retail markets. Post-harvest biotechnology facilities to minimize losses of vegetables. An efficient management of production, handling, storage, pricing and marketing will increase the economic development of vegetable production and distribution system.

A. Climate

The climate factors influence the vegetable crop production and post-harvest losses. The major factors are inadequate distribution systems, insufficient marketing and storage facilities. Numerous pre- and post-harvesting practices can be adopted to minimize post-harvest losses of vegetables. Pre-harvest factors include harvesting and handling, packaging and transportation, curing, refrigeration, phytosanity and sprout control.

B. Harvest Time

Vegetables reach the peak of quality at a definite time, depending upon the variety, time of planting, location, temperature, soil type, available water, fertilizers and cultural practices. The time of harvesting is critical for quality and the manner of harvesting and handling is economically critical. Vegetables at the peak of quality are highly perishable and should be harvested, handled and processed within a few hours. The texture, sugar content, color, and volume of peas and corn are criteria for determining the time of harvesting. Serious losses occur when harvesting is earlier or later than the optimum.

C. Vegetable Sorting

Leafy vegetables are tumbled in drum-type cleaner to dislodge sand and soil particles, but these mechanical cleaning operations can bruise or crush delicate tissues and increase respiration and loss of vitamin C through oxidation. The losses of nutrients that occur during such processing depend upon the vegetable crop, cultivar, maturity, freshness and season.

The most common types of conveyors for handling individual vegetables are flighted or cupped belts. However, both types present problems when each individual vegetable must be handled separately from the others.

D. Vegetable Handling

The most obvious losses after harvest are due to mechanical injury, moisture loss, decay and aging. Abusive, rough handling and holding or transporting at undesirable high or low temperature increase these losses. Losses can be substantially reduced by following approved packaging, transport and handling practices. After over maturity the next most important factor in lowered quality of vegetables for processing is deterioration during handling. The principal hazards are:

1. Metabolic changes associated with respiration, heating, ripening and aging- changes in composition, texture, color and flavor.
2. Bruising and other mechanical injury.
3. Moisture loss, with resulting wilting and shriveling.
4. Mold, mildew and other microorganisms by heat of respiration.

E. Moisture Loss

Loss of moisture with consequent wilting and shriveling is one of the obvious ways in which freshness is lost. Serious wilting may occur within an hour when leafy vegetables are harvested on a hot sunny day. Moisture losses of 3 to 6% are to cause marked loss of quality for many kinds of vegetables. Moisture losses may be reduced by lowering the air temperature, raising the relative humidity, reducing air movement or by protective packaging. Vegetables with greater exposed surfaces per unit volume have a faster rate of water loss. The type of protective surface is also important. Carrots have less protective waxy covering than apples or pears and consequently lose water faster. Tomatoes have a relatively impermeable skin and lose moisture mainly through the stem scar.

F. Vegetable Storage

The only reasons for holding vegetables for processing in common or refrigerated storage are to provide a regular supply and to allow the ripening to even up. Chilling injury may occur with certain vegetables during rapid cooling. Transportation and distribution of vegetables are the most important areas of post-harvest losses. Physical and mechanical injuries can occur during the hauling, grading and packaging operations before shipment, which may not be readily apparent in vegetables such as potatoes until they have been stored for a period of time. The greatest increase in injury occurred between the time the potatoes were in the wholesale warehouse and the time they were placed on retail shelves for sale. The actual transporting of potatoes from shipping point to destination increased hard and serious bruises by 5%. During distribution, which causes more bruising than any other operation, the hard and serious bruising increased by 12.8%. While the vegetables seriously injured during harvesting, handling and storage may still be processed into some form of human food, the vegetable

products like potato tubers seriously injured during transportation and distribution may be lost completely for human use. Potatoes can be stored for about 1 year with small losses, due to recent developments in storage technology.

Refrigeration or low temperature storage can most effectively extend the shelf life of horticultural produce and reduce their post-harvest losses. Refrigeration is produced mechanically by the evaporation of a compressed, liquefied gas (e.g., ammonia, Freon) in a closed system. Refrigeration is the most widely used short-term preservation method for a variety of vegetables. It is used throughout the distribution chain by commercial firms, retail outlets and the consumer. Vegetables can be kept in good condition for several months in cold storage.

Although most vegetables are processed right after harvest, asparagus, carrots, bell peppers, onions, potatoes and others are sometimes stored under controlled temperature and humidity for some time prior to processing in order to suit the operating capacity of the plant. The recommended temperature and humidity for storage prior to processing are designed to suit the operating capacity of the plant.

Leafy vegetables should be promptly cooled to about 32F and held there until processing. Wilting and disorders increases in severity as temperature increases. Vacuum cooling is the most common method of pre-cooling although hydro-cooling is used on some leafy vegetables. High humidity (about 95%) is essential to prevent wilting.

Root crops such as beets, carrots, radishes and turnips, are generally stored at 32°F to retain their quality. Decay can cause substantial losses in root crops during even a week or ten days if they are held above 40F. Rapid cooling of root crops to storage temperature is not as critical as for leafy vegetables. However, roots should be brought into desirable temperature range promptly after harvesting due to respiration can rapidly reduce quality. A high relative humidity is essential for storage of cold requiring roots if desiccation is to be avoided particularly during prolonged storage of root crops.

Storage at a few degrees above their freezing point is desirable for all of the commonly grown leaf, stem, and bud vegetables and, for the most part, the root vegetables. Storage life of the leafy vegetables is only a few days, even in optimum environments. The root crops, including carrots, parsnips, turnips, beets and horseradish, which are adapted to storage for several months, are commonly held in ventilated storage. Other vegetables, such as potatoes, carrots, sweet potatoes, turnips, dry onions and cabbage are usually stored under ventilation and may be refrigerated to extend their storage life beyond their growing season. Vegetables including cucumbers, eggplant, green beans, okra, sweet potatoes, squash and tomatoes are native to subtropical or tropical areas are not adapted to low temperatures.

Controlled Atmosphere (CA) storage is one of the most important technologies in vegetable storage systems. Controlled atmosphere storage is a system for holding fresh vegetables in an atmosphere that differs substantially from normal air in respect to the proportion of nitrogen, oxygen and carbon dioxide. The composition of the atmosphere may be altered by restricted venting of the storage room or the container by scrubbing the atmosphere of carbon dioxide or oxygen or by adding individual gases to the container while reducing the proportion of others. This method if combined with refrigeration retards respiratory activity and may delay softening, yellowing, changes in quality and other deteriorative processes by maintaining an atmosphere of higher carbon dioxide and oxygen than in normal air. The limits of tolerance vary according to a function of the temperature, duration of storage, concentrations of supplemental gases, type and physiological age, and anatomy and morphology of the vegetable produce involved.

CA storage has proved beneficial to extend the life for vegetables that deteriorate rapidly or those that complete ripening after harvest. Temperature and duration of storage and commodity to be stored are the interdependent factors, each influencing the decision of use of the gas mixture in CA storage.

VII. VEGETABLE PROCESSING TECHNOLOGIES

Processing begins in the field with many vegetables. This is true with mobile cutters for greens, viner/shellers for peas and beans, juice extractors for tomatoes, and graders/washers for many vegetables. Advantages are that harvesting/processing can be stopped or started at any point to accommodate variation in the field. There is no lag in time in which freshly harvested sometimes badly bruised product can deteriorate while waiting for the next step in processing and most of the refuse including vines, shells, leaves and other organic waste is scattered over the field to be incorporated into the soil. There are several steps common to the preparation of most vegetables for processing.

Harvest in the immature tender stage, before any portion becomes fibrous and tough. Corn should be full grown, but tender; peas and beans should be green; stalks of asparagus, stems of greens and shells of snap beans should be without fiber. There is a tendency for most vegetables to be harvested after the peak of quality.

Grade to remove trash, over mature, diseased, insect infested vegetables, and other materials that would impart an off flavor to the product. This may be with a roller grader/sizer, a blower, or rod/shaker, followed by hand inspection. Bruising or cutting which might cause loss of juices should be avoided.

Weigh to ascertain pay rate, yield and production rate. Rinse in water to remove surface dirt, insects and small trash not removed by the blower. A detergent may be used on vegetables taken from the soil, such as potatoes, sweet

potatoes and turnips and leafy vegetables like spinach and turnip greens, provided it is thoroughly rinsed off.

Prepare as required for individual vegetables. This includes peeling, shelling, shucking, trimming and cutting and dicing.

Vegetable processing steps include handling, transportation, refrigeration, molding, washing, trimming, blanching, freezing, canning, drying, packaging, use of chemicals, radiation, storage and ultimately cooking or heating.

Vegetables are processed into more stabilized products that can be used the whole year round in the world market by canning, freezing, dehydrating and ionizing radiation. Some processed products are canned soups, chutney, catsup, instant dehydrated mashed potatoes, etc. The processing of vegetables is as follows:

1. Removal of water- to reduce moisture content of vegetables to lower activity of microorganisms;
2. Heat sterilizing- to destroy or inactivate enzymes and microorganisms (Suitable packaging prevents entry of microorganisms into processed products.);
3. Lowering temperature- to slow down most biochemical reactions that can deteriorate food;
4. Providing a chemical environment that will not permit certain deteriorative actions to proceed;
5. Sterilizing with ionizing radiation to destroy enzymes and microorganisms.

In most cases, combinations of preservation technologies are recommended. For example, heat sterilizing effectively destroys microorganisms, then sealing in a container prevents further contamination, and storage of the canned product under refrigeration reduces deterioration normal for any canned product, cold storage of dried products extends their storage life, etc.

A. Blanching

Blanching can fulfill one or several of the following purposes:

1. Inactivation of enzymes prevents discoloration or development of unpleasant taste during storage. Colors caused by the presence of chlorophyll or carotenoids are also protected from enzymatic degradation.
2. Proteins are forced to coagulate and shrink under liberation of water. If this shrinkage happened during sterilization of canned products, they would appear to be underweight. Also, starch that could otherwise cause a cloudy appearance can be removed.
3. Oxidation during frozen storage will be reduced.
4. Many products obtain a clearer color.
5. Defective parts become more visible so the product can be sorted more effectively.
6. The microbial status is improved because vegetative cells, yeast and mold are killed.
7. Cooking time of the finished product is shortened. If the blanching periods for the individual components in mixtures are adjusted, the heating requirement for the preparation of the finished product is equalized.

When water or steam is used for heating, leaching of vitamins, flavors, colors, carbohydrates, and other water-soluble components takes place. If products are going to be frozen after blanching, a chilling step will generally take place before transporting the product into the freezer. A good blanching technique must fulfill the following essential demands:

1. A uniform heat distribution to the individual units of the product.
2. A uniform blanching time to all units of the product.
3. No damage to the product during the entire blanching and cooling process.
4. A high product yield and quality.
5. Low consumption of energy and water.
6. Tough, reliable design, giving an operation without problems even when running in continuous three-shift operation. This also includes quick and proper cleaning.
7. The design must also provide a pleasant working environment for the staff without any unnecessary noise, heat radiation, and loss of steam and process water with foam and product particles flushing on the floor.

When blanching vegetables before freezing, inactivation of the enzymes is dependent upon both time and temperature of the heat treatment. Other effects of heating, which may respond differently to time and temperature conditions, include color changes, softening, gelling of starch and extraction of various soluble components.

B. Canning

Canning is the major method of preserving vegetables, and is founded on the most effective method of destruction of microorganisms. In canning process, the vegetable is placed inside the container, the air is removed by vacuum, and the cans are hermetically sealed. The cans are placed in the retort, and sterilized with steam. The basic heat penetration characteristics are convection and conduction. The constancy of the rate of heat penetration for a given product in a given size container and the ability to measure these constants with accuracy have

resulted in the remarkable safety of commercially canned vegetables.

C. Freezing

There are three types of freezing processes. The individually quick-frozen vegetables are frozen by the fluidized bed process and then packed in suitable containers. The second process involves placing the unfrozen prepared vegetables in a container and then freezing it. The individual particles do not cohere and the final package contains individual portions of the food rather than a solid block. Commercial freezing is conducted with moving air, termed blast-freezing. Air is accelerated by fans and passed over the vegetables. With advances in refrigeration engineering, many plants are now freezing foods at −40°C.

The third freezing process is that of immersing the vegetables in a liquid. Some of the liquids used for vegetables freezing are liquid nitrogen, liquid carbon dioxide and Refrigerant 12. Vegetables freeze extremely rapidly in contact with such liquids. Refrigerant 12, a fluorinated hydrocarbon, can be adjusted to various temperatures. The use of such liquid nitrogen, liquid carbon dioxide and Refrigerant 12 meets food safety regulation.

D. Fermentation

Fermented vegetables are the food products by the fermentation of lactic acid bacteria, which are preserved primarily by acidification. Olive products and sauerkraut are solely produced by fermentation. Some cucumber pickles are produced by fermentation, in which spices and salt are added before fermentation and fermentation occurs in the presence of these seasonings. This is called the genuine dill fermentation, but is rapidly being displayed by salt stock and fresh pack pickling methods in which fermentation does not occur and the acid is added directly to the product in the final container. A wide variety of vegetables are pickled commercially. Pickling is usually combined with some type of heat treatment in the final container to prevent secondary fermentation and subsequent spoilage. A recent development in the pickled vegetable industry has been the development of the fresh pack or pasteurized cucumber and other vegetable pickles. For example, cucumbers are packed directly into jars, then covered in brine which is made of salt and vinegar, preferably containing some lactic acid and seasonings. The residual sugar in the cucumber can be fermented by the action of the lactic acid bacteria.

CONTENTS

I. INTRODUCTION

China is the birthplace of soybeans. In Oriental countries such as China, Korea and Japan, soy foods have been consumed for thousands of years. In the1800s, soybeans were introduced to America, but large-scale production of soybean began only after World War II. In the first part of the 20th century, soybeans were known to the Westerners as an oilseed and feed-stuff only. Aside from the image problem, the major obstacles in the utilization of whole soybean for foods in the Western society include the beany flavor and the flatulence factor. Substantial use of soybeans for

foods did not take place until recent decades, where a small part of defatted soy meal was used or processed further for human foods. However, since 1980s, soybeans have been used for making a variety of soy foods in America. Hence, some soybeans are known as vegetable legumes and soy foods are popular vegetable foods. In very recent years, because several soybean components have been discovered to possess health benefits, hence, soy foods have become health foods. Consumption of soy foods in America has increased dramatically in the last few years. Soy foods are finding their ways in the main stream supermarkets. The total retail value of soy foods has exceeded 4 billion US dollars. The United States of America produces one half of the world soybeans, which are estimated to be approximately 159 million metric tons (1). Only approximately 5% of the US soybeans are used for making foods. However in the last three years, it was estimated that the annual soy food market had increased by 25% per year. Soymilk, tofu and meat analogs are the three major soy food types in the USA. The increases in soymilk and tofu retail values in the USA are about 40–50% and 15–20%, respectively, each year since 1997 (P. Golbitz, personal communication, 2000), while the overall growth of the US food industry has been only 3% per year. It has been predicted by the United Soybean Board that by the year of 2010, soyfoods' retail value will reach 100 billion dollars in the United States.

Soy protein has long been known to have a good nutritional quality. Recent discoveries of potential health benefits of soy foods include reducing the risk of cardiovascular diseases, preventing certain cancers, reducing postmenopausal syndromes, and increasing bone mass density all contribute to the recognition of soybean as a health food. US Food and Drug Administration has approved a health claim for processed foods containing soy proteins that states 'consumption of 25 gm soy proteins per day in conjunction with a low cholesterol diet would reduce the risk of heart disease.' All of these will continue to enhance the consumption of this ancient Oriental food crop in America and other parts of the world.

Tofu has found its history dated back to the China's Han Dynasty approximately 2000 years ago. Tofu has been an integral part of the Chinese food culture; it is indispensable in the diets of Chinese and the people of several other East Asian countries, including Japan and Korea. Soybeans have contributed to the health of Chinese people in the history. We believe that a large-scale prolonged protein malnutrition has never occurred in China might be attributed to the ready availability of soy foods. Soy foods are not only nutritious but also very delicious, which have been included in thousands of dishes of Chinese foods. Because of the functional properties and health benefits reported in recent years, soy foods are gaining acceptance increasingly in the Western society.

Since its original invention, tofu manufacture process has been improved greatly. Many manufacture and utilization methods have been developed in various countries and regions. Japan has taken the leadership role in the advancement of the science and technology for tofu making. It is well known that making tofu is not a difficult task. Many people can claim that they can make tofu. However, making excellent quality tofu consistently is not an easy matter. The principles of tofu making are simple, which consist of two main stages: (a) the preparation of soymilk and (b) the coagulation of soymilk to form bean curd that is then made into various types of tofu. However, many factors involve in the processing of tofu and raw bean components affect substantially the quality of tofu. There have been several great books related to tofu making, including the "The Science of Tofu" (2), the "Tofu & Soymilk Production, the Book of Tofu, Volume 2" (3), and the "Soybeans: Chemistry, Technology and Utilization," (4). In this chapter, we focus on recent studies related to soybean quality and tofu making and try to organize available information together to show how various factors affect tofu quality.

II. TOFU PROCESSING METHODS

Tofu manufacturing requires a series of unit operations. Generally, three steps are critical in determining product type: (a) soymilk extraction and solid content, (b) coagulation method (types of coagulants, breaking or not after curd formation), and (c) pressing or not. However, all methods for making various tofu products begin with similar steps for soymilk as shown in Figure 171.1. The traditional Chinese method separates raw soymilk from the okara (residue) before heating. In the Japanese process, heating the slurry "go" prior to separation facilitates soymilk extraction and increases tofu yield. However, Beddows and Wong (5) reported that yield and quality of silken tofu made by a laboratory scale with the slurry filtration prior to heating are better than that with heating prior to residue separation. Both Chinese and Japanese methods for extracting soymilk are known as the traditional Oriental methods because of the presence of beany flavor in the final soymilk product. Regarding the beany flavor, several modern methods aimed at improving soymilk taste and flavor have been developed in the past decades. We will discuss this in more detail in the lipoxygenase section. In tofu industry, many manufacturers worldwide have adopted the Japanese process because of higher tofu yield, available tofu manufacturing machines, and a lower beany flavor than the Chinese process. Some industries wash the okara one or two times to extract residual proteins/soluble solids and use the wash water to grind the soybeans to improve yield.

After soymilk is produced, various steps are used to manufacture different types of tofu. Tofu in the market is

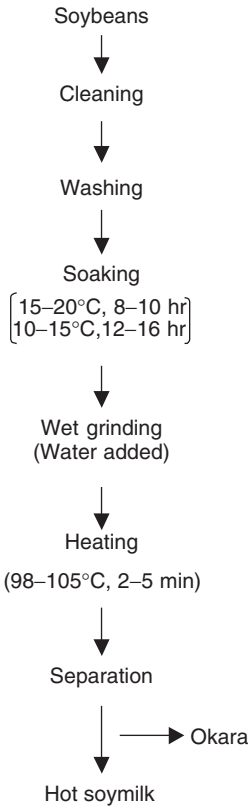

FIGURE 171.1 Initial steps in the preparation of soymilk for tofu making.

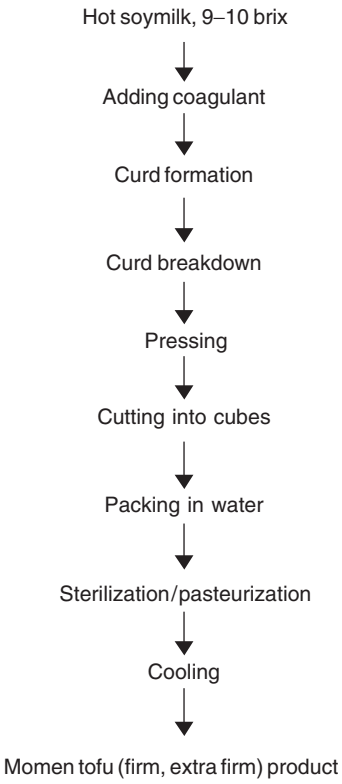

FIGURE 171.2 Scheme for momen tofu production.

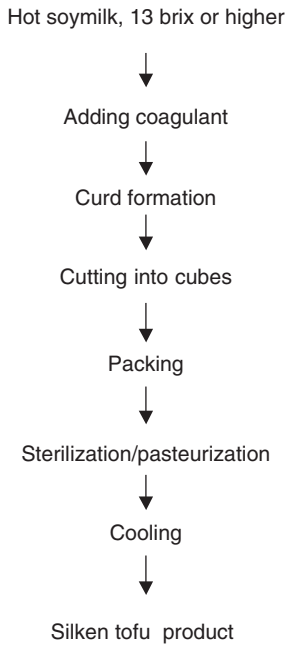

FIGURE 171.3 Scheme for Silken (Kinugoshi) tofu production (no curd breaking and no pressing).

generally classified into soft, firm, and extra firm tofu, based on water content and textural properties. Tofu is classified into momen (regular), kinugoshi (silken), soft, packed silken, and aseptic tofu, depending on processing methods. Figures 171.2 to 171.5 describe the methods used in the tofu industry for the production of momen tofu, silken (Kinugoshi) tofu, filled packed silken tofu, and soft tofu, respectively.

A. Soaking

After proper washing, soybeans are soaked in water to soften their cellular structure for water grinding. Soaking time depends on water temperature, the soybean variety, and the age of soybeans. Temperature is the main factor affecting the rate of water uptake, with higher rate associated with higher temperature (6). Generally, soaking in ambient water takes 8–10 hours in summer and 16–18 hours in winter. After soaking, the beans weigh approximately 2.2–2.3 times of their initial weight (3).

B. Grinding

After soaking, soybeans are ground with water into slurry using a stone-mill or a stainless steel grinder. The amount of water added during grinding depends on the type of final products. For example, the water dosage for silken tofu, soft tofu, and regular tofu is 5, 7–8, and 10 times of raw soybean weight, respectively (2). Proper grinding gives appropriate small particle sizes in the slurry and

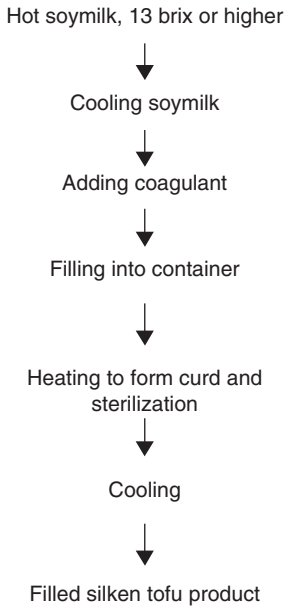

FIGURE 171.4 Scheme for manufacturing filled silken tofu (cold filling and curd formed in container).

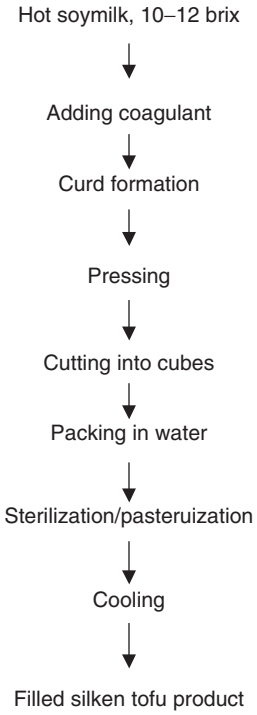

FIGURE 171.5 Scheme for manufacturing soft tofu (no curd breaking).

facilitates the extraction of solid and nutrients into the soymilk. The smaller the particles, the better the extraction, but okara (residues) becomes more difficult to separate. The water temperature of grinding affects not only the flavor of soymilk, but also the texture of tofu. Tofu firmness decreases as the water temperature of grinding increases between 0°C and 50°C (7). They found that the relationship is related to the content of sulfhydryl groups (-SH) in soymilk. The decrease of –SH group may be caused by a lipid oxidation activated by lipoxygenases in soybeans. Since water composes of 88–90% of tofu weight, it plays an important role in determining the tofu taste. The source and quality of water are always an important concern to tofu manufacturers. Water, containing a proper amount of minerals (about 100 mg/L) including calcium, magnesium, sodium, potassium, iron, and manganese, provides a harmonious and mellow taste (2).

C. Heating

The step of heating is essential during the tofu processing not only for killing microorganisms in the slurry, improving nutritional quality by inactivating trypsin inhibitor (TI), and reducing beany flavor, but also for denaturing proteins so that they can coagulate into curd in the presence of a coagulant. Before heating, soy protein molecules maintain their native globular structures in which the hydrophobic regions are wrapped inside. Upon heating, the soy proteins are denatured resulting in native molecules unfolded, and their hydrophobic groups expose to outside, consequently protein solubility decreases due to aggregation. What extent of heat treatment is considered adequate for soymilk and tofu making? Hackler et al. (8) conducted a study of heat treatment on nutritive value of soymilk protein fed to weaning rats, and found that heat treatment should be sufficient to inactivate 80–90% of trypsin inhibitors for maximizing nutritive values. Trypsin inhibitors are heat resistant. At 100°C, 14 min are required to inactivate 80% TI or 30 min to have 90% TI destruction. Wilson (9) suggested that the time/temperature requirement for soymilk be based on 85% TI inactivation. Trypsin inhibitors are water-soluble proteins, a part of which may be released in the whey during pressing of tofu making. Thus, the slurry used for tofu making requires shorter heating time than that for soymilk as the final product. Watanabe (2) recommends that boiling at 100°C for 3–5 min is required for tofu making.

The optimum heating time of soymilk for making tofu corresponds approximately to the maximum amount of sulfhydryl groups. If heating is not adequate, soy proteins do not dissociate into subunits; but in excessive heating, sulfhydryl groups are oxidized by air (10). Tofu prepared with soymilk, which has been heated at 100°C up to 60 min, is softer than that from usual preparations (100°C, 3 min) (11). This may be due to the oxidation of sulfhydryl groups of soy protein during excessive heating, resulting in the decreases of sulfhydryl group content and tofu hardness. In the Japanese method, cooking the slurry for about 7 to 14 min at 100°C gives the best soymilk solid and protein recovery, especially for tofu (12). In the Chinese method, the hardness of tofu increases slightly

from 0 to 12 min of boiling soymilk, but decreased significantly after 30 min and 60 min of boiling (13). Amino acid composition of soymilk has no significant changes when heating at 93°C, but the amount of cystine and tryptophan decrease while heating at 121°C from 0 to 121 min (14). Approximate 30% of cystine and methionine are destroyed after 30 min of boiling soymilk (15). In some tofu factories, the slurry is heated by a continuous pressure cooker at various pressure increasing from 80°C to 105°C for times ranging from 4–20 min.

D. Separation of Soymilk

In the Japanese process, soymilk is extracted from the slurry after heating. The separation of a small volume of slurry can be done by filling the slurry in a cotton cloth bag then pressed by hands. Industrial processing can be done by drum pressing, screw pressing, centrifugation, or shaker-filtration. The efficiency of soymilk separation depends on the extraction pressure and pressing time, the pore size of the filter or screen, the particle size of slurry, and whether the okara is re-washed or re-pressed. When the okara is re-washed and re-pressed to extract more protein and solids, the yield of tofu can increase by 15–20%. Okara contains 76–80% of moisture (24–20% solids) after being well pressed. About 29% of the solids and 17% of the protein in the original soybeans are remained in the pressed okara that has not been washed (3). On dry weight basis, okara comprises 25–28% protein, 9–11% lipid, 40–44% insoluble fiber, 13–15% soluble fiber, and 4–5% soluble carbohydrate (16). Most of total fiber in soybeans is concentrated in okara.

E. Coagulation of Soymilk

Coagulation is the most important and the most difficult step in tofu making because it depends on the complex interrelationship of many variables, including soybean variety, soymilk concentration and pH, temperature, type and amount of coagulant, and coagulation method. Hot soymilk is usually coagulated to form curd by adding a salt or an acid coagulant. Tofu coagulants are classified into four basic types: (A) nigari-type or chloride-type coagulant, including magnesium chloride, calcium chloride, and sea water; (B) sulfate-type, including calcium sulfate and magnesium sulfate; (C) glucono-delta-lactone (GDL); (D) acidic coagulants including citrus juices, vinegar, and lactic acid (3). Each type of coagulant has its advantages and disadvantages.

1. Type of Coagulants

Nigari or chloride-type coagulants include natural nigari, refined nigari, calcium chloride, and seawater. Natural nigari, known as 'bittern' in the West, is extracted from seawater by removing most or all of the table salt (NaCl) and water. It consists primarily of $MgCl_2 \cdot 6H_2O$ (92.3%) plus all of the other salts and trace minerals in seawater (3.8% $MgSO_4$, 1.7% NaCl, 1.2% KCl, and 1% $CaSO_4$). Refined nigari is a relatively pure magnesium chloride (99.5%). Calcium chloride ($CaCl_2$) is not found in seawater, it is not a traditional nigari-type coagulant. However, it gives tofu excellent flavor, almost identical to that made from natural nigari or magnesium chloride nigari. Moreover, it is the cheapest nigari-type coagulant and the food-grade type produced in the U.S. and on the GRAS (Generally Recognized as Safe) list. In Japan, most tofu industries use nigari-type coagulants in combination with calcium sulfate rather than alone. Nigari-type coagulants make the most delicious tofu, prized for its wonderful subtle sweet flavor and aroma. However, they have some disadvantages compared with calcium sulfate and GDL. They react very rapidly with soymilk, so their use requires more skill and attention and must be added slowly. Due to the extremely quick reaction of nigari with soymilk, the coagulated bean curd is destroyed while agitation is still going on. The nigari-coagulated bean curd does not incorporate so much water as the sulfate type, consequently produce tofu with lower yields and coarser texture than that made with calcium sulfate. Nigari alone is not suitable for making silken tofu from hot soymilk, because the high temperature and high solids content of soymilk make it extremely difficult to solidify uniformly with nigari in such a short reaction time. However, filled silken tofu can be made with nigari if the soymilk is cooled to a low temperature (e.g. 4°C) prior to coagulant addition, and followed by heating to slowly coagulate the proteins.

Sulfate-type coagulants (especially calcium sulfate known as gypsum) are the most widely used tofu coagulants in the world. They have low water solubility (3.0 g/L at room temperature), which is an important factor in determining the speed of the coagulation reaction. Because of their low solubility, they react slowly with the soymilk; consequently allow the formation of bean curds with a high water-holding capacity. Thus, they give 15 to 20% higher bulk yields than nigari. The resulting tofu has a soft and smooth texture. Calcium sulfate can be used to make regular, firm, soft, silken, and even packed (package-filled) tofu, whereas it is not easy to make the latter two types with nigari. Calcium sulfate is easy to use even by relatively unskilled tofu makers. Even if agitation is carried out slowly or the dosage varies slightly, the differences in tofu yield and texture are not very large. Calcium sulfate as tofu coagulant produces tofu with a mild or bland flavor; however, the taste is slightly inferior to that of nigari tofu.

GDL is an oxidation product of glucose. It is manufactured from corn starch by a fermentation process, and was first used for silken and packed tofu production during the 1960s in Japan (3). GDL is fundamentally different from nigari and gypsum-type coagulants, in which an acid

rather a salt does the coagulation. Upon being dissolved in water, it is slowly hydrolyzed (about 2–3 hr) to gluconic acid by water. The pH of 1% fresh aqueous solution at room temperature is 3.5, it drops to 2.5 due to the conversion to gluconic acid within 2–3 hr. For packed and silken tofu, GDL is dissolved in previously cooled soymilk and forms gluconic acid gradually, then heat coagulates soymilk with this acid to form homogeneous solidified curd with rich water holding property in the container. The GDL gives tofu a slightly acidic flavor and tender jello-like texture. For better flavor and texture, GDL is often used in combination with a calcium sulfate.

The acid-type coagulants, including lactic acid, acetic acid, and lemon juice, work well as natural coagulants. However, the yield of tofu is low, the texture is slightly crumbly, and the flavor of tofu is a little tart, when compared with nigari and calcium sulfate as coagulants (17,18).

2. Soymilk Concentration

The solid concentration of soymilk is related to "water-to-bean ratio" that is defined as the total weight of water added to the beans during soaking, grinding, and cooking divided by the original weight of the soybeans (3). The ratio of water:beans can be very critical to affect protein extraction yield and the properties of tofu . In the range of 9:1 to 14:1, 10:1 gave the best result in protein recovery (19). For making regular tofu, the best water-to-bean ratio is about 10:1 which results in a soymilk with 6.0 to 6.3% solids and 3.0% protein (12). However, 5:1 to 7:1 ratios are required for making soft tofu or silken tofu (10). The amount of coagulant required to reach the optimum coagulation varies with the concentration of soymilk. Watanabe et al. (12) reported that more coagulant is required for more concentrated soymilk (in the range of 3% to 8%) to reach the same level of whey transparency, and the dosage for calcium sulfate was about 10–20% more than that for nigari. In our laboratory, we found that the coagulant concentration required to reach the optimum coagulation of silken tofu increases linearly with the soymilk solid content in the range from 6% to 11%, and the concentration for magnesium chloride is about 13–15% more than that for calcium chloride (unpublished data).

3. Coagulant Concentration

The amount of coagulant added into soymilk affects greatly the yield, texture, taste, and aroma of tofu. In general, by observing curd formed and whey produced during pressing, tofu makers could tell whether the amount of coagulant is appropriate or not. When a proper amount of coagulant is used, the whey is transparent and amber or pale yellow. In the case of too much coagulant used, the whey is yellowish color and the curds have a coarse or crumbly texture. If too little coagulant is added, the whey is cloudy and some uncoagulated soymilk may be remained. Several methods have been compared to determine the optimum amount of coagulant in tofu making, including light transmittance of whey (%T), whey volume, pH of whey, and conductance of whey (19). Among these methods, they found that whey transmittance and conductance correlated with coagulant concentration, and concluded that measuring the conductance of the coagulating soymilk was faster and more reproducible than obtaining pH and transmittance values of the whey. A rotational viscometer (viscograph) is applied by researchers to measure the optimum concentration of coagulant for the coagulation of soymilk (20,21). Among five coagulants studied, with an increase in coagulant concentration from the minimum required concentration (from 0.15% to 0.5% of soymilk volume depending on coagulant), there is an increase in whey volume and decreases in the moisture of tofu (22). Sun and Breene (23) found negative correlations between calcium sulfate concentration and both yield and protein recovery of tofu from five soybean varieties.

4. Coagulation Temperature

The soymilk temperature for adding coagulant affects coagulation rate as well as tofu quality. The yield and moisture content of tofu decrease as the temperature of coagulation increases, whereas the hardness and elasticity increase (15). When soymilk is at high temperature, proteins possess high active energy that can lead to fast coagulation, resulting in the formation of curd with low water holding capacity, consequently, tofu has hard texture and low bulk yield. The hotter the soymilk at the time of coagulation, the less the amount of coagulant required. When tofu is coagulated at a high temperature, a small increase in the amount of coagulant may lead to a large decrease in yield. In the tofu industry, the temperature of coagulation varies from one factory to another, depending on the type of coagulant used. Generally, coagulation temperature ranges from 68°C to 95°C for those using nigari, while those using calcium sulfate prefer the range from 70°C to 80°C in Japan. Beddows and Wong (5) reported that the optimum coagulation temperature is 75–80°C for silken tofu with gypsum as coagulant in a small bench scale. Shih et al. (24) reported that the optimum coagulation temperature is 85–91°C for soft tofu with modified nigari (mostly $CaSO_4$) in a medium scale. The operational temperature of coagulation also varies from one region to another. In America, tofu makers prefer a relatively high temperature, 85°C, for using nigari and calcium sulfate, since less coagulant is required, the curd forms quickly, and the tofu has firm and dense texture but no significant drop in yield.

5. Coagulation Methods

The addition method, the stirring speed at which the coagulant is added, and the continuous stirring time after

the coagulant is added have very definite effects on the tofu yield and quality. Traditionally, calcium sulfate in a suspension is added to soymilk, which has been stirred vigorously by hand with a paddle, and the mixture continues to be mixed 6 to 8 more times. Nigari-type coagulant could be divided to three portions and added in three steps in order to coagulate soymilk slowly and get high yield and smooth texture. The first portion of nigari is poured from a height of several feet into the soymilk being swirled with a paddle. Coagulation starts from the bottom of the container and slowly works up, while the uncoagulated soymilk constantly rises to the surface. The second portion is sprinkled over the soymilk surface that is covered and stand for about 5 min, then the last portion is also sprinkled over the surface, and allow to stand for 15–20 min to solidify completely (3). Generally, the controlling techniques of this coagulation rely on the experienced tofu maker's judgement.

Stirring soymilk by a motorized stirrer and the effect of mixing speed and time had been investigated by researchers (25,26). By using a small scale for silken tofu (250 mL soymilk), Beddows and Wong (25) found that the stirring speed during coagulant addition was critical and the optimum speed for tofu yield, texture, and protein recovery was 240–280 rpm for 30 sec. By using a medium scale research equipment for soft tofu (4.5 L soymilk per batch, mold size is shown as (Figure 171.6), tofu made at 285 rpm stirring speed of a stirrer (Model RZR1, Caframo LTD, Wiarton, Ontario, Canada) equipped with a paddle (7 cm × 7 cm) has lower yield but higher firmness than tofu made at 207 rpm stirring speed (26) (Table 171.1). We found that yield decreased when stirring time increased to 30 sec, and tofu texture was affected as stirring time increased to 25 sec. By using a medium scale and a stirrer fixed at 285 rpm, we have determined the optimum combinations of soymilk solids, coagulant concentration, soymilk temperature for adding coagulant, and stirring time after adding coagulant for soft tofu making (24). Tofu yield is affected mainly by soymilk solid content and coagulant concentration. Tofu solids and protein content are affected by soymilk solids, coagulant concentration, and stirring time. Solid content of soymilk is the most important factor affecting textural properties of tofu. The optimum combinations are soymilk 11.8 to 12.3 °Brix, coagulant 0.27 to 0.32% of soymilk volume, stirring temperature 85 to 91°C, and stirring time 5 to 11.3 sec (24).

FIGURE 171.6 The tofu mold used by the medium-scale method.

F. Pressing of Curd

For momen tofu and soft tofu, pressing the bean curd to expel the soy whey is necessary as shown in Figure 171.2 and Figure 171.5. The pressures and duration of pressing can influence moisture content, yield, and texture of tofu. A range of values has been used for both parameters among different researchers (Table 171.2). Generally, silken tofu is not pressed after coagulation, however, Beddows and Wong

(25) reported the optimum pressure applied to silken tofu was 4 to 6 g/cm^2 for pressing until dripping ceased. They found that below 4 g/cm^2 the tofu was very soft with little or no retention of cut shape and that above 8 g/cm^2, tofu was hard and rubbery. Gandhi and Bourne (27) showed that when the pressure increased from 4.79 to 19.1 g/cm^2, the moisture content of tofu decreased from 82% to 60% and yield decreased from 2.0 kg to 1.2 kg per kg whole dry soybeans. From a commercial standpoint, most manufacturers apply a light initial pressure of 2 to 4 g/cm^2 for about 5 to 10 min and a stronger pressure of about 5 to 15 g/cm^2 for 10 to 15 min to make soft tofu; for firm tofu, a pressure of 20 to 100 g/cm^2 is used for 20 to 30 min (3). In our laboratory, we apply a pressure of 21.8 g/cm^2 for 10 min, followed by 43.6 g/cm^2 for another 10 min, and adding to 65.4 g/cm^2 for 30 min for making soft tofu by a medium scale (24,26). Because of several variables, tofu-making process differs in various research laboratories, which reported data that were difficult to compare. Therefore, there is a need to standardize the procedures for determining quality of soybeans for tofu making.

III. ROLES OF SOY PROTEINS IN TOFU MAKING

A. Storage Proteins of Soybeans

Soy proteins constitute about 35–45% of the soybeans on a dry basis. Approximately 90% of the proteins are storage protein and are extractable with water or dilute salt solutions. Most of the storage proteins in soybeans are globulin. As soybean seeds mature, many organelles, such as nucleus, mitochondria, and endoplasmic reticulum, disappear and storage proteins deposit in large protein bodies that are surrounded by many small oil bodies. Storage proteins have no biological activities and 90% of them locate in cotyledons (28). Soy proteins consist of discrete groups of polypeptides that have a wide range of molecular size. A typical ultracentrifuge pattern of water-extractable soy proteins has four major fractions designated as 2S, 7S, 11S, and 15S on the basis of their sedimentation rates. Each fraction is a complex mixture of proteins. The 7S and 11S proteins are the two major storage proteins in soybeans, which comprise approximately 70% of storage protein. The 2S fraction accounts for about 20% of the extractable proteins, which contain protease inhibitors (the Kunitz and the Bowman-Birk trypsin inhibitors) and cytochrome C (29). The 7S fraction has been classified into three major components with different physicochemical properties named β-conglycinin, γ- conglycinin, and basic 7S globulin (30, 31). β-conglycinin is the most prevalent of these three and accounts for about 30% to 35% of the total seed protein, which is used interchangeably with 7S protein since it is the major 7S protein. The 11S fraction, designated as glycinin, accounts for an additional third of the total seed protein and is generally simple protein. The 15S fraction accounts for approximately 10% of the total seed protein, which is an aggregate of 11S protein (32).

B. β-conglycinin (7S Protein)

β-conglycinin (7S) is a complex protein which exhibits polymorphism in its subunit composition. It is a trimer with a molecular mass of 150–200 kDa. Four subunits are identified: three major (α, α', and β) and one minor (γ) (33). β-Conglycinin exhibits molecular heterogeneity, in which 7 molecular species are isolated and their subunit composition identified as α'ββ, αββ, αα'β, ααβ, ααα', ααα, and βββ (34,35,36). β-conglycinin is a glycoprotein, its α and α' subunits contain two carbohydrate moieties and the β subunit one (33). β-Conglycinin undergoes a complex association-dissociation phenomenon in response to changes in ionic strength and pH. At neutral pH, β-conglycinin is a 7S-form globulin when the ionic strength is ≥ 0.5, but as a 9S dimer at ionic strength of ≤ 0.2 (37). The subunits of β-conglycinin are held primarily by hydrophobic forces (38). The molecular mass of subunits of β-conglycinin are estimated to be 57–59 kDa for α and α' subunit and 42–44 kDa for β and γ subunits by gel electrophoresis and gel filtration (33).

C. Glycinin (11S Protein)

Glycinin is a major storage protein of soybeans and accounts for approximately 35% of the total seed protein. It is a hexamer with a molecular weight of around 300–380 kDa. Each subunit is composed of an acidic polypeptide (A_n) with a molecular mass of approximately 35 kDa and a basic polypeptide (B_n) with a molecular mass of approximately 20 kDa. The acidic and basic polypeptides

are linked together by a single disulfide bond shown as A_n-S-S-B_n (39). It is known that initially a single polypeptide precursor is synthesized and then processed posttranslationally to form the acidic and basic polypeptides (40). The disulfide linkage between the acidic and basic polypeptides forms after subunit synthesis and may help stabilize the subunit after posttranslational modification. Five subunits are identified by Nielsen et al. (41) and Utsumi et al. (42): $A_{1a}B_{1b}$ (G1), A_2B_{1a} (G2), $A_{1b}B_2$ (G3), $A_5A_4B_3$ (G4), and A_3B_4 (G5). Among these subunits, two groups can be separated based on sequence homologies (39). Group I subunits, $A_{1a}B_{1b}$, $A_{1b}B_2$, A_2B_{1a}, are uniform in size (~58 kDa), relatively rich in methionine and cysteine, and exhibit about 90% sequence homology. Group II subunits, A_3B_4 and $A_5A_4B_3$, exhibit a smaller level of homology (about 60–70%), and contain less methionine and cysteine, but are larger (~62–69 kDa) than group I. The $A_5A_4B_3$ (G4) subunit is synthesized as a single polypeptide precursor similarly to the others, but the acidic polypeptide is cleaved to produce A_5 and A_4 polypeptides (40). Most major subunits of glycinin are present in most soybean varieties except the subunit $A_5A_4B_3$ (39). In Japan, about 20% of soybean varieties are absent of subunit $A_5A_4B_3$ in glycinin (43). Glycinin, having different subunit compositions, exhibits distinguishable functional properties.

Glycinin hexamers can dissociate to their constituent polypeptides, subunits, and half-molecules under various pH, ionic strength, and temperature (42). At pH 7.6 and an ionic strength of 0.5, glycinin forms hexamer complexes (11S), whereas at pH 3.8 and an ionic strength of 0.03, glycinin exists as trimers (7S) (44,45). The dissociation of 11S to 7S seems to be correlated with significant changes at the secondary and, to a lesser extent, the tertiary structures. When ionic strength is below 0.2, the basic polypeptides shift more to the exterior of the molecule (44).

D. Gelation of Purified Soy Proteins

Generally, denaturation is essential for proteins to form gel, which results in an altered conformation of the protein and changes in physical and biological properties. Upon heating, soy proteins initially undergo a stepwise dissociation of subunits, followed by unfolding of the polypeptides that subsequently associate and aggregate to form precipitates or progels (46). Glycinin and β-conglycinin exhibit apparent denaturation temperatures of 90°C and 75°C, respectively. The difference in the thermal transition temperatures of these two proteins results from inherent differences in their structures. Glycinin is more heat-stable than β-conglycinin (47).

The gel-forming ability induced by heating soy proteins is one of the most important functional properties with respect to their usage in the food systems. Glycinin and β-conglycinin show different gel-forming properties and their gelation mechanisms are different. A soluble aggregate model describes how glycinin forms the gel structure (48,49,50). The model could be regarded as a three-stage process. When glycinin solution (5%) is heated, glycinin aggregates (MW 8000 kDa) are formed; then on subsequent heating, it undergoes association resulting in gel formation; finally, the gel network structure is stabilized through further formation of non-covalent bonding (such as hydrophobic interaction and hydrogen bonding) and disulfide cross-links by subsequent heating. The network structure of β-conglycinin heat-induced gel is hypothesized as a randomly aggregated assembly of clusters (51). Upon heating of β-conglycinin (7.5%), soluble aggregates are formed (MW about 1000 kDa), then associate with each other randomly to form a cluster; finally clusters aggregate randomly to form a gel. The gelation rate of β-conglycinin is slower than that of glycinin (52). 11S gels prepared in the presence of calcium sulfate are harder and show larger breaking stress, breaking strain, and young modulus than crude 7S gels (52,53). The 11S gel has a higher water-holding capacity, higher tensile value, and higher hardness and expands more on heating than the 7S gel (54). Sulfhydryl-disulfide interchange reaction is important in the formation and maintenance of the structural matrix of 11S-globulin gel. No SH/S-S exchange reaction participates in the 7S-gel formation, whereas hydrophobic interactions and hydrogen bonds play an important role in the formation and maintenance of the gel network of 7S protein (55). The gel formed by β-conglycinin is transparent in contrast to the turbid gel of glycinin globulin (51).

For glycinin, the rates of gelation and the hardness and turbidity of gels are affected markedly depending on the subunit composition (56). Subunit $A_5A_4B_3$ is closely related to gel formation because of an easy cleavage of hydrophobic bond between A_5 and A_4 polypeptides during heating. Cultivars containing the A_4 polypeptide in glycinin form glycinin gels faster than cultivars without A_4 (57). Soybean cultivars without the A_4 polypeptide that is identified as A_5 by Nishinari et al. (58) produce a harder and more solid-like protein gel than those cultivars with the A_4 polypeptide in glycinin (59). Subunit A_3B_4 is related to the gel hardness because the A_3 acidic polypeptide plays an important role in increasing the hardness of the gel. Nakamura et al. (57) found that the hardness of glycinin gels is different among varieties, depending on the percentage of A_3, which is the largest constituent acidic polypeptide of glycinin. However, Tezuka et al. (60) reported that tofu curd made from soybeans containing glycinin with only subunit $A_5A_4B_3$ is the hardest among those made from soybeans containing subunit A_3B_4 or Group I subunit ($A_{1a}B_{1b}$, $A_{1b}B_2$, A_2B_{1a}) in their glycinin protein. The roles of glycinin and β-conglycinin subunits in influencing certain characteristics of tofu texture remain to be clarified in the future.

The turbidity of the gels is positively related to the numbers of the free -SH residues, and is caused by the basic polypeptides that are dissociated from glycinin during heating (61). The turbidity of the gel from the glycinin globulin containing A_3B_4 subunit is the smallest because of fewer -SH groups in this subunit. The contribution of the constituent subunits of β-conglycinin to the physical properties of β-conglycinin gels is not clear. In a mixed system, glycinin is related to hardness and unfracturability of the gels, while β-conglycinin largely contributes to the elasticity of the gels (42). During gel formation, glycinin and β-conglycinin interact each other through association between basic polypeptides of glycinin and β-subunits of β-conglycinin to form composite aggregates (62).

E. Soy Proteins in Tofu Making

Generally, crude proteins constitute more than 50% of the total solids of tofu on dry basis. Soy proteins are the dominant components in tofu dry matter, which provide the major network structure of tofu gel. Soy proteins form gel by a combination of heating and the addition of a coagulant, which is either an acid or divalent salt or a combination of both. Tofu is a complex food system that is very different from the thermally induced purified protein gels. Although both types of gels require protein denaturation, the exact mechanisms for tofu gelation are not identical. Tofu is made from heated soymilk that is a turbid solution containing approximately 5% protein and 3% lipid. Therefore, tofu is an emulsion gel system. The tofu emulsion is permanent since heating is not able to separate lipids from the protein system. For tofu making, a coagulant is required, while heat-induced protein gel does not need a coagulant. Besides protein and lipid, other components in soymilk such as phytate, isoflavones, saponins, and lipoxygenases also may play important roles in coagulation of proteins during curd formation. Because of the complexity of the soymilk-tofu system, the mechanisms of tofu formation are also complex, and are not fully understood. To clearly identify the mechanisms that affect the tofu gel properties by using real soymilk is very difficult. Some studies have been conducted to understand the interactions between non-protein constituents (e.g. phytate and lipid) and proteins on coagulative reaction in tofu making (53,63). However, there is a lack of a comprehensive approach to put all factors together in one picture to understand the gel formation in tofu making.

Early researchers found that isolated glycinin-rich proteins produce firmer gels than β-conglycinin-rich proteins by either heat or calcium (53,54). Recent studies have shown that various soybean cultivars have various ratios of 11S/7S proteins that may influence the textural quality of tofu. In our laboratory, we found that the β-conglycinin (7S) and glycinin (11S) contents in 13 varieties are 17.2–23.1% and 36.3–51.3% of total proteins, respectively, and the 11S/7S protein ratio varied from 1.64 to 2.51 among the varieties (64). Furthermore, we found positive correlations existed between tofu firmness and the 11S/7S ratios in various (13 to 16) soybean cultivars (64,65). However, conflicting results on the relationships between 11S/7S ratio and tofu firmness have been reported by other researchers (55,59,66,67). The conflicting report may be partly due to different methods used for processing, because of a lack of standard methods for tofu research. We have found that processing methods affect 7S- and 11S-protein content of tofu and their contribution to tofu hardness, yield and sensory quality. Thus, processing methods have an impact on the relationships between 11S/7S ratios and textural quality since different coagulation processes and pressing steps are used for preparing tofu (64).

Yagasaki et al. (68) reported that cultivars, having a higher glycinin/β-conglycinin ratio, had a higher gel firmness than that with a lower ratio. However, on a closer examination of their report, it is apparent that firmness does not increase above 1.3 of the 11S/7S ratio in four cultivars (Figure 171.7). Therefore, in a complex system such as soybeans/soymilk (which is very different from the purified protein system), there is a limit of the firming effect due to the increase in 11S/7S ratio. In other words, above certain ratio, the tofu firmness does not increase. A similar phenomenon has been observed in one of our studies (69). We added purified 11S protein to the soymilk systems prepared from three cultivars while maintaining a constant protein concentration in soymilk for tofu making. The results showed that the increase in firmness was cultivar-dependent and the increase was not substantial (Figure 171.8). Therefore, in the soymilk system as opposed to the purified protein system, other biochemical constituents may play important roles in determining the tofu yield and quality. Further research is needed to continue to elucidate the effect of individual components and their interactions to understand the fundamental biochemistry of tofu making.

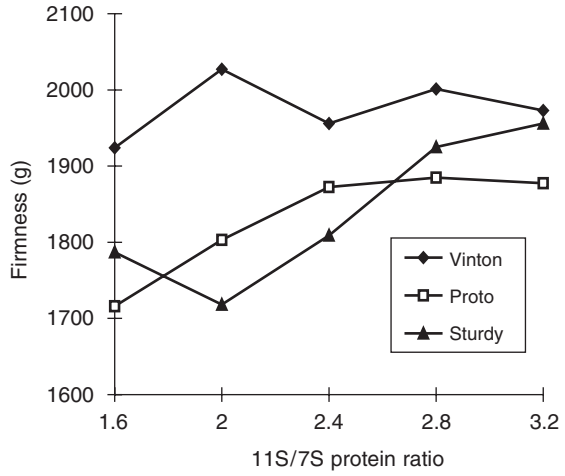

FIGURE 171.8 Firmness of tofu as affected by modified 11S/7S protein ratio in soymilk (means of two treatment replicates).

IV. MOLECULAR MODELS FOR TOFU CURD FORMATION

A. Role of Protein Charges

The gelation process of tofu has been studied in a mixed protein system by adding glucono-δ-lacton (GDL) or calcium sulfate (70). For both GDL and calcium systems, protein mixture containing higher 11S proportion has faster gelation. 11S-protein forms a continuous matrix and 7S is a discontinuous filler. The roles of 11S and 7S are interchanged with each other at a lower 11S proportion. The gelation mechanism of tofu gels induced by coagulants in an imitative 7S and 11S protein mixture has been hypothesized (70). The negatively charged groups of soy proteins denatured by heat are decreased by adding cations through the action of coagulants such as GDL, calcium sulfate, and magnesium chloride, then the neutralized protein molecules are able to aggregate due to a reduction in electrostatic repulsion. Finally, the gel network is stabilized by the formation of hydrogen bonds and hydrophobic interactions.

B. Role of Lipids in Curd Formation

Soymilk and tofu contain approximately 30% lipids on a dry basis. Lipids influence the gelation of soy proteins and play an important role in texture and sensory quality of the products (71,72). In raw soymilk, approximately 60% of total lipid are associated with the protein particles, however, only 3% of total lipid are found in the protein particles of cooked soymilk (73). After being heated to 65°C, a part of lipids and almost all α and α' subunits of β-conglycinin in the particulate fraction begin to liberate to soluble fraction. Above 90°C, almost all neutral lipids in the protein particles of raw soymilk are liberated to a floating fraction, but about one half of the phospholipids remain in the particles (73,74). Coagulation of soymilk depends on the concentration of coagulant, the pH of soymilk, and temperature, which is an external factor and accelerates the soymilk coagulation. In fact, the addition of coagulant causes not only protein coagulation and gelation but also the incorporation of lipids into the protein gel (75). It has been observed that when soymilk coagulates and forms a gel, the lipid droplets are located in the networks of the protein gel (53).

C. Role of Phospholipids in Curd Formation

The polar phospholipids are believed to play an important role in combining the particulate proteins with neutral lipids (73). Some significant amount of lipids exist in isolated 11S and 7S proteins from hexane-defatted soy meal (0.8% and 2.3%, respectively), more than 50% of these lipids are phospholipids. Phospholipids bind to the hydrophobic sites of β-conglycinin (76). Phospholipids bind stronger to the 7S protein than to the 11S protein, because 7S protein is more hydrophobic than 11S protein. The removal of lipids, particularly the phospholipids, from the surface of 7S proteins by extraction with chloroform:methanol solution makes 7S proteins vulnerable to form insoluble aggregates thus decreasing the ability to complex with protein particles. Adding phospholipids to soymilk increases the formation of protein particles. Lecithin-supplemented gels exhibit a fine network structure. Soy proteins depleting in phospholipids could be damaging to their neutral lipid binding ability. Therefore, soybean curd network structure could be promoted by phospholipids that act to combine neutral lipids in the protein network.

D. Hypothesized Molecular Model of Tofu Curd Formation

A protein particle theory with the incorporation of soy lipids in the protein network for understanding the mechanism of tofu formation has been proposed (73,74,77–80). In raw soymilk, proteins could be separated to particle and soluble fraction by centrifugation. The particle fraction is composed of large (> 100 nm) and medium (100–40 nm) particles. The soluble fraction is considered as the supernatant proteins (< 40 nm). The large particles, in which 70% are 11S globulin, constitute 40% of the total proteins in raw soymilk. The medium-sized particles are formed by a combination of the supernatant proteins with each other. Lipids are mainly present in the particle (large) fraction. The protein particles play an essential role for tofu curd formation with calcium chloride; the content of the particles in soymilk determines the density of the network; the more particles, the finer network are formed (78). Tezuka et al. (81) reported that 11S protein-rich cultivars contain more protein particles than the 7S protein-rich cultivars. Therefore, the glycinin (11S) is essential for protein particle

formation in soymilk. The cultivars having greater protein particle contents produce firmer tofu than that with lower protein particle contents (60).

As mentioned above in the section on lipids, lipids of soymilk can be separated in the floating fraction by centrifugation after heating. When $CaCl_2$ is added to soymilk, the floating fraction (lipids) decreases, which occurs before the formation of protein aggregates. When a half of the proteins coagulate with coagulant, almost all the lipids in soymilk are trapped and become inseparable. The decreases in the floating fraction (lipids) with addition of $CaCl_2$ are parallel to the increases of the coagulation of particulate proteins. This indicates that lipid conjugates with particulate and soluble proteins and become inseparable by the association with particulate protein. The protein particles are essential for the incorporation of lipids into aggregates. The lipid incorporation due to the conjugation of lipids and protein particles explains why lipids incorporated are stable against oozing and separation of the oil phase from the continuous hydrophilic phase in further storage and cooking of tofu.

The pH decrease and calcium binding with proteins also play important roles on the formation of tofu curd. A decrease of pH was observed when calcium chloride combined with soy proteins (53). When a coagulant such as calcium chloride is added into soymilk, the protein particles precipitate at lower concentrations of calcium than that of the soluble proteins, resulting in protein solubility decreases and accompanying with a pH decrease. The pH decrease promotes proteins aggregation by reducing the electric repulsion, and liberates the hydrated water of proteins, while calcium ions bind to proteins through the carboxyl groups of the glutamyl and aspartyl residues and the imidazole groups of the histidine residues. The binding of calcium to proteins brings the association of protein molecules and accelerates the formation of curd.

According to the studies reviewed above, the mechanism of tofu curd formation could be summarized in following three steps. (a) In raw soymilk before heating, the total of the large and medium-sized particles constitute more than 50% of the proteins in soymilk. Most of the particles are large particles. Most lipids are present in the protein particles. (b) When the soymilk is heated up to 90°C, the proteins denature and the lipid droplets are liberated to floating fraction. Approximate three quarters of the large particles are degraded to supernatant proteins, but the medium-sized particles increase due to the combination of β subunit of 7S and the basic polypeptide of 11S from the supernatant proteins that contain mainly 11S and 7S globulin. (c) The addition of coagulant (calcium ion, magnesium ion or GDL) to the heated soymilk is the key step. At low concentration of coagulants, protein particles combine with lipid droplets and the gel network is first formed through the binding of calcium to protein particles to neutralize the negatively charged protein molecules and to cause protein aggregation due to a reduction in electrostatic repulsion. When a half of the proteins are coagulated with coagulant, almost all the lipids in soymilk are trapped and become inseparable by the association with particulate proteins. Further addition of coagulants leads to a decrease in pH. The soluble proteins aggregate at a higher concentration of coagulant and bind to the protein particles-oil droplet complex to form a stable tofu-curd emulsion network. These reactions are illustrated stepwise in the postulated models from left to right (Figure 171.9).

V. ROLE OF PHYTIC ACID IN TOFU MAKING

Phytic acid content in seeds varies widely, it comprises 1~2% of soybeans on a dry basis and accounts for about

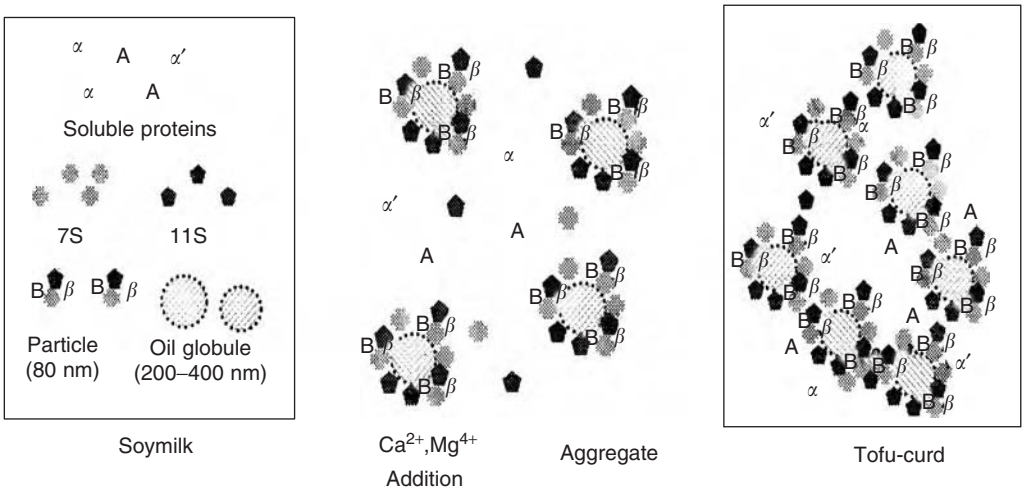

FIGURE 171.9 Postulated molecular models of the formation of tofu-curd (79).

70%~80% of the phosphorus in seeds (82). Phytate is structurally integrated with the protein bodies as phytin,a mixed potassium, magnesium, and calcium salt of inositol (83). It is reported that phytate attaches to the glycinin at pH between 2.5 and 5.0, and the extent of binding increases with decreasing pH; above the pI (isoelectric point) of glycinin (pH 4.9), no binding is found (84). Phytate has strong chelating ability with multivalent metallic ions, especially zinc, calcium, and iron. According to Graf (85), calcium ion can bind to phytic acid over a wide pH range (pH 4.8 to 10.4); the degree and tightness of binding are affected by pH, temperature, ionic strength, and size and valence of the cation. The affinity of phytic acid for calcium increases sharply with pH; the higher the pH (alkaline), the higher affinity; the affinity in pH 10.4 is a thousand-fold higher than in pH 4.8. A portion of phytate in soymilk is bound to particulate and soluble proteins (about 35% and 23%, respectively), the others are present in the free form (about 42%) (78). Therefore, when calcium is added to soymilk, it binds to phosphate groups of phytate and binds to proteins as well. The role of phytic acid in the coagulation step during tofu-making has been related to a decrease in pH after calcium salt is added (78,81). When calcium is added, the phytate-calcium salts form at approximately the neutral pH (6.6), and hydrogen ions are liberated, which are bound originally with phosphate groups in phytate. Therefore, the pH decrease upon the addition of calcium may be mainly due to the formation of phytate-calcium salts. The decrease in pH of soymilk from approximately 6.6 to 5.8 after adding calcium chloride allows the use of a lower concentration of Ca salts for coagulation. When calcium is present, it binds simultaneously to proteins and phytate, calcium binding to proteins can retard the decrease of pH because of less phytate-calcium formation. Tofu curd contains both types of calcium bound to protein or phytate.

Phytate is very important in relation to the speed of coagulation during tofu making. It has been found that higher content of phytic acid results in a slower coagulation of soymilk during tofu making, and gives a higher tofu yield (53). Therefore, the phytate content in soymilk can affect the textural properties of tofu. In other words, a decrease in phytate increases the speed of coagulation and makes the gel harder. We have found that phytic acid contents in soybeans and in soymilk are correlated positively to tofu yield, but negatively to tofu hardness ($p < 0.01$) (86). Significant positive relationships exist between soybean phytate and tofu yield ($r = 0.93$) and between soymilk phytate and tofu yield ($r = 0.95$). Negative correlations between soybean phytate and tofu hardness and brittleness are observed ($r = -0.92$ and -0.84, respectively). Negative correlation coefficients are found between soymilk phytate and tofu hardness and brittleness ($r = -0.94$ and -0.86, respectively).

VI. ROLES OF ISOFLAVONE AND SAPONINS IN TOFU MAKING

Isoflavones are a subclass of the more familiar flavonoids and have an extremely limited distribution in nature. Soybeans and soy foods are the major foods containing significant amount of isoflavones. The main isoflavones found in soybeans are genistein, daidzein, and glycitein, each of which exists in four chemical forms, as an aglycone form (genistein, daidzein, and glycitein), a β-glucoside form (genistin, daidzin, and glycitin), a malonylglucoside form (6”-*O*-malonylgenistin, 6”-*O*-malonyldaidzin, and 6”-*O*-malonylglycitin), and an acetylglucoside form (6”-*O*-acetylgenistin, 6”-*O*-acetyldaidzin, and 6”-*O*-acetylglycitin). Saponins are widely distributed in plants, which are glycosides and composed of a sapogenin that makes up the aglycone moiety, and a sugar. The sapogenin is a triterpeneoid alcohol; at least 5 sapogenins have been found in soybeans (87). Xylose, arabinose, galactose, glucose, rhamnose, and glucuronic acid have been found in the glucoside portion of soy saponins. Saponins exist in two groups, A and B (88,89,90). The group A saponins consist of 6 different kinds of saponins (Aa, Ab, Ac, Ad, Ae, and Af), which are acetyl-soyasaponins. The group B saponins, on the other hand, consist of 8 kinds of saponins (Ba, Bb, Bb’, Bc, Bd, Be, BdA, and BeA), which are not acetylated and are different from the group A. BdA is the major natural soybean saponin in soybean seeds (90). Saponins are polar compounds because of the associated sugars (oligosaccharides), which are found in the soybean meal in amounts of approximately 0.5% of the dry weight (91).

Isoflavone content varies among soybean varieties, which contain approximately 1 to 4 mg/g soybean. The isoflavone content of soybeans is markedly affected by crop year and growing condition (92,93). Isoflavones are quite heat stable. Although isoflavones are not destroyed by heat in conventional food-processing operation, heating causes a change in the conjugation profile of the isoflavones in soy products. Baking or frying of isolated soy protein and textured vegetable proteins does not alter total isoflavone content but increases the β-glucoside conjugates at the expense of 6”-*O*-malonylglucoside (94). Wang and Murphy (92) reported that cooking did not influence the isoflavone retention during tofu making, but it did alter the distribution of isoflavones by dramatically decreasing in malonylglucoside forms and increasing in acetylglucoside forms. Minimal heat processing can convert substantial amounts of malonylglucoside to the β-glucosides. Total isoflavone content in soy products decreased most likely due to leaching of isoflavones into water during processing. Wang and Murphy (95) reported that 61%, 44%, and 53% of total isoflavones were lost during the processing of tempeh, tofu, and soy protein isolate, respectively.

It is known that isoflavones and saponins impart the bitter and astringent aftertastes in the flavor of soy

products. Okubo et al. (96) reported that glucoside forms of saponins and isoflavones are the major compounds that cause objectionable aftertaste in soybeans, and saponin A groups contribute most strongly to the undesirable taste. The undesirable taste becomes weaker when saponins decompose from glucoside forms to aglycone forms, while isoflavone glucosides show a reverse tendency. The aglycones of isoflavones have stronger objectionable aftertastes than those of glucosides (96,97).

Saponins, glycitin, and glycitin derivatives are present primarily in hypocotyl, and all of these substances can give objectionable aftertaste. The previous consideration has been to remove these compounds by processing methods. In Japan, good-taste tofu has been prepared by the Namashibori technique by squeezing raw extract, which is prepared from seedcoat-removed and hypocotyl-removed soybean materials (2). In the method, the soybean is first cracked, and seedcoat and hypocotyl are removed. The resulting materials are soaked in water for a short period of time and then ground to make the slurry "go" and filter. The raw soymilk is boiled and the brown foams (which contain saponins) are scooped away. However, in light of potential health benefits of these isoflavone and saponin compounds (98), a different strategy may be needed to preserve these compounds to produce soy foods with the maximum health benefits.

There are many excellent reviews (99,100,101,102) addressing the potential benefits and adverse effects of consuming diets containing isoflavones from soy foods. Four major potential benefit effects of isoflavones include (a) heart disease prevention (103,104); (b) cancer prevention, particular with respect to breast (105,106,107), prostate (108,109), and colon (110) cancers; (c) bone mass density increase to prevent osteoporoosis (111,112); and (d) reducing post-menopausal syndromes in women (99). In animal study, soybean isoflavones can reduce experimental metastasis of melanoma cells in mice (113). The two major concerns are potential adverse effects in infants having a high intake of isoflavones from soy-based formula (114,115) and possible reproductive disorders in adults having a high isoflavone intakes (116). However, there is no direct evidence to show the adverse effects of isoflavones in human. Among 12 isoflavones, genistein has been reported as the most potent inhibitor of cancer-cell growth (117). Aglycone forms of isoflavones have been found with faster absorption and in higher amount than their glucosides in human gut (118,119). Genistein has been reported having the highest antioxidant activity than genistin, daidzin, and daidzein do (120).

VII. EFFECT OF LIPOXYGENASE ON TOFU MAKING

Lipoxygenase is an iron-containing dioxygenase, which catalyzes the oxidation of polyunsaturated fatty acids such as linoleic acid, producing unsaturated fatty acid hydroperoxides which are broken to produce cis-n-hexenal, which is the major source of grassy-beany off-flavor in soy food. Soybeans are the most abundant lipoxygenase source known by researchers, which contain four lipoxygenase isozymes, identified as L-1, L-2, L-3a, and L-3b. The L-3a and L-3b are so similar in behavior and composition that they are often considered a single type as L-3 (121). Lipoxygenase separates with the 7S fraction in the ultracentrifuge with a molecular weight of about 100,000, which contains one atom of iron per mole of protein. The lipoxygenase L-1 is heat stable, which activity loses 50% by heating at 69°C for 25 min (122); it has an optimum pH at 9, and is most active on free fatty acids, but is not activated by calcium ions. In contrast, L-2 and L-3 are less heat stable, with activities losing 50% by heating at 69°C for only 0.7 min or less (122), with pH optimum at 7. Lipoxygenase L-2 and L-3 are more active on fatty acid esters and triglycerides than on free fatty acids, and their activities are increased by calcium ions. It has been reported that L-3 is the most abundant one in mature soybeans. The L-2 is the least abundant but has the highest specific activity, which is mainly responsible for the production of grassy-beany flavors (123). The lipoxygenase isozymes show differences in their product region specificity. When linoleic acid is a substrate, the L-1 prefers the 13 position as the site for hydroperoxidation, whereas the L-2 prefers equally the position 9 and 13, and the L-3 prefers more the position 9 (65%) than the position 13 (35%) (124,125).

The lipoxygenases are rapidly activated when the substrate is available and in the presence of water. Therefore, the beany flavor is mainly developed in the step of grinding because the enzyme and lipid are liberated, as well as excess water is present. Wilkens et al. (126) found that as the temperature of slurry increases, both the number and the volume of volatiles decrease; when beans are ground at 80°C or above, no volatiles are formed. Heat inactivation of lipoxygenases during grinding in the presence of hot water and/or in the absence of air/oxygen is very critical in eliminating beany flavor from soybeans, since beany flavor is difficult to be eliminated after it is formed. Additional vacuum treatment of hot soymilk may reduce beany flavor formed. However, using heat to inactivate lipoxygenases in whole soaked beans may cause a decrease of protein solubility, loss of protein functionality, and loss of solid recovery. Therefore, several techniques involving milder heat treatment of soybeans, adjusting moisture or pH, or using aqueous alcohol to soak soybeans, or their combinations have been developed to make non- or low-beany flavor soy product (4). Genetic elimination of lipoxygenases from the seeds provides a new approach to eliminate beany flavor (127,128). Lipoxygenase-null soybean variety has the functional properties of normal soybean variety but with less beany

flavor in soy foods (129). Soymilk made from lipoxygenase-free soybeans has less cooked beany aroma, less cooked beany flavor and less astringency, and is rated darker and more yellow than that made from soybeans with normal lipoxygenase (130).

In addition to potential deterioration of tofu flavor, lipoxygenase has been found to affect tofu texture (7,131). Grinding soaked soybeans in the temperature range of 2 to 50°C promotes lipoxygenase activity, which oxidizes lipids to hydroperoxides and subsequently oxidizes the free –SH group to disulfide bonds, and possibly cysteinic acid or cysteic acid. The oxidation of –SH affects its availability to participate in the interchange of free –SH groups with disulfide bonds during heating to form protein networks, thereby decreasing the firmness of the tofu product. Firmer tofu products could be prepared by grinding soybeans under an anaerobic condition. Lipoxygenases can degrade sulfhydryl group in soymilk during grinding even at low temperature (2°C) or in a nitrogen atmosphere (N_2) (131). Among lipoxygenases, L-2 isozyme has the greatest SH-degrading capability.

VIII. EFFECT OF SOYBEAN STORAGE ON TOFU MAKING

Soybeans are subject to transportation and storage after harvest before processing into various soy products. Soybeans may be stored up to one year or longer after harvest in a wide variety of environmental circumstances before they are processed. It has been understood that both the quality of edible soybeans and the viability of soybean seeds decrease gradually with prolonged storage. The process of storage-induced biological changes in soybean seeds is generally known as aging. The mechanism of soybean aging has not been completely understood. A commonly acceptable hypothesis is that lipid peroxidation plays an important role in the initial stage of seed aging process (132,133,134). Hydroperoxides, which are highly reactive free radical compounds generated from lipid peroxidation of polyunsaturated fatty acids in the presence of oxygen, can abstract hydrogen from adjacent hydrocarbon chains resulting in not only destruction of the lipid itself, but also damage to cell membranes and other cellular components. In addition, hydroperoxides can break down to form secondary volatile oxidation products, which may contribute to the off-flavor formation in soy products during storage of soybean (135). Both enzymatic and non-enzymatic oxidation may be involved in the deterioration of the aged seeds.

The magnitude of the quality deterioration of seeds depends upon storage conditions, including time, temperature, relative humidity (RH), and microbial contamination. Among these factors, relative humidity/water activity is the most important. Low humidity may effectively preserve the original bean qualities even at a high temperature (136). The reported changes of components in soybeans induced by storage include surface discoloration that may be caused by enzymatic reactions such as polyphenolase on tannins and by non-enzymatic Maillard reactions between reducing sugars and free amines, a loss in protein extractability (137, 138), an increase in the acidity or decrease in pH (139), and a decrease in phospholipid content (140). Phospholipids are completely destroyed by storing beans at 14% moisture, and 40°C for four weeks (141). Nakayama et al. (142) also found that phospholipids were decreased during soybean storage at 35°C. Storage of soybeans influences physicochemical properties of proteins including decreases in nitrogen solubility index (NSI), decreases in extractability of glycinin and β-conglycinin, and changes in subunit composition of glycinin (59,143). When soybeans are stored in adverse conditions, soymilk quality is significantly decreased by a darkened color and a lower solid extractability, and the yield and quality of tofu are decreased by having off-flavor and a coarser texture (139). The deterioration of functional properties of soy proteins, including viscosity, gel forming ability, and emulsion stability during storage has been reported (144). Soybeans stored in adverse conditions (84% RH and 30°C) deteriorate significantly after 2 months, in which mold appears and off flavor is generated, tofu yield decreases significantly, and texture of tofu becomes coarse and hard. However, soybeans in conditions of 57% RH 20°C, cool 4°C, or in an uncontrolled ambient temperature condition in North Dakota could retain their soymilk and tofu qualities for up to 18 months (86).

In general, whole soybeans are more resistant to deterioration during storage than soy meal or damaged beans including split and seedcoat cracking. Usually, the amount of broken or damaged beans tends to increase with prolonged storage, especially when moisture content is low ($< 13\%$) (144). Yield of tofu decreases significantly beyond 30 days of storage in the condition of 85% relative humidity and 30°C for both whole and physically damaged soybeans. Furthermore, higher damage ratios cause greater losses in tofu yield (139). The off-flavor of tofu develops as soybean storage time increases. Since soybeans contain a high amount of polyunsaturated lipids, oxidation of unsaturated lipids caused by lipoxygenases, the secondary products of hydroperoxides caused by lyase, and volatile materials derived from the Maillard reactions may play important roles in off-flavor formation of tofu during storage of soybeans in adverse conditions. Besides flavor deterioration, the hydroperoxides as well as their secondary products may interact with food proteins or amino acids through protein-protein crosslinks, protein scission, protein-lipid adducts, and amino acids damage to cause deterioration (145).

Locher and Bucheli (146) stored soybeans under conditions of 4°C, 45% RH and 30°C, 82% RH to assess the degradation of soluble sugars and their relationship with seed deterioration. They reported that substantial hydrolysis of stachyose, raffinose, and verbascose occurred under

conditions of 30°C, 82% RH, and that reducing sugar content in soybeans was first reduced and later non-reducing oligosaccharides in the soybeans were hydrolyzed. A part of the reducing sugars formed by hydrolysis of the oligosaccharides may participate in the non-enzymatic glycosylation and in the Maillard reactions with the amino residues in the soy proteins (147). Sugar content in soybeans and tofu has significance in color and sweetness of the products. As mentioned in previous section, phytic acid affects the coagulation of soymilk during tofu making by decreasing pH after calcium salt is added. We found that phytate in soybeans degrades gradually with storage time in the adverse environment. However, under the mild or cold conditions, hydrolysis of phytate also could occur, but at a lesser degree (86). The hydrolysis of phytate in soybeans during storage contributes not only to the decrease of soymilk pH, but also to the loss in chelating ability with calcium ions, and subsequently affects protein coagulation behavior to lead to a reduction in the product yield and changes of textural quality (Table 171.3).

The enzyme, β-glucosidases, can hydrolyze glucosides of isoflavones to their aglycones (148). Storage of soybeans may affect the activities of β-glucosidases in the conversion of glucosides of isoflavones to more bitter aglycones. In raw soybeans, malonylgenistin is the major isoflavone form, representing 48% of overall total isoflavones, followed by malonyldaidzin, malonylglycitin, and genistin, respectively (149). The three malonylglucosides compose of 87% of overall total isoflavones. As the storage time is prolonged in adverse conditions such as 84% relative humidity and 30°C, the contents of malonylglucosides are significantly decreased to less than 1% of the overall total isoflavones after 9 months. In contrast, the content of aglycones shows a significant increase along with storage time. In the beginning, aglycones compose only 1% of the overall total isoflavones, whereas they compose 80% in 5 months, then up to 97% of the overall total isoflavones after 9 months of storage under adverse conditions (Table 171.4). Tofu made from soybeans stored under high humidity and high temperature conditions would have stronger aftertaste than that made from soybeans stored under mild conditions, because the former contains more aglycone isoflavones (genistein and daidzein), which have much stronger aftertaste than the corresponding glucoside isoflavones (genistin and daidzin). Soybeans for tofu making could be kept in cold or mild conditions (57% RH, 20°C) for a long period of time (up to 18 months) without increasing the aftertaste because of only very little conversion occurred from malonylglucosides to aglycones (Table 171.5).

IX. EVALUATION OF SOYBEAN CULTIVARS FOR TOFU MAKING

It is well known that good tofu can only be prepared from good soybeans. Cultivar, location (environment of growth) and handling practice at harvest, and storage practices post-harvest can affect soybean chemical compositions, which affect curd formation and sensory properties of tofu. The differences in tofu properties may be truly from the soybeans themselves, but there is a possibility due to differences in preparation methods. Soybean cultivar is one of the factors in influencing the quality of tofu. Soybean cultivar, soybean quality, cultivation environment, and

processing conditions all affect the resulting tofu. Over the years, substantial interest has been placed on the understanding of the quality of various soybean cultivars for tofu making. This has a practical importance in soybean trading since a good quality identity-preserved soybean cultivar would commend a premium. Several researchers have reported the differences in the quality of various soybean cultivars for making tofu. Soybean cultivars with higher protein content have generally lower oil and total sugar content. The chemical composition of soybeans is closely related to that in soymilk and tofu (150–152). The higher protein content in soybeans, the higher protein contents in soymilk or in packed tofu. Soybean cultivars vary in chemical composition resulting in significant differences in textural properties of tofu, and the cultivars with higher protein contents may not produce tofu with harder texture, because protein content alone is not adequate to explain the observed to hardness. Therefore, a thorough understanding of the protein structures in various cultivars is important to relate to tofu quality. The structures of soy proteins may be affected by cultivar as well as storage of soybeans.

In marketing soybeans for foods, the buyers and processors are interested in knowing the suitability of soybeans for making tofu because soybean quality will affect the processing procedures, tofu yield, consumer

acceptability, sale and profit of the tofu products. The desire for good quality of soybeans by the processing industries have led the soybean breeders to breed specialty soybeans for tofu uses. Tofu makers prefer large size, round shape, yellow soybeans with clear hilum, high protein, high sugar, and high nitrogen solubility for tofu making (153). These physical and chemical characteristics are associated with variety. However, color of hilum is not related to color of tofu. Tofu with white and less reddish color is preferred in Japan. Even though large-size soybeans are preferred in the market, size of soybeans does not affect tofu yield and quality (151,154–156). Some small size beans could also make good tofu. Uniformity is important. Soybeans fail to be hydrated will adversely affect the yield of tofu.

There is no standard method to evaluate soybean quality for making tofu. It is important that an evaluation method has the ability to detect the differences of soybeans with different quality characteristics, and such a method could produce a similar trend of results in a large-scale tofu manufacture process. Since manufacturing processes of tofu vary from manufacturer to manufacturer, one evaluation method can not be applied to all manufacturers. However, for a simple purpose of comparison among different varieties for tofu making one method developed for a specific tofu product may be appropriate. Most methodologies reported for tofu making are small-scale methods and have not been described in detail. Except the method reported by our lab (154) all other reported studies have not compared the reported small-scale method with a large-scale method.

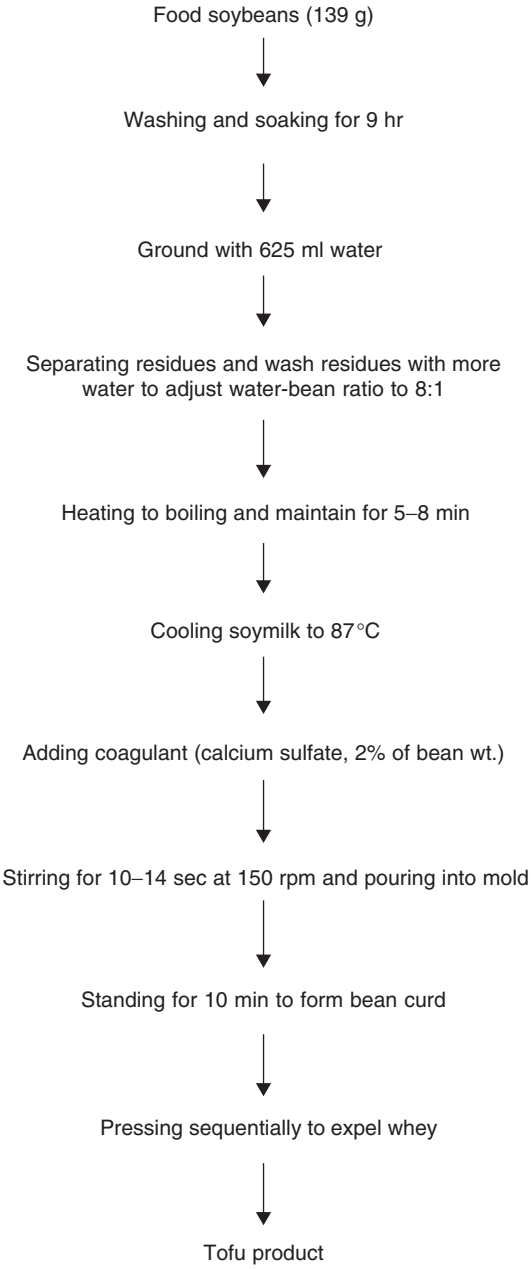

FIGURE 171.10 Procedures of tofu making for a small-scale method.

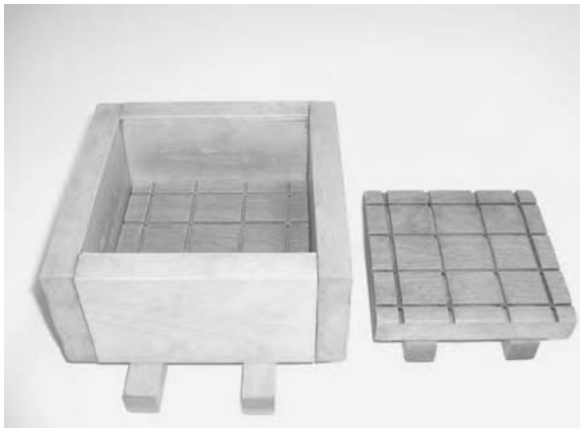

FIGURE 171.11 The tofu mold used by the small-scale method. Right: top piece for pressing.

FIGURE 171.12 The tofu mold used by the production-scale machine equipped in North Dakota State University.

FIGURE 171.13 The automatic production-scale machine (made by Ta-Ti-Hsing Machinery Co., Taoyuan, Taiwan) for soymilk and tofu production equipped in North Dakota State University.

Small-scale (139 g bean per experiment) and large-scale (6500 g bean per experiment) processing methods were developed and applied for making soymilk and soft tofu from 13 soybean varieties (154). A diagram for making soft-tofu with small scale is shown in Figure 171.10. The tofu molds for small and large scale are shown in Figure 171.11 and Figure 171.12, respectively. The automatic production-scale soymilk and tofu machine in our laboratory is shown in Figure 171.13. The results revealed that the small bench and the large-scale method correlated significantly ($p \leq 0.05$) in tofu yield, color, texture, and chemical composition (moisture, protein, lipid, ash, calcium and magnesium) (Table 171.6). Since tofu quality made by the small-bench scale was well correlated to the production method, the bench scale method may be used for determining the quality of soybeans for making tofu. Our research indicated that the quality and yield of tofu were significantly affected by soybean cultivars and processing methods (Table 171.7). Although a production-scale method has been suggested by Murphy et al. (59) for determining the soybean quality for suitability of commercial processing, the bench scale method developed in our laboratory is appropriate for evaluating soybean quality using a small quantity, since tofu quality made by the small-bench scale is well correlated to a production method.

TABLE 171.6
Correlation Coefficient of Soymilk and Tofu Physico-Chemical Properties between Small Bench-Scale Method and Large-Scale Methods

Physicochemical Property	Correlation Coefficient (r)[a]
Soymilk	
Protein	0.94***
Lipid	0.71**
Ash	0.93***
Tofu	
Yield	0.82***
Moisture content	0.78**

172 Biochemistry and Fermentation of Beer

Ronnie Willaert
Department of Ultrastructure, Flanders Interuniversity Institute for Biotechnology,
Vrije Universiteit Brussel

CONTENTS

I. INTRODUCTION

The production of alcoholic beverages is as old as history. Wine may have an archeological record going back more than 7.5 thousand years, with the early suspected wine residues dating from early to mid-fifth millennium B.C. (1). Clear evidence of intentional winemaking first appears in the representations of wine presses that date back to the reign of Udimu in Egypt, some 5000 years ago. The direct fermentation of fruit juices, such as that of grape, had doubtlessly taken place for many thousands of years before early thinking man developed beer brewing and, probably coincidentally, bread baking (2). The oldest historical evidence of formal brewing dates back to about 6000 B.C. in ancient Babylonia: a piece of pottery found there shows workers either stirring or skimming a brewing vat.

Nowadays, alcoholic beverage production represents a significant contribution to the economies of many countries. The most important beverages today are beer, wine, distilled spirits, cider, sake and liqueurs (3). In Belgium ("the beer paradise"), beer is the most important alcoholic

beverage, although the beer consumption declined the last 40 years: from 11,096,717 hl in 1965 to 10,059,513 hl in 2001 (4). In this time frame, wine consumption doubled from 1,059,964 hl to 2,215,579. Another trend is the spectacular increase in waters and soft drinks consumption (from 5,215,056 hl to 24,628,781 hl).

In this chapter, the biochemistry and fermentation of beer is reviewed. Firstly, the carbohydrate metabolism in brewer's yeast is discussed. The maltose metabolism is of major importance in beer brewing since this sugar is in a high concentration present in wort. For the production of a high quality beer, a well-controlled fermentation needs to be performed. During this fermentation, major flavor-active compounds are produced (and some of them are again degraded) by the yeast cells. The metabolism of the most important fermentation by-products during main and secondary fermentation is discussed in detail. The latest trend in beer fermentation technology is the process intensification using immobilized cell technology. This new technology is explained and some illustrative applications – on small and large scale – are discussed.

II. THE BEER BREWING PROCESS

The principal raw materials used to brew beer are water, malted barley, hops and yeast. The brewing process involves extracting and breaking down the carbohydrate from the malted barley to make a sugar solution (called "wort") which also contains essential nutrients for yeast growth, and using this as a source of nutrients for "anaerobic" yeast growth. During yeast fermentation, simple sugars are consumed, releasing energy and producing ethanol and other flavoring metabolic by-products. The major biological changes, which occur in the brewing process, are catalyzed by naturally produced enzymes from barley (during malting) and yeast. The rest of the brewing process largely involves heat exchange, separation, and clarification which only produces minor changes in chemical composition when compared to the enzyme catalyzed reactions. Barley is able to produce all the enzymes which are needed to degrade starch, β-glucan, pentosans, lipids and proteins which are the major compounds of interest to the brewer. An overview of the brewing process is shown in Figure 172.1, where also the input and output flows are indicated. Table 172.1 gives a more detailed explanation of each step in the process.

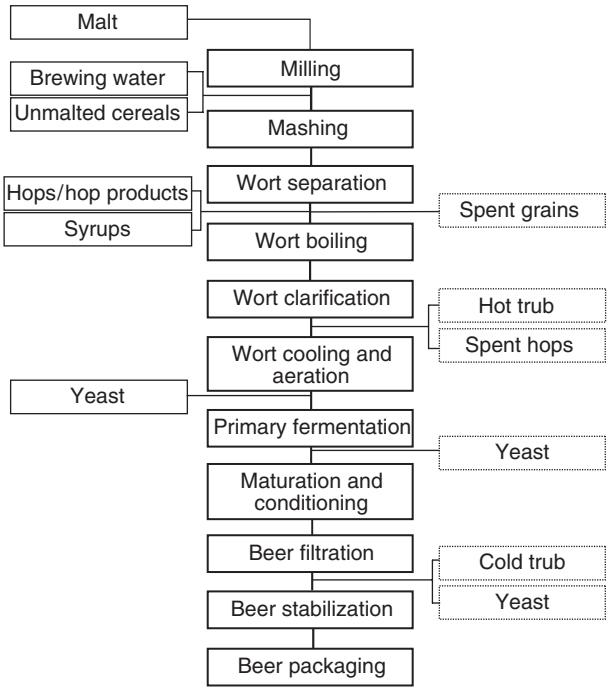

FIGURE 172.1 Schematic overview of the brewing process (input flows are indicated on the left side and output flows on the right side).

III. CARBOHYDRATE METABOLISM – ETHANOL PRODUCTION

A. Carbohydrate Uptake

Carbohydrates in wort make up 90–92% of wort solids. Wort from barley malt contains the fermentable sugars sucrose, fructose, glucose, maltose and maltotriose together with some dextrin material (Table 172. 2). The fermentable sugars typically make up 70–80% of the total carbohydrate (6). The three major fermentable sugars are glucose, and the α-glucosides maltose and maltotriose. Maltose is by far the most abundant of these sugars, typically accounting for 50 to 70% of the total fermentable sugars in an all-malt wort. Sucrose and fructose are present in a low concentration. The unfermentable dextrins play little part in brewing. Wort fermentability may be reduced or increased by using solid or liquid adjuncts.

Brewing strains consume the wort sugars in a specific sequence: glucose is consumed firstly, followed by fructose, maltose and finally maltotriose. The uptake and consumption of maltose and maltotriose is repressed or inactivated at elevated glucose concentrations. Only when 60% of the wort glucose has been taken up by the yeast will the uptake and consumption of maltose start. Maltotriose uptake is inhibited by high glucose and maltose concentrations. When high amounts of carbohydrate adjuncts (*e.g.* glucose) or high-gravity wort are employed, the glucose repression is even more pronounced, resulting in fermentation delays (7).

The efficiency of brewer's yeast strains to effect alcoholic fermentation is dependent upon their ability to utilize the sugars present in wort. This ability very largely determines the fermentation rate as well as the final quality of the beer produced. In order to optimize the fermentation

TABLE 172.1
Overview of the Brewing Processing Steps: from Barley to Beer

Process	Action	Objectives	Time	Temperature (°C)
Malting				
Steeping	Moistening and aeration of barley	Preparation for the germination process	48 h	12–22
Germination	Barley germination	Enzyme production, chemical structure modification	3–5 d	22
Kilning	Kilning of the green malt	Ending of germination and modification, production of flavoring and coloring substances	24–48 h	22–110
Milling	Grain crushing without disintegrating the husks	Enzyme release and increase of surface area	1–2 h	22
Mashing + wort separation	Addition of warm/hot water	Stimulation of enzyme action, extraction and dissolution of compounds, wort filtration, to obtain the desired fermentable extract as quick as possible	1–2 h	30–72
Wort boiling	Boiling of wort and hops	Extraction and isomerization of hop components, hot break formation, wort sterilization, enzyme inactivation, formation of reducing, aromatic and coloring compounds, removal of undesired volatile aroma compounds, wort acidification, evaporation of water	0.5–1.5 h	> 98
Wort clarification	Sedimentation or centrifugation	Removal of spent hops, clarification (whirlpool, centrifuge, settling tank)	< 1 h	100–80
Wort cooling and aeration	Use of heat exchanger, injection of air bubbles	Preparing the wort for yeast growth	< 1 h	12–18
Fermentation	Adding yeast, controlling the specific gravity, removal of yeast	Production of green beer, to obtain yeast for subsequent fermentations, carbon dioxide recovery	2–7 d	12–22 (ale) 4–15 (lager)
Maturation and conditioning	Beer storage in oxygen free tank, beer cooling, adding processing aids	Beer maturation, adjustment of the taste, adjustment of CO_2 content, sedimentation of yeast and cold trub, beer stabilization	7–21 h	−1–0
Beer clarification	Centrifugation, filtration	Removal of yeast and cold trub	1–2 h	−1–0
Biological stabilization	Pasteurization of sterile filtration	Killing or removing of micro-organisms	1–2 h	62–72 (past.) −1–0 (filtr.)
Packaging	Filling of bottles, cans, casks and kegs; pasteurization of small volumes in packings	Production of packaged beer according to specifications	0.5–1.5 h	−1–room temp.

efficiency of the primary fermentation, a detailed knowledge of the sugar consumption kinetics which is linked to the yeast growth kinetics, is required (8).

1. Maltose and Maltotriose Metabolism

The yeast *S. cerevisiae* transports the monosaccharides across the cell membrane by the hexose transporters. There are 19, or possibly 20, genes encoding hexose transporters (9). The disaccharide maltose and the trisaccharide maltotriose are transported by specific transporters into the cytoplasm, where these molecules are hydrolyzed by the same α-glucosidase yielding two or three molecules of glucose, respectively (10,11).

Maltose utilization in yeast is conferred by any one of five *MAL* loci: *MAL1* to *MAL4* and *MAL6* (9,12). Each locus consists of three genes: gene 1 encodes a maltose transporter (permease), gene 2 encodes a maltase (α-glucosidase) and gene 3 encodes a transcriptional activator of the other two genes. Thus, for example, the maltose transporter gene at the *MAL1* locus is designated *MAL61*. The three genes of a *MAL* locus are all required to allow fermentation. Some authors persist in using gene designations such as for the *MAL1* locus: *MAL1T* (transporter = permease), *MAL1R* (regulator) and *MAL1S* (maltase). The five *MAL* loci each map to a different chromosome. The *MAL* loci exhibit a very high degree of homology and are telomere linked, suggesting that they evolved by translocation

TABLE 172.2
Carbohydrate Composition of Worts (Adapted from (5))

Origin	Danish	Canadian	British
Type of Wort	Lager	Lager	Pale Ale
Original Gravity	1043.0	1054.0	1040.0
Fructose (g/l)	2.1	1.5	3.3
(%)[a]	2.7	1.6	4.8
Glucose (g/l)	9.1	10.3	10.0
(%)[a]	11.6	10.9	14.5
Sucrose (g/l)	2.3	4.2	5.3
(%)[a]	2.9	4.5	7.7
Maltose (g/l)	52.4	60.4	38.9
(%)[a]	66.6	64.2	56.5
Maltotriose (g/l)	12.8	17.7	11.4
(%)[a]	16.3	18.8	16.5
Total ferm. sugars (g/l)	78.7	94.1	68.9
Maltotetraose (g/l)	2.6	7.2	2.0
Higher sugars (g/l)	21.3	26.8	25.2
Total dextrins (g/l)	23.9	34.0	25.2
Total sugars (g/l)	102.6	128.1	94.1

[a] percent of the total fermentable sugars.

from telomeric regions of different chromosomes (13). Since a fully functional or partial allele of the *MAL1* locus is found in all strains of *S. cerevisiae*, this locus is proposed as the progenitor of the other *MAL* loci (14). Gene dosage studies performed with laboratory strains of yeast have shown that the transport of maltose in the cell may be the rate-limiting step in the utilization of this sugar (15). Constitutive expression of the maltose transporter gene (*MALT*) with high-copy-number plasmids in a lager strain of yeast has been found to accelerate the fermentation of maltose during high-gravity (24°P) brewing (16). The constitutive expression of *MALS* and *MALR* had no effect on maltose fermentability.

The control over *MAL* gene expression is exerted at three levels. The presence of maltose induces, whereas glucose represses, the transcription of *MALS* and *MALT* genes (17–19). The constitutively expressed regulatory protein (*MALR*) binds near the *MALS* and *MALT* promotors and mediates the induction of *MALS* and *MALT* transcription (20–22). Experiments with *MALR*-disrupted strains led to the conclusion that MalRp is involved in glucose repression (23,24). Relatively little attention has been paid to posttranscriptional control, i.e., the control of translational efficiency, or mRNA turnover, as mechanisms complementing glucose repression (25). The addition of glucose to induced cells has been reported to cause a 70% increase in the lability of a mRNA population containing a fragment of *MALS* (17). The third level of control is posttranslational modification. In the presence of glucose, maltose permease is either reversibly converted to a conformational variant with decreased affinity (26,27) or irreversibly proteolytically degraded depending on the physiological conditions (28,29). The latter phenomenon is called catabolite inactivation. Glucose repression is accomplished by the Mig1p repressor protein, which is encoded by the *MIG1* gene (30). It has been shown that Mig1p represses the transcription of all three *MAL* genes by binding upstream of them (31). The *MIG1* gene has been disrupted in a haploid laboratory strain and in an industrial polyploid strain of *S. cerevisiae* (32). In the *MIG1*-disrupted haploid strain, glucose repression was partly alleviated; i.e., maltose metabolism was initiated at higher glucose concentrations than in the corresponding wild-type strain. In contrast, the polyploid Δ*mig1* strain exhibited an even more stringent glucose control of maltose metabolism than the corresponding wild-type strain, which could be explained by a more rigid catabolite inactivation of maltose permease, affecting the uptake of maltose.

Recently, the gene A*GT1*, which codes for a α-glucoside transporter has been characterised (33). *AGT1* is found in many *S. cerevisiae* laboratory strains and maps to a naturally occurring, partially functional allele of the *MAL1* locus. Agt1p is a highly hydrophobic, postulated integral membrane protein. It is 57% identical to Mal61p (the maltose permease encoded at *MAL6*) and is also a member of the 12-transmembrane domain superfamily of sugar transporters (34). Like Mal61p, Agt1p is a high-affinity, maltose/proton symporter, but Mal61p is capable of transporting only maltose and turanose, while Agt1p transports these two α-glucosides as well as several others including isomaltose, α-methylglucoside, maltotriose, palatinose, trehalose and melezitose. *AGT1* expression is maltose inducible and induction is mediated by the Mal-activator.

Brewing strains of yeast are polyploid, aneuploid, or, in the case of lager strains, alloploid. Recently, Jespersen and co-workers (35) examined 30 brewing strains of yeast (5 ale strains and 25 lager strains) with the aim of examining the alleles of maltose and maltotriose transporter genes contained by them. All the strains of brewer's yeast examined, except two, were found to contain *MAL11* and *MAL31* sequences, and only one of these strains lacked *MAL41*. *MAL21* was not present in the five ale strains and 12 of the lager strains. *MAL61* was not found in any of the yeast chromosomes other than those known to carry *MAL* loci. Sequences corresponding to the *AGT1* gene (transport of maltose and maltotriose) were detected in all but one of the yeast strains.

Wort maltotriose has the lowest priority for uptake by brewer's yeast cells and incomplete maltotriose uptake results in yeast fermentable extract in beer, material loss, greater potential for microbiological stability and sometimes atypical beer flavor profiles (7). Maltotriose uptake from wort is always slower with ale strains than with lager strains under similar fermentation conditions. However, the initial transport rates are similar to those of maltose in a number of ale and lager strains. Elevated osmotic

pressure inhibits the transport and uptake of glucose, maltose and maltotriose with maltose and maltotriose being more sensitive to osmotic pressure than glucose in both lager and ale strains. Ethanol (5% w/v) stimulated the transport of maltose and maltotriose, due in all probability to an ethanol-induced change in the plasma membrane configuration, but had no effect on glucose transport. Higher ethanol concentrations inhibited the transport of all three sugars.

B. Wort Fermentation

Before the fermentation process starts, wort is aerated. This is a necessary step since oxygen is required for the synthesis of sterols and unsaturated fatty acids, which are incorporated in the yeast cell membrane (36). It has been shown that ergosterol and unsaturated fatty acids increase both in concentration as long as oxygen is present in the wort (*e.g.* (37)). A maximum concentration is obtained in 5–6 hours after pitching, but the formation rate is dependent upon pitching rate and temperature. Unsaturated fatty acids can also be taken up from the wort, but all malt wort does not contain sufficient unsaturated lipids to support a normal growth rate of yeast. Adding lipids to wort, especially unsaturated fatty acids, might be an interesting alternative (38,39). The oxygen required for lipid biosynthesis, can also be introduced by oxygenation of the separated yeast cells.

Different devices are used to aerate the cold wort: ceramic or sintered metal candles, aeration plants employing venturi pipes, two component jets, static mixers, or centrifugal mixers (40). The principle of these devices is that very small air (oxygen) bubbles are produced and quickly dissolve during turbulent mixing.

As a result of this aeration step, carbohydrates are degraded aerobically during the first few hours of the "fermentation" process. The aerobic carbohydrate catabolism takes typically 12 h for a lager fermentation.

During the first hours of the fermentation process, oxidative degradation of carbohydrates occurs through the glycolysis and Krebs (TCA) cycle. The energy efficiency of glucose oxidation is derived from the large number of $NADH_2^+$ produced for each mole of glucose oxidized to CO_2. The actual wort fermentation gives alcohol and carbon dioxide *via* the Embden-Meyerhof-Parnas (glycolytic) pathway. The reductive pathway from pyruvate to ethanol is important since it regenerates NAD^+. Energy is obtained solely from ATP-producing steps of the Embden-Meyerhof-Parnas pathway. During fermentation, the activity of the TCA cycle is greatly reduced, although it still serves as a source of intermediates for biosynthesis (41).

Lagunas (42) observed that during aerobic growth of *S. cerevisiae*, respiration accounts for less than 10% of glucose catabolism, the remainder being fermented. Increasing sugar concentrations resulting in a decreased oxidative metabolism is known as the Crabtree effect. This was traditionally explained as an inhibition of the oxidative system by high concentrations of glucose. Nowadays, it is generally accepted that the formation of ethanol at aerobic conditions is a consequence of a bottleneck in the oxidation of pyruvate, *e.g.* in the respiratory system (43–47).

A reduction of ethanol production can be achieved by metabolic engineering of the carbon flux in yeast resulting in an increased formation of other fermentation product. A shift of the carbon flux towards glycerol at the expense of ethanol formation in yeast was achieved by simply increasing the level of glycerol-3-phosphate dehydrogenase (48–51). The *GDP1* gene, which encodes glycerol-3-phosphate dehydrogenase, has been overexpressed in an industrial lager brewing yeast to reduce the ethanol content in beer (52). The amount of glycerol produced by the *GDP1*-overexpressing yeast in fermentation experiments – simulating brewing conditions – was increased 5.6 times and ethanol was decreased by 18% compared to the wild-type strain. Overexpression did not affect the consumption of wort sugars and only minor changes in the concentration of higher alcohols, esters and fatty acids could be observed. However, the concentrations of several other by-products, particularly acetoin, diacetyl and acetaldehyde, were considerably increased.

IV. METABOLISM OF BIOFLAVORING BY-PRODUCTS

Yeast is an important contributor to flavor development in fermented beverages. The compounds which are produced during fermentation, are many and varied, depending on both the raw materials and the microorganisms used. The interrelation between yeast metabolism and the production of bioflavoring by-products is illustrated in Figure 172.2.

A. Biosynthesis of Higher Alcohols

During beer fermentation, higher alcohols (also called "fusel alcohols") are produced by yeast cells as by-products and represent the major fraction of the volatile compounds. More than 35 higher alcohols in beer have been described. Table 172.3 gives the most important compounds which can be classified into aliphatic (n-propanol, isobutanol, 2-methylbutanol (or active amyl alcohol), and 3-methylbutanol (or isoamyl alcohol)) and aromatic (2-phenylethanol, tyrosol, tryptophol) higher alcohols. Aliphatic higher alcohols contribute to the "alcoholic" or "solvent" aroma of beer, and produce a warm mouthfeel. The aromatic alcohol 2-phenylethanol has a sweet aroma and has a positive contribution to the beer aroma, whereas the aroma of tyrosol and tryptophol are undesirable.

Higher alcohols are synthesized by yeast during fermentation *via* the catabolic (Ehrlich) and anabolic pathway (amino acid metabolism) (62–64). In the catabolic pathway,

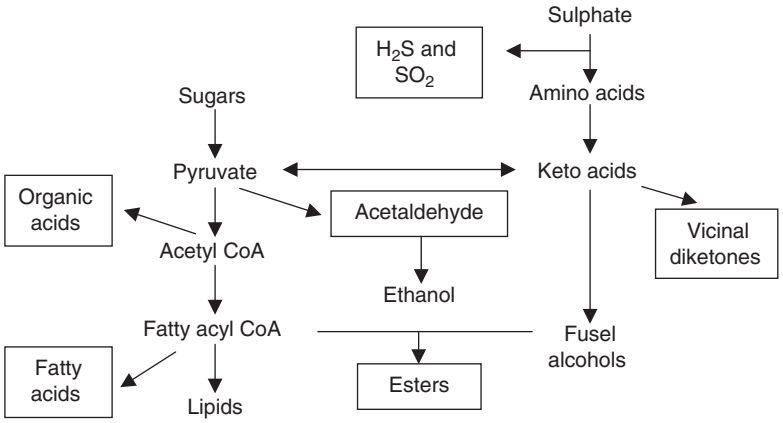

FIGURE 172.2 Interrelationships between yeast metabolism and the production of flavor active compounds (53).

TABLE 172.3
Major Higher Alcohols in Beer (54)

Compound	Flavor Threshold (mg/l)	Aroma or Taste[b]	Concentration Range (mg/l) Bottom Fermentation	Concentration Range (mg/l) Top Fermentation
n-Propanol	600[c], 800[b]	Alcohol	7–19 (12)*[f]	20–45[i]
Isobutanol	100[c], 80–100[g], 200[b]	Alcohol	4–20 (12)[f]	10–24[i]
2-Methylbutanol	50[c], 50–60[g], 70[b]	Alcohol	9–25 (15)[a]	80–140[i]
3-Methylbutanol	50[c], 50–60[g], 65[b]	Fusely, pungent	25–75 (46)[a]	80–140[i]
2-Phenylethanol	5[a], 40[c], 45–50[g], 75[d], 125[b]	Roses, sweetish	11–51 (28)[f], 4–22[g], 16–42[h]	35–50[g], 8–25[a], 18–45[i]
Tyrosol	10[a], 10–20[e], 20[c], 100[d,g], 200[b]	Bitter chemical	6–9[a], 6–15[a]	8–12[g], 7–22[g]
Tryptophol	10[a], 10–20[e], 200[d]	Almonds, solvent	0.5–14[a]	2–12[g]

the yeast uses the amino acids of the wort to produce the corresponding α-keto acid *via* a transamination reaction. The excess oxoacids are subsequently decarboxylated into aldehydes and further reduced (alcohol dehydrogenase) to higher alcohols. This last reduction step also regenerates NAD^+.

Dickinson and co-workers looked at the genes and enzymes, which are used by *S. cerevisiae* in the catabolism of leucine to isoamyl alcohol (65), valine to isobutanol (66), and isoleucine to active amyl alcohol (67). In all cases, the general sequence of biochemical reactions is similar, but the details for the formation of the individual alcohols are surprisingly different. The branched-chain amino acids are first deaminated to the corresponding α-ketoacids (α-ketoisocapric acid from leucine, α-ketoisovaleric acid from valine and α-keto-β-methylvaleric acid from leucine). There are significant differences in the way each α-ketoacid is subsequently decarboxylated. Recently, the catabolism of phenylalanine to 2-phenylethanol and of tryptophan were also studied (68). Phenylalanine and tryptophan are first deaminated to 3-phenylpyruvate and 3-indolepyruvate, respectively, and then decarboxylated. These studies revealed that all amino acid catabolic pathways studied to date use a subtle different spectrum of decarboxylases from the five-membered family that comprises Pdc1p, Pdc5p, Pdc6p, Ydl080cp and Ydr380wp. Using strains containing all possible combinations of mutations affecting the seven *AAD* genes (putative aryl alcohol dehydrogenases), five *ADH* and *SFA1* (other alcohol dehydrogenase genes), showed that the final step of amino acid catabolism can be accomplished by any one of the ethanol dehydrogenases (Ahd1p, Ahd2p, Ahd3p, Ahd4p, Ahd5p) or Sfa1p (formaldehyde dehydrogenase).

In the anabolic pathway, the higher alcohols are synthesized from α-keto acids during the synthesis of amino acids from the carbohydrate source. The pathway choice depends on the individual higher alcohol and on the level of available amino acids available. The importance of the anabolic pathway decreases as the number of carbon atoms in the alcohol increases (63) and increases in the later stage of fermentation as wort amino acids are depleted (69). Yeast strain, fermentation conditions and wort composition all have significant effects on the combination and levels of higher alcohols which are formed (69).

Conditions which promote yeast cell growth – such as high levels of nutrients (amino acids, oxygen, lipids, zinc, …), increased temperature and agitation – stimulate

the production of higher alcohols. The synthesis of aromatic alcohols is especially sensitive to temperature changes. On the other hand, conditions which restrict yeast growth – such as lower temperature and higher pressure – reduce the extent of higher alcohol production.

B. Biosynthesis of Esters

Esters are very important flavor compounds in beer. They have an effect on the fruity/flowery aromas. Table 172.4 shows the most important esters with their threshold values which are considerably lower than those for higher alcohols. The major esters can be subdivided into acetate esters and C_6–C_{10} medium-chain fatty acid ethyl esters. They are desirable components of beer when present in appropriate quantities and proportions but can become unpleasant when in excess. Ester formation is highly dependent on the yeast strain used (72,73) and on certain fermentation parameters such as temperature (74–76), specific growth rate (75), pitching rate (75,77,78) and top pressure. Additionally, the concentrations of assimilable nitrogen compounds (53,76,79), carbon sources (80–83), dissolved oxygen (76,84–86) and fatty acids (87,88) can influence the ester production rate.

Esters are produced by yeast both during the growth phase (60%) and also during the stationary phase (40%). They are formed by the intracellular reaction between a fatty acyl-coenzyme A and an alcohol:

$$R'OH + RCO\text{-}ScoA \rightarrow RCOOR' + CoASH \quad (172.1)$$

This reaction is catalyzed by an alcohol acyltransferase (or ester synthethase). Since acetyl CoA is also a central molecule in the synthesis of lipids and sterols, ester synthesis is linked to the fatty acid metabolism (see also Figure 172.2).

Alcohol acetyltransferase (AAT) has been localized in the plasma membrane (89) and found to be strongly inhibited by unsaturated fatty acids, ergosterol, heavy metal ions and sulphydryl reagents (90). Subcellular fractionation studies conducted during the batch fermentation cycle, demonstrated the existence of both cytosolic and membrane-bound AAT (91,92). In term of controlling ester formation on a metabolic basis, it has further been shown that ester synthesizing activity of AAT is dependent on its positioning within the yeast cell. An interesting feature of this distribution pattern is that specific rates of acetate ester formation varied directly with the level of cytosolic AAT activity (93).

The *ATF1* gene, which encodes alcohol acetyltransferase, has been cloned from *S. cerevisiae* and brewery lager yeast (*S. cerevisiae uvarum*) (94). An hydrophobicity analysis suggested that alcohol acetyltransferase does not have a membrane-spanning region that is significantly hydrophobic, which contradicts the membrane-bound assumption. A Southern analysis of the yeast genomes in which the *ATF1* gene was used as a probe, revealed that *S. cerevisiae* has one *ATF1* gene, while brewery lager yeast has one *ATF1* gene and another, homologous gene (*Lg-ATF1*). The AAT activities have been compared *in vivo* and *in vitro* under different fermentation conditions (95). This study suggested that ester synthesis is modulated by a repression-induction of enzyme synthesis or processing the regulation of which is presumably linked to lipid metabolism.

The ester production can be altered by changing the synthesis rate of certain fusel alcohols. Hirata *et al.* (96) increased the isoamyl acetate levels by introducing extra copies of the *LEU4* gene in the *S. cerevisiae* genome. A comparable *S. cerevisiae uvarum* mutant has been isolated (97). The mutants have an altered regulation pattern of amino acid metabolism and produce more isoamyl acetate and phenylethyl acetate.

Isoamyl acetate is synthesized from isoamyl alcohol and acetyl coenzyme A by AAT and is hydrolyzed by esterases at the same time in *S. cerevisiae*. To study the effect of balancing both enzyme activities, yeast strains with different numbers of copies of *ATF1* gene and isoamyl acetate-hydrolyzing esterase gene (*IAH1*) have been constructed and used in small-scale sake brewing (98). Fermentation profiles as well as components of the resulting sake were largely alike. However, the amount of isoamyl acetate in the sake increased with increasing ratio

TABLE 172.4
Major Esters in Beer (70)

Compound	Flavor Threshold (mg/l)	Aroma	Concentration Range (mg/l) in 48 Lagers
Ethyl actetate	20–30, 30[a]	Fruity, solvent-like	8–32 (18.4)*
Isoamyl acetate	0.6–1.2, 1.2[a]	Banana, peardrop	0.3–3.8 (1.72)
Ethyl caproate (ethyl hexanoate)	0.17–0.21, O.21[a]	Apple-like with note of aniseed	0.05–0.3 (0.14)
Ethyl caprylate (ethyl octanoate)	0.3–0.9, 0.9[a]	Apple-like	0.04–0.53 (0.17)
2-Phenylethyl acetate	3.8[a]	Roses, honey, apple, sweetish	0.10–0.73 (0.54)

* Mean value.

[a] (71).

of AAT/Iah1p esterase activity. Therefore, it was concluded that the balance of these two enzyme activities is important for isoamyl acetate accumulation in sake mash.

The synthesis of acetate esters by *S. cerevisiae* during fermentation is ascribed to at least three acetyltransferase activities, namely alcohol acetyltransferase (AAT), ethanol acetyltransferase and isoamyl AAT (99). To investigate the effect of increased AAT activity on the sensory quality of Chenin blanc wines and distillates from Colombar base wines, the *ATF1* gene of *S. cerevisiae* was overexpressed. Northern blot analysis indicated constitutive expression of *ATF1* at high levels in these transformants. The levels of ethyl acetate, isoamyl acetate and 2-phenylethyl acetate increased 3- to 10-fold, 3.8- to 12-fold, and 2- to 10-fold, respectively, depending on the fermentation temperature, cultivar, and yeast used. The concentrations of ethyl caprate, ethyl caprylate and hexyl acetate only showed minor changes, whereas the acetic acid concentration decreased by more than half. This study established the concept that the overexpression of acetyltransferase genes such as *ATF1* could profoundly affect the flavor profiles of wines and distillates deficient in aroma.

In order to investigate and compare the roles of the known *S. cerevisiae* alcohol acetyltransferases, Atf1p, Atf2p and Lg-Atf1p, in volatile ester production, the respective genes were either deleted or overexpressed in a laboratory strain and a commercial brewing strain (100). Analysis of the fermentation products confirmed that the expression levels of *ATF1* and *ATF2* greatly affect the production of ethyl acetate and isoamyl acetate. GC-MS analysis revealed that Atf1p and Atf2p are also responsible for the formation of a broad range of less volatile esters, such as propyl acetate, isobutyl acetate, pentyl acetate, hexyl acetate, heptyl acetate, octyl acetate, and phenyl ethyl acetate. With respect to the esters analyzed in this study, Atf2p seemed to play only a minor role compared to Atf1p. The *atf1*Δ*atf2*Δ double deletion strain did not form any isoamyl acetate, showing that together, Atf1p and Atf2p are responsible for the total cellular isoamyl alcohol acetyltransferase activity. However, the double deletion strain still produced considerable amounts of certain other esters, such as ethyl acetate (50% of the wild-type strain), propyl acetate (50%), and isobutyl acetate (40%), which provides evidence for the existence of additional, as-yet-unknown ester synthases in the yeast proteome. Interestingly, overexpression of different alleles of *ATF1* and *ATF2* led to different ester production rates, indicating that differences in the aroma profiles of yeast strains may be partially due to mutations in their *ATF* genes.

Recently, it has been discovered that the Atf1 enzyme is localized inside lipid vesicles in the cytoplasm of the yeast cell (101). Lipid vesicles are small organelles in which certain neutral lipids are metabolized or stored. This indicates that fruity esters are possibly by-products of these processes.

C. Biosynthesis of Organic Acids

Important organic acids detected in beer include acetate, lactate, succinate, pyroglutamate, malate, citrate, α-ketoglutarate and α-hydroxyglutarate (102). They influence flavor directly when present above their taste threshold, and by their influence on beer pH. These components have their origin in raw materials (malt, hops) and are produced during the beer fermentation. Organic acids which are excreted by yeast cells, are synthesized *via* amino acid biosynthesis pathways and carbohydrate metabolism. Especially, they are overflow products of the incomplete Krebs cycle during beer fermentation. Excretion of organic acids is influenced by yeast strain and fermentation vigor. Sluggish fermentations lead to lower levels of excretion. Pyruvate excretion follows the yeast growth: maximal concentration is reached just before the maximal yeast growth, and is next taken up by the yeast and converted to acetate. Acetate is synthesized quickly during early fermentation and is later partially reused by the yeast during yeast growth. At the end of the fermentation, acetate is accumulated. De reduction of pyruvate results in the production of D-lactate or L-lactate (most yeast strains produce preferentially D-lactate). The highest amount of lactate is produced during the most active fermentation period.

The change in organic acid productivity by disruption of the gene encoding fumarase (*FUM1*) has been investigated and it has been suggested that malate and succinate are produced *via* the oxidative pathway of the TCA cycle under static and sake brewing conditions (195). Using a NAD^+-dependent isocitrate dehydrogenase gene (*IDH1*, *IDH2*) disruptant, approximately half of the succinate in sake mash was found to be synthesized *via* the oxidative pathway of the TCA cycle in sake yeast (103).

Sake yeast strains possessing various organic acid productivities were isolated by gene disruption (104). Sake fermented using the aconitase gene (*ACO1*) disruptant contained a two-fold higher concentration of malate and a two-fold lower concentration of succinate than that made using the wild-type strain. The fumarate reductase gene (*OSM1*) disruptant produced sake containing a 1.5-fold higher concentration of succinate, whereas the α-ketoglutarate dehydrogenase gene (*KGD1*) and fumarase gene (*FUM1*) disruptants gave lower succinate concentrations. In *S. cerevisiae*, there are two isoenzymes of fumarate reductase (FRDS1 and FRDS2), encoded by the *FRDS* and *OSM1* genes, respectively (105). Recent results suggest that these isoenzymes are required for the reoxidation of intracellular NADH under anaerobic conditions, but not under aerobic conditions (106).

Succinate dehydrogenase is an enzyme of the TCA cycle and thus essential for respiration. In *S. cerevisiae*, this enzyme is composed of four non-identical subunits, i.e., the flavoprotein, the iron-sulfur protein, the cytochrome b_{560}, and the ubiquinone reduction protein

encoded by the *SDH1*, *SDH2*, *SDH3*, and *SDH4* genes, respectively (107–110). Sdh1p and Sdh2p comprise the catalytic domain involved in succinate oxidation. These proteins are anchored to the inner mitochondrial membrane by Sdh3p and Sdh4p, which are necessary for electron transfer and ubiquinone reduction, and constitute the succinate:ubiquinone oxidoreductase (complex II) of the electron transport chain. Single or double disruptants of the *SDH1*, *SDH1b* (which is a homologue of the *SDH1* gene), *SDH2*, *SDH3* and *SDH4* genes have been constructed and shown that the succinate dehydrogenase activity was retained in the *SDH2* disruptant and that double disruption of *SDH1* and *SDH2* or *SDH1b* genes is necessary to cause deficiency of succinate dehydrogenase activity in sake yeast (111). The role of each subunit in succinate dehydrogenase activity and the effect of succinate dehydrogenase on succinate production using strains which were deficient in succinate dehydrogenase, have also been determined. The results suggested that succinate dehydrogenase activity contributes to succinate production under shaking conditions, but not under static and sake brewing conditions.

D. Biosynthesis of Vicinal Diketones

Vicinal diketones are ketones with two adjacent carbonyl groups. During fermentations, these flavor-active compounds are produced as by-products of the synthesis pathway of isoleucine, leucine and valine (ILV pathway) (see Figure 172.3) and thus also linked to amino acid metabolism (112) and the synthesis of higher alcohols. They impart a "buttery," "butterscotch" aroma to alcoholic drinks. Two of these compounds are important in beer, i.e. diacetyl (2,3-butanedione) and 2,3-pentanedione. Diacetyl is quantitatively more important than 2,3-pentanedione. It has a taste threshold around 0.10–0.15 mg/l in lager beer, approximately 10 times lower than that of pentanedione (113).

The excreted α-acetohydroxy acids are overflow products of the ILV pathway which are non-enzymatically degraded to the corresponding vicinal diketones (114). Tetraploid gene dosage series for various *ILV* genes have been constructed and the obtained yeast strains were used to study the influence of the copy number of *ILV* genes on the production of vicinal diketones (115,116). It was shown that the *ILV5* activity is the rate limiting step in the ILV pathway and responsible for the overflow (Figure 172.3). The non-enzymatic oxidative decarboxylation step is the rate-limiting step and proceeds faster at a higher temperature and a lower pH (117,118). The produced amount of α-acetolactate is very dependent on the used yeast strain. The production increases with increasing yeast growth. For a classical fermentation, 0.6 ppm α-acetolactate is formed (119). At high aeration, this value can be increased to 0.9 ppm and in cylindro-conical fermentations tanks even to 1.2–1.5 ppm.

Yeast cells posses the necessary enzymes (reductases) to reduce diacetyl to acetoin and further to 2,3-butanediol, and 2,3-pentanedione to 2,3-pentanediol. These reduced compounds have much higher taste thresholds and have no impact on the beer flavor (120). The reduction reactions are yeast strain dependent. The reduction occurs at the end of the main fermentation and during the maturation. Sufficient yeast cells in suspension are necessary to obtain an efficient reduction. Yeast strains which flocculate early during the main fermentation, need a long maturation time to reduce the vicinal diketones. Diacetyl can be complexed using SO_2. These complexes can not be reduced, but diacetyl can again be liberated at a later stage by aldehydes. This situation is especially applicable to yeast strains, which produce a lot of SO_2. Worts which are produced using much adjuncts can be

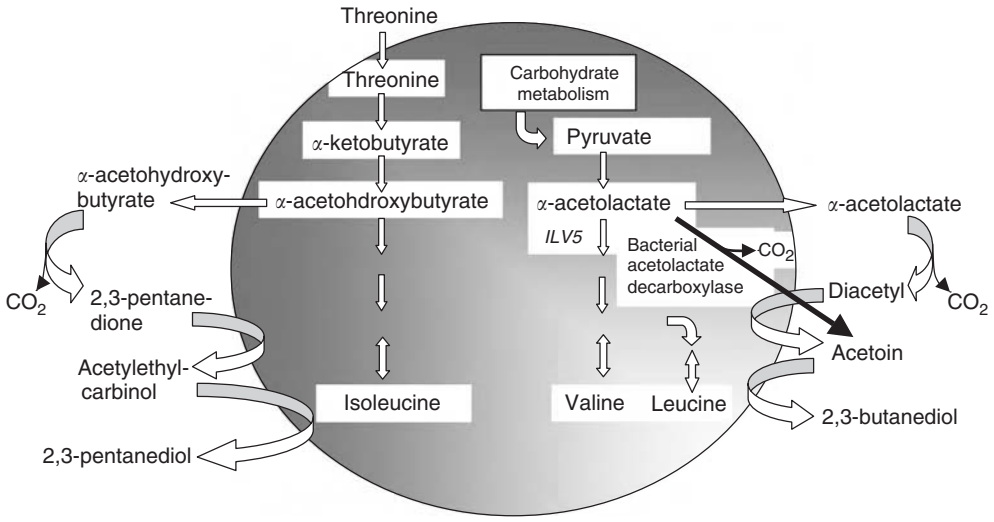

FIGURE 172.3 The synthesis and reduction of vicinal diketones in *S. cerevisiae*.

low in free amino acid content. These worts can give rise to a high diacetyl peak at the end of the fermentation.

There are several strategies which can be chosen to reduce the vicinal diketones amount during fermentation:

1. Since the temperature has a positive effect on the reduction efficiency of the α-acetohydroxy acids, a warm rest period at the end of the main fermentation and a warm maturation are applied in many breweries. In this case, temperature should be well controlled to avoid yeast autolysis.
2. Since the rapid removal of vicinal diketones requires yeast cells in an active metabolic condition, the addition of 5–10% Krausen (containing active, growing yeast) is a procedure that gives enhanced transformation of vicinal diketones (54). This procedure can lead to overproduction of hydrogen sulphide, depending upon the proportions of threonine and methionine carried forward from primary fermentation.
3. Heating up the green beer to a high temperature (90°C) and holding it there for a short period (ca. 7–10 min) to decarboxylate all excreted α-acetohydroxy acids. To avoid cell autolysis, yeast cells are removed by centrifugation prior to heating up. The vicinal diketones can be further reduced by immobilized yeast cells in a few hours (typically at 4°C) (see further).
4. Adding the enzyme α-acetolactate decarboxylase (121,122). This enzyme decarboxylates α-acetolactate directly into acetoin (see Figure 172.3). It is not present in *S. cerevisiae*, but has been isolated from various bacteria such as *Enterobacter aerogenes*, *Aerobacter aerogenes*, *Streptococcos lactis, Lactobacillus casei, Acetobacter aceti* and *Acetobacter pasteurianus*. It has been shown that the addition of α-acetolactate decarboxylase from *Lactobacillus casei* can reduce the maturation time to 22 h (121,123). An example of a commercial product is Maturex L from Novo Nordisk (Denmark) (124). Maturex L is a purified α-acetolactate decarboxylase produced by a genetically modified strain of *Bacillus subtilis*, which has received the gene from *Bacillus brevis*. The recommended dosage is 1–2 kg per 1000 hl wort, to be added to the cold wort at the beginning of fermentation.
5. Using genetic modified yeast strains:
   a. Introducing the bacterial α-acetolactate decarboxylase gene into yeast chromosomes (125–132). Transformants possessed a very high α-acetolactate decarboxylase activity, which reduced the diacetyl concentration considerably during beer fermentations.
   b. Modifying the biosynthetic flux through the ILV pathway. Spontaneous mutants resistant to the herbicide sulfometuron methyl have been selected. These strains showed a partial inactivation of the α-acetolactate synthase activity and some mutants produced 50% less diacetyl compared to the parental strain (133).
   c. Increasing the flux of α-acetolactate acid isomeroreductace activity encoded by the *ILV5* gene (134). Since α-acetolactate acid isomeroreductace activity is responsible for the rate-limiting step, increasing its activity reduces the overflow of α-acetolactate. A multicopy transformant resulted in a 70% decreased production of vicinal diketones (135), whereas an integrative transformant gave a 50% reduction (136). A tandem integration of multiple *ILV5* copies resulted also in elevated transciption in a polyploidy industrial yeast strain (137).

V. SECONDARY FERMENTATION

During the secondary fermentation or maturation of beer several objectives should be realized:

- sedimentation of yeast cells,
- improvement of the colloidal stability by sedimentation of the tannin-protein complexes,
- beer saturation with carbon dioxide,
- removal of unwanted aroma compounds,
- excretion of flavor-active compounds from yeast to give body and depth to the beer,
- fermentation of the remaining extract,
- improvement of the foam stability of the beer,
- adjustment of the beer color (if necessary) by adding coloring substances (*e.g.,* caramel),
- adjustment of the bitterness of beer (if necessary) by adding hop products.

In the presence of yeast, the principal changes that occur are the elimination of undesirable flavor compounds – like vicinal diketones, hydrogen sulphide and acetaldehyde – and the excretion of compounds enhancing the flavor fullness (body) of beer.

A. Vicinal Diketones

In traditional fermentation lagering processes, the elimination of vicinal diketones required several weeks and determined the length of the maturation process. Nowadays, the maturation phase is much shorter since strategies are used to accelerate the vicinal diketones removal (see above). Diacetyl is used as a marker molecule. The objective during lagering is to reduce the diacetyl concentration below its taste threshold (< 0.10 mg/ml).

B. Hydrogen Sulphide

Hydrogen sulphide plays an important role during maturation. Hydrogen sulphide, which is not incorporated into

S-containing amino acids is excreted by the yeast cell during the growth phase (see Figure 172.4). The excreted amount depends on the used yeast strain, the sulphate content of the wort and the growth conditions (139). At the end of the primary fermentation and during the maturation, the excess H_2S is re-utilized by the yeast. A warm conditioning period at 10–12°C may be used to remove excessive levels of H_2S.

Brewing yeasts produce H_2S when they are deficient in the vitamin pantothenate (140). This vitamin is a precursor of coenzyme A, which is required for metabolism of sulphate into methionine. Panthothenate deficiency may therefore result in an imbalance in sulphur-amino acid biosynthesis, leading to excess sulphate uptake and excretion of H_2S (141).

Sulphite is a versatile food additive used to preserve a large range of beverages and foodstuffs. In beer, sulphite has a dual purpose, acting both as an anti-oxidant and an agent for masking of certain off-flavors. Some of the flavor stabilizing properties of sulphite are suggested to be due to complex formation of bisulphate with varying carbonyl compounds, of which some would give rise to off-flavors in bottled beer (142). Especially, the unwanted carbonyl *trans*-2-nonenal has received particular attention since it is responsible for the "cardboard" flavor of some types of stale beer. It has been suggested that it would be better to use a yeast strain with reduced sulphite excretion during fermentation and to add sulphite at the point of bottling to ensure a good flavor stability (143). Therefore, a brewer's yeast disabled in the production of sulphite has been constructed by inactivating both copies of the two alleles of the *MET14* gene (which encodes for adenylylsulphate kinase). Fermentation experiments showed that there was no qualitative difference between yeast-derived and artificially added sulphite, with respect to *trans*-2-nonenal content and flavor stability of the final beer.

The elimination of the gene encoding sulphite reductase (*MET10*) in brewing strains of *Saccharomyces* results in increased accumulation of SO_2 in beer (144). The inactivation of *MET2* resulted into elevated sulphite concentrations

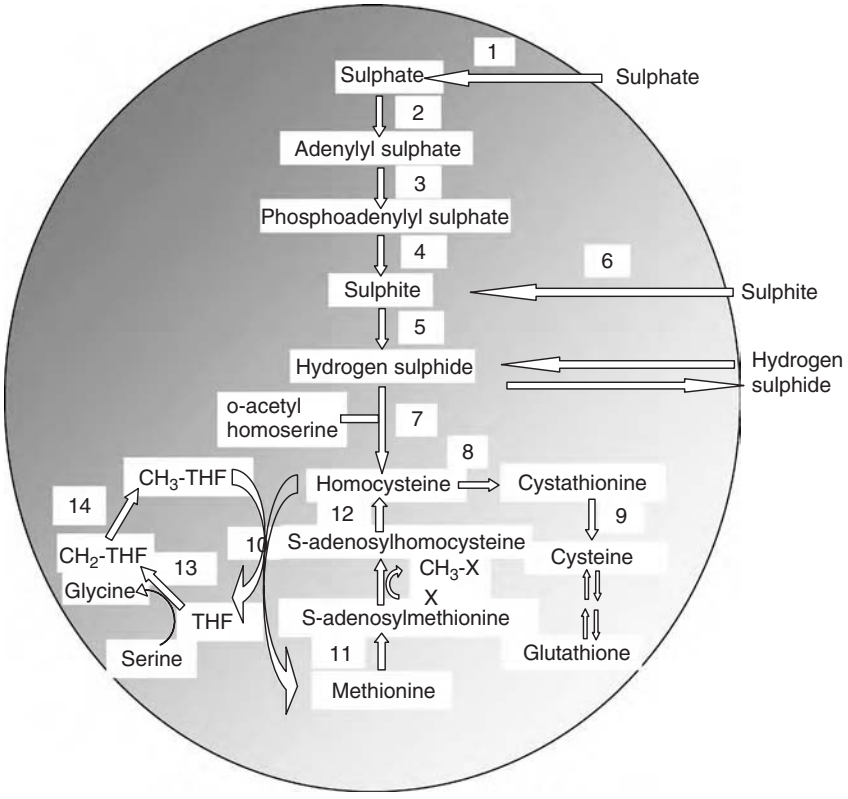

FIGURE 172.4 The re-methylation, transulfuration, and sulfur assimilation pathways. Genes and enzymes catalyzing individual reactions are: 1. sulphate permease; 2. ATP sulphurylase; 3. *MET14*: adenylylsulfate kinase (EC 2.7.1.25); 5. *MET10*: sulfite reductase (EC 1.8.1.2); 6. sulphite permease; 7. *MET17*: *O*-acetylhomoserine (thiol)-lyase (EC 2.5.1.49); 8. *CYS4*: cystathionine β-synthase (CBS; EC 4.2.1.22); 9. *CYS3*: cystathionine γ-lyase (EC 4.4.1.1); 10. *MET6*: methionine synthase (EC 2.1.1.14); 11. *SAM1* and *SAM2*: *S*-adenosylmethionine synthetase (EC 2.5.1.6); 12. *SAH1*: *S*-adenosylhomocysteine hydrolase (EC 3.3.1.1); 13. *SHM1* and *SHM2*: serine hydroxymethyltransferase (SHMT; EC 2.1.2.1); 14. *MET12* and *MET13*: methylenetetrahydrofolate reductase (MTHFR; EC 1.5.1.20). "X" represents any methyl group acceptor; THF, tetrahydrofolate; CH_2-THF, 5,10-methylenetetrahydrofolate; CH_3-THF, 5-methyltetrahydrofolate (partly adapted from (136)).

in beer (145). Beers produced with increased levels of sulphite showed an improved flavor stability.

The production of H_2S could be reduced by the expression of cystathione synthase genes from *S. cerevisiae* in a brewing yeast strain (146).

C. Acetaldehyde

Aldehydes – in particular acetaldehyde (green apple-like flavor) – have an impact on the flavor of green beer. Acetaldehyde synthesis is linked to yeast growth. Its concentration is maximal at the end of the growth phase, and is reduced at the end of the primary fermentation and during maturation by the yeast cells. As with diacetyl, levels may be enhanced if yeast metabolism is stimulated during transfer, especially by oxygen ingress. Removal also requires the presence of enough active yeast. Fermentations with early flocculating yeast cells can result in too high acetaldehyde concentrations at the end.

D. Development of Flavor Fullness

During maturation, the residual yeast will excrete compounds (i.e., amino acids, phosphates, peptides, nucleic acids, …) into the beer. The amount and "quality" of these excreted materials depend on the yeast concentration, yeast strain, its metabolic state and the temperature (54). Rapid excretion of material is best achieved at a temperature of 5–7°C during 10 days (147).

When the conditioning period is too long or when the temperature is too high, yeast cell autolysis will occur. Some enzymes are liberated (*e.g.* α-glucosidase) which will produce glucose from traces of residual maltose (54). At the bottom of a fermentation tank, the amount of α-amino-nitrogen can rise to 40–10000 mg/l, which account for an increase of 30 mg/l for the total beer volume. The increase in amino acid concentration in the beer has a positive effect on the flavor fullness of the beer. Undesirable medium chain fatty acids can also be produced in significant amounts if the maturation temperature is too high (148). Measurement of these compounds indicates the level of autolysis and permits the determination of the most appropriate conditioning period and temperature.

VI. BEER FERMENTATION USING IMMOBILIZED CELL TECHNOLOGY

The advantages of continuous fermentation – such as greater efficiency in utilization of carbohydrates and better use of equipment – led also to the development of continuous beer fermentation processes. Since the beginning of the 20th century, many different systems using suspended yeast cells have been developed. The excitement for continuous beer fermentation led – especially during the 1950s and 1960s – to the development of various interesting systems. These systems can be classified as: (i) stirred *versus* unstirred tank reactors, (ii) single-vessel systems *versus* a number of vessels connected in series, (iii) vessels which allow yeast to overflow freely with the beer ("open system") *versus* vessels which have abnormally high yeast concentrations ("closed" or "semi-closed system") (5,149–151). However, these continuous beer fermentation processes were not commercially successful due to many practical problems, such as the increased danger of contamination (not only during fermentation but also during storage of wort in supplementary holdings tanks which are required since the upstream and downstream brewing processes are usually not continuous), changes in beer flavor (152) and a poor understanding of the beer fermentation kinetics under continuous conditions. One of the well known exceptions is the successful implementation of a continuous beer production process in New Zealand by Morton Coutts (Dominion Breweries) which is still in use today (5,150).

In the 1970s, there was a revival in developing continuous beer fermentation systems due to the progress in research on immobilization bioprocesses using living cells. Immobilization gives fermentation processes with high cell densities, resulting in a drastic increase in fermentation productivities compared to the traditional time-consuming batch fermentation processes.

The last 30 years, immobilized cell technology has been extensively examined and some designs have reached already commercial exploitation. Immobilized cell systems are heterogeneous systems in which considerable mass transfer limitations can occur, resulting in a changed cell yeast metabolism. Therefore, successful exploitation of ICT needs a thorough understanding of mass transfer and intrinsic yeast kinetic behavior of these systems.

A. Carrier Materials

Various cell immobilization carrier materials have been tested and used for beer production/bioflavoring. Selection criteria are summarized in Table 172.5. Depending on the particular application, reactor type and operational conditions, some selection criteria will be more appropriate. Examples of selected carrier materials for particular applications are tabulated in Table 172.6.

B. Applications of Immobilized Cell Technology (ICT) in the Brewing Industry

1. Flavor Maturation of Green Beer

The objective of flavor maturation is the removal of diacetyl and 2,3-pentanedione, and their precursors α-acetolactate and α-acetohydroxybutyrate, which are produced during the main fermentation (see above). The conversion of α-acetohydroxy acids to the vicinal diketones is the rate-limiting step. This reaction step can be

TABLE 172.5
Selection Criteria for Yeast Cell Immobilization Carrier Materials (153)

High cell mass loading capacity
Easy access to nutrient media
Simple and gentle immobilization procedure
Immobilization compounds approved for food applications
High surface area-to-volume ratio
Optimum mass transfer distance from flowing media to center of support
Mechanical stability (compression, abrasion)
Chemical stability
Highly flexible: rapid start-up after shut-down
Sterilizable and reusable
Suitable for conventional reactor systems
Low shear experienced by cells
Easy separation of cells and carrier from media
Readily up-scalable
Economically feasible (low capital and operating costs)
Desired flavor profile and consistent product
Complete attenuation
Controlled oxygenation
Control of contamination
Controlled yeast growth
Wide choice of yeast

TABLE 172.6
Some Selected Applications of Cell Immobilization Systems Used for Beer Production

Carrier Material	Reactor Type	Reference
Flavor maturation		
Calcium alginate beads	Fixed bed	(154)
DEAE-cellulose	Fixed bed	(155)
Polyvinyl alcohol beads	Fixed bed	(156)
Porous glass beads	Fixed bed	(129,157)
Alcohol-free beer		
DEAE-cellulose beads	Fixed bed	(158,159)
Porous glass beads	Fixed bed	(160)
Silicon carbide rods	Monolith reactor	(161)
Acidified wort		
DEAE-cellulose beads	Fixed bed	(162)
Main fermentation		
Calcium alginate beads	Gas lift	(163)
Calcium pectate beads	Gas lift	(164)
κ-Carrageenan beads	Gas lift	(165)
Ceramic beads	Fixed bed	(166)
Gluten pellets	Fixed bed	(167)
Polyvinyl alcohol beads	Gas lift	(156)
Porous glass beads	Fixed bed	(168)
Porous chitosan beads	Fluidized bed	(169,170)
Silicon carbide rods	Monolith reactor	(171)
Spent grains	Gas lift	(172)
Wood chips	Fixed bed	(173,174)

accelerated by heating the beer – after yeast removal – to 80–90°C during a couple of minutes. The resulting vicinal diketones are subsequently reduced by immobilized cells into their less-flavor-active compounds.

The traditional maturation process is characterized by a near-zero temperature, low pH and low yeast concentration, resulting in a very long maturation period of 3 to 4 weeks. Using immobilized cell technology this long period can be reduced to 2 hours. An ICT maturation process using a packed-bed bioreactor with DEAE-cellulose beads has been successfully integrated in Synebrychoff Brewery (Finland) for the treatment of 1 million hl per year (175). Alfa Laval and Schott Engineering developed a maturation system based on porous glass beads (176). This system has been implemented in several breweries in Finland (179), Belgium and Germany. The German company Brau & Brunnen has also shown an interest in the Alfa Laval maturation technology. In 1996, a 30000 hl/year pilot scale system was purchased and installed in their plant (178). The Alfa Laval maturation system has been implemented in a medium-sized German brewery (Schäff/Treuchtlingen) (179). De obtained beers yielded overall good analytical and sensorial results.

2. Production of Alcohol-Free or Low-Alcohol Beer

The classical technology to produce alcohol-free or low-alcohol beer is based on the suppression of alcohol formation by arrested batch fermentation (180). However, these beers are characterized by an undesirable wort aroma since the wort aldehydes have only been reduced to a limited degree (158,181,182). The reduction of these wort aldehydes can be quickly achieved by a short contact time with the immobilized yeast cells at a low temperature without undesirable cell growth and ethanol production. A disadvantage of this short contact process is the production of only a small amount of desirable esters.

Controlled ethanol production for low-alcohol and alcohol-free beers have been successfully achieved by partial fermentation using DEAE-cellulose as carrier material which was packed in a column reactor (158,183). This technology has been successfully implemented by Bavaria Brewery (The Netherlands) to produce malt beer on an industrial scale (150000 hl/year) (162). Several other companies – i.e., Faxe (Denmark), Ottakringer (Austria) and a Spanish brewery – have also implemented this technology (178). In Brewery Beck (Germany), a fluidized-bed pilot scale reactor (8 hl/day) filled with porous glass beads was used for the continuous production of non-alcohol beer (157,160,184). Yeast cells immobilized in silicon carbide rods and arranged in a multichannel loop reactor (Meura, Belgium), have been used to produce alcohol-free beer at pilot scale by Grolsch Brewery (The Netherlands) and Guinness Brewery (Ireland) (185).

Nuclear mutants of *S. cerevisiae* which are defective in the synthesis of tricarboxylic acid cycle enzymes – i.e. fumarase (186) or 2-oxoglutarate dehydrogenase (187) have been immobilized in calcium pectate gel beads and used in a continuous process for the production of non-alcoholic beer (188). These strains produced minimal amounts of ethanol and they were also able to produce much lactic acid (up to 0.64 g/dm^3).

3. Production of Acidified Wort Using Immobilized Lactic Acid Bacteria

The objective of this technology is the acidification of the wort according to the "Reinheidsgebot," before the start of the boiling process in the brewhouse. An increased productivity of acidified wort has been obtained using immobilized *Lactobacillus amylovorus* on DEAE-cellulose beads (162,189). The pH of wort was reduced below a value of 4.0 after contact times of 7 to 12 min using a packed-bed reactor in downflow mode. The produced acidified wort was stored in a holding tank and used during wort production to adjust the pH.

4. Continuous Main Fermentation

The Japanese brewery Kirin developed a multistage continuous fermentation process (166,190,191). The first stage is a stirred tank reactor for yeast growth, followed by packed-bed fermenters, and the final step is a packed-bed maturation column. The first stage ensures adequate yeast cell growth with the desirable free amino nitrogen consumption. Ca-alginate was initially selected as carrier material to immobilize the yeast cells. These alginate beads were later replaced by ceramic beads ("Bioceramic®"). This system allowed beer to be produced within three to five days.

The engineering company Meura (Belgium) developed a reactor configuration with a first stage with immobilized yeast cells where partially attenuation and yeast growth occurs, followed by a stirred tank reactor (with free yeast cells) for complete attenuation, ester formation and flavor maturation (171,192). Silicon carbide rods are used in the first reactor as immobilization carrier material. The stirred tank (second reactor) is continuously inoculated by free cells which escape from the first immobilized yeast cell reactor.

Labatt Breweries (Interbrew, Canada) in collaboration with the Department of Chemical and Biochemical Engineering at the University of Western Ontario (Canada) developed a continuous system using κ-carrageenan immobilized yeast cells in an airlift reactor (165,178,193). Pilot scale research showed that full attenuation was reached in 20–24 hours with this system compared to 5–7 days for the traditional batch fermentation. The flavor profile of the beer produced using ICT was similar to the batch fermented beer.

Hartwell Lahti and VTT Research Institute (Finland) developed a primary fermentation system using ICT on a pilot scale of 600 l/day (174). Woodchips were used as the carrier material that reduced the total investment cost by one third compared to more expensive carriers. The results showed that fermentation and flavor formation were very similar compared to a traditional batch process, although the process time was reduced to 40 hours.

Andersen and co-workers (194) developed a new ICT process in which the concentration of carbon dioxide is controlled in a fixed-bed reactor in such a way that the CO_2 formed is kept dissolved, and is removed from the beer without foaming problems. DEAE-cellulose was used as carrier material. High gravity beer of acceptable quality has been fermented in 20 hours at a capacity of 50 l/h.

I. INTRODUCTION

The technology of fermentation is a valuable asset of the Chinese culture. This chapter introduces the fermentation technology of Chinese wine or "jiu" (alcoholic beverages) in order to promote the Chinese wine culture, strengthen the cultural exchange by joining together the ancient tradition and modern cultures on alcoholic beverages, and enhance the development of fermentation industry. Readers should note that the term "jiu" used in this chapter refers to Chinese alcoholic beverages (a very broad term including those made from fruits, cereals, animal milks, distilled spirits, and various specialty alcoholic beverages and liqueurs). The term Chinese wine in this chapter will not comply with U.S. regulations that will be mentioned where applicable to provide readers a frame of reference.

History of Chinese alcoholic beverages. Alcoholic fermentation has a long history in China. The most primitive Chinese "jiu" was made from the piling of wild fruits and natural fermentation; it was called "hou jiu," which mean "ape/monkey wine," as the fruits most likely were collected by the apes or monkeys. Historic records on "jiu" fermentation showed that humans developed this technology at least 4000 to 5000 years ago. There were lots of artifacts related to "jiu" fermentation unearthed from the Dawenkou Cultural Relics in Shandong Province in China. These discoveries showed that man already knew how to make "jiu" at that time. This period was about 2300 BC, and approximately coincided with the Chinese legend that the daughter of Emperor "Shun" commanded the capture of yellowed-haired monkey to make "jiu." There was the "jiu" meaning "wine/alcoholic beverage" on the carvings on bones from the "Shang" Dynasty, indicating that the alcoholic fermentation industry was already well developed at that time. In the "Yueling" or "Orders of Months" chapter in the "Lizi" or "the Book of Manners," there was already descriptions on the processes of making "jiu" in Ancient China. Later, there was also "The Six Must-Have Method:"

- must have all the cereals;
- must have the proper starter(s) and its/their carrier(s);
- the soaking must be sanitary;
- the underground water must have pleasant flavor;
- the ceramic vessels must be of good quality; and
- the heating must be proper.

In the ancient times, in order to obtain the flavor-specific "jiu," it was common to utilize the fragrances from flowers, either alone or in combination in the fermentation. However, the above descriptions on "jiu" was limited to regularly fermented "jiu;" there is no accurate record on when distilled alcoholic beverages (spirits) started to appear. In the Ming Dynasty, the famous herbist, Lee Shizhen, pointed out in his "Ben Cao Gang Mou" or "Outline of Herbs" that distilling "jiu" was not an ancient methodology; it was invented in the Yuan Dynasty. The strong "jiu" and fermented mash were heated in containers, forcing the alcohol to evaporate, and the condensed droplets (of alcohol) were collected. Whether distilled spirit was really "invented" in the Yuan Dynasty, there is no conclusion. However, distilling the strong "jiu" and fermented mash is a fermentation technology unique in the whole world, and it is an invention of ancient Chinese.

Utilizing starch as the raw material in "jiu" making requires two important biochemical steps: saccharization and fermentation. These two steps are accomplished by using the "jiu qu" or "starter." "Jiu qu" is an important invention in the Chinese fermentation technology; it is the world's earliest "compound fermentation reagent" containing multi-microorganisms. In the "Shuo Ming" or "Description of Life" chapter of the "Shang Shu" or "the Book of Highest Honor," it was recorded that the "qu" and "nie" (sprouted cereals) were required to make "jiu" and "li" (sweet wine), respectively. The "qu" contains many beneficial microorganisms providing the necessary starch hydrolyzing enzymes and the enzymes required for converting the sugars into alcohol in the fermentation of "jiu."

The ancient technology of making "qu" is being improved gradually. It started out from the individual "qu" to "shenyi" or "overcoat," and then finally to the current "qu" ball or cake. The quality of "qu" also is improved gradually. In order to inhibit the undesirable or harmful microorganisms and develop the beneficial microorganisms, the ancient Chinese even added various herbs or juices from selected plants in the production of "da (large) qu" and "sui (small) qu." These techniques are still preserved today. For example, the addition of laliaocao

(Polygonanum hydropiper L.) in the making of "xiao qu" with even more than 90 various herbs in the "xiao qu" for "Dong jiu," and more than 40 herbs in the "da qu." "Hong qu" ("red qu") is a big branch of technology in making "qu." "Outline of Herbs," and "Tian Gong Kai Wu" or "Development of New Products," recorded the production of "hong (red) qu." At the present time, the main "qu" series in China are the "da qu," "xiao qu" and "hong qu." There are both saccharifying agents and fermenting agents. This way of making "qu" not only is suitable in the cultivation and selection of beneficial microorganisms, but also effective methodology in preserving the stocks of microorganisms, and their enzymatic activities. This invention is unique to the Chinese in the technology of making "qu" and "jiu" fermentation. In other countries of the world, saccharification by malt followed by the addition of yeast are still being used in the production of alcoholic beverages from cereals such as beer and whiskey. However, in China, the production of "jiu" using "qu" reflects a parallel action of saccharification and alcoholic fermentation. It was not until the 19th centuries that Europeans understood the action of Chinese "qu," and called it "starch fermentation."

In the ancient times, the Chinese also has stringent requirements on the water used and fermentation season. In the "Qi Ming Yao Shu" or "Important Technologies in Governing the Qi People," it was indicated that river water was best. If the location for making "jiu" is far from the river, use water from wells with sweet taste; water with slightly salty taste is not good or suitable. The season for making "jiu" is when the new crop is ripe, i.e., in the Fall after harvest. The "jiu" with origins from the ancient past that are still being made are "da qu bai jiu" or white "jiu" made with "da qu," "xiao qu huang jiu" or yellow "jiu" made with "xiao chu," "tian jiu niang" or sweet fermented "jiu," and others. Their fermentation methods are Chinese unique technologies, and they are also the pride of the Chinese race. The "bai jiu" and "huang jiu" are the most famous traditional "jiu," and they can be called the Chinese national "jiu."

II. FERMENTATION OF "BAI (WHITE) JIU"

A. Characteristics and Classification of Chinese "Bai Jiu"

"Bai jiu" are distilled spirits made from raw materials with starch and fermentable sugars after fermentation and distillation. The alcohol content is high, and therefore is called "lei xing jiu" or "shao jiu" (potent "jiu" or "burning "jiu"). A poem from the Tang Dynasty has the verses as follows: "fresh litchi is red as the cock's comb; the first odor of "shao jiu" is like the fragrance of amber." This showed that "shao jiu" originated before the Tang Dynasty. According to old Chinese literature and subsequent speculations, the distilled "bai jiu" may originate from the modification of "huang jiu." The production characteristics of Chinese "bai jiu" are the wide variation of raw materials, unique technology, numerous products and wide variations in flavor.

Chinese "bai jiu" usually are classified by two methods. The first method is based on the "qu" used. They can be classified into four (4) types — "Da qu jiu," "Xiao qu jiu," "mixed Da-xiao method qu bai jiu" and "gluten qu bai jiu."

The second method is based on the aroma: they can be classified into five (5) types.

- The first kind has paste-like aroma, e.g., "Maotai jiu." Its flavor characteristics are exceptional paste aroma, fragrant, rich body, and long-lasting — the flavor can last overnight, and the flavor stays in the glass after it is emptied.
- The second kind is rich odor type "jiu," e.g., "Luzhou da qu jiu," "Wulangyi" or "Five grain liquid." Their main characteristics are their rich flavor from the fermentation tank, sweet taste, balanced flavor, and long-lasting. The rich odor of this "jiu" is due to mainly capronyl ethyl ester.
- The third kind is light-odor "jiu," e.g., "Shanxi Fen jiu." Its characteristics are light, pure aroma, with balanced taste, sweet and soft, and its residual taste is clean and pure. The aroma comes from the combination of acetyl ethyl ester and lactyl ethyl ester.
- The fourth kind is rice-aroma type such as "Quilin Sanhua (three flowers) Jiu," and "Guangtong mi (rice) jiu" with clear, sweet, clean and pure flavor. Their characteristics are honey-type odor, clear, soft, clean, with pleasing aftertaste. The odor is like honey-type with the combination of fermented "Huang jiu" and lactyl ethyl ester. The main flavoring compounds are β-benzyl ethyl ester, and capronyl ethyl ester.
- The fifth kind is a combination of two or more of the above-mentioned types, such as "Meijiang jiu" (with a combination of "Luzhou dai qu jiu" and fruity flavors), and the "Bai Sha Yi Jiu" from Shanxa, Wunan Province (a mixture of "Luzhou Da Qu Jiu" and "Maotai Jiu" with its typical flavor).

In the northern provinces, there are some "jiu" with bland flavor. They are produced by new technology utilizing artificially-constructed old-fermentation tanks. They carry a light "Lozhou Da Qu Jiu" flavor. With improved quality, they may be considered as similar to "Fen Jiu" and "Lozhou Dai Qu Jiu." Besides the above-mentioned, the "Chen Liang Jiu (Prolonged, Fermented Jiu)" from the

Laolong Winery in Xanyang Province carries a woody odor that is unusual. In general, except for the "Fen Jiu" which carries a clean light odor, most "bai jiu" carry to some extent the flavor of "Luzhou Da Qu Jiu."

B. "Da Qu Jiu"

"Bai Jiu" made with "Da Qu" as the saccharifying and alcoholic fermentating agents are called "Da Qu Jiu." Most of the famous Chinese "Bai Jiu" and the local quality "Jiu" are produced using the "Da Qu" method. The technology is described as follows:

1. Preparation of the "Da Qu"

a. Raw materials and proportions

Raw materials. Raw materials for "Da Qu" usually include wheat, barley, peas, and other beans/peas and other cereals.

Proportions. Proportions of raw materials vary among factories. In general, a ratio of 120–130 kg barley to 38 kg wheat is used for "Da Qu" type "Jiu." For the lighter "Fen Jiu" and "Xi Feng Jiu," the "Da Qu" is prepared with 60% barley and 40% green peas on a weight basis. For the stronger type such as the "Luzhou Da Qu" and the paste-aroma type "Maotai Da Qu," the "Da Qu" is prepared using only wheat.

b. Time to prepare the "qu"

In general, "qu" is prepared in late Spring to before mid-Autumn. For example, the "Fen Jiu Qu" is prepared in Qing Ming (April) to the 10th month in the Chinese lunar calendar (about November), and it is called "Tao Fa (peach flower) Qu." The "Luzhou Qu" is prepared in the Summer, and is called "Fu (hot summer) Qu." The "Maotai Jiu Qu" is prepared starting from the 5th month (about June) in the lunar calendar. However, most of the "qu" is now prepared all year round. With proper control of the preparation requirements, "qu" can be prepared all year round without difficulty.

c. Technology of "qu" preparation

Based on the incubation temperature, the technology can be divided into the "high temperature qu" and "intermediate temperature qu."

i. High temperature "qu" technology (40–45 days)

Figure 173.1 is a schematic flow chart of preparing "high temperature qu."

Grinding of the wheat. "High temperature qu" is prepared with wheat only. The husk should be removed before the grinding process. The wheat kernels are soaked (wetted) in 5–10% water for 3–4 hours before grinding with a steel grinder, with the bran flattened and the endosperm disintegrated into coarse wheat flour.

Mixing of the "qu" ingredients. The ingredients such as the wheat bran and flour, water and inoculum are added continuously in appropriate ratios into the mixer. After thorough mixing, the mixture is conveyed into the presser for the "pressing" process. The water added depends on the moisture content of the wheat component, and weather during the preparation period (temperature and relative humidity). In general, the water added for barley and green pea "qu" is controlled within the range of 45–56%, pure wheat "qu" at 37–40%; and barley, wheat and pea "qu" about 40% of the weight of the raw materials. Temperature of added water is controlled at 30–35°C in the winter, and 14–16°C in the summer. The traditional procedure of preparing "high temperature qu" is to add a fixed amount of inoculum during the mixing process. This procedure is still being used today. The amount of inoculum is 4–5% of the wheat flour in the summer, and 5–8% in the winter. In general, it is believed that the residual "qu" from the previous year containing abundant microorganisms with white "qu" is a better choice.

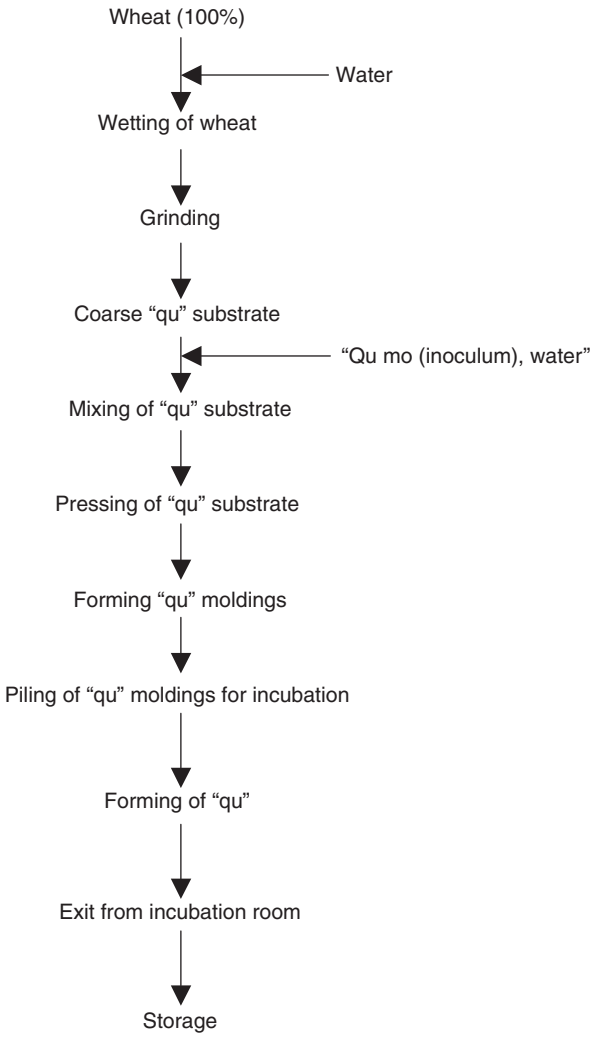

FIGURE 173.1 Generalized schematic flowchart for manufacturing of high-temperature "qu."

Pressing of the "qu" bricks. The purpose of pressing is to press the "qu" mixture into brick form. In the past, it was done manually. The requirements for pressing "qu" are as follows: the angles must be proper, same thickness, smooth and uniform surface, uniform moisture inside and out, and on the hard side so that they will not shatter during transportation. For a good brick of "qu," the sides must be tightly packed with a looser interior so that the microorganisms can penetrate and reproduced. This manual pressing process is mostly replaced by mechanical means today.

Piling and inocubation of the "qu" bricks. This process includes four (4) steps: piling, covering with hay and water sprinkling, turnover, and breaking. After the "qu" bricks are made, they are left in the open air for 2–3 hours to smoothen and dry out the surface. The bricks are then firmer and are ready for transfer to the incubation room. The floor areas around the walls should be covered with hay, about 15 cm thick in order to maintain the temperature. The bricks are then laid with three bricks in one direction and another three bricks in the opposite direction in one row. These bricks are separated 2 cm apart with hay to facilitate mold development. When one layer is completed, hay is laid on top of these bricks, about 7 cm thick. Another layer of bricks is put on top, with bricks laid in a position opposite to the lower layer so that there is good air circulation. These bricks are piled to 4–5 layers high. Other rows are then piled up until enough space is left for turnover later.

Covering with hay and sprinkling with water. The top layer of "qu" bricks is covered with hay to maintain the temperature and relative humidity. The relative humidity is maintained by sprinkling water on the hay. Amount of sprinkling water usually is more in the summer than in the winter, and the amount is limited to not letting the water get into the bricks.

Turnover. When the piles of "qu" bricks are covered with hay and water sprinkled on to it, the windows and doors in the incubation room are closed. The microorganisms then start to grow on the surface of the "qu" bricks, and the temperature of the bricks starts to increase. The brick temperature will reach to about 63°C in 5–6 days in the summer, and 79 days in the winter. Relative humidity is almost saturated in the room. At this point, the "qu" bricks are covered with a coat of microorganisms. After that, the bricks are turned over the first time. After another week, the bricks are turned over the second time to dry up the bricks faster. The purpose of turning the bricks is to adjust the temperature and relative humidity to allow even maturation for each brick. When the bricks are turned over, the wet hay between bricks and on the floor should be replaced with dry hay to facilitate air circulation. In order to facilitate the maturation and drying, the distance between bricks can be increased, and the bricks can be stood on their ends. Most of the mycelia penetrate inward after the bricks are turned over; the drying process is then the process for the mold to penetrate inside the brick. During this period, if the moisture level in the bricks is too high, this will delay the rate of mold development. The timing for turnover should be carefully controlled. Too early turnover decreases the highest achievable temperature in the "qu" brick. The "Da qu" produced then has too much white mold; too late turnover causes the development of black mold. For proper production, the requirement is to have lots of yellow mold. At the present time, the time to turn over the bricks is determined by the temperature and the taste of the "qu" bricks. That is, when the brick reaches a temperature of about 60°C and a sweet taste, it is time to turn the bricks.

Breaking the "qu" bricks. After the "qu" bricks are turned over, the temperature usually will decrease by 7–12 °C. After 67 days, the temperature will again reach to its peak, and then decreases gradually. The bricks start to dry up. About 15 days after turned over, the doors and windows can be opened slightly to exchange the air. After 40 days (50 days in winter), temperature of "qu" bricks drops down to about room temperature. The bricks are almost completely dry. They can then be broken up and transferred out from the incubation room. If wet and heavy bricks are noticed at the bottom of the piles (moisture content above 15%), these bricks must be placed in a ventilated area or hut to complete the drying process.

Storage of matured "qu." There are three colors for the high temperature "qu:" yellow, white and black. Traditionally, the golden yellow "qu" with chrysanthemum (yellow) center or red center have the "qu" paste odor and flavor. White "qu" has strong saccharifying activity, but not as good as the yellow "qu." After the "qu" bricks are broken, they should be stored for three months; these are called aged "qu." The enzymatic activities of aged "qu" are lower than the newly-made "qu," but aged "qu" has better odor. Also, during fermentation, rate of temperature increase is slower, and less acid is produced in the final product.

ii. Technology of preparing intermediate temperature "qu" (20–30 days)

Figure 173.2 is a schematic flowchart in preparing the intermediate temperature "qu."

Grinding of raw materials. Mix 60% barley and 40% peas (weight basis), and grind them together. Powder going through a 20 mesh screen should be 20% in the winter, and 30% in the summer.

Pressing of "qu" bricks. The powered raw material is mixed with water and filled into the pressing machine to make "qu" bricks. The "qu" bricks contains 36–38% water, and weighs 3.2–3.5 kg each. The formed bricks should have smooth surface, proper angles, and uniform thickness.

Incubation of "qu." The procedure in preparing "Qing Cha Qu" is used as an example.

- Lining the room. The incubation room should be pre-adjusted to room temperature of 15–20°C, with temperature lower in the summer. The floor

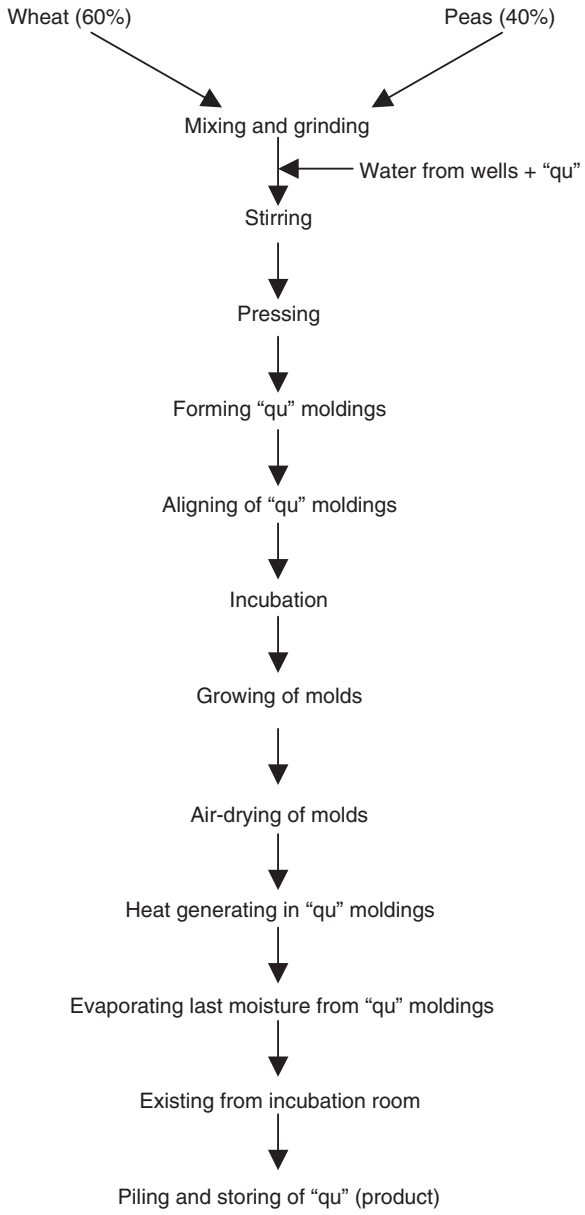

FIGURE 173.2 Generalized schematic flowchart for production of medium-temperature "qu."

of the incubation room is lined with hay. The "qu" bricks are laid on the side in rows with space of 2–3 cm apart, closer in the winter and farther apart in the summer. Each row is 34 cm apart. Above each layer is laid with reed and bamboo rods. There are three layers of "qu" bricks arranged in "empty squares and inverted cone" shapes.

- Growth of molds. The "qu" bricks are naturally dried briefly after the alignment. The bricks are then covered above and around with mats or hemp bags to maintain the temperature. Evaporation is rapid in the summer time; cool water can be sprinkled on top. Doors and windows are then closed. Temperature inside the room starts to increase. Generally after one day, molds start to grow on the surface of the bricks with appearance of white mold mycellium and spots. Temperature can rise to 38–39°C in about 36 hours in the summer, and about 72 hours in the winter. In practice, the temperature rise in "qu" bricks should be gradual to provide proper growth. At this time, rhizomoid type molds and sporadic molds with powdery spots start to appear; also there are pin-head sized creamy or yellowish yeast colonies. If the designed temperature is reached, but the molds on the surface do not developed properly, a remedy is to uncover part of the mats slowly to release the heat and extend the incubation time for a few hours to allow proper mold growth. However, it is important to maintain the relative humidity.
- Drying of the mold. When the "qu" bricks reach a temperature of 38–39°C, the window and doors in the incubation chamber should be opened to ventilate the moist air and lower the room temperature. At the same time, the mats should also be removed. Layers of "qu" bricks should be turned over (reversed) and the space between bricks should be increased to help reduce the moisture and temperature. This is to control the growth of microorganisms on the brick surface, and avoid too much mycelia. This process will fix the shape of the bricks, and is called the "drying of molds." The "drying of molds" should be done at the right time. If it is done too late, the mycelia will be too long, the brick surfaces will wrinkle and inhibit the evaporation of moisture from the interior of the bricks. If the drying is done too early, the amount of mycelia is not enough, and affects the proper growth of microorganisms inside the bricks as the bricks are not porous enough. The initial temperature for "drying of molds" is 28–32°C, allowing more extensive cross ventilation, and avoiding the dried up and cracking of the brick surface. The period of "drying of molds" is 2–3 days; stacking the brick layers once everyday; the first stacking increases the brick layers from 3 to 4, and the second stacking from 4 to 5.
- Rise in temperature. Two to three days after "drying of molds," the bricks are no longer sticky on the surface. The windows and doors are closed and temperature rise stage begins. After entering the incubation room for 5–6 days, the bricks start to increase in temperature. When the temperature reaches 36–38°C, turnover of

bricks starts. The reeds are removed, and the layers of bricks increases from 5 to 6, and the bricks are aligned in the "mirror image of λ" shape. The bricks are turned over twice each day. At this time, the bricks are further dried twice, with the windows and doors opened and closed twice in the daytime and at night. Temperature of "qu" bricks rises and drops twice, with temperature starting from 38°C increasing gradually to 45–46°C. This will take 4–5 days. After this period, it enters the high temperature stage, and the bricks are stacked to 7 layers.

- High temperature stage. At this stage, the growth of microorganisms is still vigorous. The mycelia penetrate from the outside inward, and the moisture and heat migrate from inside outward. The room temperature is maintained at 44–46°C for 7–8 days by opening and closing the windows and doors. The temperature cannot be higher than 48°C, or lower than 28–30°C. At this high temperature stage, the bricks are turned over once everyday. At the end of this high temperature stage, basically 50–70% of the bricks are mature (ready).
- Post-high temperature stage. At this stage, the bricks gradually dry up with brick temperature dropping gradually from 44–46°C to 32–33°C, until the brick surface no longer feels hot. Then the bricks enter the holding period. Three to five days after this post-high temperature period, moisture from the centers of bricks continues to evaporate and this helps dry the bricks further.
- Holding period. At the post-high temperature period, the brick centers still have 10–20% moisture, and require additional heating to evaporate; because at this stage the bricks themselves will not generate any more heat. Supplemental heating to maintain 32°C room temperature and 28–32°C will evaporate the residual moisture from the bricks completely.
- Exit from incubation room. The "qu" bricks, after exiting from the incubation room are piled up together, with 1 cm space in between.

Characteristics of three kinds of intermediate temperature "qu." In the "jiu" manufacturing process, three kinds of "qu" [Qingcha (clear, soft center), post high temperature and red center] are used in definite proportion. The procedures for producing the three kinds of "qu'' are the same, except that there are differences in controlling the brick temperature.

- "Qingcha qu." The highest temperature for the "qu" bricks is 44–46°C, and the cooling temperature is limited to 28–30°C. It requires mild heating and extensive cooling.
- "Post-high temperature qu." The highest temperature in the bricks from the "rise in temperature" stage to "high temperature" stage is 47–48°C. The bricks are held at the high temperature for 5–7 days. The cooling temperature is limited to 30–32°C. It requires extensive heating and moderate cooling.
- "Red center qu." In the "qu" preparation stage, the cooling and "rise in temperature" stages are not that clearly distinguishable. The rise in temperature to 38°C is rapid. The windows and doors are opened and closed twice during daytime and at night, causing the temperature to rise and drop twice. Temperatures of the bricks are controlled by adjusting window openings. Starting from the "rise in temperature" stage to the "high temperature stage," the highest temperature is 45–47°C, with the lowest cooling temperature limit at 34–38°C.

2. Fermentation with "Da Qu"

The world famous Chinese "jiu" ("Maotai jiu," "Fen jiu," and "Luzhou da qu jiu") are made using "da qu" as the saccharifying and fermenting agents. They differ not only from other "bai jiu," but also they differ among themselves in the fermentation processes. They are representative, and at the same time unique.

3. Fermentation of "Fen Jiu"

"Fen jiu" is produced in the Xinghua village, Fenyang County, Shanxi Province. It was claimed to have a history of about 1,500 years. This "jiu" has alcohol content of 65° Proof. It is bright, transparent, clear to mouthfeel, smooth, fragrant, and long lasting in the mouth after consumption. It is one of the world famous alcoholic beverages – it won the Gold Medal at the 1915 World Expo in Panama, and the title of "National Famous Jiu" four times in the National "Jiu" Evaluation Conference in the past 50 years.

The technology of "Fen jiu" production has "seven musts:"

- people must know the essence;
- cereal must be edible;
- water must be sweet;
- "qu" must be made at the right time;
- utensils must be clean;
- crocks must be moist;
- fire (heating) must be gradual.

Its characteristics are: "da qu" made from 60% barley and 40% peas, locally grown "Yibazhua variety" sorghum, and "double distillation of raw material methodology." It differs from the "continuous mash" methodology that continuously produces raw materials in the mash

from the previous distillation, and at the same time utilizes the effect of the bran. In the "double distillation methodology," bran is not used in the first fermentation, but after the first fermentation. Bran is added in large quantity, up to 25% or 50%, mixed well before the distillation. The raw material is used only twice. The main reason is that the "jiu" odor may be different from different batches.

"Fen jiu" is produced by "double fermentations." In the first fermentation, the completely steamed raw material and the "qu" are put in a small-mouthed big-belly ceramic croak and sealed. The croak is buried in the ground and fermented for 21 days. The mash is then distilled. "Qu" is added to the residual mash, fermented again for 21 days, and distilled. The distillates from the two distillations are used to formulate "fen jiu." Figure 173.3 is a general flowchart of the process.

Wetting of the raw material. Ground sorghum (500 kg) and 200–300 kg water (60–65% of the weight of raw material) are mixed and rested for 7–8 hours to allow the penetration of water into the raw sorghum. Temperature of water is 50–65°C in the winter and 28–32°C in the summer.

Steaming of raw materials. After wetting of the raw material, The sorghum used in "fen jiu" production is steamed separately in croaks. After steaming, water (100 kg, 30% of the raw material) is added immediately, and cooled. The steamed sorghum must be cooked thoroughly but not sticky, with the typical cooked sorghum odor without any foreign odor.

Addition of "qu." When the cooked sorghum is cooled down to 20–30°C, "qu" is added. The ratio is 250 kg sorghum to 30 kg "qu," and the ratio of the three kinds of "qu" is "Qingcha:" post-high temperature: red center, 30:30:40. 20–25°C is the preferred temperature for addition of "qu."

Loading to croak and fermentation. Ceramic croaks of 225 kg or 127 kg capacity are used. They are buried under the ground, with the croak mouth leveled with the ground. For 1,100 kg raw material, 8 croaks of 225 kg capacity or 16 croaks of 127 kg capacity are used. Distance between croaks is 10–24 cm. Croaks must be washed thoroughly and rinsed with huajao (Chinese pricky ash) water once before use. The loading temperature of mash is 10–16°C, with a lower temperature in the summer time. The moisture in the mash is controlled at 52–53%. The croaks are covered with a stone slab and sealed with the residual mash after distillation. The cover is then covered with rice husk to maintain temperature.

The whole fermentation process can be divided into three stages: initial, intermediate and final with control of intermediate temperature and gradual fermentation; temperature during fermentation being gradual increased in the initial stage, maintaining high temperature in the intermediate stage and gradual decline in the final stage. This is what is called "the gradual initial, steady intermediate, and gradual decline final rhythm." The traditional fermentation period

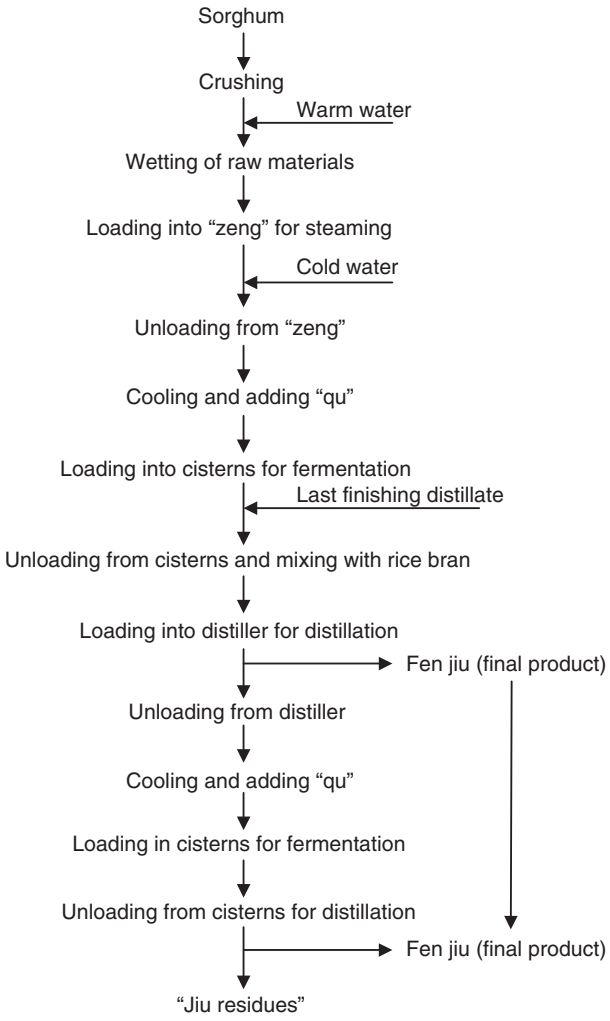

FIGURE 173.3 Generalized schematic flowchart of production of "fen jiu."

was 21 days, and is now extended to 28 days to increase the aroma. During the fermentation, control of temperature is very important. Because area in the fermentation room is much large than the size of the croak, effect of room temperature is more significant, especially in the summer. Traditionally, the temperature of the croak is cooled by surrounding the croaks in the ground with cool water; and in the winter, cover the croaks with barley stalks. During the 21 or 28 days of fermentation, the fermentation has to be checked every other day. Usually, this is conducted in 1–12 days. After this period, inspection is not necessary. If an apple aroma is noticeable in the fermentation room, it is indicative of normal fermentation. As the fermentation progresses, the solid residual matters will gradually sediment to the bottom of the croaks. The more residual matter sediment to the bottom, the more "jiu" will be produced. In normal situations, the residual sediment will sink to the bottom to about a quarter depth of the croak.

Unloading from croak and distillation. The sediment from the first fermentation is recovered and laid on the

cooling platform, followed by addition of cereal bran, about one quarter of the sediment. After mixing, the mixture is loaded to the special earthenware for distillation. The procedure is also specific for "Fen jiu" production. Water is first boiled from the bottom of the earthenware. The amount of water is added, and a fine-toothed comb is placed in the earthenware, followed by the residual sediment-bran (4 inches thick). Then the residual "jiu" from the last distillation is added. When steam/alcohol starts to appear from the mixture, more sediment-bran mixture is added. When the mixture starts to get hot by touch, another 4 inches of mixture is added, until the whole earth ware is full. The mixture in the earthenware is placed in a flat but a concave manner.

The "jiu" obtained from the first distillation is also called "first residual Fen jiu." Its main composition is as follows: total acids 0.0413 g/100 ml, total esters 0.549 g/100 ml, total aldehydes 0.00924 g/100 ml, and alcohol 48.5–80.5 v%. From the above composition analysis, it is clear that the esters content is fairly high, with strong flavor/fragrance. This is related to the long fermentation time.

Second fermentation. The residues left from the first fermentation has residual starch content of 14–16%. It has to be fermented for the second time. The procedure is as follows:

- collect the residue from the earthenware after distillation,
- add 25–30 kg warm water (at 35°C), (the so-called cover up liquid),
- cool rapidly to 30°C,
- add to "da qu" at the rate of 10% of the residue quantity,
- mix well and wait until the temperature lowers to about 20°C,
- load into the croak,
- seal the croak for the second fermentation.

The water content is controlled at 59–61%. Because the substrate has less starch and more bran, it is looser than the first fermentation. Lots of air is carried into the croak, and this is not favorable for the fermentation. Therefore, this mash must be pressed appropriately, and sprayed with the distillate from the first fermentation. The second fermentation takes 28 days. The mash from the second fermentation is called "second mash." After it is taken out from the croak, bran/husk is added to it before distillation. After the second fermentation, the residue will not go through another fermentation, but sold as wine mash residue. A comparison of the compositions of the mash before and after fermentation, respectively, is as follows: starch content 16.57–22.5% vs. 8.85–11.03%; moisture content 56.0–60.4% vs. 58.5–67.2%; acidity 0.92–1.45% vs. 1.92–2.85%; sugar content 2.9–3.78% vs. 0.31–0.338%; alcohol none vs. 5.2–5.8%.

Second distillation. After the second fermented mash is recovered from the croak, small amount of rice husk is added before distillation like the first distillation. The distillate is called "secondary Fen jiu." Its main composition is as follows: total acids 0.059 g/100 ml, total esters 0.2777 g/100 ml, total aldehydes 0.01012 g/100 ml, and alcohol 50–80 v%. The first and second distillates are stored for three years before formulation according to specifications. The main chemical composition of "Fen jiu" is as follows: alcohol 65 v%, total acidity <0.1 g/100 ml; total aldehydes $< 0.03\%$ g/100 ml; total esters <0.30 g/100 ml; higher (long chained) alcohols <0.02 g/100 ml; methanol <0.04 g/100 ml; furfural < 0.0008 g/100 ml; lead < 0.3 ppm; solids < 0.04 g/100 ml.

4. Fermentation of "Maotai Jiu"

Figure 173.4 is a generalized schematic flowchart of "Maotai jiu" manufacturing. The production of "Maotai jiu" is an example of "continuous mash" fermentation methodology. It has its own unique fermentation technology.

First fermentation. Grain sorghum is ground to contain 80% coarse particles and 20% fine particles, the "qu" is ground to a powder. For 100 kg of ground sorghum, 45 kg of water at 80°C is needed. Water is sprinkled in

Sorghum → Grinding → Wetting (45%) → Steam cooking → Cooling of cooked sorghum → Mixing with "qu" (32%) → First fermentation in tank → Unloading from tank → Mixing with raw sorghum (1:1) → First steam distillation → First distillate + First residue → Cooling of first residue → Mixing of first residue with "qu" (40%) → Second fermentation in tank → Unloading from tank → Mixing with raw sorghum (1:1) → Second distillation → Second distillate + Second residue → Cooling of second residue → Mixing with "qu" (32%) → Third fermentation → Third distillation → Third distillate + Third residue → Cooling of third residue → Mixing with "qu" (20%) → Fourth fermentation → Fourth distillation → Fourth distillate + Fourth residue → Cooling of fourth residue → Mixing with "qu" (15%) → Fifth fermentation → Fifth distillation → Fifth distillate + Fifth residue → Cooling of fifth residue → Mixing with "qu" (15%) → Sixth fermentation → Sixth distilation → Sixth distillate + Sixth residue → Cooling of sixth residue → Mixing with "qu" (8%) → Seventh fermentation → Seven distillation → Seven distillate + Seventh residue → Cooling of seventh residue → Mixing with "qu" (8%) → Eighth fermentation → Eighth distillation → Eighth distillate + Eighth residue (to be discarded).

FIGURE 173.4 Generalized schematic flowchart of "Maotai Jiu" manufacturing.

with continuous turning over of the ground sorghum to allow even absorption of water. Let stand for 20 minutes before loading the wetted sorghum to earthenware for steaming with high heat for 2–3 hours. When the grain sorghum is completed cooked, they can be taken out from the earthenware, and let cool to 32°C before mixing with the "qu" powder. For 100 kg sorghum, 32 kg "qu" powder is used. After mixing thoroughly, the mixture is loaded to the fermentation tank, sealed with yellow earth, and ferment for 1 month.

Second fermentation. For 100 kg of groundup sorghum, sprinkle with 45 kg of water, and leave aside. Take out the mash from the first fermentation. For 100 kg of fermented mash, add 100 kg pre-wetted sorghum. Mix thoroughly and load the mixture to earthenware for distillation. The distillate from this process is not for sale. When the residue after fermentation is cooled to 32°C, the distillate is sprinkled back to the mash. For 100 kg of this mash, add 40 kg "qu," and mix thoroughly before loading to the fermentation tank, and seal with yellow soil. This second fermentation lasts for 1 month.

Third fermentation. The fermented mash is taken out and mixed with wetted raw material (1:1) thoroughly before loading to earthenware for fermentation. This collected distillate is called "Huisha Mao jiu." When the mash after distillation is cooled to 32–33°C, for 100 kg add 32 kg "qu." The fermentation tank is again loaded, sealed, and fermented for 1 month.

Fourth fermentation. The fermented mash is distilled. The distillate is called "Dahui Mao Jui" with exceptionally strong flavor. When the residual mash after distillation is cooled to 32–33°C, 100 kg of mash is mixed with 20 kg "qu," and fermented for 1 month.

Fifth fermentation. The fermented mash is distilled. This distillate is call "Original tank Mao Jiu," and it has exceptionally good quality with very fragrant odor. The cooled mash after distillation is again mixed with "qu" at a ratio of 100 kg to 15 kg. Again, the mixture is fermented for 1 month.

Sixth fermentation. The fermented mash is distilled. This distillate is called "Huizao Mao jiu." This distillate has fragrant odor. The distilled mash is again cooled to 32–33°C, mixed with "qu" at a ratio of 100 kg to 15 kg, and fermented for 1 month.

Seventh fermentation. The distillation procedure is repeated, and the distillate is still called "Huizao Mao jiu." This distillate has a lower quality with a bitter dregs taste. The cooled, distilled mash is again mixed with "qu" at a ratio of 100:8, and fermented for 1 month.

Eighth fermentation. The mash is distilled and the distillate is called "Zhuizao jiu." The taste of the distillate is strong in the bitter dregs taste. The cooled, distilled mash is again mixed with "qu," and fermented for 1 month. The mash is distilled for the last time and the distillate is also called "Zhuizao jiu" with even stronger bitter "tank" taste. The fermented residue is not used for further fermentation, and is sold as animal feed.

The distillates are stored in barrels separately according to their quality, and aged. The aged distillate is at least 3 years old and can be over 20 years. They are then formulated according specification. The main chemical composition of "Maotai jiu" is as follows: alcohol 52.8 v%, total acids 0.115 g/100 ml; total aldehydes 0.0631 g/100 ml; total esters 0.2886 g/100 ml; fusel oils 0.3300 g/100 ml; furfural 0.0025 g/100 ml.

"Maotai jiu" is produced in Maotai town, Renhuai County, Guizhou, China. It has a history of over 200 years. The alcohol content is 60 v% with unique fragrant, mainly taste odor. It is smooth, with the long-lasting residual odor and taste, particular the emptied glass gives a comfortable and loved paste taste, and lasts for a long time. The fermentation methodology is also unique. The "jiu" went through addition of raw material twice, eight distillations, and eight times addition of "qu." Every addition of "qu" will go through a 1-month fermentation period. Therefore, it takes 8–9 months, sometimes even a year to complete the whole process. Because it takes a long fermentation period, the product has good fragrance. However, it take much larger amount of "qu" as compared to other "jiu," and 1 kg of "jiu" takes 27 kg of sorghum, and 3 kg or more "qu." The rate of "jiu" produced is low and therefore cost more to produce.

5. Fermentation of "Luzhou Da Qu Jiu"

Luzhou Old Cellar Special "jiu" is a product of the "Qu Jiu Factory" in Luzhou City, Sichuan Province. It has a long history, and has a reputation that spans over 200 years ago. This "jiu" belongs to the rich fragrance type, and is a representative in this category. The raw materials are sorghum, and intermediate heat "da qu" made from wheat as the saccharifying and fermenting agents. It utilizes mixed steaming and mixed heating, "thousand year" old mash, 45–60 days fermentation, and distillation by layers. The distillate is collected by quality, stored and aged, and carefully formulated into the final product. The "jiu" is colorless, transparent, possesses rich cellar fragrance, smooth and rich body, sweet and clean taste, long-lasting unique flavor. The alcohol content is 59–61 v%.

"Luzhou da qu jiu" is famous for its old cellar. The oldest cellar is claimed to be 380 years old (the Wen Yong Sheng Factory). The so-called cellar is the fermentation tank. It is a deep tank dug out from the ground of various sizes. After the tank is formed, it is surrounded with a layer of yellow soil. It is the general perception of consumers that old cellars are good. This is because after long fermentation periods, the "jiu" will penetrate through the surface layer of soil in the cellar. Therefore, the soil around old cellars, about 1 meter around, turned black because of the "jiu" penetration. When the new raw materials mixes

with the old mash and interacts with soil that has changed quality, it gives the "jiu" a special fragrance. This fragrance is not produced in new cellars. All the new cellars carry a new soil flavor. Production of "Luzhou da qu jiu" applies the traditional continuous residual methodology. It is typical of its mixed-steaming and mixed-heating old cellar continuous residual methodology. The production technology is close to the "Laowu Jan" (old earthenware) methdology. Figure 173.5 is a generalized schematic flowchart for the production of "Luzhou da qu jiu."

Treatment of raw materials. The sorghum is ground to pass the 20 mesh sieve, with 28% coarse particles. The "da qu" is ground to a power.

Unloading of mash and mixing with raw materials. Production of "Luzhou da qu jiu" applies continuous mash methodology, and the mash is called "thousand year old" mash. This mash is mixed with new raw materials. In normal situation, the old cellar has four (4) earthenware loads of old mash, it is unloaded to mix with one earthenware load of new raw materials. After distillation, four earthenware loads of residue are loaded to the cellar, and one earthen ware of the residue is discarded. At the bottom of the cellar, the mash contains more water than the upper layers. After the upper layers of mash are unloaded for mixing with new raw materials, the bottom three layers of mash have to go through a "water reduction" process. The common ratio of mash and raw materials is as follows: for each earthern ware, 500 kg of mash, 20–130 kg of ground sorghum, and 20–25% (weight of raw materials) of rice husk.

Loading of earthenware, steaming raw materials, and distillation. The mash and the raw materials are well mixed. Let it stand for an hour to hydrate the raw materials. After loading to the earthenware, the steaming of raw materials and distillation of mash are conducted at the same time. Before loading the earthenware, enough water is added, and 1 kg of rice husk is spread on the bamboo comb. Th mash loaded to the earthenware should be loose, and the heating should be gradual. The criteria for the procedure are light, loose and even. When steam starts to come up, heating should be turned down. The quantity of steam should be controlled, without pressure, and no escape. The mash in the earthenware should be higher on the sides and lower in the center. Usually, it takes 35–45 minutes to load an earthenware, The temperature of the liquid "jiu" is 35°C. Collect the first 0.5 kg of "jiu," and

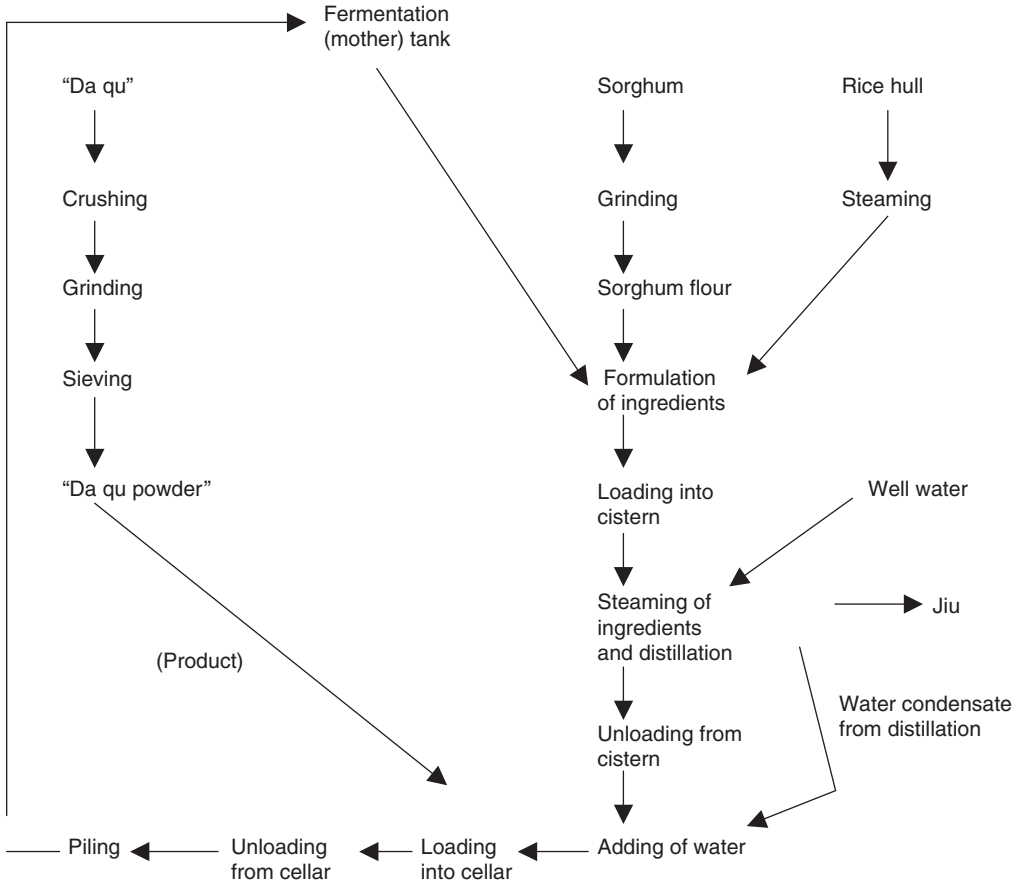

FIGURE 173.5 Generalized schematic flowchart for production of "Luzhou Da Qu Jiu."

the time required is about 15–20 minutes. The rate of "jiu" coming out is about 34 kg per minute. The guidelines are gradual steaming in distillation, and extensive steaming at the end. The average alcohol content of the "jiu" for storage is controlled at 61 v%.

Unloading from earthenware, adding water and spreading of "qu." The traditional process is to add the cooling water collected from the distilling process at a ratio of 100 kg sorghum flour to 70–80 kg water. In this process, hot water (above 80°C) is sprayed onto the mash to allow proper water absorption. In the cellar, water is not added to the bottom two layers, and the other layers have water added a different levels. In general, the water content is controlled at 53–55%. The mash is put on screens to lower its temperature to 13°C (2–3°C below room temperature in the summer). Then the "da qu" power is added to the mash. The amount is 20% of the sorghum power in the mash; however, the dregs returned to the earthenware require only half of the amount of "da qu" needed for the mash. Because returned dregs do not have new raw materials, the temperature entering the cellar is 20–21°C, and it is 18–21°C for the mash. The changes in the composition between the entering mash and the exiting mash, respectively are as follows: moisture 53–54% vs. 55–58%; starch concentration 14–16% vs. 8–10%; acidity 1.4–1.8%, vs. 2.3–3.4%; mash esters 0.43–0.6 g/100g vs. 0.6–0.8 g/100 g; moisture content before mixing with raw materials 53–57% vs. 48–49% after mixing.

Fermentation in the cellar. Fermentation facility. Factories that produce "Luzhou da qu jiu" use earthen cellars, the capacity is 8–12 cubic feet. The phrase "thousand years old cellar, and ten thousand years old dregs" means the older the cellar, the better the product. The earthen cellar already adapts to the activities of butyric bacteria with formation of butyric and caproic acids, and their esters. The older the cellar, the more microorganisms and metabolites are there, and the richer the flavor in the final "jiu." The cellar is made with yellow soil, with the bottom of the cellar built with yellow soil preferred. On the walls are inserted bamboo "nails." The cellar walls are covered with a 10 cm thick "plaster" of fine, soft yellow soil without any sand particles mixed with the "yellow water (liquid)" sipped out from the fermented mash. The cellar is covered with a firmly pressed layer of 30 cm yellow soil. After 7–8 rounds of fermentation, the yellow soil in the newly constructed cellars start to turn black. After a year of fermentation, the soil will change gradually to "blackish white" in color with texture changing from soft to hard and brittle. Quality of the product improves gradually with time and changes in the soil quality. After twenty more years, the soil quality again change from hard and brittle to soft and brittle, and the color is again changed from "blackish white" to black, with red and green colors. This product has a rich fragrance. At this stage, the product reaches the standard of "old cellar," and the quality of the product also improves gradually, getting better every year thereafter.

Criteria for "entering the cellar." The following criteria for "entering the cellar" in the production of "Luzhou da qu jiu" must be strictly controlled:

- starch concentration, 14–16% in the summer and 16–17% in the winter;
- temperature, 1–2°C lower than room temperature and about 18–20°C;
- moisture content, 57–58% in the summer and 53–54% in the winter;
- acidity, below 2% in the summer and 1.4–1.8% in the winter.

Managing the fermentation. After loading, the mash (equivalent to two layers on the earthenware) must be pressed firmly to reduce air in the cellar and inhibit growth of aerobic microorganisms, and gradually induce the normal fermentation. The factory that produces "Luzhan da qu jiu" limits the period of fermentation to 60 days. The longer the fermentation period, the higher the ester content in the final product. During the fermentation period, temperature of the mash increases by 10–15°C. In order to improve the product quality, the factories nowadays generally apply the "returned 'jiu' " and "dual bottom rotation fermentation" technologies to fully utilize the end distillates, and let part of the mash ferment twice in order to increase the rich fragrance. After the mash enters the cellar, they are sealed with pressed yellow soil. Room temperature is checked regularly. Rice husk covers the soil to maintain temperature. "Luzhou da qu jiu" is characterized with its rich fragrance and odor. The main components in "Luzhou da qu jiu" are as follow: alcohol 60 v%, total acids 0.108 g/100 ml; total aldehydes 0.069 g/100 ml; total esters 0.3784 g/100 ml; fusel oils 0.330 g/100 ml; furfural 0.002 g/100 ml.

"Luzhou da qu jiu" applies fermentation in old cellars, mixing of new raw materials and old mash, and contact with soil that has changed quality. These give the "jiu" a rich and unique fragrance. Production of "Lozhou da qu jiu" is a typical example of using "mixed steaming and mixed heating" procedure. By using this procedure, small amounts of esters, ketones, and fragrant materials from the new raw materials are carried over into the "jiu" through the distillation and steaming of the raw materials. This procedure increases the fragrance in the "jiu," the so-called "raw material fragrance."

C. "Xiao Qu Bai (White) Jiu"

"Xiao qu" is used as the saccharifying and fermenting agents to conduct the fermentation, and after fermentation, the collected distillate is "xiao qu jiu." The application of "xiao qu" to produce "jiu" has a long history in

China. However, the production of the distilled "xiao qu jiu" today was started around the Yuan Dynasty. Its unique methodology is well known not only within China as an effective fermentation technology, but also internationally. "Xiao qu jiu" is very popular in the southern provinces of China, particularly preferred by the working class in Fujian, Guangdong, and Guangxi. It is also popular among the overseas Chinese in Southeastern Asia, and in Hong Kong and Macau. It is a light fragrant "bai jiu." When compared to the "da qu jiu," it is different not only in its production methodology, but also in the flavor of the products. Its characteristics are incubation of the microorganisms with the rice kernels, semi-solid fermentation, use of small amount of "qu," short fermentation period, smooth "jiu" quality, and high "jiu" production rate. "Guilin sanhua jiu" in Guangxi (58 v% alcohol), and "Xiangsan (mountain in Hunan province) jiu" are well known "xiao qu jiu."

"Xiao qu" is the saccharifying and fermenting agents for production of "xiao qu jiu." It possesses the dual purpose of saccharifying and fermenting actions. It is made from rice flour or rice bran as the raw material, with addition of Chinese herbs, inoculation with starter (original inocula), and incubation. The microorganisms in the "xia qu" consist of mainly Rhizopus, and Mucor molds, and yeast. From the microbial incubation standpoint, this is natural growth incubation. The handling of raw materials and addition of Chinese herbs can provide effective microorganisms a beneficial growing environment; in addition, it applies the inoculation of starter from long-term natural incubation. In recent years, there are also pure cultures of Rhizopus microorganisms and yeast available for inoculation; this can further guarantee the extensive growth of microorganisms. "Xiao qu" not only produces "bai jiu'' (white wine), it can also be used to produce "huang jiu" (yellow wine). "Xiao qu" such as Sichuan "Qionglai lai mi (rice) qu and kang (bran) qu," "Fujian Xiamen bai yao," "Zhejiang Ningbo bai yao," "Shaoxing jiu yao," "Suzhou tian (sweet) jiu yao" are all famous "bai yao (xiao qu)." "Xiao qu" applied Chinese herbs originated from various sources, and the numbers of herbs also varied, from 1 to 15, including precious ones. In the Ming Dynasty, over 100 kinds of herbs were used. In the old days, there were reasons for using a few herbs. It is now proven through production practices, use of a few herbs, or even without using herbs can also produce good "jiu."

1. Production of "Xiao Qu"

"Xiao qu" is made from rice flour or rice bran as the raw material, with the addition of Chinese herbs, inoculation of starter and incubation. There are all kinds of "xiao qu," but they can be grouped into "yao (herb) xiao qu" (jiu qu ball, or cake), "herbless bai qu," "pure cultures mixed qu," "concentrated tian jiu yao." There are differences among various places in the use of raw materials and production technologies; but, in general, grain(s) are the main ingredient, and the Chines herb(s), and "guan yin earth (bentonite)" as supplemental materials. Some also use rice and others use only the rice bran. The shapes of "xiao qu" may be perfect cubes, round, and round cakes, and also different sizes. For example, "Zhijiang Wuyi (black coat) hong (red) qu" can be 0.1 to 160 g each.

a. Production of "yao xiao qu"

"Yao xiao qu" is called "jiu" herb, or jiu qu" balls. Its characteristics are the use of raw rice flour as the substrate, addition of Chinese herbs and starter (inoculum). Some also have white clay powder as the bulking agent. The addition of herbs and their amount vary with places, some use only one herb, called "single herb xiao qu;" and some use up to 10 herbs. This is called "multi-herb xiao qu." There is also pure culture "yao xiao qu." "Guilin jiu qu" balls are "single herb xiao qu;" it is made from raw rice flour with addition of one herb and inoculation with the starter and incubation. Figure 173.6 is a generalized schematic flowchart on the production of "Guilin Sanhua jiu qu" balls.

Production of the raw "qu" balls. Pearled rice is soaked for 3–6 hours, dripped dry and crushed for production of "qu" balls. For every batch of 15 kg rice flour, add 13% Chinese herb powder, starter 2%, and water 60%. The ingredients are mixed, made into cakes, and pressed flat. Cut the cakes into approximately 2 cm cubes, and sieve them into balls. These balls are evenly coated with 5 kg of fine rice flour, 0.2 kg starter powder. After coating, these balls are the raw "jiu yao balls." They are loaded into small bamboo sieves, and placed in the "qu" room for incubation.

Incubation of "qu" balls. This is managed in three stages. In the first stage, the room temperature is maintained at 28–30°C for 20 hours, and the mold growth is extensive. When the mold mycelia start to fall, surface of the "raw jiu yao balls" shows white bubbles. It is time to lift up the mats from the "jiu yao balls." The temperature at this time is generally about 33–34°C, but cannot be over 37°C. In the second stage, after 24 hours, yeast growth is extensive, and room temperature should be controlled within 28–30°C, and the product temperature cannot be over 35°C. This stage should be maintained for 24 hours. For the third stage of 48 hours, product temperature drops gradually, and the "jiu" balls are mature, and they can be transferred from the incubation room to the drying room for dehydration, or solar dried. These mature "jiu" balls are stored until use. The whole process takes 5 days to complete.

Quality criteria. The sensory quality of "jiu" balls is judged by its white or slightly yellow color with no black color appearance, porous structure, and possesses the

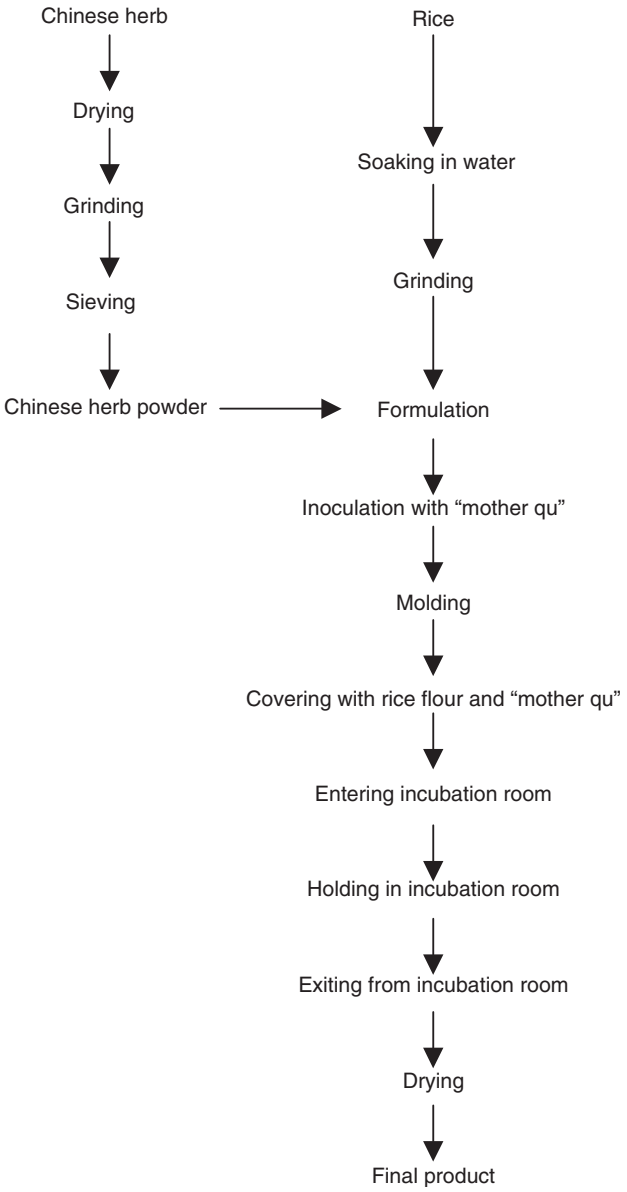

FIGURE 173.6 Generalized schematic flowchart on production of "Guilin Sanhua Jui Qu ball."

characteristic fragrance of "jiu yao." The chemical indices are moisture 12–14%, and total acidity not higher than 0.6 g/100 g.

2. Production of "Jiu Qu Cakes"

"Jiu qu cakes" are also called "da (large) jiu cakes." They are made from rice and soybeans with addition of Chinese herbs and white clay soil, followed by inoculation and incubation. These "jiu cakes" are cubical in appearance, $20 \times 20 \times 30$ cm in dimension, each piece weighing 0.5 kg, containing mainly Rhizopus molds and yeasts. Examples are "jiu cakes" for the production of Guangdong "Chunxiang mi jiu (pure fragrance rice jiu)," and "Xiwei (soy paste-flavored) yubingshao jiu." Figure 173.7 is a generalized schematic flowchart for production of "jiu qu cakes."

Ratio of raw materials is rice 100 kg, soybeans 20 kg, "jiu starter" 1 kg, "jiu herbs" 10 kg (small tangerine leaves 9 kg and cinnamon barks 1 kg), bulking agent 40 kg. The rice should be cooked under low or ambient pressure with 80–85% (weight of rice) water. The soybeans are cooked thoroughly under ambient pressure for 16–20 hours. The cooked rice is spread on the "bed" for cooling to about 36°C and mixed with the cooled, cooked soybeans, "qu," "qu herbs," and bulking agent. The mixture is transferred to a machine for pressing into cake forms. When these cakes are at a temperature of 29–30°C, they are transferred to the incubation room and left there for 7 days. The incubation process depends on the changes in weather and the quality of raw materials. The temperature and relative humidity are adjusted accordingly. When the incubation is complete, they are transferred to the drying room at 60°C for a three-day dehydration to moisture content of 10% to complete the process.

3. Fermentation of "Xiao Qu Jiu"

Polished rice quality is very pure, absent of bran, and low in lipid and protein contents. This is beneficial for low-temperature, progressive fermentation, producing a pure quality with unique fragrance. There are many quality "jiu" produced in the southern provinces in China. They are manufactured using rice as the raw material and application of "xiao qu" in the fermentation process. Examples such as "Guilin sanhua jiu," and "Guangdong yuebingshao jiu" enjoy a very good reputation.

a. Fermentation of "Guilin sanhua jiu"

"Guilin sanhua jiu" is produced in the Guilin City of Guangxi province. The alcohol content is 56–58% and belongs to the "rice fragrance type xiao qu jiu." Its characteristics are a very clear body, smooth, and long-lasting pleasant. In 1957, it was awarded the 1st prize among the "xiao qu jiu" in China, and also awarded as one of the quality "jiu" in the 3rd and 4th National "Jiu" Evaluation Conference. This product is sold to Japan, Southeastern Asia countries, Hong Kong and Macau, and enjoys popularity.

The fermentation methodology is a common practice since the Tang and Song Dynasties. It is believed that quality of "jiu" can be determined by the appearance of bubbles produced; long-lasting and agglomeration of small bubbles are considered as having high alcohol content, and also good quality. Thus, many manufacturers practice the triple distillation process to get to 56–58 v% alcohol stage. The "jiu," because of surface tension, produced three levels of various sized bubbles, then disappears gradually. In the industry, it is termed "triple

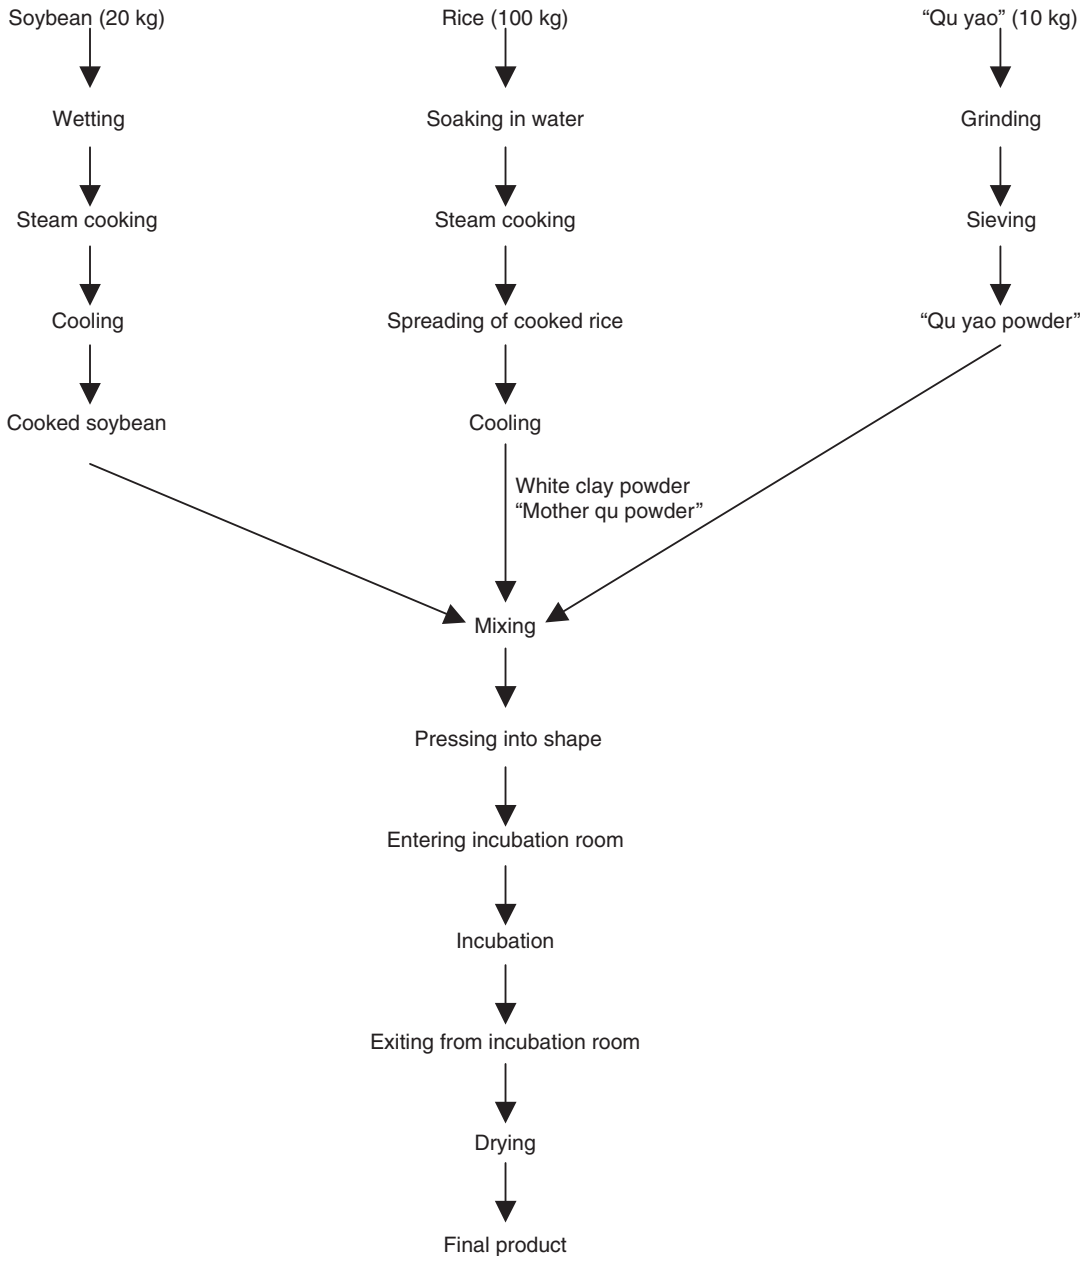

FIGURE 173.7 Generalized schematic flowchart on production of "jiu qu" cake.

distillation" or "piling of three levels of bubbles," thus the name "sanhua" meaning the three levels of bubbles. This term is still used today.

"Sanhua jiu" uses high quality rice as the raw material, the traditional "jiu yao," and semi-solid fermentation technology by cultivating the microorganisms, followed by saccharification and alcoholic fermentation. The water comes from wells in "Li jiang (river)." The mash is sealed in ceramic croaks and stored in caves for over two years. The product is then carefully formulated. Figure 173.8 is a generalized schematic flowchart on the production of "Guilin sanhua jiu."

Steaming the rice. The rice is washed briefly, steamed thoroughly, and contains 62–63% moisture. The rice is then loaded into the grinder, disintegrated and cooled to 36–37°C. The "xiao qu" powder is added at a rate of 0.8–1.0% of the raw material and mixed thoroughly.

Loading to croaks and culturing of the microorganisms. After mixing the raw materials, the mixture is loaded to the culturing croaks, about 15–20 kg each raw material juice. The rice is loaded at a thickness of 10–13 cm. Dig a hole in the center to facilitate aeration. When the mixture is cooled to 32–34°C, cover the croak with a bamboo sieve, and proceed with the saccharification. After about 20–22

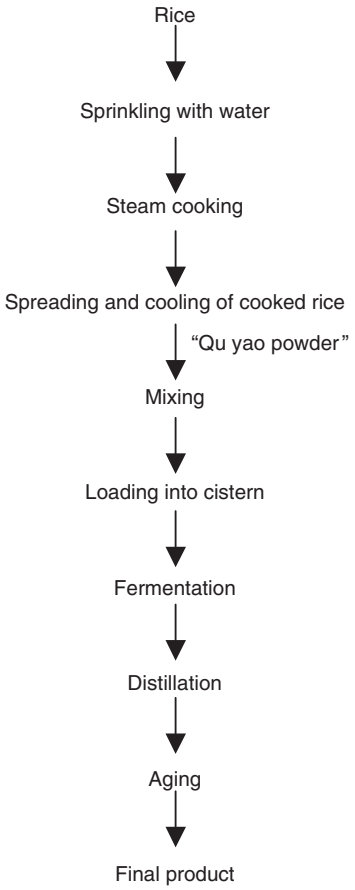

FIGURE 173.8 Generalized schematic flowchart on production of "Guilin Sanhua Jiu."

hours, intermediate product temperature should increase to 37–39°C. It is important to maintain and lower the temperature, if necessary and not to exceed a maximum of 42°C. After 20–24 hours, degree of saccharification should reach 70–80%.

Transferring to croak for fermentation. After the saccharification process, water is added and mixed to lower the intermediate product temperature to 35–36°C. The amount of water is 120–125% of the raw material. In normal situation, the mash after water addition contains 9–10% sugar, total acids not higher than 0.7%, alcohol content of 2–3 v%. After mixing with water, the mash is transferred to a larger croak, two croaks of cultures for each fermentation croak. In the fermentation room, it is important to control the temperature. In normal situation, after 6–7 days of fermentation, sugar content in the mature mash is close to zero, with 11–12 v%, total acids not higher than 1.5%. The mash is ready for distillation.

Distillation. Traditionally distillation is conducted in a distillation kettle in the earthen hearth. Besides using the traditional kettle, "Guilin sanhua jiu" production also applies the vertical or horizontal distillation equipment. The distillation technology usually is stepwise, discarding the beginning and the end distillates. For the first 2–2.5 kg, the distillate contains more impurities, and should be collected separately. The main distillate is collected in a separate croak until the alcohol content is 58 v%. When the distillation is below 58 v%, it is considered as the end distillation. It is collected separately and is added to the second distillation. During distillation, the heating should be even to avoid burning of the mash, or raising the pressure too high and causing mash loss. Temperature of the cooler should be maintained not higher than 55°C, to avoid temperature of the "jiu" too high and the loss of alcohol through vaporization. When the color of the beginning distillate is yellowish with burnt or other odor, it is close to acceptable.

Aged fermented product. When the distillate has been inspected for acceptable quality, it is stored for production of "aged fermented product." Criteria of product to be acceptable are as follows:

- Sensory quality: colorless, good odor, smooth, and long-lasting taste.
- Physicochemical indices (g/100 ml): Alcohol 58, total acids 0.06–0.10, total aldehydes < 0.01, fusel oils < 0.15, total esters > 0.12, methanol < 0.05, turbidity $< 50°$, total solids < 0.1, lead 1.0 mg/liter.

b. Fermentation technology of "Yubingshao jiu"

"Soy-taste flavored yubingshao jiu" is a unique product from the Guangdong Province. This product is different from all the "bai jiu" produced in China. The raw material is rice. The technology is semi-solid fermentation with partial saccharification and partial fermentation progressing at the same time. This fermentation technology is common in the southern provinces in China. The most unique characteristics in this product are low alcohol content (29.5 v%), and a special meaty odor from soaking fat animal meat in the collected distillate for 3 months. Because the fat meat is soaked in the distillate, it absorbs the undesirable taste. Therefore, the product is smooth and not spicy hot. Figure 173.9 shows a generalized schematic flowchart for the production of "yubingshao jiu."

Steaming rice, cooling and mixing with "qu." Criterion for steaming rice is that it must be thorough without any uncooked centers. This is to increase the alcohol production rate. The cooled rice is spread loosely on the rice bed for cooling to 35°C in summer, and 40°C in winter. The temperature of the cooled rice must be even. There should not be lumps of rice. After cooling, "qu" is mixed in at a rate of 1.8–2.0 kg of "qu cake" for every 100 kg of uncooked rice. The "qu cake" is ground to powder before sprinkling on the cooled rice. After mixing, it is ready for loading to croaks.

Loading of croaks and fermentation. Before loading, the croaks are filled with 6.5–7 kg of water. The

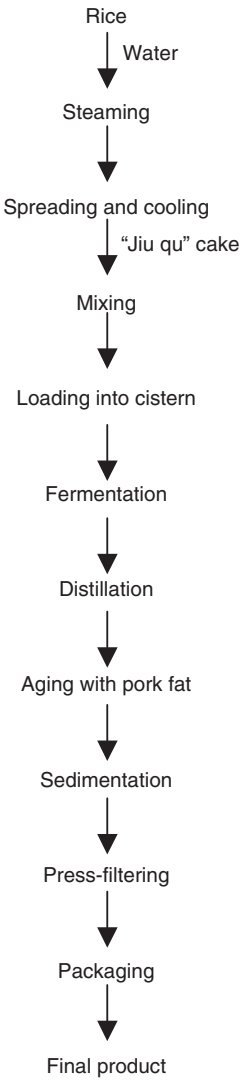

FIGURE 173.9 Generalized schematic flowchart on production of "Yubingshao Jiu."

rice-"qu" mixture is loaded at a rate of 5 kg of rice per croak. The croaks are sealed and stored in the fermentation room. During fermentation, temperature in the fermentation room should be controlled at 26–30°C, and product temperature below 30°C, and not over 40°C. Fermentation time is 15 days in the summer, and 20 days in the winter.

Distillation. When the fermentation is complete, the croaks are taken out for distillation. Removing the beginning and end distillates reduces the impurities with high boiling point, and guarantee the smoothness of the product.

Aging with fat meat. When the collected distillate is filled into the croak, fat pork is added for the soaking process. For every 20 kg "jiu" in a croak, 2 kg of fat pork is soaked for 3 months. The pork fat is gradually dissolved with absorption of impurities and induction of the esterification reaction. The degree of maturation is increased, the "jiu" is smooth and pleasant to taste. At the same time, it provides an unique "soy paste" flavor.

Quality indices of final product. The quality indices for "yubingshao jiu" are as follows:

- Sensory quality:
- Color – Clear, transparent, colorless or slightly yellowish, no suspensions and sediments.
- Odor – Pure fragrant, possessing the unique soy paste flavor in the "yubingshao jiu."
- Taste – Smooth to the taste, also having soy paste-meaty flavor, without bitter or other undesirable taste.
- Physicochemical indices: alcohol 29.5 v% (in croaks) and 30.5 v% (in bottles), total acids $<$ 0.08 g/100 ml, total esters $>$ 0.15 g/100 ml, total aldehydes $<$ 0.1 g/100 ml, amino acids $<$ 0.002 g/100 ml, methanol $<$ 0.06 g/100 ml, fusel oils $<$ 0.2 g/100 ml, Solids $<$ 0.02 g/100 ml, cyanides $<$ 0.5 ppm, lead $<$ 1 ppm.

D. Famous Chinese "Bai Jiu"

In the 4th National "Jiu" Evaluation Conference conducted in Taiyuan City, Sanxi Province in 1984, 13 "jiu" were given the Chinese Famous "Bai Jiu" title. They are Maotai Jiu, Fen Jiu, Wuliangyi, Gujing Gong Jiu, Luzhou Da Qu Jiu, Dong Jiu, Jiannan Chun Jiu, Xifeng Jiu, Quanxiang Da Qu Jiu, Yanghe Da Qu Jiu, Shuanggou Da Qu Jiu, Lang Jiu, and Huanghelou Jiu. The fermentation technologies for "Moutai Jiu," "Feng Jiu," and "Lozhou Da Qu Jiu," together with "Guilin Sanhua Jiu" and "Yubingxiao Jiu" have already been described. Readers interested in the production of other "jius" should consult the references at the end of this chapter.

E. Quality of "Bai Jiu"

In general, quality determination of "bai jiu" relies on sensory evaluation of its color, odor, taste and body to differentiate their quality, and thus determine their classification. Physicochemical analyses are then applied to evaluate their quality.

1. Color of "Bai Jiu"

Sensory evaluation of "bai jiu" color basically includes the evaluation of the color hue, transparency, suspended matter and sediments by visual observation.

- Colorless. "Bai jiu" belongs to distilled spirits, and should be colorless, transparent, absent from suspended matters and sediments. However, some "bai jiu" after long periods of aging, may be slightly yellowish. If this color does not affect the clearness and transparency, it is considered normal.

- Colors. When the "bai jiu" is contaminated, it may be yellow, black, blackish brown, brown, or blue in color; and they are considered as abnormal.
- Loss of luster. The loss of luster in "bai jiu" may be due to the following reason: in formulating "bai jiu," water was added, thus decreases the solubility of higher alcohols, higher fatty acids and esters, and cause diffraction. If the original "jiu" is high in alcohol with minimal amount of impurities, it is not easy to lose luster and show the appearance of milkiness, and not transparent when water is added.
- Sediments in "bai jiu." "Bai jiu" showing sediments of white, brown, bluish black or grayish white color is considered as abnormal.

2. Odor of "Bai Jiu"

Many odorous components have been identified from "bai jiu." These components include esters, acids, carboxyl compounds, and sulfur-containing compounds. Their presence in "bai jiu" is very limited. However, under proper formulation, can give "bai jiu" pleasant and unique fragrance. The characteristic fragrance in different "bai jiu" is an indication of the balance of the different odor components.

- Esters. Esters are the main group of components in "bai jiu." Common fragrant "jiu" or famous "jiu" contains a higher esters content, on the average of 0.2–0.6 g/100 ml. C_1–C_4 straight chain fatty acid ethyl esters are the major esters in "jiu." When the ethyl acetate is strong, they show the odors of apple and banana, and pear and pineapple odors when they are weak. When the ethyl butyrate is strong, its shows unpleasant odor, even objectional; however, when they are weak, they show the odor of rum. When the ethyl caproate is strong, it gives a spicy hot and objectional odor; when they are weak, they give the unique "cellar odor" in "bai jiu." Ethyl lactate is not that significant in odor, but increases the rich sensation.
- Alcohols. Besides ethyl alcohol, the main alcohols in "bai jiu" are the higher alcohols with isopentyl alcohol as the main one and others such as butyl alcohol, propyl alcohol, isopropyl alcohol, isobutyl alcohol, amyl alcohol, normal hexyl alcohol, and heptyl alcohol. Small amounts of higher alcohols gives "bai jiu" its characteristic odor, and support the ester odor. This combination gives a more complete odor in "bai jiu" and forms the characteristic odor on "bai jiu." Alcohols and fatty esters interact and form esters, and can increase the odor to some extent. However, if the concentration is too strong, it will give objectional odor. The β-benzyl ethyl ester in the alcohols is an essential component in the odor of "bai jiu." The concentration of higher alcohols in "bai jiu" should be under 0.3 g/100 ml.
- Aldehydes. Small amount of aldehydes can assist the vaporization of the odors, and give the "jiu" a pleasant odor, such as acetylaldehyde, an important compound in the odor of the beginning distillate. The furfural is a harmful substance giving an irritating odor; however, when its concentration is lower than 0.003%, it can give an "explosive" pleasant odor. All the better "jiu" contains certain amount of furfural, on the average of 0.002–0.003 g/100 ml. The other aldehydes such as isopentyl aldehyde, hexyl aldehyde, and vanillin that can also allow the "jiu" to form a good flavor. However, if the aldehyde content is too high, it will give the "jiu" a taste too "spicy hot," and irritating, in addition to the harmful effect. Propenyl aldehyde also irritates the eyes to tear. This compound, and crotyl aldehyde, and glyceryl aldehyde all give irritating odor.
- Acids. Fatty acids are the major acids in "bai jiu." Generally, acetic acid is the most abundant, followed by propionic acid, lactic acid, succinic acid, caproic acid, citric acid, butyric acid, and isobutyric acid. In addition, there are citronellic acid, oleic acid, pyruvic acid, et al. Organic acids provide the traditional odor to the "jiu," and also give "jiu" the proper taste. Small amounts of organic acids with few carbons help the odor in "jiu." For example, acetic acid gives the pleasant acid odor and taste. Butyric acid has the cellar soil odor and slightly sweet. Caproic acid has the soil odor and slight spicy hot. Propionic acid has a sharp odor, and sour with slightly sweet taste. Lactic acid has a mild acid odor and gives the "jiu" a rich and smooth taste, too much will give a stringent taste. Succinic acid balances the "jiu" odor and taste. These organic acids balance the "explosive" action of "jiu;" when the contents are balanced, the "jiu" gives the consumer a cool, clear, smooth and long-lasting sensation. If the contents are too high, the acid odor is strong and irritating. Fatty acids, starting from the propionic acid, give objectional odor; buytric acid has a sweat odor; amyl acid, caproic acid, and heptylic acid have strong sweat odor. However, these objectional odors will decrease with the increase in carbons in the molecules. Caprylic

acid is only slightly objectional in odor, and in fact shows a weak pleasant odor. Acids with more than eight carbons have weaker acid odor, and have slight resinous odors. Total acids in "bai jiu" should be about 0.1 g/100 ml.

- Phenols. At the present time, research on the effect of phenolic compounds on the odor of "jiu" is still very limited. Whether vanillyl phenol and other phenols are related to the soy paste odor is still not conclusive. However, it is generally believed that these kinds of compounds are beneficial to the long-lasting properties; for example, vanillyl has a mild and creamy odor.
- Alpha-di-keto compounds. When the contents of compounds such as diacetyl and acetoin in "jiu" are limited, they give "jiu" a honey-like sweet and pleasant odor. When the content is excessive, they give out odor like sour milk.
- Objectional odors commonly occurred in "bai jiu." In is fairly common to have objectional sweat odor in "bai jiu" due to excessive butyric acid and its esters. Using excessive amount of rice bran or the bran not cleaned and cooked properly will produce objectional furfural odor. Too much fusel oil will also cause objectional odor. When decayed raw materials or supplementary materials are used directly in the production process, the "bai jiu" will show these decay odors. When the raw materials contain too much fatty substances, these substances will oxidize and develop rancid odor. Use of rubber tubing in the transportation of distillate or use of rubber lining in bottle caps will give the product rubber odor. Acrolein, crotyl aldehyde, thioalcohol, and hydrogen sulfide will give rotten odors. When the raw materials contain too much protein, interaction with alkaline substances will also give rotten odor. Formaldehyde and related substances, particularly acrolein, will irritate the nose and give eyes a hot sensation and induce tears.

No matter how complicate the odorous substances are in "bai jiu," there are always one main odorous substance combined with other supplementary substances to give the characteristic odor. Research on "jiu" odors always consider the "jiu tone" and divide the various "jiu" odors into various categories, such as "Luzhou da qu jiu" odor, "Maotai jiu" odor, "Fen jiu" odor, and "Mi (rice)" odor. The sensory quality of "bai jiu" odor is a balance of the various odors, providing a pleasant sensation with outstanding main odor. At the same time, the overflow and residual odors should be considered. "Jiu" with good overflow odor give the consumer an overflow sensation of odors once the "jiu" is in the mouth, like a hiccup manner, indicating the "jiu" contains more low-boiling point odorous substances. "Jiu" with long-lasting characteristics give the consumer a residual sensation after the "jiu" is swallowed or even when hiccup takes place. This indicates that the "jiu" contains more esters, particularly the high boiling-point odorous substances.

3. The Taste of "Bai Jiu"

The taste of "bai jiu" is determined by the tasting organ (tongue). Basically, "bai jiu" taste can be categorized into sweet, sour, spicy hot, bitter and salty. The sensory quality of "jiu" taste should be evaluated, besides the odor, based on its balanced taste sensation.

- Sweet taste. The sweet taste of "bai jiu" comes basically from the alcohols, particularly the poly-alcohols. All poly-alcohols have sweet taste functional groups and assist in sweet taste functional groups. For example, glycerol, 2, 3 butanediol, erythritol, normal amyl alcohol, and mannitol, with the increase in hydroxyl groups, will increase the sweet taste. The sweet taste of erthritol is important in the sweet taste in fruits. These poly-alcohols not only contribute the sweet taste, (twice as sweet as sucrose, and mannitol having very sweet taste), but also they are viscous, and can contribute to "jiu" its the rich body, giving a mouth feel of smoothness. Maotai is particularly smooth, and this is related to its high glycerol content of 9.5–9.7 ppm. Besides the alcohols, diacetyl possesses the honey-like sweet odor and taste. Acetoin and diacetyl both can contribute to the rich sensation in "jiu." Sweet taste compounds are present in the raw materials themselves and are produced during fermentation. For example, the phytic acid in corn, is hydrolyzed during fermentation into inositol and phosphoric acid, the former being a sweet taste compound in "jiu," and the latter can facilitate the production of glycerol.
- Sour taste. Sour taste is due to the stimulation of hydrogen ions. Acids are the major sour compounds in "jiu." With limited amount of acids, the "jiu" has a light taste, and short aftertaste; excessive acids give the sour sensation, and coarse taste in the "jiu." Appropriate amount of acids will balance the "jiu" taste, and during aging, gradually form the aromatic esters. Acids also affect the sweet taste of "jiu," too much acid reduces its sweet taste, and affects its sweet aftertaste. The acids in "jiu" can be divided into volatile acids and non-volatile acids. Formic acid, acetic acid, propionic acid, butyric acid,

valeric acid, caproic acid, caprylic acid and others are volatile acids. The larger the molecular weight, the softer the smoother taste. The smaller the molecule, the more irritate it is. Lactic acid, citric acid, tartaric acid, succinic acid, and gluconic acid and others are non-volatile acids. They can increase the rich sensation of the "jiu."

- Bitterness. Bitterness in "jiu" is due to mainly the excessive amount of fusel oils, excessive succinic acid, small amount of tannins, too much phenolic compounds and furfural. Fusel oils formed from higher alcohols are important odorous compounds in "jiu," but too much is the source of bitterness. Isobutanol has bitter taste; normal propanol is very bitter, dilute n-butyl alcohol is a very good odorous compound, but in high concentration it is bitter. Most of the alkaloids are bitter. The bitterness on one hand is carried in from the raw materials, such as the tannins in sorghum; on the other hand, the bitterness is related to the technology involved. For example, the ipomeamarone in diseased sweet potato is a bitter substance. It can be carried over during the distillation process into the final product, and give strong bitter taste. Excessive use of "qu," particularly the "qu" made from wheat bran, can carry over large amounts of spores from the *Aspergillus niger* and give a strong bitter taste. Use of "qu" containing green penicillium mold or too little water in the cellar, bottom mash too acid, inappropriate sealing of cellars/croaks, mash temperature too high entering the cellar or croaks all are possible sources of bitterness.
- The spicy hot and pungent taste. A strong irritation of the taste nerve will give a spicy hot sensation. High concentration of alcohol gives a spicy hot sensation, also it can irritate the nerve system to give the nose the irritation sensation. The main components in "bai jiu" causing the spicy hot sensation comes from the aldehydes. Very minute concentration of acetaldehyde can cause the spicy hot sensation. Glyceraldehyde facilitates eye tears and also causes spicy hot sensation. Excessive amounts of acetal, furfural, and higher alcohols also cause spicy hot sensation. Newly distilled "jiu" after a period of storage or distilled over bulking agent can reduce the spicy hot sensation.
- Salty taste. All halogenic ions give the salty sensation. All alkaline sulfates, nitrates and organic acid salts have salty taste. During the fermentation production process, if the water quality is not good with high degree of hardness will also give " bai jiu" the alkaline ions and salts and thus causing slight saltiness and coarseness in the final product. However, presence of limited amount of salts (such as sodium chloride) can facilitate the tasting sensation, and give the "jiu" a rich taste.
- Astringency. Some compounds can cause coagulation of the proteins on the surface of the tongue, and then the stringency action and thus the stringency sensation. For example, presence of minute amount of the oxidative product of tyrosine, 2,5-dihydroxyl acetate, can cause bitter stringent sensation. Excessive amount of lactic acid, ethyl lactate, higher alcohols, and tannins all can cause bitter astringency in "bai jiu." When excessive rice bran is used in the fermentation process, this mishandling not only gives the "jiu" the furfural odor, but also the astringent taste. Lower fermentation temperature in the winter, and incomplete fermentation, give the distilled "jiu" significant stringent sensation on the tip of the tongue.

The taste of "bai jiu" emphasizes on the "taste tone." Excessive sweetness, sourness, bitterness and astringency all will lower the quality of "jiu." Good "jiu" must be balance on its taste; in addition, it must also possess richness, smoothness, sweetness, and long-lasting characteristics.

4. The Body of "Bai Jiu"

When odorous and tasting components are mixed together, it is called the flavoring components. When the flavoring compounds dissolve in water, they form the volatiles and solid matters. Alcohol, water, volatiles, and solid matter together form the "jiu" body. The main component in the "jiu" body is water, then the alcohol, volatiles, and solid matter, including the minute amounts of aromatic compounds and taste components. Because of the differences in raw materials in the production of "bai jiu," the kinds of "qu," and fermentation technologies, the kinds of matters and amounts forming the "jiu" body are also different, thus forming the various characteristics in different "jiu" bodies. In sensory evaluation, the components in "bai jiu" are reflected in the color, odor and taste of the product, then through the combined sensation on these characteristics and abstract judgement, the "jiu" body is determined. In general, the requirements for "jiu" body are normal color, odor, and taste, and the components forming the "jiu" body are properly balanced with characteristic flavor.

5. Sanitary Indicators for "Bai Jiu"

Sanitary indicators for "bai jiu" production must follow the National Standard GB2757-81 of the People's Republic of China (Table 173.1).

TABLE 173.1
Sanitary Standards for Distilled Spirits and Formulated "Jiu" GB2757-81 (China)

Item	Index
Methanol (g/100 ml)	
Cereals as raw materials	≤0.04
Root crop(s) as raw materials	≤0.12
Fusel oils (g/100 ml)	≤0.15
Rice as raw materials	≤0.20
Cyanides (mg/100 L, as HCN)	
Casava as raw materials	≤5
Casava substitutes as raw materials	≤2
Lead (mg/L, as Pb)	≤1
Manganese (mg/L, as Mn)	≤2
Food additive(s)	According to GB 2760-81 (China)

Notes:

1. Distilled spirit means the "bai jiu" collected through distillation, using sugar or starch as the raw materials gone through saccharification and fermentation.
2. Formulated "jiu" means using fermented "jiu" or distilled spirits as the basal "jiu," with addition of edible supplementary substance(s).
3. Sensory indices: Clear and transparent liquid [formulated "jiu" can have color], absence of precipitate, foreign matters, and objectional odor.
4. Indices as based on 60 v% alcohol distilled spirit; if above or lower than 60 v%, adjust accordingly.

6. Harmful Materials in "Bai Jiu"

In the production of "bai jiu," some harmful materials are produced. Some of these harmful materials come from the raw materials, and some are produced during the fermentation process. Proper procedures must be taken to lower the contents of these harmful materials.

- Fusel oils**.** Fusel oils are aromatic components in "jiu." However, when the content is too high, it is harmful to consumers. The poisoning and anesthetic effects of fusel oils are stronger than ethanol (they can cause the nerve system full of blood, and cause headache). The toxicity increases with the increase in molecular size of the fusel oils. The oxidation of fusel oils in the body is slower than ethanol, and stay in the body longer. The main components in fusel oils are isoamyl alcohol, amyl alcohol, isobutanol, propanol et al., with the toxic effects for isobutanol and isoamyl alcohol the greatest. When there are more protein contents in the raw materials, the fusel oils content is also higher. The boiling points of fusel oils are generally higher than ethanol (78°C for ethanol, 97°C for propanol and 131°C for isoamyl alcohol). During distillation, careful control of the distillation, and removal of the beginning and end distillates can reduce the fusel oil content in the final product.
- Aldehydes**.** The aldehydes in "jiu" are the result of oxidation of various sized alcohols, and are also produced in the fermentation process. Lower boiling point aldehydes include formaldehyde, and acetaldehyde; high boiling aldehydes include furfural, butyl aldehyde, amyl aldehyde, hexyl aldehyde. The toxicity of aldehyde is greater than alcohols, and formaldehyde is more toxic; its toxicity is 30 times greater than methanol. It is natural toxic compound, and can coagulate proteins. Ten grams of formaldehyde can be fatal. In acute toxicity, there appears coughing, chest pain, burning fever, dizziness, loss of consciousness and vomiting. Furfural is also toxic to the body. When rice husk, corn cobs, and wheat bran are used as supplemental materials, the furfural and other aldehydes are higher in the distillates. In order to lower the aldehyde contents in "bai jiu," the following procedures should be followed: lesser amounts of rice bran and rice husk should be used, or these materials are distilled separately; strict control of distillation temperature; and removal of beginning and ending distillates.
- Methanol. The toxicity of methanol is fairly high in the human body, 4–10 g will show significant toxicity effect. The oxidation products of methanol, formic acid and formaldehyde are even more toxic. The toxicity of formic acid is 8 times higher than methanol, and formaldehyde is 30 times higher than methanol. Consuming too much "bai jiu" will lead to accumulation of methanol in the body and not easy to excrete, and its metabolites are the formic acid and formaldehyde. Even small amount of methanol can cause toxicity. Acute toxicity of methanol will show the following symptoms: headache, vomiting, stomachache, and blurred vision, followed by shortness of breath, paralysis of the breathing central mechanism, coma and even death. Chronic toxicity will show irritated membrane symptom, dizziness, lethargic sleep, headache, indigestion, blurred vision, and buzzing in the ear, followed by blindness. The source of methanol is the hydrolysis of pectic substances. In the selection of raw materials for fermentation, it is important to select those with low pectic substances. In addition, it is critical to separate the methanol out from the rest of the "jiu."

- Lead. Lead is a very toxic heavy metal, 0.04 g can lead to acute toxicity, and 0.20 g can lead to death. Lead toxicity through "jiu" consumption is not common, mainly in chronic toxicity. When 10 mg is absorbed everyday, toxicity is shown in a short time. Nowadays, the regulation is a maximum absorption of 0.2–0.25 mg in 24 hours. With the increase of lead absorption in the body, symptoms include headache, dizziness, loss of memory, poor sleep, weakness in hand holding capacity, anemia, full-stomach, and constipation. The main cause of lead in "bai jiu" is the dissolution of lead from distillation apparatus, cooling apparatus, tubing, and holding containers. The higher lead content in the equipment, the more lead dissolved from them.
- Cyanides. The cycanides in "bai jiu" come mainly the raw materials such as cassava, and wild plants. In the fermentation process, they are hydrolyzed to form hydrocyanic acid (hydrogen cyanide). Light toxicity includes dripping of saliva, vomiting, diarrhea, rapid breathing. The more serious situation is hard to breathe, whole body seizure, coma, and death within a few minutes to 22 hours. The ways to remove cyanides are as follows: extended soaking of raw materials; enough ventilation during steaming to remove the vapor; drying of the raw materials to vaporize the cyanides; or adding 2% *Aspergillus niger*, maintaining 40% moisture, mixing at 50°C, holding at this temperature for 12 hours, and steaming for 45 minutes to vaporize the hydrocyanic acid. The finer the raw material, the better the removal effect.
- Mycotoxins. Due to decay with quality changes in wheat, rice, corn, peanut, et al., they may be contaminated with mycotoxins. Some of the metabolites from mycotoxins are toxic. When foods are made from these raw materials, consumers can ingest carcinogens at the same time. It is important to store the raw materials properly to avoid mold growth and quality changes.
- Agricultural chemicals (pesticides). If excessive agricultural chemicals are applied in the production of cereals and root crops, they will be absorbed and stay as residues in the fruits or tubers. In the production of "jiu," these harmful substances will be carried over to the "jiu," special attention must be paid to particularly the organic chloro- and phospho-compounds. In order to avoid poisoning from agricultural chemicals, the raw materials must be carefully inspected; and the promotion of biologically control and appropriate use of agricultural chemicals.

III. FERMENTATION OF "HUANG (YELLOW) JIU"

"Huang ju" is not only one of the oldest alcoholic beverages in China, but also in the world. About 3,000 years ago, fermentation of "huang jiu" was already common in China. In "Shi Jing (Book of Poems)," it was proven that "rice is harvested in the tenth month (lunar calendar), and this is used to make "jiu" for the Spring." There are a wide variety of "huang jiu," and their names are quite different, some based on color such as "yuanhong (winner red) jiu," some based on geographic location, such as "Shaoxing jiu," some based on the fermentation technology such as "Jia fan (additional rice) jiu." At the present time, all these "huang jiu" have a bright yellow color; that is why they are called "yellow (huang) jiu." There are many kinds of "huang jiu." The current classification system is based on the sugar content and they are divided into three groups: sugar content over 10% is called "sweet huang jiu" such as "Shaoxing xiangxue (flavored) jiu" and "Fujian michenchen (very sweet) jiu;" sugar content between 5–10% is called semi-sweet "jiu" such as "Shaoxing shanniang (carefully fermented) jiu," "Fujian lao (old) jiu;" sugar content below 5% is called dry "huangjiu" such as "Shaoxing yuan hong jiu," "Ja fan jiu," and common "huang jiu."

A. Raw Materials and Methodology

1. Water Used in Fermentation

Many places famous for their "jiu" are related to the quality of their water. The world famous "Shaoxing jiu" cannot be separated from the water in the "Jian Lake." It is best to use spring water, river water away from towns and cities, centers of wide, clean rivers or lakes, or water from wells. Clarified tap water can also be used. However, tap water contains too much iron; if this is used, it is important to remove the iron, and meet the requirements for "jiu" fermentation.

2. Cereal and Its Treatment

The raw materials can be either rice or millet. In the southern provinces of China, it is common to use rice. Rice is again divided into glutinous rice, nonglutinous rice and long grain rice. In the northern provinces of China, it is more common to use millet. Either rice or miller can be used to make "jiu," however, it is best to use glutinous rice. All the famous "huang jiu" nowadays are made from glutinous rice, and more important good quality glutinous rice. That is, the rice should be soft in texture, large kernels, white centered, and containing high percentage of starch. In addition, it is important to use a new crop of rice, because aged rice is broken easily, and its lipids can get rancid and affect negatively the "jiu" quality.

Treatment of the rice. The rice used for production of "huang jiu" must be polished, soaked, steamed, and cooled. Polishing of rice removes the outer layers of cells containing the proteins, lipids, ash and vitamins. Temperature during fermentation rises gradually, with production of high purity "jiu." In addition, polished rice absorbs water rapidly, thus can be steamed, gelatinized, and saccharified. The traditional method in making "Shaoxing jiu" is to soak the rice for 18–20 hours, so that the rice can absorb water and expand, and more importantly, the availablity of sour soaking water. For steaming of rice, the requirements are: soft interior but with firm exterior, no white centers, loosely separately and not sticking together, cooked thoroughly but not mushy, and uniform. The cooked rice must be cooled rapidly to the temperature for microorganisms to grow. The cooling process can be "sprinkle cooling" and "spread cooling." In the production of the starter, it is customary to use "sprinkle cooling" and for the actual fermentation, "spread cooling" is used. It is required that cooling is rapid and even, and no lumps of hot rice.

B. The "Qu," "Jiu Yao" and "Jiu Mo (Mother Jiu)"

The "qu" and "jiu yoa" are the "da qu" and "xiao qu" described earlier. They are commonly called the saccharifying agents. In the production of "huang jiu," a fixed amount of "qu" is added, and "jiu yao" is only used in the production of "sprinked rice jiu mo." The traditional production technology for "Shaoxing jiu" is to use "qu" and "jiu yao" at the same time. The new technology of "large tank fermentation" uses "qu" as the saccharifying agent, and does not use "jiu yao," but uses pure cultured "jiu mo" to replace the "sprinkled rice jiu mo" as the fermenting agent. There are many kinds of "qu" and jiu yao" with various names. "Qu" can be "wheat qu" or "rice qu," based on the source of raw material. Within wheat "qu," there are "cake qu," "grass-wrapped qu," and "hanging qu," and within the "rice qu," there are "red qu," "black coat qu," and "yellow coat qu," "Jiu yao" can be "white yao" or "black yao."

1. Production of "Wheat Qu"

In the traditional fermentation technology of producing "huang jiu," the "qu" used are either "grass-wrapped qu," "cake qu" or "hanging qu." They are all naturally incubated "qu" with better quality. Figure 173.10 is a generalized schematic flowchart for the production of "wheat qu." The procedures are discussed as follows.

Rolling and crushing. Wheat kernels are sieved, rolled, and crushed into 3–5 pieces per kernel.

Mixing with "qu" and shape forming. The rolled broken wheat is loaded to the barrel to be mixed with "qu." First, water (20%) is added, mixed with the broken wheat kernels to wet the wheat pieces to 23–25%. They are rapidly turned over to let water absorbed evenly. In order to increase the quality of "qu," small amount of aged "wheat qu" is added as seeds. The mixture is then mixed well and spread in boxes to be pressed into cakes. The cakes must be firmly pressed so that they will not fall apart. The cakes are then taken out from the boxes and cut into smaller cakes.

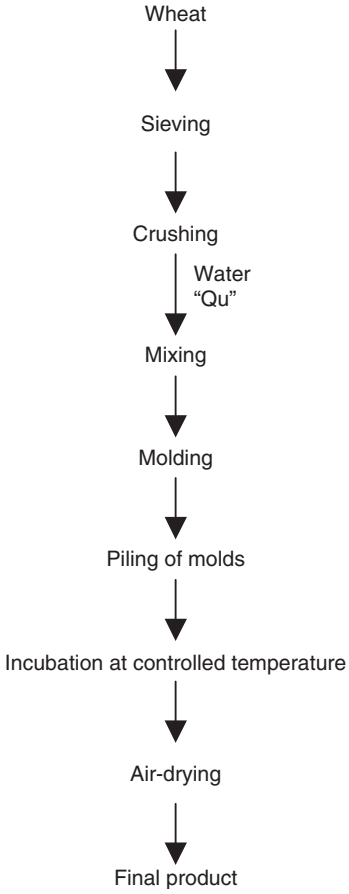

FIGURE 173.10 Generalized schematic flowchart on production of wheat "qu."

Piling of "qu." The incubation must be sanitary. The walls are sanitized with lime slurry. The floor is covered with rice husk and bamboo mats to maintain temperature. The small cakes are then transferred into the room gently without breaking them. They are aligned and stood in T-shape to facilitate air circulation and growth of saccharifying fungi to grow.

Incubation under controlled temperature. After the raw materials are transferred into the room, the windows and doors are closed to maintain the temperature. In general, the entering temperature is about 26°C. After 3–5 days, growth of mold mycelia is abundant, the highest temperature can reach 50°C. At this time, lowering of temperature should be practiced by removal of temperature

maintaining materials and appropriate opening of windows. As incubation continues, product temperature drops rapidly. After 20 days, the "wheat qu" forms hard cakes. They should be piled in # shape for ventilation and drying. Excellent "huang qu" has small amount of greenish yellow spores, the "qu" cakes are hard and porous with moisture content of 15–18% and high saccharifying activity.

There are also procedures to produce pure cultured "wheat qu" using thick layers and ventilation. Generally, they include stepwise culture of the pure microorganism from test tube culture, to Erlemeyer flask culture, to enlarged capacity culture of "wheat qu."

2. Production of "Hong (Red) Qu"

"Hong qu" is a famous typical Chinese product. It is made by reproducing the "hong qu" on rice. In the production of "hong qu," the "Gutian hong qu" and "Jianou hong qu" from the Fujian Province are the most famous. Because of the differences in raw materials and managing methods, "Gutian hong qu" can be divided into three groups: "Ku (storehouse) qu," "Qing (light) qu," and "Se (color) qu." Specific gravity of "Ku qu" is larger, and is used mainly for production of "jiu;" "Qing qu" is lighter, and is used production of "jiu" and for dyeing; "Se qu" is used mainly as a food coloring. "Hong qu" is also used in the production of soy cheese, "dregs fish," "dregs meat," and in medication. There are also pure cultures of "hong qu" available nowadays. The source "qu" for "Gutian hong qu" comes from "Jianou tu (earth) qu." "Tu qu" is also called "Black-coat hong qu." Its outer appearance is pitch black with red shade; its cross-section is red in the center with a pitch black with red shade exterior. Isolated microorganisms from it include *Monascus*, *Aspergillus niger*, and yeast. Therefore it has very strong starch liquefying activity and fermenting activity. In the past, "tu qu" was used as the original starter for "Gutien hong qu." Nowadays, some people just break up the "hong qu" and use these broken pieces as original starter. "Qu gong (male qu), and "qu mo (female qu)" are the most original starters for "Gutien hong qu."

a. "Jianou tu qu"

Preparation of raw materials. The "qu gong" and "qu mo" usually are prepared in the summer and stored for later use.

- "Qu gong." One hundred (100) kg of rice is washed, soaked, steamed, and spread cooled to 40°C. Eighty (80) grams of "qu gong powder," and 500–800 g "qu mo slurry" are mixed into the cooled rice. Let the temperature rise to 43°C, turn over and transfer to the incubation room. Temperature is then maintained at 38–40°C. Water is sprayed on once. After 4–5 days, the "qu" is taken out for drying. A good product should be hard particles with pure greenish red color.
- "Qu mo." One hundred (100) kg of rice is washed, soaked, steamed, and spread cooled to 40°C. Ten to twenty (10–20) grams of "qu gong" powder," and 1,600 g "qu mo slurry" are mixed into the cooled rice. Let the temperature rise to 43°C, turn over and transfer to the incubation room. Temperature is then maintained at 38–40°C. After 4–5 days, the "qu" is taken out for drying. A good product should be hard particles with slightly red color.
- "Qu mo slurry." Wash 1–1.5 kg of rice, add about 7.5 kg water, cook to a porridge, cooled to 32°C, and mix with 1 kg of "qu mo powder." After 7 days of fermentation, the slurry should show alcoholic odor, and spicy hot taste. The "qu mo slurry" is then ready for use.
- Rice. Select good quality rice.
- For production of 100 kg "tu qu," it takes 200 kg rice, 80 g "qu gong powder" and 1.5 kg "qu mo slurry."

Figure 173.11 is a generalized schematic flowchart for production of "jianou tu qu."

Technology essentials.

- **Spreading the rice and mixing with starter.** Rice is soaked for 12 hours after washing, and drip-dry. The rice is then loaded to earthenware ("zeng"), steamed until steam comes out from the "zeng," and the "zeng" is then covered. Continue the steaming for 20 minutes to a stage of completely cooked but not mushy. Cooked rice is transferred to a cooling bowl, spread out, turned over and cooled to 30°C. Fixed amounts of "qu mo powder" and "qu mo slurry" are mixed in evenly. After mixing, the mixture is loaded to a stacking cart, covered with clean and sterilized hemp bags, and transferred to the incubation room.
- **Culturing at controlled temperature.** In general, steaming of rice and inoculation are done in the morning, then transferred to the incubation room at controlled temperature at noon and left overnight. Product temperature rises to about 40°C. The next morning, the "qu"-rice mixture is transferred to a convex earthenware and pile up the mixture to a hip form. The mixture is turned over once at noon to release the heat and provide even contact with the mold mycelia. In the afternoon, spread out the "qu"-rice mixture flat on the earthenware evenly. At this time, growth of mold mycelia is vigorous. On the third day, turn over the mixture once in the morning and once in the afternoon. At this time, the rice grains start to show a red shade on white background. On the

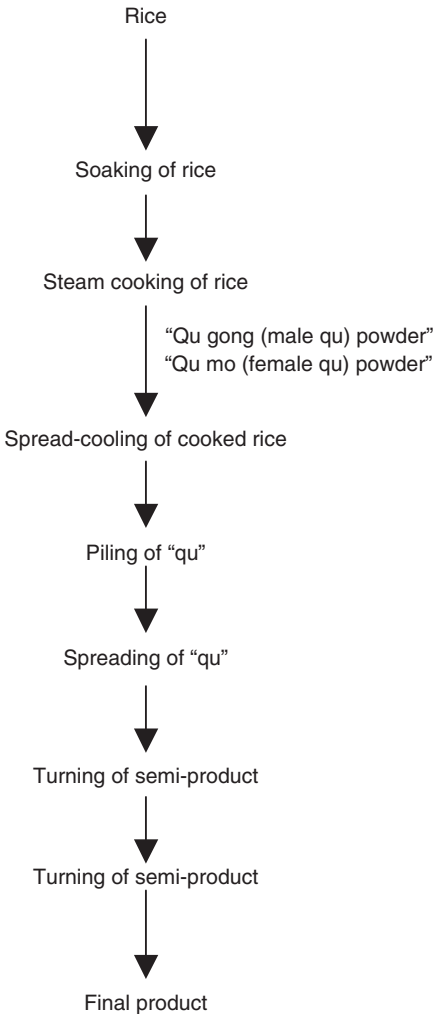

FIGURE 173.11 Generalized schematic flowchart on production of "Jian Ou Tu Qu."

fifth day, take out the mixture, load it on a bamboo (slightly porous) container and for soaking in water, drip-dry, and again transfer to the incubation room and maintain the temperature. The mixture is again turned over in the afternoon. On the morning of the sixth day, collect the mixture in bamboo containers, soak in dilute lime solution, drip-dry, and transfer to the incubation again. Product temperature is maintained at 32–37°C. On the seventh day, mixture is turned over once in the morning and once in the afternoon. At this time, *Aspergillus niger* starts to develop on the exterior, the surface is greenish black, and interior center is reddish with dull black shade. On the eighth day, the mixture is taken ot from incubation, and sun-dried to form the final product.

b. "Gutian hong qu"

Raw materials. The main ingredients are "qu starter," quality vinegar, and rice. The "qu starter" is the "Jianou tu qu." Ferment the rice with "tu qu." The residue is saved for later use. In the production of "Ku qu," and "Qing qu," it is appropriate to use vinegar aged for one year; however, in the production of "se qu," because it takes a long time, the quality requirement for vinegar is even higher. Vinegar aged over three years is needed, because of its sweetish sour taste, and mild and long lasting characteristics. In the production of "qing qu," it is better to use polished nonglutinous rice; however, in "ku qu" production, carefully polished long grain rice should be used, and the cross-section of this rice shows a shade of blue, and is commonly called "blue boned rice."

Production flowchart. Figure 173.12 shows a generalized schematic flow chart for the production of "Gutien hong qu."

Technology essentials.

- **"Qu starter" ratios and "qu" mixing.** Rice after soaking, steaming and cooling to 40°C is ready for "qu" mixing. In the production of "ku qu," 100 kg of rice is mixed with 7.5 kg of "jiu" residue. In the production of "qing qu," 100 kg of rice is mixed with 7.5 kg "tu jiu" residue, and 10.75 vinegar. In the production of "se qu," 100 kg of rice is mixed with 10 kg of "tu qu" residue, and 15 kg vinegar. First, the "tu qu" residue is mixed with vinegar to form the "vinegar residue;" then this "vinegar residue" is mixed with a part of the rice; and finally, this portion of the rice is mixed with the rest of the rice. It is important that the mixing is thorough.
- **Management inside the incubation room.** The well-mixed rice is transferred to the incubation room and piled up on the "qu" beds. They are covered with clean hemp bags for 24 hours to maintain temperature. Mold mycelia grow abundantly, and the rice temperature rise gradually. At 35–40°C, the rice is kneaded and flattened. The kneading is conducted every 4–6 hours to adjust the temperature. After 3–4 days, mold mycelia penetrate gradually to the rice interior, showing red spots. At this time, the rice is loaded to bamboo containers, rinsed with water for 10 minutes to allow water absorption. After drip-drying, the rice is piled again for 12 hours till the temperature rises again to "hot" stage, the rice is then spread loosely and flatly. After this stage, the rice is turned over every 6 hours. When the mold mycelia are abundant and start to excrete red pigment, and the rice kernels show a dry state

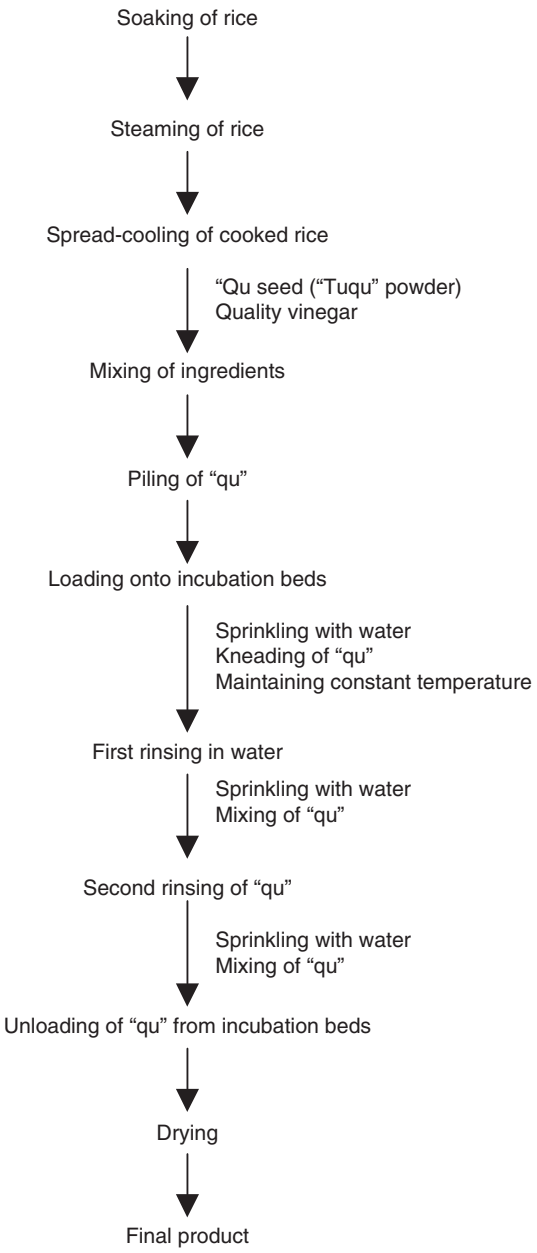

FIGURE 173.12 Generalized schematic flowchart on production of "Gutian Hon Qu."

(making noise when turned over by hand), appropriate water can be sprinkled on. Pay attention to adjustment of room temperature controlling the product temperature to 28–30°C. This stage takes 3–4 days, and the rice turned bright red. This is called "first watering." After this stage, water is sprinkled on appropriately to maintain proper temperature and relative humidity. If too much water is sprinkled, temperature will be too high, and the "qu" start to decay or produce very long mycelia. When it is too dry, the "qu" mold does not grow properly. Therefore, temperature and relative humidity must be controlled carefully. The "qu" is turned over every 6–8 hours, and last for 3–8 days. This is called "second watering." The "qu" particles show transparent red on the exterior with characteristic "qu" odor. At this stage, they can be taken out for drying. In general, the production rate yield (to the rice) is 50% for "ku qu," 33% for "qing qu" and 25% for "se qu."

c. "Jiu yao"

"Jiu yao" is a traditional, innovative method of preserving the quality "qu" culture in China. It is the saccharifying agent for producing "sprinkled rice jiu mo." "Jiu yao" has the white "yao" and the black "yao," with the white "yao" being more common. The white "yao" is made from coarse powder of dry long grain rice, "Laliaocao" powder, and water as the raw materials through a natural cultivation process.

Figure 173.13 is a generalized schematic flowchart for the production of "Ningbo bai (white) yao." Raw materials include 1875 kg of rice flour, 126–157 g, "Laliaocao" powder, 400–500 g "qu mo," and 10.5–11.5 liter of water. The mixture is incubated under controlled temperature. The procedure is similar to the "Gulin yao xiao qu" (see Figure 173.6).

d. "Jiu mo"

Based on the source of lactic acid, "jiu mo" can be divided into two kinds. The first kind is lactic acid produced by the Rhizopus and Mucor molds in the "sprinkled rice jiu mo." The other kind is "rapid fermentation jiu mo" with artificially added lactic acid and high temperature saccharifying "jiu mo."

e. "Sprinkled rice jiu mo"

"Sprinkled rice jiu mo" is also called "jiu niang (ferment or mother)." The names came from the sprinkling of cold water on cooked rice. Figure 173.14 is a generalized schematic flowchart for the production of "sprinkled rice jiu mo."

Raw materials. For every "gang" (earthen ware), use 125 kg glutinous rice, "jiu yao" 0.187–0.25 kg, 19.5 kg "wheat qu," and 375 kg water.

Loading of "gang," nest forming and saccharification. Drip-dry the sprinkle-cooled rice before loading into the "gang" (container). Before use, the "gang" should be sun-dried, and sanitized with lime solution and boiling water. Loading of rice is controlled at 27–30°C, or even as high as 32°C on cold days. The rice is mixed twice with the "jiu yao" powder and evenly. The rice-"jiu yao" mixture is loaded in a concave shape inside the "jang," with additional "jiu yao" powder sprinkled on it. Room temperature should be controlled. The Rhizopus mold will grow

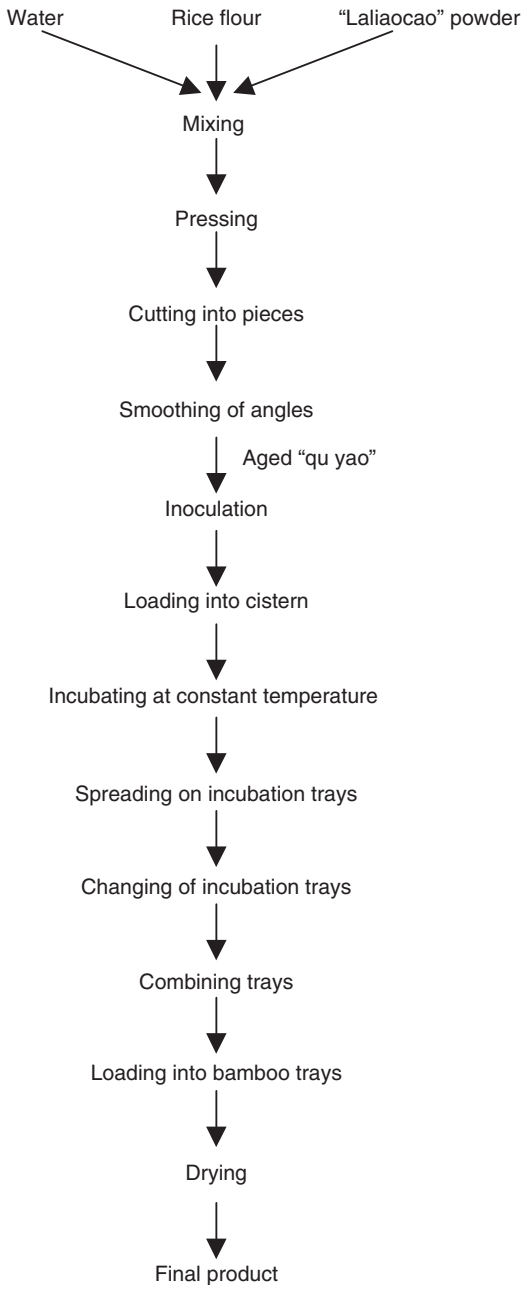

FIGURE 173.13 Generalized schematic flowchart on production of "Ningbo bai yao."

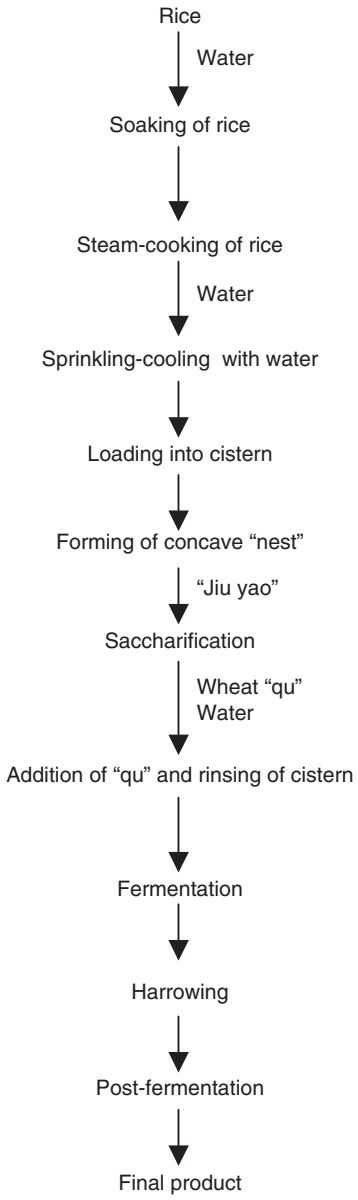

FIGURE 173.14 Generalized schematic flowchart onsprinkled rice "Jiumo (mother jiu)."

rapidly on the rice kernels. In a short time, the white mycelia on the rice kernels will be visible with excretion of saccharifying enzymes to saccharify the starch. Usually after 36–48 hours, the concave bottom starts to have a sugary liquid.

Addition of "qu" and rinsing of "gang." Because of the availability of sugars and the presence of Rhizopus and other molds, sugars are converted to lactic and other organic acids. This appropriately adjusts the pH of the sugary liquid, inhibits growth of undesirable microorganisms, and allows the reproduction of yeast followed by the production of alcohol. When the sugary liquid rises to the height of four-fifths of the rice, the broken "wheat qu" and water can be added and mixed thoroughly. Rinse the interior of the "gang," dilute the fermenting mash, increase the nutrients and oxygen, and facilitate the extensive reproduction of yeast.

Fermentation and harrowing. Because the yeast is reproducing extensively, the alcoholic fermentation is vigorous, and increases the product temperature. When the temperature raises to 28–30°C, use a wooden harrow to mix the mash. This is commonly called "first harrowing." The purpose of this harrowing not only lowers the temperature and has an even temperature for the rice and the sugary liquid, but also removes the carbon dioxide, provides fresh air, facilitate the yeast reproduction, and

avoids the overflow of the mash, and contamination of undesirable microorganisms. Therefore, harrowing is one of the important steps in the fermentation of "huang jiu." After the first harrowing, harrowing is conducted every 3–5 hours to maintain the product temperature maintained at 26–30°C . Generally the number of harrowing is based on the room temperature and changes in the product.

Post-fermentation. About seven days after the loading of "gang," the "gangs" are filled up and sealed. This procedure is to reduce the contact with air, continue the post-fermentation to produce more alcohol and increase the quality of "jiu mo." The complete fermentation process takes 20–30 days and the alcohol content is 15 v% or above. The mash is then used as "jiu mo."

"Sprinkled rice jiu mo" can also be used as a commercial product for direct consumption. This is commonly called "Kuai (rapid) jiu." However, the product flavor is fairly simple.

f. "Rapid fermentation jiu mo" and "high temperature saccharifying jiu mo"

Both the "rapid fermentation jiu mo" and "high temperature saccharifying jiu mo" are pure-cultured yeast. The principle of pure culturing of yeast is to inoculate the yeast to "huang jiu" yeast with a single cell, then gradually increase the culturing to reproduce large amount of yeast and form the "jiu mo." The scale-up process is as follows: Original microorganism → Slant culture in test-tube → Erlemeyer flask culture → Karl's jug culture → "jiu mo."

C. Fermentation and Pressing

The uniqueness of "Huang jiu" fermentation is open fermentation, simultaneous saccharification and alcoholic fermentation. The mash is a high concentration mash fermented at a low-temperature for a long time, thus producing a high concentration of alcohol. On the basis of procedures, the fermentation methodology generally can be divided into three categories: "sprinkled rice" method, "spread rice" method, and "feed rice method." The "sprinkled rice" method has already been described earlier under the section of "jiu mo" production. The following describes the traditional "spread rice" and "fed rice" methods.

1. "Spread Rice" Method

"Yuan hong jiu" is the most popular, and largest in quantity produced "Shaoxing jiu" by following the traditional production technology. Its fermentation technology is a combination of "sprinkled rice" and "spread rice" methodologies.

a. Equipment

The main equipment includes the large cistern (croak), and small jugs. Generally, large cisterns are used for the initial and main fermentation, and the small jugs are used for the slow post-fermentation.

b. Flowchart

Figure 173.15 is a generalized schematic flowchart for the production of "yuan hong jiu."

c. Procedures

- **Raw materials.** The following raw materials are used for each cistern: 144 kg glutinuous rice, 2.5 kg of "wheat qu," 5–8 kg of "sprinkled rice," 84 kg of "starchy water (slurry)," and clear water 112 kg. Traditionally, a ratio of 3 portions of starchy water vs. 4 portions of clear water is practiced. The "starchy water" contains total acids of 0.7%. When a ratio of 3 portions "starchy water" vs. 4 portions of clear water is used, the total acids concentration is about 0.3–0.4%, which is just right for yeast reproduction.
- **Procedures before loading cistern. See above.**
- **Loading of cistern.** The tools for loading the cisterns must be sanitary or even sterilized. After adding the clear water, it is followed by the rice, "jiu mo," mashed "wheat qu," and lastly the "starchy water." The mixture is mixed thoroughly. Temperature at loading should be maintained at 24–26°C, with a maximum of 28°C.
- **Saccharification and alcoholic fermentation.** After loading the cisterns, saccharification and alcoholic fermentation start to proceed. In the initial stage of fermentation, it is basically the reproduction of yeast, and the temperature increase is slow. Temperature should be maintained carefully. After 12 hours, the yeast population in the mash already reaches to a large number, and the main fermentation is initiated. Because of the vigorous yeast fermentation, large amount of sugars are converted to alcohol and carbon dioxide, with release of heat; temperature rise is more rapid, even with "si si" sound. Bubbles will push the mash to the top of the liquid, forming a thick layer. At this time, the taste of the mash is sweet with mild "jiu" flavor. The temperature is 4–7°C higher than loading the cisterns. At this stage, it is important to check the temperature. When the temperature reaches a certain level, harrowing should be started.

Traditionally, the initiation of harrowing can be either the high temperature process or the low temperature process. For the high temperature process, the mash should reach 35°C for the first harrowing in order to lower the temperature. For the low temperature process, harrowing of the mash is initiated at 30°C. Fermentation temperature should not be higher than 30°C. Because of the differences

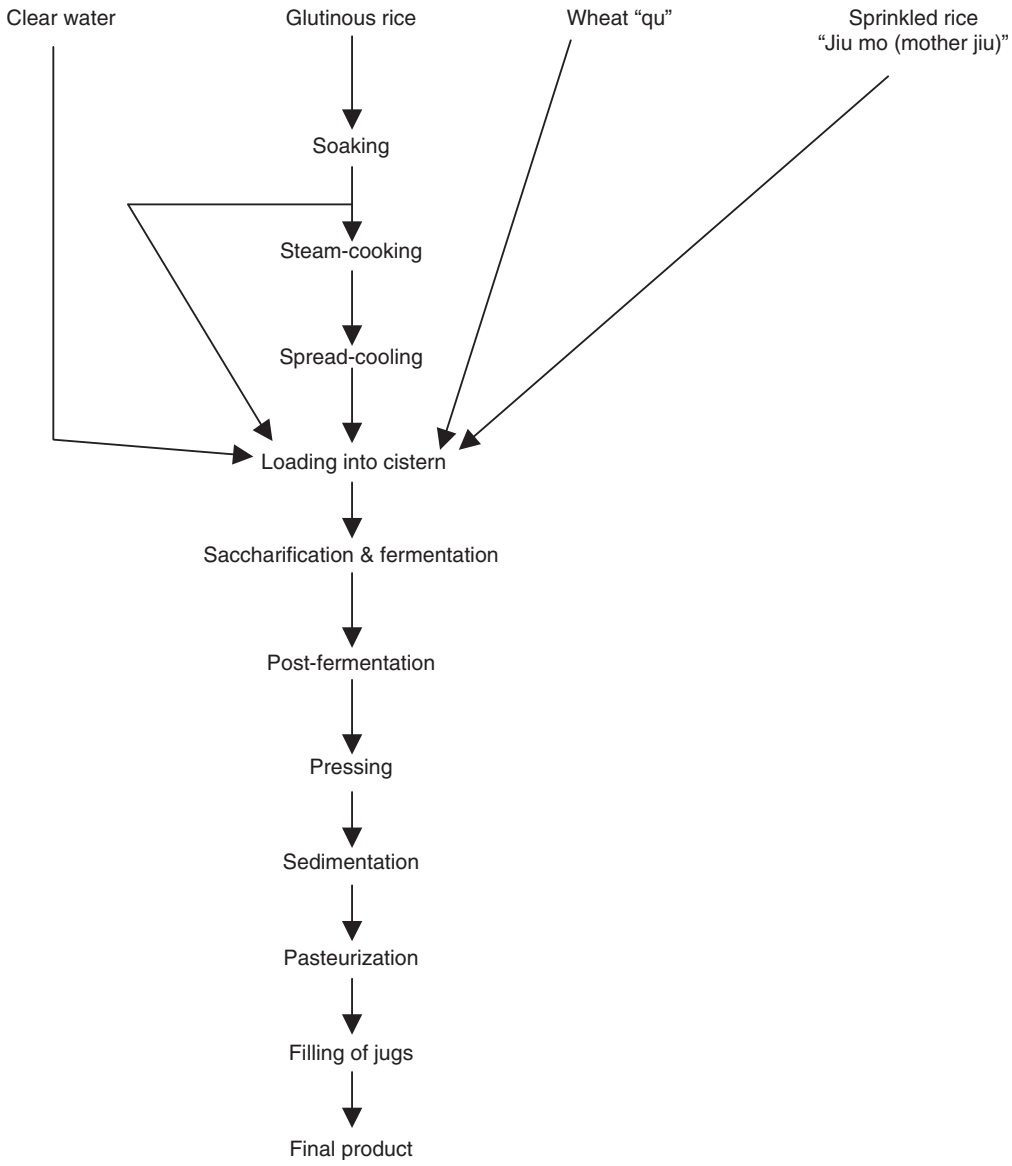

FIGURE 173.15 Generalized schematic flowchart on "Yuanhong Jiu" production.

in the initiation of harrowing, the flavor of the final products is affected. For the high temperature process, because of the higher temperature, yeast ages early with a decrease in fermentation activity. The final product has more solutes with a rich sweet taste. This is commonly called the "hotly made jiu" or " sweet to the mouth jiu." In the low temperature process, the fermentation is complete, with lower acid and higher alcohol contents. This process can easily reach the sugarless stage, and the product is dry, and is commonly called the "coolly made jiu."

Consumers usually prefer the "hotly made jiu." Therefore, it is common to harrow the mash at high temperature. After the first harrowing, product temperature starts to drop; thereafter, the following harrowing depends on the situation. If the room temperature is low, and the product temperature rises slowly, the time in between for harrowing should be extended, and vice versa. After the fourth harrowing, it is customary to harrow the mash once in the morning and again in the evening. The main reasons are to lower product temperature and proceed the saccharification and alcoholic fermentation evenly. However, under low room temperature, the number of times on harrowing should be reduced in order to reduce the loss of alcohol. After 6–8 days, when the product temperature and room temperature are getting close, and the residues are sinking to the bottom, it is the end of the main fermentation. Harrowing should also be terminated and the mash is transferred to jugs to proceed the post-fermentation.

- **Post-fermentation.** After the main fermentation, the alcohol content in the mash is already very high, but some starch and sugars are still not fermented. Therefore, it requires post-fermentation and continues the fermentation to increase the alcohol content. Since the alcohol content is already in the range of 13–14 v%, fermentation is very slow, and therefore requires a long time to achieve, usually 70–80 days. After the long fermentation period, the "jiu" flavor is also better. Post-fermentation usually is conducted in jugs as their mouth is small and is easy to seal off, avoiding the excessive evaporation of alcohol and the invasion of undesirable microorganisms. The procedure to fill the jugs is to transfer the mash from the cisterns to clean and sanitized small jugs, each holding 25 kg of "jiu." They are piled in cellars or outdoors for post-fermentation. Every three jugs are piled up together, and their mouths are sealed with paper, then the ceramic cover. The product temperature fluctuates with the outdoor temperature. In cold days, the jugs can be piled up facing the sun, and in warm days, they should be piled in the cool shade or outdoor to avoid too high a temperature that can cause acid spoilage.

2. "Feed Rice" Method

This method is to divide the raw materials into batches. The first batch is used to produce the "jiu mo," and the rest of the raw materials are added in batches to continue the fermentation. The characteristics of this method is as follows:

- Because of numerous feeding of rice to the mash, more raw materials can be used. This allows the use of small amount of "jiu mo" and produce large amount of "huang jiu."
- The yeast will continuously receive new nutrients, and conduct the reproduction several times. Thus, as compared to common "jiu mo," more new yeast cells are produced and they don't age easier. The fermentation is always vigorous.
- Because the raw materials are added in installments, the yeast and acids in the "jiu mo" are not extensively diluted at once. Yeast dominates in the mash and prevents the growth of undesirable microbes. The fermentation can be conducted safely.
- It is easier to control the fermentation temperature and other technologies. This is beneficial for the control and adjustment, and easier to adapt to the environment.
- Because of the vigorous fermentation, the mash is also turned over vigorously. Fermentation in large cistern thus facilitates the natural harrowing. It has been proven that "feed rice" method fermentation is beneficial in lowering the product temperature and controlling the fermentation temperature. The mash is not easy to have acid spoilage. Yeast has a stronger fermentation capacity, and the fermentation is more complete with increases in "jiu" production rate and "jiu" quality. Thus, the "feed rice" method is getting more popular in the "huang jiu" factories.

In the Zhejiang area of China, there are more factories using the "feed rice" method. In Japan, the production of sake also applies the "feed rice" method. The detail procedures vary with the number of feedings and the ratio of raw materials fed to the mash. Based on the experiences in China and other countries, the following points need special attention:

- It is better to limit the number of feedings to 2 to 3.
- The time between each feeding should be 24 hours.
- Among the various feeding, the ratio is less at the beginning and more afterwards. With the gradual increase in the amount of rice, it will also increase the reproduction of yeast. In the later stages, with larger amount of rice added, the final product is also sweeter.
- For the first feeding, the amount should not be too big to avoid the sudden proportional decrease of acids and yeast. If the undesirable microorganisms are not properly inhibited before fermentation, acid spoilage occurs more often.
- Temperature at the beginning of fermentation should be lower, and increase gradually. After the completion of the final rice feeding, temperature should reach to the maximum as specified.
- Even though the total amounts of water and "qu" added are the same, the appropriate amounts added at the time of feeding can be adjusted according to the actual situation. However, the increased or decreased amount should be proper and not vary too much.

3. Pressing, Filtration, and Sterilization

After the long fermentation, even though the mash contains the basic ingredients of "huang jiu," the "jiu" and its residues are mixed together, this mash can not be considered as a final product. In order to separate the liquid and solids, it is necessary to proceed with pressing,

and filtration. Sterilization and packaged in hermetically sealed containers are also necessary to avoid quality change and spoilage.

D. Famous Chinese "Huang Jiu"

"Shaoxing jiafan (additional rice) jiu" and "Fujian chengang (sediment in cistern/croak) jiu" have been rated as "National Famous Jiu" in every "Jiu" Conference in China. There are many kinds of "huang jiu," and their fermentation technologies also vary considerably. The following are examples of fermentation technologies on Chinese famous "jiu" and some with typical location characteristics.

1. "Shaoxing Jiu"

There are many variations of "Shaoxing jiu." Their fermentation technologies basically are the "sprinkled rice" method and the "spread rice" method. Based on the ratios of their raw materials, there can be over 10 different kinds, such as "Yuanhong (winner red) jiu," Shanniang (well fermented) jiu," Xiangxue (flavored) jiu," et al. The technology for "Yuanhong jiu" fermentation has already been described (see above). The following are the technologies for three other "Shaoxig jiu."

a. "Shaoxing jiafan jiu"

"Shaoxing jiafan jiu" is produced in the "Shaoxing Jiu Fermentation General Company" in Shaoxing City, Xijiang Province, China. "Shaoxing" is famous for its "jiu" production. It was mentioned in one of the oldest classics on Chinese history " Lu's Chun Qiu (Dynasties)" over 2,000 years ago, and has been subsequently mentioned in the "Jiu Jing (Book of Jiu)" in the Tang Dynasty. "Shaoxing jiu" also enjoyed a good reputation in the Ming and Qing dynasties. It won the Gold Medal in the World Expo in Panama in 1915. Since then, it was world famous and is now exported to over 50 countries.

"Shaoxingjiafan jiu" uses glutinous rice as the raw material, and the "wheat qu" and jiu yao" as the saccharifying and fermenting agents. After soaking, steaming, saccharification and alcoholic fermentation, pressing and storage, the "jiafan jiu" is thus produced. The storage period is at least 3–5 years, with some 10–20 years. This "jiu" is nutritious, with 17 amino acids, among them 7 are essential; this exceeds beer and grape wines. It is named as "liquid cake" and is equivalent to the Japanese national alcoholic beverage, sake. The amino acid content in "Shaoxing jiafan jiu" is 5,600 mg per liter, this is over 30% higher than the Japanese sake. "Shaoxing jiafan jiu" belongs to the dry type "huang jiu," the sugar content is less than 1%, with alcohol content 16.5 to 17.5 v%, and total acids < 0.45 g/100 ml. The product is orange-yellow in color, transparent with luster, rich odor, savory, sweet and smooth with long-lasting taste.

"Jiafan jiu" has in the ingredients additional cooked rice. In reality, it is a thick mashed fermented "jiu."

- *Ingredients*. The standard formula for each cistern has the following ingredients: glutinous rice 144 kg, "wheat qu" 25 kg, "starchy water" 50 kg, clear water 68.6 kg, and 50 v% residual "jiu" 5 kg.
- *Fermentation technology*. The fermentation technology is basically the same as "yuanhong jiu" but with the following variations:
  - Because the amount of rice is larger, the mash viscosity is larger, and the temperature during the main fermentation rises faster. Therefore, the temperature of raw materials entering the cistern should be 2–3°C lower than in "yuan hong jiu," and the temperature maintenance criterion is less stringent. Besides, for the ease of temperature control, this product can be fermented in the very cold period of the year.
  - Because of the longer peiod of fermentation, it takes 10–15 days for the rice kernels to be completely settled to the bottom of the cistern, before loading to the small jugs for post-fermentation. Before loading into the jugs, they are filled with 5 kg of 50 v% "residue jiu" and small amount of mash liquid from the "sprinkled rice jiu mo." This is to increase the alcohol content and the fermentation capacity, and prevent the possibility of acid spoilage. The post-fermentation period takes 80–90 days.
  - Because the mash is more viscous, the fermentation usually is not complete, resulting in more residues and causing difficulty in pressing. The pressing time usually is double of that for "yuanhong jiu."

b. "Shaoxing shanniang jiu"

"Shanniang jiu" is also called "tao (formulated) jiu," and uses "jiu" to replace the water in the "jiu" fermentation. It is a semi-sweet "jiu." The flavor of this "jiu" is sweet, rich, and unique. Its nutritional values and mouth feel are equivalent to high-quality sweet grape wine. In 1979, it was named as one of the excellent quality "jiu."

Ingredients. For every cistern, the ratio of ingredients is as follows: glutinous rice 144 kg, "wheat qu" 25 kg, "starchy water" 50 kg, "Sprinkled rice qu mo" 15 kg, "yuanhong jiu" (aged for 3 years) 100 kg.

Fermentation technology. The technology is similar to "yuanhong jiu." The difference is that yeast reproduction is inhibited and the fermentation is slow due to the large amount of "yaunhong jiu" added, and the mash has an alcohol content of over 16%. The sugars cannot be

digested and remain at over 7% during the whole process. In order to facilitate the yeast reproduction and fermentation, it is required that the loading temperature for the cistern is 1–2°C higher than that in the fermentation of "yuanhong jiu;" also the temperature maintenance should be strengthened. Besides, because of the alcohol content, fermentation is slow, and the fermentation time requires 80 days. Because of the mash viscosity, the pressing time also takes longer.

c. Shaoxing xiangxue jiu"

The fermentation technologies for "xiangxue jiu" and "shanniang jiu" are similar, both replacing water with "jiu" in the production process; however, "residue jiu" is used instead of "yuanhong jiu." In the production process, "Sprinkled rice" method is used in the fermentation of "xiangxue jiu." Because "xiangxue jiu" is made with sweet "jiu niang" together with "residue jiu," both the alcohol and sugar contents are increased. The production is not limited by the weather, and a warm environment is very suitable for the production of "jiu niang;" therefore, it is commonly produced in the summer.

Even though the "xiangxue jiu" is made with "residue jiu," with its long fermentation, the mouth feel is sweet and rich; it does not show the spicy hot taste as in "bai jiu," but provide the characteristic, rich "Shaoxing jiu" flavor. The key to "xiangxue jiu" production is its appropriate time for saccharification. That is, when the sugar is accumulated to a fairly high level, a large amount of "residue jiu" is added, and inhibits the fermentation by yeast. The sugar content in the mash is basically fixed, and forms a "jiu" with very high levels of sugar and alcohol. The fermentation technology is as follows:

Figure 173.16 is a generalized schematic flowchart of Shaoxing xiangxue jiu" production.

For each cistern, the ingredients are as follows: glutinous rice 100 kg, "wheat qu" 10 kg, 50 v% aged "residue jiu" 100 kg, and "jiu yao" 0.187 kg.

Fermentation technology. The procedures on forming the concave shaped raw materials are the same as the "sprinkled rice jiu." Thirty-six to forty hours after this stage, the sugary liquid in the concave raw materials fills up the cavity. Ground up "wheat qu" is then added to the sugary liquid, mixed with the rest of the raw materials, and continues to maintain the temperature to facilitate the saccharification. After another 24 hours, the sugars have accumulated to a high level, and the 50 v% "aged residue jiu" can be added. The mash is harrowed evenly, covered and left standing without disturbance. The mash is harrowed every 3 days. After 2–3 harrowings, the cistern is covered with another clean cistern. The exterior two mouths of the cisterns are covered with lotus leaves as the cushion, and sealed with a mixture of salt solution (nigari) and earth. After 3–4 months, the mash is recovered for pressing.

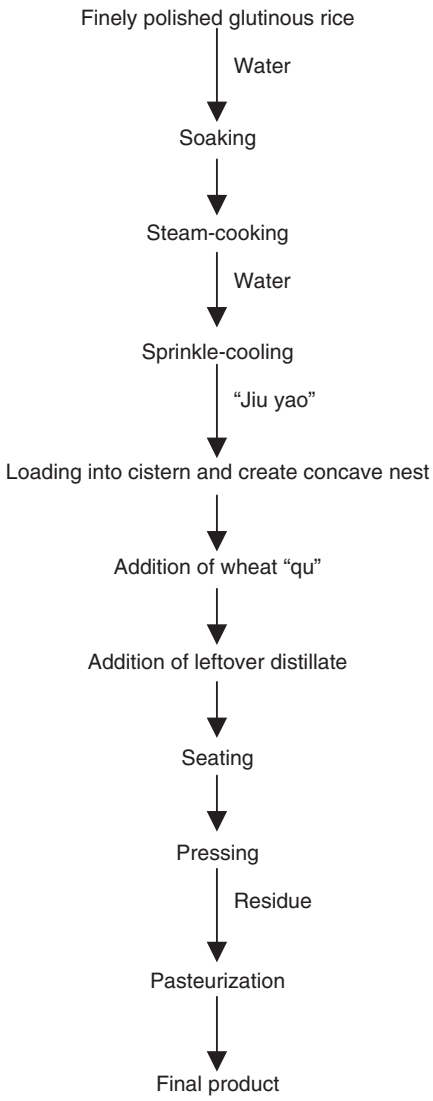

FIGURE 173.16 Generalized schematic flowchart on production of "Shaoxing Xiangzue Jiu."

"Xiangxue jiu" does not require addition of caramel for coloring and shows a transparent golden yellow color. The filtrate is heat-treated to coagulate the colloidal materials and clarify the "jiu liquid." Because the sugar and alcohol contents are fairly high, they can be filled into jugs without sterilization.

Table 173.2 is a comparison of the major chemical components in several kinds of "Shaoxing jiu."

2. Fujian Chengang Jiu

"Shenjang jiu" is a product of "Longyan Jiu Factory" in the western part of Fujian Province, China. The production of this "jiu" has a history of about 160 years. Currently, the factory utilizes the water from Luopan Fountain for the fermentation process. In the 2nd and 3rd "Jiu" Evaluation Conference, this "chengang jiu" was

TABLE 173.2
Main Components in "Shaoxing Jiu"

Components	Yuanhong Jiu	Jiafan Jiu	Shanniang Jiu	Xiangxue Jiu
Specific gravity	0.992	0.995	1.0349	1.073
Alcohol (%, v/v)	15.60	17.80	16.70	19.40
Solubles (mg/100 ml)	3.325	4.450	15.65	24.44
Sugar (g/100 ml)	0.38	0.78	6.5	20.00

Volatile acids (g/100 ml)	0.06	0.027	0.054	0.056
Nonvolatile acids (g/100 ml)	0.42	0.43	0.406	0.22

named one of the famous "jiu" in China. The fermentation technology for this "jiu" is unique using glutinous rice, "hong qu" and specially made "yao xiao qu" as the saccharifying and fermenting agents, and precise procedures in its production. In its production process, the mash has to rise three times and settle three times. Lastly the residue sediments sink to the bottom, thus the meaning of "shenjang" or "sediment to the bottom of the cistern jiu." This "Longyan chengang jiu" is a sweet "huang jiu," with sugar content as high as 24%, about 20% alcohol, and rich in amino acids. It is nutritious, with reddish brown and lustrous color, clear and transparent, rich and smooth with a full body, balanced in flavor and long lasting. The fermentation technology of this "jiu" is similar to "xiangxue jiu," utilizing the "sprinkled rice" method for the initial fermentation, followed by the addition of distilled rice "jiu" to form the sweet "jiu" with high alcohol and sugar contents, but not very sweet.

a. Ingredients

For each cistern, the formulation is as follows: glutinous rice 40 kg, "jiu yao" 0.186 kg, "hong qu" 2 kg, "bai qu 0.065 kg, 53% distilled rice "jiu" ("bai jiu") 34 kg.

b. Fermentation essentials

The "bai jiu" is added in two increments. At the beginning, only small amount of "bai jiu" is added, this is beneficial for the saccharification and fermentation to proceed. With proper control of temperature and prevention of acid spoilage during fermentation, the rest of the "bai jiu" is added to meet the specified alcohol content and fix the sugar content in the mash. The production procedure for this product is to wait until the sugary liquid is about three-fifths in the concave "nest," then add in "hong qu" and 17.6% or 6 kg of the 53 v% distilled rice "jiu" ("bai jiu"). The saccharification process is allowed to proceed for 3–4 days, and the rest of the "bai jiu" (26 kg) is then added. Let stand for 50–60 days, then the mash is pressed, the filtrate is heated, filled in the jugs, sealed, and stored for a fixed period to form the product.

E. Quality of "Huang Jiu"

1 The Color, Odor and Taste of "Huang Jiu"

a. Color

The color of "huang jiu" varies with the product, ranging from light yellow to reddish brown or black. The color of "huang jiu" may come from the red pigments of glutinous rice and wheat, pigments from the "qu" such as the "red pigments in "hong qu," and the melanoids formed during the storage period. Besides, large proportion of the "huang jiu" has caramel added to improve its color. Iron, copper and manganese ions can also form compounds that give or facilitate the color.

b. Odor

There are many odorous compounds in "hunag jiu," and they vary considerably. However, there is no single compound discovered that is outstanding, and these odorous compounds among themselves can increase or decrease the odor of the product. Therefore, the odor of "huang jiu" is very complex, and quality "huang jiu" has its own odor requirements with absence of undesirable odor. The main odorous compounds in "huang jiu" are made up of mixtures of esters, acids, carboxyl compounds, and phenolic compounds.

c. Taste

The taste of "huang jiu" is a balance of sweetness, sourness, bitterness, astringency, and spicy hot sensation.

- **Sweetness.** Sweetness comes mainly from the sugars, with dextrose the highest in content. General "huang jiu" contains only limited sugars, and is not too sweet. However, sweet "huang jiu" contains more sugar, and its sweetness is significant. Besides, "huang iu" contains gycerol, 2,3-butanediol, and alanine that give sweet taste, and a rich sensation to the product.
- **Sourness.** A common saying is that if there is no acid, there is no "jiu." Acids decrease the sweetness and intensify the rich taste. The acids

in "huang jiu" are mainly organic acids, and they are formed mainly during the yeast fermentation that produces alcohol. Lactic and succinic acids have the highest contents. Succinic acid not only gives "jiu" the sour taste, but also together with glutamic acid, guanylic acid, and inosinic acid gives the umami (savory) taste. General "huang jiu" should have total acids about 0.4%, and for sweet "huang jiu" the total acids can be higher.

- **Bitterness and astringency.** The bitterness in "huang jiu" comes mainly from some amino acids, peptides, butanol, 5′-methyl sulfonic acid, and amines. Some "hunag jiu" has burnt rice or caramel that can also give bitterness. The astringency in "huang jiu" comes from lactic acid and amino-butyric acid, the added lime also carries over to "jiu" the astringent taste. Very small amounts of bitter and astringent substances do not give the "jiu" undesirable taste, but instead give "jiu" a rich and balanced mouth feel. Most of the "huang jiu" do not carry significant bitter or astringent taste.
- **Spicy hot sensation.** The spicy hot sensation comes mainly from the alcohol, and also the fusel oils. Newly fermented "jiu" usually gives an irritating spicy hot sensation. After long term storage, the spicy hot sensation decreases, and instead gives a rich and smooth flavor. This is due to the oxidation of alcohols to form aldehydes, and then organic acids. The ethanol and fusel oils react with the organic acids to form esters. In addition, the binding of alcohol molecules to the water molecules also reduces the spicy hot sensation.

2. Quality Standards of "Hunag Jiu"

Currently, Chinese national standards for "huang jiu" do not exist. However, the "huang jiu" standards from the Xijiang Province, China can be used for reference (Table 173.3).

3. Sanitary Standards of "Huang Ju"

"Huang jiu" is fermented "jiu," and fermented "jiu" must meet the national GB2758-81 Fermented "Jiu" Sanitary Standard (see Table 173.4).

IV. FERMENTATION OF "GUO (FRUIT) JIU"

A. Traditional Chinese "Guo Jiu"

1. Selection of Raw Materials

All fruits contain sugars; with suitable treatment, they all can be fermented into "jiu." However, the cultivar and quality of the fruit used for fermentation have significant effects on the final products. The flavor components in "guo jiu" is very complex, and there are two sources for these compounds. One source is fermentation: the growth activity of yeast and its related chemical reactions produce esters, alcohols, aldehydes and organic acids. Another source is from the components of essential oils from the fruits themselves; they are carried into the "guo jiu" and contribute to the total flavor of the final products. Until now, the flavor profiles of "guo jiu" can not be completely duplicated, and true "guo jiu" with good flavor can not be made with other raw materials.

Although all fruits can be used for fermentation, the use of quality raw materials is essential in the production of quality "guo jiu." The meaning of quality raw materials

TABLE 173.3
Quality Standard for "Huang Jiu" in Zhejiang Province, China

Product	Sensory Indicators			Alcohol (%, v/v)	Total Acids (g/100ml)	Sugars (g/100 ml)
	Color	Aroma	Taste			
Shaoxing Yuanhongjiu	Orange-yellow, clear	Typical "huang jiu" smooth aroma, absence of objectional odor	Absence of acid spoilage & objectional odor	15–16.5	≤0.45	None
Shaoxing Jiafan jiu	Same as above	Same as above	Same as above	16.5–17.5	<0.45	None
Shaoxing Shanniang jiu	Same as above	Same as above	Same as above	<15	<0.55	<6
Shaoxing Xiangxue	Same as above	Same as above	Same as above	18–22	<0.4	<19
Wuyi Hongqujiu	Same as above	Same as above	Same as above	15–16.5	<0.5	None

Sanitary Standard of Fermented "Jiu," GB2758-81 (China)

Item	Index			
1. Sensory evaluation	Clear liquid, absence of precipitates, foreign matters, objectional odor and taste.			
2. Physicochemical analyses				
Residual sulfur dioxide, (g/kg, free sulfur dioxide)	≤0.05			
Aflatoxin B_1 (μg/kg)	≤5			
3. Bacterial numbers	*Draft beer*	*Regular beer*	"*Huang jiu*"	*Grape wine*
Total bacterial counts (unit/ml)	None	≤50	≤50	≤50
E. coli colonies (unit/100 ml)	≤50	≤3	≤3	≤3

Note: Fermented "jiu" is an alcoholic beverage without distillation using sugar or starch as the raw materials gone through saccharification and fermentation.

is that the fruits must meet certain criteria: the cultivar and kind of fruit must have high sugar content and lots of juice, and it is easy to extract the juice; in addition, the quantity of acids, tannins, and pectins should also be considered. Because the sugars are fermented into alcohol, they are related to the production rate and quality of the final product. Appropriate amounts of acids are beneficial to the reproduction of yeast, inhibit the invasion of undesirable microorganisms, facilitate the solution of plant pigments and ferment the raw materials into tasty "guo jiu." It can also combine with the alcohols to form esters in the storage and aging processes. "Guo jiu" with too little acids has a flat taste, and too much acids give the "guo jiu" a sour taste and lower the quality of the product. The amount of tannins when appropriate can also inhibit the growth of harmful microorganisms, and also facilitate the clarification of "guo jiu." However, if the tannin content is too high, it inhibits the reproduction of yeast, and the "guo jiu" will have an astringent taste, which is also undesirable. With too much pectins, it creates difficulty in juice extraction and clarification; in addition, it also gives too much methanol in the final product.

From the standpoint of world production of alcoholic beverages from fruits, the majority is wine made from grapes. However, from the standpoint of chemical composition, color, odor and taste, other fruits such as citrus fruits (oranges, mandarin oranges, and tangerines), lizhi (litchi, lychee), and pears are also suitable raw materials. The fruits used for fermentation must be fully ripe in order to obtain high sugar contents and their rich flavor and color. Decayed fruits, in principle, are not suitable for the production of "guo jiu."

2. Flowchart for Production

In the production of "guo jiu," it is generally divided into two categories, one utilizing the pigments in the fruit skin, and the other having the residues removes. They are schematically shown in Figure 173.17.

3. Technology Essentials

a. Extraction of juice

Generally, in the production of "guo jiu," juice is extracted before fermentation. However, in the production of colored "guo jiu" like the "yang mei (plum) jiu," the extraction or pressing process is conducted after the fermentation; the fruits are crushed followed by fermentation to extract the pigments from the skin. Before extraction of fruit juice, wash the fruits to remove the dust, soil, and microorganisms. For fruits on which pesticides have been sprayed, this is very critical. Besides, the fruit skin, hearts and seeds have complicated composition, and give undesirable flavor to the product. Therefore, removal of skin, hearts, and seeds is a necessary step to improve product quality. Fruit juice is usually extracted by pressing the crushed fruits mechanically.

b. Improving the fruit juice

Sugar and acid contents in fruits usually are not at the desirable levels and ratios. In order to guarantee the proper fermentation with expected product quality, it is necessary to adjust the sugar and acid contents. Fruit juice generally contains 10–15% sugars, and every 1.7 g glucose (or 1.6 g sucrose) is needed to produce 1 ml ethanol. This amount can only produce "guo jiu" with 6–9 v% alcohol. "Guo jiu" with alcohol content lower than 10 v% is called weak "jiu;" not only the taste is flat, it is also difficult to preserve. The standard "guo jiu" to go with meals should have alcohol content above 14%, and fruit acids 0.5%. In order to meet these requirements, the sugar content in fruit juices should be 25% or higher with 0.5% fruit acids. It is very difficult for natural fruit juice to reach these requirements and therefore, adjustment of these contents is common. It is also true for colored "guo jiu" fermentations including the residues (skin, hearts and seeds).

The adjustment of sugar contents can be accomplished in three ways: addition of sugar, addition of alcohol, and increasing the raw materials (jiu niang). In the production of "guo jiu" with alcohol content in the 16–18 v% range,

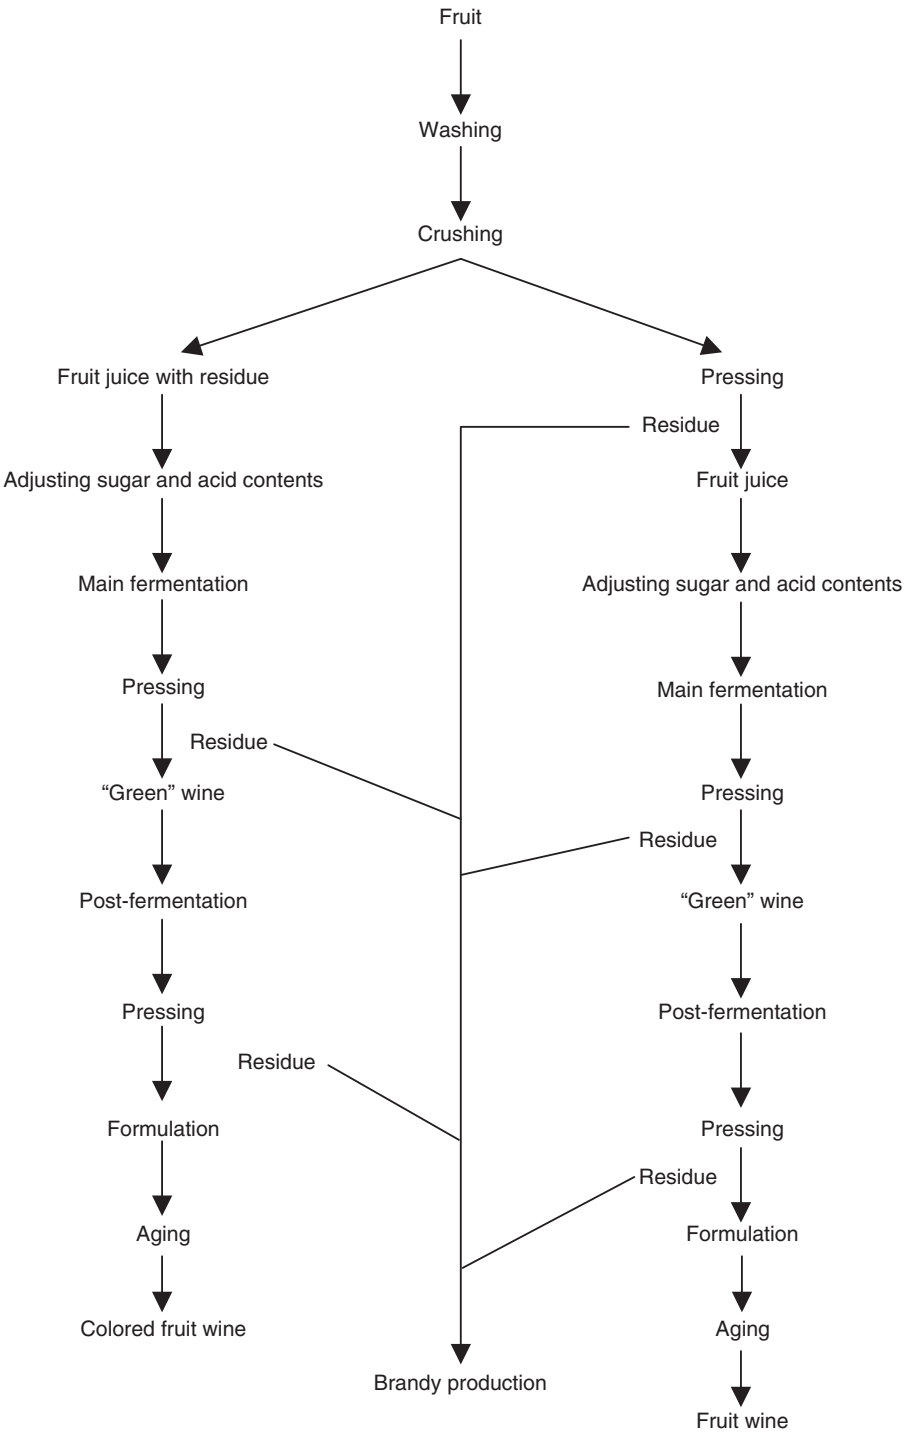

FIGURE 173.17 Generalized schematic flowchart on fruit wine production.

the only way is appropriate addition of alcohol or brandy to increase the alcohol content, and sugar cannot be added before the fermentation. This is because yeast in "guo jiu" fermentation cannot reproduce and produce alcohol in an environment of 15–16 v%. Addition of sugar to 27% is practiced only in the production of sweet "guo jiu" so that the residual sugar stays in the "guo jiu," giving the product a sweet taste. In the production of this kind of "guo jiu," when the alcohol content reaches to the desired alcohol content, the mash is cooled immediate or is treated with sulfur dioxide to terminate the fermentation, and proceeds with the aging process. In the production of high quality "guo jiu," the sugar content is achieved by vacuum concentration of the fruit juice.

The adjustment of acidity in fruit juice is accomplished by measuring first the total acids and converting this total acidity into citric acid for most fruit juices, and tartaric acid for grape juice, then adjusting the acidity accordingly by various means. If the fruit juice is low in sugar and acidity lower than 1%, addition of sugar is good enough without adjusting the acidity. If the fruit juice has normal sugar content but slightly higher acidity, the acidity can be adjusted by neutralizing the acid with calcium carbonate. For the removal of every 0.1% acidity in 100 liters of fruit juice, addition of 78.2 g calcium carbonate is needed. If acidity is not that high, it is better to remove the acids after fermentation. In the presence of suitable amount of acids, this is beneficial for the yeast reproduction and fermentation, and at the same time, inhibits the invasion of harmful microorganisms. In addition, this will facilitate the solubilization of pigments, and have a positive effect on flavor formation. In the production of colored "guo jiu," water can be added to dilute the substrate followed by addition of sugar, because addition of calcium carbonate will change the color of the anthocyanin pigments. If acid concentration is too low, citric acid, malic acid or tartaric acid can be added according to the fruit variety to total acids of 0.5% standard.

4. Fermentation of the Fruit Juice

a. Fermentation equipment

- **Fermentation room and storage room.** Fermentation rooms should have the following criteria: room temperature maintained at about 20°C with relative humidity at 75%, good ventilation, no direct sunshine, and easy drainage. Criteria for storage rooms are similar with room temperature maintained at 10–15°C. They are usually constructed at the lower level of fermentation rooms.
- **Fermentation containers.** Tanks for main fermentation and barrels for post-fermentation storage can be made of hard wood. The fermentation tanks can also be constructed with concrete, stones, or bricks. For smaller factories, "gang," jugs, or ceramic containers can be used.
- **Fermentation systems.** Open systems are used for fermenting juice with fruit residues, and closed systems are used for fermenting juice without fruit residues.
- **Fermentation methods.** Fermentation methods can be natural, semi-natural, or artificial. In natural fermentation, the fruit juice is not sterilized and without addition of yeast, it relies on the wild yeast adhered to the fruit surface. In the semi-fermentation method, fruit juice is not sterilized but yeast is added. In the artificial method, the fruit juice is sterilized with addition of pure-cultured yeast. The oblong strains of yeast for beer fermentation and the yeast for grape juice fermentation (*Saccharomyces urarum*) are suitable yeasts for "guo jiu" production. Fruit juices can be sterilized by heat treatment or sulfur dioxide treatment. Heat treatment is pasteurization. In the sulfur dioxide sterilization, enough sulfiting agent(s) are added to the crushed fruits or fruit juice at one time. The sulfiting agent(s) can be 6% sulfurous acid, liquid sulfur dioxide, or potassium thiosulfite. Table 173.5 is a comparison of sulfiting agent(s) for various treatments.

Potassium bisulfite continues 57.5% sulfur dioxide in the solid form. When added to fruit juice, it can release sulfur dioxide. Six hours after addition of potassium bisulfite, it can achieve the sterilizing effect. At this time, 5% yeast slurry can be added. The treated fruit juice contains 100 ppm sulfur dioxide. It can inhibit 99.9% of the wild yeast, bacteria, and mold; but the tamed yeast can tolerate this amount of sulfur of dioxide. The yeast slurry can be cultivated gradually to a larger scale through four expansion stages.

- **Fermentation process and management.**
  Main fermentation. Eight to twelve hours after inoculation, yeast reproduction is very vigorous, continuously producing carbon dioxide with bubbles coming up to the surface. When main fermentation enters the intermediate

TABLE 173.5
Amount of Sulfur Dioxide Used before Fermentation (per 1,000 Liters of Fruit Juice)

Condition of Fruits	6% H_2SO_3 (Liters)	Liquid SO_2 (g)	$K_2S_2O_5$ (g)
Fruits in good clean condition, about 20°C, total acids ≥0.8%	1.1	65	12
Fruits in good clean condition, about 20°C, total acids 0.6–0.8%	1.5	90	180
Fruits in cracked, individually moldy, above 25°C, total acids ≤0.6%	4.2	250	380

stage (large bubbles not common at this stage), the containers must be sealed tightly with bolts. During main fermentation, controls of fermentation temperature and air conditioning are important steps; room temperature should be about 20°C, and product temperature is maintained at 25–28°C. The fermentation must be ventilated properly in order to introduce clean air into the fermenting mash. For smaller fermentation containers, they can be stirred or transferring to different containers to achieve the introduction of air into the mash. At the end of the intermediate stage of main fermentation, there is no need for introduction of air. Under normal situation, fermentation with residues in mash takes 8–10 days to complete the main fermentation with vigorous fermentation for 3–4 days. With residue removed, it takes 12–15 days to complete with 5–6 days of vigorous fermentation. At the end of main fermentation, sugar content is about 1%, and the concentration of the mash is close to °Brix degree. Product temperature is the same as room temperature, with minimal carbon dioxide bubbles, and no noise heard. Residue settles to the bottom of the container, and the fermenting fluid is fairly clear. The bottom of the fermentation container has large amount of yeast sediment, indicating the end of the main fermentation.

Post-fermentation. With the main fermentation completed, the fluid is transferred to different containers promptly to remove the dead yeast cells, insoluble minerals, proteins, pigments, et al. The main purpose is to allow the "guo jiu" absorb a certain amount of oxygen which is beneficial to post-fermentation; avoiding the autolysis of dead yeast cells which can create turbidity and undesirable odor in the product; and permitting part of the tannins and pigments to oxidize and sediment. When the "guo jiu" is transferred to the storage barrels, the containers should be filled as full as possible to exclude air and prevent growth of acetic bacteria, newing bacteria, and other harmful microorganisms. After the containers are bolted, they are stored at 10–15°C in the stored room to conduct the post-fermentation. This takes 20–30 days. In this post-fermentation period, room temperature and product temperature are the same, with minimal amount of carbon dioxide produced. At the end of the process, no carbon dioxide is produced; yeast cells, proteins, and tannins combined together form the sediment; insoluble pigments and micro-fruit tissue particles also settle. The liquid is clear, and the flavor is mature with increase in pleasant odor but still "spicy hot."

Clarifiction of "guo jiu." Clarity is an important indicator in "guo jiu." Therefore, clarification of the "go jiu" must be conducted through either the natural or artificial method. Natural clarification takes a long time, so artificial clarification is applied in most cases. Artificial clarification can be conducted through one of the following methods:

Filtration. Filtration applies porous materials to separate the solids from the liquid; in "guo jiu," the suspended particles are separated from the final product. Common filtration medium usually presents a cloudy phenomenum in "guo jiu;" when it is used in combination with centrifugation, a better effect can be achieved. However, if pretreatment such as coagulation and chilling are not applied, the resulting "gui jiu" even though it has been clarified, its clarity is not stable.

Clarification. Clarification by means of coagulation is a common practice in the production of "guo jiu." The principle is the addition of hydrophilic coagulant(s) such as gelatin, egg white, or marine colloid to interact with the suspended particles in "guo jiu" and precipitate out the suspended matter.

Enzymatic method. With "guo jiu" containing more pectic substances such as apple jack, citrus (i.e., orange or tangerine) "jiu," application of pectic enzymes to hydrolyze the pectic substances is very effective in clarifying the "guo jiu."

- **Formulation and aging.**

Formulation. Standard "guo jiu" is also called dry "guo jiu" containing 14% alcohol, less than 1% sugars, and 0.5% acids. Some consumers do not appreciate it. Therefore, it is common to add sugar or brandy (or purified alcohol) to formulate products containing alcohol higher than 14% and sugar content 5% or above.

Aging. Newly fermented "guo jiu" has a spicy hot sensation and the flavor is not that good. They should be filled into storage rafters and aged in low-temperature cellars to improve the flavor. The product is called aged "guo jiu." "Liquid jiu" after post-fermentation, if clarified, can be transferred into other containers. The residues has to be removed, the

liquid "jiu" filled into bottles, and corked with brandy as a liquid seal. If the "jiu" has evaporated, it is replenished as needed to avoid contamination of harmful microorganisms, and the aging process is conducted. In this aging period, "guo jiu" experiences a series of slow oxidation, esterification, and synthesis, and improves the flavor of "guo jiu." For colored "gui jiu," the insoluble pigments, tannins, et al., precipitate out during this long aging period, and give the "guo jiu" a transparent yellow or bright red color. In addition, the solubilization of compounds from the wooden rafters can also facilitate the flavor. Therefore, aged "guo jiu" has a smooth and pure taste, with rich fragrance, and attractive color. In addition, because of the binding action of alcohol with other compounds, the irritating properties have decreased considerably, and the product is smooth and has a pleasant mouth feel. The ideal environment for aging "guo jiu" is 10–15°C, relative humidity in the air is about 75%. Aging for "guo jiu" takes a longer time, at least 6 months, with some 2–3 years. This is not economical from the production standpoint. Process used to shorten this aging period is called accelerated aging. The methods can be heat-treatment (25 days at 50°C), cold treatment (0.5°C which is higher than the freezing point of "guo jiu" for 3–5 days), alternate cold and heat treatment, or microwave treatment.

Bottling and sterilization of "guo jiu." When the "guo jiu" is mature, it can be bottled, heated to 65°C in hot water for 15 minutes, sealed when it is still hot, and have the mouth covered with a plastic envelop. If the "guo jiu" has higher alcohol content, or has a reservation unit of 80 or higher, it can be preserved without changes and does not require sterilization. It can be bottled and sealed directly.

5. Examples of "Guo Jiu" Fermentation

a. Citrus "jiu"

Citrus production is large. Citrus includes mandarin oranges, tangerine, oranges and lemon. Except for lemon that is sour, all the other citrus fruits are suitable for fermentation. The edible flesh in citrus fruits is about 65%, and their chemical compositions differ because of kinds, cultivars and maturity. As the fruit juice contains too little sugar (8–10%), and too much acid (about 1%), it must be adjusted for fermentation. The bitter substances (neohesperidin and naringin) in the citrus flesh must be removed during fermentation. The aromatic compounds in citrus fruits are very complex, and include water-soluble substances such as formic acid, acetaldehyde, ethanol, acetone, and esters of olefine alcholols (enols), phenyl acetic acid, formic acid, acetic acid and capric acid. Besides, small amount of the essential oils in the citrus peels (mainly capric and caprylic aldehydes) is mixed into the juice. The fruit flesh also contains water-soluble pigments such as anthocyanins and flavones, and fat-soluble carotenoids that are oxygenated derivatives and show a yellowish color. Fruit flesh is rich in vitamin A precursor and vitamin C.

Fermentation technology. Select citrus fruits (such as mandarin orange, tangerine and orange) that are ripe, not damaged, juicy and suitable for fermentation. The peels are removed, fruit flesh are crushed but avoid crushing the seeds (as citrus seeds contain the bitter substances naringin and limonin), and juice extracted. The juice extraction rate is about 70%, modified as needed, and sterilized or not sterilized before filling the fermentation containers. Add yeast at a rate of 5% and maintain the mixture at 20–25°C. After 12 hours, fermentation starts with the vigorous period in 5 days, and completes in 15 days. The mash can then be transferred to other containers for post-fermentation at 10–15°C for about 1 month. With the completed fermentation, the "jiu" is transferred for the second time, and according to needs, add citrus brandy and sugar to adjust the contents (for dry "jiu," sugar is not added), and proceed with the aging process for 6 months or longer. The product "jiu" is clear, transparent, golden yellow, with sweet and cool taste and characteristic citric aroma.

b. Lizhi (litchi, lychee) "jiu"

Lizhi is a typical Chinese fruit with fruit aroma like sweet osmanthus, and very juicy. The sugar content is on the high side (about 12–25%), and sugar-acid ratio is also suitable for fermentation with minimal modification. It is a better common fruit for fermentation. Lizhi "jiu" is rich in aroma, smooth and has good mouth feel. It should be pointed out that lizhi season is the hot summer. Lizhi has less tannins, and the risk in fermentation is higher. Special attention is needed.

Fermentation technology. Select thick fleshed, undamaged, and ripe fruits. After removal of shell and seeds, the juice is extracted, modified accordingly, sterilized with sulfur dioxide, filled into containers, and stirred evenly. After 6 hours of still standing, add lizhi shell previously cleaned and soaked in alcohol for 30 minutes. The amount is 1% of the fruit juice to increase the tannin in the fruit juice. At the same time, seed yeast slurry of 5% is added to initiate the fermentation. After 6 hours, fermentation starts, and enters the vigorous period in 24 hours. After 3–4 days, the fermentation slows down. The lizhi shell can be dragged out, and after about 7 days, the main fermentation is completed. The "jiu" is then transferred to other containers for post-fermentation.

The chemical composition of litchi varies considerably among varieties. In general, the fruit flesh is about 72% of the fruit, the juice recovery rate is about 80%, and the alcohol production rate is about 85%. For small schedule fermentation of "lizhi jiu," temperature control is more difficult, and spoilage is fairly common. From preliminary investigation, use of high sugar concentration (33%) for fermentation, or even better use of lizhi syrup to dissolve the sugar, and inoculation with high temperature-tolerant yeast can provide successful fermentation. With post-fermentation completed, the "jiu" does not require additional adjustment. The flavor of this kind of "lizhi jiu" is better than the "jiu" produced by fermentation followed by adjustment. This method is also suitable for preliminary preservation of peak season production of lizhi. That is, enough sugar is added to the lizhi flesh at a ratio of 1 to 0.5–1, and proceeds with natural fermentation. This can maintain the flavor, and this mixture can then be used for fermentation to produce "lizhi jiu."

c. Plum "jiu"

Plum has purplish red color and is juicy, with 8% sugars, and 1.2% acids. It is also suitable for "jiu" fermentation. The fermentation method can follow the technology with residues, or follow the technology with residues removed, and the latter is better. The uniqueness of this fermentation is that the juice has more acids, and they cannot be neutralized with alkaline. To avoid color change, the options are addition of sugar to adjust the acidity, or dilution of juice to modify the composition. The "guo jiu" produced has bright red color with suitable mouth feel and characteristic light aroma, light red grape wine (Figure 173.18).

d. Longan "jiu"

Longan is also called "dragon eye," and is also one of the typical Chinese fruits. The longan "jiu" produced has a light aroma and a prospective future. The chemical composition of longan varies with cultivars. In general, the fruit has about 55% flesh, 20% shell, and 25% seed. The juice rate is about 70%, with about 15% sugars. Acids are on the low side, (usually less than 0.3%), and have slightly too much nitrogen ammonia (about 0.1%). Special attention should be paid to these characteristics.

Fermentation technology. Basically it is similar to the technology for litchi "jiu." Because the juice rate is low and has more nitrogen ammonia, warm water in the same amount of the juice is added to the residual pulp, mixed and soaked for 1 hour for the second extraction. The two extractions are combined, and adjust for sugar and acid contents. Potassium dihydrogen phosphate (0.05%) and a suitable amount of sulfur dioxide should also be added before filling the fermentation rafters. After 6 hours of still standing, yeast slurry (5%) is added. Proceed with fermentation. For each (metric) ton of longan, 650 kg of longan "jiu" can be produced.

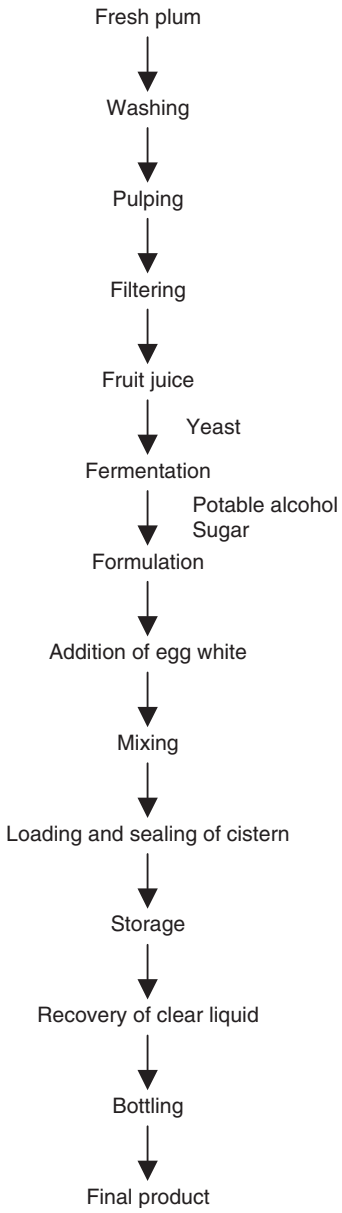

FIGURE 173.18 Generalized schematic flowchart for production of plum "jiu."

B. Chinese Grape Wines

1. Classification

There are numerous kinds of grape wines. There are four ways of classifying them:

- **Based on color.** Red grape wines are produced with grapes having pigments in their colored skins and/or flesh. They can be dark red, bright red, or ruby red. White grape wines are produced with grape juice from green or red grapes. Their colors can be either light yellow or golden yellow.

- **Based on sugar content.** According to the requirements established at the International Grape Wine Conference in Madrid, Spain in 1973, they can be categorized into:
  - sweet grape wine (sugar content higher than 5%);
  - semi-sweet wine (sugar content between 1.2–5.0%);
  - dry grape wine (sugar content less than 0.4%); and
  - semi-dry grape wine (sugar content between 0.4–1.2%).
- **Based on fermentation method.** Based on the fermentation methods, grape wines can be naturally fermented or enhanced. For natural fermented grape wines, they are produced using grape juice only without the addition of alcohol (brandy) or sugar. The enhanced fermentation utilizes addition of alcohol (or brandy) to increase the alcohol content (enhanced dry grape wine), or addition of alcohol and sugar to increase both the alcohol and sugar contents (enhanced sweet grape wine).
- **Based on the carbon dioxide content.** Based on the carbon dioxide content, grape wines can be categorized into still wines without any carbon dioxide or sparkling wines containing carbon dioxide. The latter is again divided into naturally sparkling (like the French champagne) or artificially adding carbon dioxide (generally called sparkling wine).

2. Fermentation of Red Grape Wine

Production of red grape wine can follow the technology on wine with residues. Its technology includes the following major steps:

- **Crushing and removal of stem.** Select good quality red grapes for the fermentation. Use a pulper to crush the grapes and remove the stems. The pulp is checked for sugars and acids, and adjusted accordingly, followed by addition of sulfur dioxide. The adjusted pulp is filled into fermentation tanks or barrels, about three-fourths deep to avoid overflow of the skins in the mash due to production of carbon dioxide.
- **Main fermentation.** Six hours after the filling the fermentation tanks, a 5–10% cultured yeast slurry is added, and sealed with bolts. Fermentation temperature is controlled at 20–25°C. If temperature rises above 33°C, cooling to lower the temperature is initiated. The fermenting mash is stirred regularly, and periodically checked for temperature, sugar and alcohol contents. Main fermentation usually takes 5–6 days at 25°C, 10–15 days at 20°C, with residual sugar of about 1%.
- **Post-fermentation.** After the main fermentation, the liquid "jiu' is immediately transferred to the fermentation rafters with proper bolting to conduct the post-fermentation. Post-fermentation is weak, and should be conducted at about 20°C. After 15–20 days, there should not be any more carbon dioxide released, and the sugar content is lowered to 0.1%. The post-fermentation is then completed.
- **Aging.** Three to five days after the post-fermentation, the residues in the fermenting mash should be removed by transferring fermentation rafters or barrels. During the transfer, the "jiu" is in contact with air. This allows the dissolved carbon dioxide to escape. After the removal of residue, the containers are again bolted to proceed with the aging process at temperature controlled between 10–15°C. The second transfer of fermentation containers should be conducted 1.5–2 months after post-fermentation, usually in early winter. At this point, the newly fermented "jiu" is basically clear and transparent. After this stage, the "jiu" is transferred to another container at the end of spring and early winter each year. The production rate of red grape wine from completely sound grapes is 80 kg per 100 kg of grapes: 70 kg from the original fluid "jiu," and 10 kg from pressing the residues.

3. Fermentation of White Grape Wines

Green grapes or red grapes with white flesh can be used for fermenting white grape wines. The fermentation technology usually follows that for fermentation with residues. Management of the fermentation is basically similar to red grape wine, but more precise. The technology is as follows:

- **Crushing, sprinkling with juice and pressing.** The grapes are crushed with a crusher, but the stems are not removed. Sprinkling with juice is generally conducted in a rotary sprinkler, the juice recovered is generally slightly cloudy with recovery rate of 50–55%. Pressing is usually conducted with a continuous presser.
- **Sulfiting, addition of tannins, and inoculation with yeast.** Grape juice recovered through the sprinkler and presser are combined for fermentation. Because green grape juice is deficient in tannins, when it is used for fermentation, 4–5 g of tannins per 100 liters of juice is added followed by immediate sulfiting, the sulfiting amount varies with the kinds of

juice available. If the juice is clearer, 25–30 g of sulfur dioxide per 100 liters of juice is needed and the treated juice is transferred to the fermentation tanks. Six hours after, 5% yeast slurry is added. For cloudy juice, it has to be clarified in a clarifying tank once before usage. For 100 liters of juice, 40–50 g sulfur dioxide is added and let stand for 24–48 hours of clarification. The cleared liquid is then transferred to the fermentation tanks with 8–10% yeast slurry added to proceed with the fermentation.

- **Main fermentation.** Fermentation is conducted in a closed system. Main fermentation starts 12–24 hours after the tanks are filled. Fermentation temperature is lower than that for red grape wine, at 18–20°C. Low temperature fermentation results with a product lighter in color with strong aroma. The main fermentation takes 10–15 days. With the peak fermentation (about 4–5 days after loading the tanks) passed, the container are bolted. When the fermenting mash shows a specific gravity of 1.005 to 1.006, the fermentation almost stops. The newly fermented liquid is transferred to another fermentation tank with removal of the sediment. The residue can be used for distillation of brandy.
- **Post-fermentation and aging.** The white grape wine transferred to the new tanks still has small amount of sugar, about 2–3%. The fermentation is continued until the specific gravity is dropped to 0.992–0.996 with a dry white grape wine essentially free of sugar. Post-fermentation takes about 20–30 days to complete. Its indicator, besides specific gravity, is its clarity. At this time, the white grape juice is transferred to another tank until full, and bolted to proceed with the aging process. When the weather is coldest, the "jiu" is transferred to another fermentation tank. Thereafter, the "jiu' is transferred to different tanks twice each year. The residues left from the old tanks and the turbid "jiu" can be used for distillation of brandy.

4. Fermentation of Sweet Grape Wines

In the fermentation of sweet red and white grape wines, the initial procedures are the same as that for dry red and white grape wines. When they are fermented to the required sugar contents, brandy or potable alcohol is added to increase the alcohol content to 16% or higher, and stop the fermentation. If the sugar content is not high enough, concentrated grape juice is added to adjust accordingly. For products with requirements that are not that specific, sugar or inverted sugar can also be used for adjustment.

One month after fermentation, the "jiu" is transferred to another fermentation tank for aging. The "jiu" is transferred again to a new tank at the end of spring next year. If the "jiu" is not clear, it can be clarified by a coagulation process with appropriate coagulant, and the aging process is then continued. Even though artificial accelerated aging is generally not used in dry grape wines, the alternate heat and cool process is used commonly in the aging of sweet grape wines to significantly increase the quality.

5. Famous Chinese Grape Wines

There are many grape wines nationally recognized in China and some received international awards. These are

- Yantai red grape wine: sweet, alcohol content 16 v%, acidity 0.7%, and sugar content 12%.
- Qingdao white grape wine: sweet, alcohol content 13 v%, and sugar content 12%.
- Beijing Chinese red grape wine: sweet, alcohol content 16 v%, and sugar content 12%.
- Minquan white grape wine: sweet, alcohol content 12 v%, sugar content 10%, total acidity 0.6%.
- Tianjing Wangchao white grape wine: semidry and semisweet, alcohol content 12 v%, sugar content 0.5–1.2%.
- Shacheng white grape wine: dry, alcohol content 12 v%, sugar content less than 0.4%.

C. Quality of "Guo Jiu"

1. Sensory Quality Standards of Grape Wines and "Guo Jiu"

- Appearance: clear, transparent, no sediment and suspended matter, no loss of luster.
- Color: bright, balanced, lustrous, no loss or change of color.
- Aroma: possess the original fruit's aroma, soft and balanced, long-lasting rich aroma, absence of objectional odor, typical characteristics.
- Taste: pure, completely balanced, smooth, clean, long-lasting, no objectional taste, typical characteristics.
- Characteristics: typical for the product.

The above standards are suggested for grape wines and "guo jiu." When all the criteria are met, the product is considered as having a full score.

2. Sanitary Standards of Grape Wines and "Guo Jiu"

Both grape wines and "guo jiu" are fermented products, their processes should meet the GB2758-81 Fermented "jiu" sanitary standards.

V. FORMULATED "JIU"

Formulated "jiu" includes essence "jiu," flavored "jiu," and Chinese herbal "jiu" or wines. Essence "jiu" is again subdivided into "fruit essence jiu" and "flower essence jiu." The former is produced by adding fruit juice and other ingredients to alcohol or "bai jiu;" the latter is produced by soaking flowers in alcohol or "bai jiu," or distillating flowers with alcohol or "bai jiu" and formulated.

A. Treatments of the Various Raw Materials

1. Alcohol and "Bai Jiu"

In the common alcohol, there are fixed amounts of methanol, fusel oils, aldehydes, and ketones forming undesirable odor and taste. They should be removed completely or reduced. Industrial ethanol must be purified to the potable level before use. Generally, the crude alcohol is treated with 0.01–0.05% potassium permanganate (predissolved in 10% solution), added slowly into the alcohol, and stirred thoroughly. The mixture is let stand overnight; 0.08–0.09% sodium hydroxide is then added before distillation. The beginning and ending distillates should be discarded, with beginning distillate being 7% of total alcohol, and ending distillate 8% of total alcohol. The middle section is retained for use in formulation. For a further purification, the alcohol collected can be treated by activated carbon to remove odor at a range of 100–200 g per 100 liters and left standing 36 hours before filtering. The so-treated alcohol must meet the GB 394-81 National Standard for Potable Alcohol. (Table 173.6)

Good quality "bai jiu" (especially brandy) does not require purification. Common "bai jiu" particularly those made from root crops and mollasses have to be purified. The method is the same as that for potable alcohol. However, because the alcohol content is lower (about 60 v%), the amounts of potassium permanganate and sodium hydroxide used should be less, about two-thirds.

2. Fruit Juice

Fresh fruits are washed, drip-dried, crushed and pressed to make the fruit juice. The fruits can also be cut into small pieces and soaked in water or "jiu," and then filtered. For dried fruits, they generally are cut into pieces, and soaked to extract the essence. The fresh or dried fruit pieces should not be too small to avoid cloudy infusion liquid. Fruit juices or extracts should be clarified before use.

3. Natural Spices

Rose flowers, clove, and mandarin orange or tangerine peels, et al. can be extracted with alcohol and distilled, or cooked in water to tender to form liquid essence.

4. Sugar and Organic Acids

Sugars and organic acids can be dissolved in water or alcohol to form solutions, or added directly. If the fruit juice has too much acids, avoid the use of neutralization, and use dilution method in the formulation.

5. Water

Distilled water or potable water that has been boiled and cooled.

6. Color(s)

Caramel or other colorings can be dissolved in small amount of alcohol to form a solution, and added accordingly.

TABLE 173.6
Standards for Potable Alcohol (Molecular Formula C_2H_5OH, M. W. 46.07) in China, GB 394-81

	Class		
Name of Index	Excellent	1st Class	2nd Class
Appearance	Transparent	Transparent	Transparent
Color, number	≤10	≤10	≤10
Odor	Absence of objectional odor	Absence of objectional odor	Absence of objectional odor
Alcohol, (%, v/v)	≥96.0	≥95.5	≥95
Sulfuric acid, number	≤10	≤15	≤100
Oxidation test, points	≥30	≥25	≥15
Aldehydes, % as acetaldehyde	≤0.0004	≤0.0010	≤0.0030
Fusel oils, % as isoamyl alcohol, isobutanol	≤0.0004	≤0.0025	≤0.010
Methanol, %	≤0.06	≤0.12	≤0.16
Acids, % as acetic acid	≤0.0015	≤0.0015	≤0.002
Esters, %, as ethyl acetyl ester	≤0.0025	≤0.0038	None
Nonvolatile matters, %	≤0.0020	≤0.0020	≤0.0025

Note: % = g/100 ml, except alcohol.

B. Formulation Methods

In the formulation of "fruit essence jiu" it is important to do preliminary formulation and sensory evaluation to determine the ratios of various ingredients and essence solution. After all the ingredients are mixed together to form a concentrate, it is left 1–2 days before filtration. Lastly, the pigment and essence solutions are added.

C. Examples of Production of "Fruit Essence Jiu"

1. "Lizhi (Litchi, Lychee) Essence Jiu"

- **Formula.** Lizhi juice 100 liters, and 90 v% alcohol 22 liter.
- **Procedure.** Select ripe lizhi fruits, remove the shell, and extract the juice. Twelve grams of sulfur dioxide per 100 kg fruit flesh can be added to prevent spoilage. For 100 liters of fruit juice, add 22 liters of alcohol. Mix thoroughly, store in sealed containers for two months, filter and pasteurize before bottling and capping.

Essence "jiu" of loquat, pineapple, mango, et al. can be produced the same way. If the juice is not sweet enough, sugar can be added accordingly. The "lizhi essence jiu" from Zhangzhou City, Fujian is of supreme quality.

2. "Logan Essence Jiu"

- **Formula.** Logan fruit flesh 500 g, "bai jiu" 1 kg.
- **Procedure.** After removing the shells and seeds, 500 g of the flesh is soaked in 1 kg of quality "bai jiu" in sealed containers. Recover the clear liquid after 15 days. The flavor is even better if aged. This "jiu" is known in Traditional Chinese Medicine as beneficial to the heart and spleen. It can calm oneself and cure insomnia, besides other claims.

3. "Loquat Essence Jiu"

- **Formula.** Loquat 350 g, vanilla beans 2 g, lemon peels half of a fruit, sugar 250 g, potable alcohol 300 g.
- **Procedure.** Put the loquat fruits and sugar in hot water (enough to cover), mash, and add the vanilla beans. When the mixture is cooled, pour into glass jugs, add alcohol and shredded lemon peels, and seal the containers. Share the containers regularly. After one month, pour the liquid into dark-colored bottles, seal and store for another 4 months. This "loquat essence jiu" helps digestion, sooths the throat and stops the coughing. Alcohol content is 40 v%. It is a good after-meal liqueur.

4. Green Plum "Jiu"

- **Formula.** Potable alcohol (65 v%), 27.75 liters, green plum essence 27.5 liter, 2.4 g, citric acid 15 g, glycerol 300 g, sugar 16 kg, a green pigment, distilled water enough to make up 100 liters.
- **Procedure.** The green plum essence is produced using the following procedure. Green plum or dried green plum 17.65 kg in a cloth bag together with 100 liters of 65 v% alcohol are put in a kettle-type distiller for reflex of 1.5 hours. The distillate of 50 v% is the "green plum essence." Distillate below 50 v% is stored for another distillation. After mixing 27.75 liters of potable alcohol and the "green plum essence," sugar is added followed by water to make syrup. Glycerol and pigment are then added. Enough distilled water is added to make 100 liters. After thorough mixing, it can be stored for 3 months, filtered and bottled.

5. Strawberry "Jiu"

- **Formula.** Strawberries 100 kg, potable alcohol, 60 kg, sucrose 6 kg, citric acid appropriate amount, and water.
- **Procedure.** Sound strawberry fruits that are bright red, ripe, with proper sweetness and sourness are used. Cultivars such as Shanghai, Yantai Jiguan (cock comb red), Baojiao Early Cultivar, et al., are suitable cultivars in China. The alcohol should be the residual distillate recovered from the production of "huang jiu" – "jiu han (sweat)." Its characteristic is its pure taste.

  Fresh fruits should be processed immediately to preserve its color and flavor. Strawberries, the "jiu han" and sugar are mixed with a ratio of 10:6:0.6. The alcohol content after pressure filtration should be controlled at about 20 v%. The filtered strawbery "jiu" is stored for a definite time to achieve the aging effect. The main components in the "jiu" such as alcohol, sugar, and acid must be prepared at the proper ratio. Except for addition of citric acid to adjust the acid concentration, other additions are not permitted to highlight the strawberry flavor, and natural color. Brown bottles should be used to prevent the color-fading effect of sunshine and strong light.

  This strawberry "jiu" has a light brown color, clear and transparent. Its has a strong strawberry aroma and also the pleasant "jiu" aroma. The taste is pure and soft, with proper sugar-acid ratio, pleasant mouth feel, and is absent from undesirable odor. The product has 16.5–17 v% alcohol, 8–8.5% sugars, and 0.45–0.50% total acidity.

D. Examples of "Flower Essence Jiu"

"Flower essence jiu" utilizes alcohol or "bai jiu" as the base; the flowers from various plants are soaked or distilled. The "flower essence jiu" is made after proper formulation. The various treatments to produce "flower essence jiu" are basically similar to "fruit essence jiu." The difference is that either fresh flowers or dried flowers are used as the aromatic materials.

1. "Meiguilu (Rose Essence Jiu)"

Rose flowers have been claimed to reduce heart pain, hyperchlolesterolemia, and chest pain, et al. Drinking of rose flower tea is said to help the complexion, strength the body, and stop diarrhea. "Meiguilu'' is a combination of the rose aroma and the "jiu" aroma, giving a product rich in rose aroma and long-lasting, and slightly sweet.

a. Production technology

- **Flower selection and picking.** There is a wide variation of color, size, and aroma in roses due to cultivar differences. In order to better guarantee the unique "Meiguilu" flavor, only cultivars with main pedals plump and red are used. The flowers are harvested in May, the peak flowering season, and processed. The flowers are harvested early in the morning when the morning fog has not disappeared, the flowers are just beginning to open and full of dews. These flowers have the richest aroma because the sun has not shone on them and evaporated their aroma.
- **Soaking of flowers.** Harvested flowers are sealed in containers and shipped back to the factory for processing. The flowers are spread in a cool, shaded area with good ventilation to lower the temperature and prevent the petals from getting soft and separating from the stem. The flowers are then mixed with "jiu" at a fixed ratio, mixed thoroughly and packed tightly in the porcelain storage containers and sealed with a plastic wrap, excluding air and preventing decay to occur. After several months of soaking, the "flower jiu" is transferred to smaller jugs and then sealed. They are stored for the next year's use.
- **Preparation of the original aroma source.** Distillation is conducted in a copper distiller. The completely "jiu"-soaked rose flowers are loaded into the distiller, heated slowly to boiling to completely extract the rose aromatic compounds. It is even better if the beginning and ending distillates are removed, with distillate maintained at 62 v% or above. The product will have a delicate, conservatively soft aroma with minimal undesirable odor.
- **Selection of basal alcohol.** It is very important to select the proper basal "jui" with quality so that the delicate rose flavor can be detected easily. It is better to use deodorized high quality potable alcohol or "bai jiu" made from cereals with clean aroma as the basal "jiu." "Jiu" with rich aroma or soy-paste aroma are not suitable because the delicate rose aroma can easily be covered by the rich cellar or soy-paste aroma, and not show off the typical rose aroma.
- **Formulation of various components.** Before formulation, calculations should be conducted based on the physiochemical indicators of the various components. Then follow the proper sequence of combining the various components together to formulate the final product. This proper sequence of combination is important as a different sequence can affect the physicochemical indices of the final product, especially the mouth feel and appearance.
- **Formulation procedures.** The basal "jiu" is pumped into the mixing chamber, then add the rose distillate and mix thoroughly. The sugar is dissolved in water in a double-jacketed steam kettle, cooked to boiling to form a 65% syrup. After filtering out the impurities, it is pumped to the mixing chamber to mix with the basal rose "jiu" with continuous stirring. Citric acid is formulated to a 50% solution with additional heating, and then added to the mixture. Distilled water is then added to make up the volume.
- **Storage and aging.** The various components in the newly formulated "Meiguilu" is not completed synchronized, with alcohol and undesirable odor. In order to give the "Meiguilu" a delicate aroma with smooth taste, it should be sealed and stored. Impurities in newly formulated "Meiguilu" will sediment in 7 days; and after three months of aging, the quality is stabilized.
- **Filtration.** When the storage period is completed, the "Meiguilu" is filtered through diatomaceous earth to clarify the product. The product should not be stored for a long time to prevent the contact with oxygen and oxidized to form extensive aged sensation. This is because the main aromatic components in rose aroma are the terpinenes. They can interact with the alcohols, aldehydes, acetones and form derivatives that are easily oxidized, and thus affect the aroma and taste of the product.

b. Quality standards

The final product should be a clear transparent liquid with pleasant rose aroma. The flower aroma and "jiu" aroma are synchronized. It should be slightly sweet with long-lasting aroma. Its physicochemical indicators are: alcohol $\geq 18 \pm 1\%$ or higher, total sugar $\leq 8 \pm 1$ g/100 ml, total acids (calculated as citric acid) ≤ 0.4 g/100 ml. The sanitary standard should meet the GB2758-81 standard of PRC.

2. "Yulan Xianglu (Magnolia Aroma) Jiu"

- **Formula.** Air dried magnola flower petals 100 g (fresh petal should be double), "gaoliang (sorghum) jiu" 5 kg, rock sugar small amount, glycerol small amount.
- **Procedure.** The magnolia petals are soaked in the basal "gaoliang jiu" overnight, and scooped out. They are steamed to extract the aroma by collecting the distillate. The rock sugar and glycerol are then added to taste. This intermediate product is sealed in containers for a few months to age. The final product has alcohol 41 v%, and sugar 3%. The color is light yellow, clear and transparent, slightly sweet, and has magnolia aroma and "jiu" aroma with a balanced soft aroma.

3. "Juhua (Chrysanthemum) Jiu"

- **Formula.** Chrysanthemum 80 g, sugar 40 g, "bai jiu" 650 g, honey small amount.
- **Procedure.** The chrysanthemum flowers are cleaned, drip-dried before putting into a container. Sugar, honey and "bai jiu" are added. The container is sealed and left in a cool and shady area. After three months, filter through cheesecloth, and store the filtrate for 15 days. This product has typical chrysanthemum's light aroma, and the taste is rich and slightly sweet. It is claimed that this "jiu" has certain curing effect for headache and dizziness, and is good for the eyes and stomach, improve appetite and relieve fatique.

4. "Guihua (Sweet Osmanthus) Jiu"

- **Formula.** Sweet osmanthus flowers 16 kg, 65 v% alcohol 330–350 kg, sugar 150 kg, citric acid 3 kg, glycerol 2 kg, distilled water enough to make up 1,000 liters.
- **Procedure.** Remove foreign matters from collected sweet osmanthus flowers. Add 32 kg 65 v% alcohol to the flowers, soak and seal the container for 7 days, filter, and soak the residue again with 20 kg alcohol for one day, then filter. Combine the two filtrates. The sugar is dissolved to make a 86 °Brix syrup. The citric acid is dissolved in 60°C hot water and is added together with the glycerol to the flower infusion. Mix thoroughly. Add the rest of the alcohol, filter and make up to 1,000 liters with distilled water. Store for three months. Filter again before bottling.

5. "Guihua (Sweet Osmanthus) Chen (Aged) Jiu"

- **Formula.** Good quality white grape wine 100 kg, sweet osmanthus flowers appropriate amount.
- **Procedure.** Aged "guihua jiu" utilizes aged white grape wine as the basal "jiu" with sweet osmanthus flowers as the flavoring. The sweet osmanthus flowers are of the common "jingui (golden sweet osmanthus)" cultivar from the Suzhou and Hanzhou areas, China. The fresh budding flowers are collected during the flowering season in November. The collected flowers after processing (rinsing and removal of foreign matters) are soaked in the aged white grape wine. With careful formulation fully balancing the aroma and taste to meet the established standard, the product has the required characteristics. The characteristics of this "Guihua chen jiu" are as follows: golden yellow, crystal clear, transparent, balanced fresh sweet osmanthus aroma and the rich aroma of white grape wine, slightly sweet and slightly sour, pleasant and aromatic to mouth feel with long-lasting aromatic taste. The product shows the unique sweet osmanthus aroma, with 15 v%, sugar 14%, and total acids 0.65 g/100 mg. This product contains glucose, fructose, organic acids, and various vitamins. The product is claimed to activate the blood circulation system, smooth muscles, increases calories, help digestion, increase appetite, and relief of fatique. It is a product that does not contain any medicinal herbs, but is a nutritious drink.

E. "Jiawei (Flavor-added) Jiu"

"Gawei jiu" utilizes alcohol, "bai jiu," and fruit wine as the basal "jiu" with the addition of Chinese herbs or seeds (dry nuts) as the aromatic material(s), and soaking of the aromatic materials to produce. It is one of the formulated "jiu." The treatment of the raw materials are basically similar to the fruit essence "jiu." These aromatic components give the products different flavor and claimed medical effects. They are unique.

1. Yantai Weimeisi (Vermouth) Jiu"

"Yantai Weimeisi jiu" is produced by the Zhangyu Grape Wine Company in Yantai, Shandong Province, China. In the early 20th century, it was called "Qiongyaojiang." It won the Golden Medal Award in the World Expo in Panama, in 1915. The name was later changed to "Weimeisi (vermouth)." It has been known as a famous "jiu" in China for a long time. Since 1952, it was named as a "National Famous Jiu" many times in the "Jiu" Evaluation Conferences. Besides its national first–class quality, its characteristics are also recognized worldwide as a Chinese vermouth, and enjoys an international reputation.

Chinese "Weimeisi jiu" utilizes superior grape cultivars such as "Longan," "Baiya," "Guirenxiang," "General Li," "Baiyu" to extract the juices for the production of grape wine. This grape wine is the basal "jiu," has to be stored for two years before formulated with valuable Chinese herb extracts such as "honghua (Carthamus tinctorius L.)," "doukou (Amomum cardamomum L. or Alpinia katsumadai Hayata)," cinnamon, clove, "dahuang (Rhei Rhizoma, Rheum palmatum L., R. tanguticum Maxim. Ex Reg., or R. officinale Baill)," "baichi (Angelicae Radix, Angelica dahurica Benth et Hook, A. anomala Lallem, or A. taiwaniana Boiss)," "longdanchao (Gentianae Radix, Gentiana scabra Bunge, G. triflora, or G. manshurica Kitag.)," chrysanthemum, et al. The extracts are prepared individually by soaking and extraction to ensure the high-quality flavor, and the continuity of the product.

"Yantai Weimeisi jiu" is dark brown in color, clear, transparent, lustrous, has a balanced aroma from plants, "jiu," and fruits, and the taste is sweet, slightly sour, and slightly bitter that are balanced and unique. The alcohol is 18 v%, with sugar 15%. This "jiu" is claimed to be appetizing, strengthens the digestive system, drives off the "wind" (Traditional Chinese Medicine terminology) and the cold, relaxes the tendons, activates the blood circulation system, and strengthens the blood and "qi (vital energy)." It is promoted as a healthy drink, and good for longevity.

2. "Zhuyeqing (Green Bamboo Leaf) Jiu"

"Zhuyeqing jiu" is one of the famous "jiu" produced in the Fen Jiu Factory, Xinghua Village, Fenyang County, Shanxi Province, China. It is an old and common "jiu" in China. It is also produced in many provinces and cities in China. It was also mentioned frequently in old Chinese literature. However, the one produced in Fen Jiu Factory of Shanxi Province enjoyed the best reputation from the old days, like the "Fen jiu." Since 1962, it has continuously won the Golden Award at the National "Jiu" Evaluation Conference, and is one of the famous "jiu" titles in China.

Before the Tang and Song Dynasties, "Zhuyeqing jiu" was produced in various places in China using "huangjiu" as the basal "jiu." The "Zhuyeqing jiu" produced in Xinghua Village, Shanxi Province utilizes its "Fen jiu" as the basal "jiu." Fresh bamboo leaves from southern China are chosen, with the addition of Chinese herbs: mandarin orange peels, male clove flowers, "muxiang (Saussurea lappa Clarke)," "tanxiang (sandal wood, Santalum album L.)," "linglingxiang" (basil, Ocimum basilicum), "zhizi (Gardenia jasminoides Ellis), "shannai (Kaempferia galanga Linn.), "danggui [Angelica sinensis (Oliv.) Diels.]," and "sharen (Amomum villosum Lour., A. longiligulare T. L., or A. xanthiodes Wall), and rock sugar. They are soaked together in the "fen jiu," and processed scientifically.

This "jiu" can be consumed independently, or as a health tonic to improve body function. "Zhuyeqing jiu" is light yellow with a green shade, clear, transparent and lustrous. It has unique aroma and "jiu" aroma, comfortable and balanced. Its taste is softly sweet, and long-lasting. It is said to be exceptional in color, aroma and taste. It has alcohol 45 v%, and sugar 10%. This "jiu" is claimed to balance the body organs, remove obstruction in "qi," support the blood system, calm the heat, reduce inflammation, detoxify, be diuretic, nourish the liver, and strengthen the digestive system. It is also claimed to be beneficial to cardiovascular disease, hypertension, and arthritis.

3. "Yuanlinqing Jiu"

"Yuanlinqing" is a product produced by the Yuanlinqing Jiu Factory, Qianjiang City, Hubei Province. It is another national famous "jiu." "Yuanlinqing jiu" utilizes sorghum as the raw material to produce a quality, lightly aromatic "Kongming daqu jiu" as the basal "jiu." Precious Chinese herbs such as "tanxiang" (sandal wood, Santalum album L.), clove, "sharen" (Amomum villosum Lour., A. longiligulare T. L., or A. xanthiodes Wall), "danggui" [Angelica sinensis (Oliv.) Diels.]," "zhizi" (Gardenia jasminoides Ellis), and other herbs, together with sugar are used to formulate this "jiu." This "jiu" combines "jiu," herbs, and sugar into one liquid, and at the same time combining the color, aroma, and taste together. Consuming it before meals can increase appetite, and consuming it after meals can increase the digestion. It is claimed that long-term consumption at suitable quantities can nourish the liver and lung, strengthen the digestive system and the body, supplement the "qi" and vitalize the blood. "Yuanlinqing jiu" has golden yellow color with a shade of green. It is clear and transparent. Its taste is a balance of the herb aroma and the "jiu" aroma; delicate, richly sweet and long-lasting, smooth and clear to the mouth, and overall long-lasting taste after consumption. It has 39 v% alcohol.

4. "Yinxing (Gingko Nut) Jiu"

- **Formulation.** Gingko nut (shell removed), 15 kg, "Hancai" (Rorippa montan) 22.5 kg.
- **Procedure.** Soak the crushed gingko nut in 65% alcohol for 24 hours, and then drip off the infusion at a rate of 5 ml per kg per minute. The ethanol is recovered for later use. The "Hancai" is cooked in water twice for 2 hours each time. The liquid is combined, filtered and concentrated to a ratio of 1:2. After cooling, alcohol is added, mixed thoroughly, rested for 24 hours and the clear liquid at the top is filtered out. Alcohol is recovered from the filtrate for later use. The filtrate is combined with the gingko nut infusion, mixed thoroughly and let stand for 3 days to precipitate the residues before filtration. The filtrate is saved for later use. Ten kg sugar is dissolved to form a syrup. Together with a suitable amount of menthol, almond essence oil, preservative and alcohol are added to the filtrate. Add hot water to a volume of 31,500 ml. The product has a specific gravity of 1.15–1.18. This product is claimed to suppress coughing, dissolve phlegm, and stop asthma. It is used in acute or chronic bronchitis, inefficient removal of phlegm, and long-lasting coughing and asthma in Traditional Chinese Medicine.

F. Chinese Herbal Wines

Chinese herbal wines have a very long history. It was mentioned in one of the oldest classics in Traditional Chinese Medicine, "The Neijing Suwan," as a solvent for medications. In Traditional Chinese Medicine, alcohol was believed to improve blood circulation, enhance the effect of medications, warm the intestine and stomach, and overcome the "wind" and "coldness." Thus, herbal wines have been viewed as important remedies by Traditional Chinese Medicine practitioners, and also enjoyed by consumers. The formulations for herbal wines are included in the many Traditional Chinese Medicine literatures, or handed down as folklore. It is not the intention of this chapter to have an extensive coverage of Chinese herbal wines, and readers should refer to references in this area for further information. However, a brief introduction of the topic with a few common examples is described below.

Chinese herbal wines can be viewed as a subcategory of formulated wines, as their preparations are very similar. The active compounds in the herbs are extracted by soaking them in the basal wine. The tincture is then recovered accordingly by filtering out the liquid and discarding the solid herbs. Sometimes, the herbs are extracted for a second time to extract the residual active components. The basal wine can be the "bai jiu" (distilled spirits), "huang (yellow) jiu" (rice wines), or fruit wines. The herbs used vary extensively among the various herbal wines, from one herb to ten or more herbs (see below) depending on the usage or effect expected. They can be tonics, remedial, or just for pleasure in nature. However, it is important to understand the nature of the formulations and match the herbal wines with the consumers' body chemistry, as the wrong match can have the negative effect, and may be harmful.

Chinese herbal wines can be sub-divided into different groups based on their intended usage, such as those used in internal medicine, and for treatment of obstetrics-gynecology, dermatitis, tumors, orthodonics, artheritis, various organs, OB, and tonics. The herbs selected are similar to those commonly used in Traditional Chinese Medicine formulations. Readers interested in this topic should consult The English-Chinese Encyclopeida of Practical Traditional Chinese Medicine, Vol. 9 Maintaining Your Health edited by Xu Xiangcai et al. (1991), and other references on Chinese Herb Formulations available elsewhere.

Several Chinese herbal tonic wines have been produced commercially for decades, such as the "Wujiapei Jiu (or Wu Chia Pi Chiew)," "Ginseng Wine," and the "Shiquangdaibu Jiu (Or, Sze Chuan Dah Poo Chiew, Ten complete herbs big tonic)." "Wujiapei Jiu" contains the herb "Wujiapei" (Acanthopanax bark, Acanthopanacis Cortex, Acanthopanax senticosus, A. gracilistylus, or A. giradii); Ginseng Jiu contains the herb ginseng; and the Shiquangdaibu Jiu contains ten herbs: Radix Ginseng (ren shen), Rhizoma Atractylodis Macrocephalae (bai zhu), Sclerotium Poriae Cocos (fu ling), Honey-fried Radix Glycerrhizae Uralensis (zhi gan cao), Radix Rhemanniae Glutinosae Conquitae (shu di huang), Radix Paeoniae Lactiflorae (bai shao), Radix Angelicae Sinensis (dang gui), Radix Ligustici Chuengxiong (chuan xiong), Cortex Cinnamomi Cassiae (rou gui), Radix Astragali Membranacei (huang qi).

Others are produced as needed according to the practitioner's guidance for special treatments. These are usually not produced commercially as the formulation is designed for individual patient's condition, even though some formulations have been available in the literature. Some consumers also produce their own herbal wines for their own consumption.

VI. "JIU" FROM THE MINORITY GROUPS IN CHINA

China is a multi-racial country with over 50 ethnic groups, and each ethnic group has its own customs and a long history of "jiu" culture. For example, in Mongolia, it is customary to have the whole family sitting in their tents at the end of the year and drink through the night with "manai-jiu (koumiss)" being their favorite. In Tibet, before their New Year, it is customary for every family to brew the

"qingkejiu (jiu made from a kind of wheat in Tibet, *Avena nuda* L.)." This "qingkejiu" is slightly yellow in color, sweet and sour, and the alcohol content is not high, like the "huang jiu," and is called by their foreign guests the "Tibetan beer." The other minority groups also have their own customs and "jiu" in their culture. In general, every minority ethnic group loves to make and consume "jiu." After all these centuries, there are considerable valuable experiences in their fermentation technology with abundant contents. However, the knowledge is only known at the layman's level, and lacks a systematic organization. Some of the products are not commercialized but only made at the household level for consumption. The following are some better known examples.

A. "Ru Jiu (Milk Wine, Kefir)" and "Marujiu (Mare's Milk Wine, Komuiss)" of the Mongolian Ethnic Group

"Ru (milk) jiu" is a group of fermented, alcoholic liquid milks. It has its unique position between fermented milks and alcoholic beverages. The common examples are "kefir" in the Mongolian Self-governing District and "koumiss" in the Xinjiang Weiwuer Self-governing District in China. These alcoholic fermented milks contain small amounts of alcohol, and can facilitate metabolism, and adjust the circulation and nerve systems. They have special physiological functions. In the rehabilitation hospitals of the former Soviet Union, these alcoholic fermented milks are used extensively in the treatment of gastrointestinal diseases, diabetes, hypertension, and cardiovascular diseases. In the Xilinhaote City of Inner Mongolia, there were also factories specially built for the industrial production of alcoholic fermented milks to meet the rehabilitation, dietary therapy and tourism industries.

In fact, kefir is a general name for "ru jiu" (milk wines), it can be made either from cow's, goat's or mare's milk; with the addition of kefir grains, the kefir grains will conduct a special fermentation to form the alcoholic fermented milk. Kefir originates in Europe, and has a long history. In Japan, commercial production of kefir has already been achieved. Initially, the alcohol content in kefir reached 1.2%; however, with the modern technology, the alcohol content can be reduced to 0.01–0.05%. In China, there is no commercial production of kefir, and most of the kefir is produced by the herbsman, and is consumed as they are produced. It is basically a homemade drink. Therefore, with inheritance of the ancestor's valuable experience, the development and utilization of kefir has a prospective market in the future. The modern production of kefir is as follows:

1. Microorganisms in the Kefir Grains

Kefir is produced through the fermentation of kefir grains. The key is in the kefir grains. There are many kinds of microorganisms in kefir grains with the presence of the following microorganisms being known: lactostreptococcus, lactobacillus, yeast, leuconostoc bacteria, and acetic acid bacteria. There exists a very complex relationship among these microorganisms. Under the condition of digesting the peptone with the formation of vitamins, the yeast and the acetic acid bacteria activate the lactic acid bacteria; and only under the presence of lactic acid bacteria, the non-lactose dependent fermentative yeast and acetic acid bacteria can grow. With the large amount of lactic acid accumulated, it provides a favorable environment for the yeast and acetic acid bacteria to grow. When the fermentative lactic acid bacteria is inhibited, the accumulation of alcohol from yeast also decreases.

2. Preparation of the Kefir Grains

The kefir grains from commercial suppliers usually are freeze-dried products. They have irregular shapes and sizes, some as large as walnuts, and the small ones as small as wheat kernels. They show a yellow color with some individual ones being white and creamy in color. A fixed amount of kefir grains is soaked in sterilized saline solution at a ratio of 1:10, and incubated at 20°C for 5 hours. The then expanded kefir grains are filtered through metal sieves and rinsed with sterile water. The rinsed kefir grains are then inoculated into sterilized milk at a ratio of 1:15, and incubated for 24 hours at 25°C, until grains are formed. The kefir grains are then sieved again, rinsed, and are incubated again (sometimes requiring several inoculations). Kefir grains from the last incubation are preserved for later use, and the filtrate is used for the inoculum for the production of kefir.

3. Procedures for Kefir Production

Good quality milk must be used as the raw material for kefir production. The raw material is generally not standardized. First, the milk is heated to 70°C, homogenized at 15 MPa pressure. The homogenized milk is then heated to 95°C for 10–15 minutes. The purposes for the heat treatment are: sterilize harmful microorganisms, and denature all the serum albumin. The denatured serum albumin has a high water affinity. This avoids the separation of serum in the product, and the viscosity can also be increased. Ultrahigh temperature can only denature the serum albumin partially, and therefore is not applicable in this situation. After heat treatment, the milk is cooled to 22–25°C. Inoculation fluid at the rate of 3–5% is added and the mixture is incubated at 22–23°C for 8–12 hours. When the total acidity reaches to 90–100 T, the mixture is shared, and slowly cooled for 10–12 hours to 4–6°C. The product can then be packed and stored at low temperature.

The main products at the end of kefir fermentation are lactic acid, ethanol, and carbon dioxide. There are also traces of acetaldehyde, diacetyl, and acetone. Kefir is

generally viscous, with a certain amount of bubbles; the product has a fresh sour taste and the light aroma of yeast. This product is suitable for lactose intolerant consumers, at the same time, prevents constipation and increases appetite. The most valuable component in kefir is the presence of 0.2–0.7% kefiran that can stimulate protein digestion in the human body.

Strictly speaking, kefir is made from cow's milk, and koumiss is made from hare's milk, and the lactose content in hare's milk is higher. Another alternative is to use skim milk with addition of serum-type lactose to increase the total solids. After fermentation, because it is also the action of lactic acid bacteria and lactose fermenting yeast, the product has lactic acid 0.8–1.0%, and alcohol about 2%, as compared to 0.6–0.9% lactic acid and about 1% alcohol if cow's milk is used as the raw material.

B. "Jiangmijiu" [Tianjiuniang (Sweet Jiu Fermentation)]

1. Formulation

Good quality "jiangmi (glutinous rice)" 1.5 kg, "tian jiu yao" (fermenting agent) 1 piece, and a small amount of sweet ormanthus essence.

2. Procedures

- The "jiangmi" is cleaned from foreign matters, soaked in a container for 24 hours, scooped out and washed cleanly.
- The washed clean "jiangmi" is flatly loaded onto a steamer lined with a piece of cloth. The rice is steamed to completely cooked using high heat.
- The cooked rice is sprinkled with water from deep wells once. If the temperature of the cooked rice is too high, it can be sprinkled again to lower the temperature. When the temperature of cooked rice is lowered to about 30°C, the rice is transferred to another clean wide-mouthed ceramic container.
- The "tian jiu yao" is ground to a fine powder, and sprinkled on the cooked rice. The rice is then pressed firmly, with a deep trough in the center. The sweet osmanthus essence is sprinkled on the trough, and then some "tian jiu yao." Lastly, some cooled, boiled water is sprinkled on it. The container cover is put on, and the container is wrapped with a cotton comforter, and left in a warm place. In the northern provinces, they can be put on the warming plates to increase the temperature, and shorten the fermentation time. After 2–3 days, the fermentation is mature. In the southern provinces, the wrapped containers can be stored by the side of cooking stoves.

3. Product Characteristics

The rice kernels are soft, and sweet with rich "jiu" aroma. When it is consumed, it should not have sour taste; instead, it should have a sweet aromatic taste. The product can be consumed as such; it is clean, cool, and sweet, especially good in the summer time. In the summer time, it can also be mixed with mung bean soup, refrigerated and consumed as a cold dessert. It has a clean aroma. This "jiangmijiu" can also be mixed with wheat flour to make cakes or steamed buns with pleasant "jiu" flavor. It is also commonly consumed boiled with eggs poached in it; this way of consumption is claimed to be good for the lactating mother with ample milk excreted. In the minority ethnic groups, it is common to treat honored guests with "jiangmijiu" as snacks.

C. "Chongyang Jiu" in the Dong Minority Ethnic Group

The "chongyang jiu" in the Dong Minority Group is basically made in the same way as the "jiangmijiu." Using glutinous rice, it is fermented in the ninth month of the lunar calendar and consumed in the new year (lunar calendar), thus the name "chongyang" meaning the ninth day in the ninth month. The only exception is that it is aged in a warm environment for extended fermentation for about 4 months. Its characteristics are that the product is very viscous and forms threads when scooping out, even sweeter than honey, rich in "jiu" aroma and pleasant to mouth feel. For consumers with small alcohol capacity, it is easy to get drunk by not noticing its potency.

D. "Zhubei (Bamboo Cup) Shui (Water) Jiu" in the LiSu Minority Ethnic Group

Both males and females in the Lisu Minority Ethnic Group enjoy drinking the "shui jiu." It has its unique way of manufacturing and consumption. "Shui jiu" is made in every family in the ninth and tenth months (lunar calendar) after the crops are harvested.

- **Formula.** Raw materials include corn, sorghum, barnyard grass or others. It is best made with barnyard grass.
- **Procedure.** The raw materials are crushed, steamed, and inoculated with "jiu yao." They are filled into containers, sealed and stored for fermentation. After a few score of days, they can be opened and diluted before consumption.
- **Method of consumption.** After the fermentation container is opened, place a cooking pot on a fire, add the pre-heated warm water in the pot. The contents from the fermentation container are scooped out, put into the warm water in the

cooking pot, and stirred briefly. The host first tastes the "shui jiu" for temperature and flavor. If the "shuijiu" is acceptable, it is filtered and filled into specially made "zhubei (bamboo cups)" and served to the guest(s). When one pot is consumed, the residue can be repeated 2–3 times. This product is sweet and rich in taste with pleasant aroma; alcohol content is not high, and it is clean to the mouth feel.

E. "Mageli Jiu" of the Korean Minority Ethnic Group

The manufacturing process for "Mageli jiu" is similar to that for the "tianjiuniang" described earlier. It is a homemade product using regular rice as the raw material in the families of the Korean Minority Ethnic Group. The product is light yellow, sweet with aroma, alcohol content lower than regular "baijiu," but higher than beer.

F. "Xiaobo (Small Bowl) Guihua (Sweet Ormanthus) Jiuniang"

This "xiaobao guihua juiniang" is made similar to the "tianjiuniang" described earlier except that it is made in small bowls and the sweet ormanthus is added later.

G. "Qingke (a Kind of Wheat in Tibet, *Avena nuda* L.) Jiu" in the Tibet and Qinghai Minority Ethnic Groups

- **Formula.** "Qingke" 500 g and suitable amount of ferment "qu."
- **Procedure.** The "qingke" is washed clean. After it is cooked, the "jiu qu" is added and mixed, allowing for saccharification to proceed and form the sweet mash (product). Fermentation temperature should be maintained at 15–18°C; too high a temperature will lead to production of too much acid, and too low a temperature will lead to flat taste product that is not sweet. It is important to cook the "qingke" thoroughly and soft, the cooked "qingke" should look like fruit flesh with a light "jiu" aroma.
- **Product characteristics.** The sweet mash is the final product. It is sweet and thick, with yellow color, and the aroma is light and sweet. It is appetizing and helps digestion, with rich highlander's flavor. In Qinghai province, the product is consumed as a common homemade product; however, the pressed filtrate is what the Tibetans will drink regularly, it is sweet and soothing.

H. Quality Standard of "Jiu" from the Minority Ethnic Groups

At this time, there is no national standards for 'jiu" from the Minority Ethnic Groups. However, the sanitary standard must follow the GB2757-81 (see Table 173.1) for distilled "jiu" and "formulated "jiu," or meet the GB2758-81 (see Table 173.4) for fermented "jiu."

CONTENTS

I. INTRODUCTION

It is the nature of change that big events erupt suddenly and noisily, grab the headlines and shake the world. Changes that often have more impact on mankind's long-term future tend to take place much more slowly and quietly. It is in our nature to pay too much attention to short-term events and tentative viewpoints; larger, seismic shifts happen on a scale too great for us to easily bring into focus. Futurists concur that the world at the start of the third millennium is on the verge of an era of massive and unprecedented change, change so dynamic and far-reaching as to make many facets of society virtually unrecognisable during the next few decades. We are already starting to feel tremors from what will be tectonic transformations. In this context, we might remind ourselves of the adage 'the future belongs to those who prepare for it.'

In an attempt to establish a compass with which the wine industry can navigate through the enormous challenges of the 21st century, a number of major wine-producing countries have made in-depth analyses of global trends in the wine business environment, and have begun to plan for the most probable scenarios. With the threat of growing wine surpluses hovering ominously, they have formulated visions and put together long-term strategies to deal with the confusing fog of technological innovations and shifting consumer preferences, recognising the consequences, both for their industry and their countries, of failure to adjust.

Change in the wine industry is not new. The fundamental principles of vineyard cultivation and vinification have remained largely unaltered over the past 7000 years, while the role of wine has changed completely. At the start of the 17th century, wine was regarded as a practical beverage, wholesome and uniquely storable. Today, consumers consider wine to be a luxury product associated with a convivial lifestyle. This dramatic shift in image and function has placed wine in the center of a high voltage field between the forces of *market pull* and *technology push*. Here tradition and innovation must become properly polarized to attract rather than repel each other to meet the demands of wine producers and the preferences of wine consumers. On the one hand, the continued existence and welfare of the producer is directly dependent on the sustainable profitability of the wine industry; on the other, the increasingly health- and environment-conscious wine consumer is looking for a diverse range of quality products at the right price. The weight is increasingly moving to the side of demanding consumer preferences, and this places the producer under pressure.

There is an increasing gap between wine production and wine consumption in today's competitive, global economic system. This mismatch of demand and supply is exacerbated by two major factors: a worldwide decrease in the consumption of alcoholic beverages, and a rapid expansion of wine production in the New World countries (Argentina, Australia, Canada, Chile, New Zealand, South Africa, USA, etc.). These countries, which now produce about 20% of the world's wine, have been quick to respond to market forces and shifting perceptions of wine quality. As a result they have gained significant market share in the past few decades, moving from 2 to 15% of the world export market (1). During the same period, the per capita consumption of wine in the Old World producing countries (France, Italy, Spain, Portugal, Germany, etc.), which now produce slightly more than half of all the world's wine, has fallen by 40 to 50% (1). There is now a fundamental realignment of wine-producing countries around the global wine league table. Leading traditional, *production-oriented* wine industries need to transform themselves into *market-driven* enterprises.

Approximately 27 billion liters of wine are produced annually from about 8 million hectares of vineyard throughout the world (2–4). This is about 5000 million liters more than the market can absorb, and the surplus, which fluctuates between 15 and 20% of the total production, has given rise to keen competition for market share (1). This excess is concentrated in the basic bulk wine category, an indication that there has been a significant shift in consumer preference from basic commodity or 'economy' wines to premium, super-premium, ultra-premium and even icon wines. Globalization and the information explosion have given today's consumers a far more sophisticated understanding of product quality and value, and they have high expectations in all price categories. The demand for artisan wines, currently only 2–3% of the market (5), is growing, yet another indication, if one is needed, that the market is driven by consumer choice, not by producers, and surpluses are nothing more than bad management. In the wine industry, gone are the days typified by Henry Ford's famous quote 'you can have any color you want as long as it is black' (or in the case of wine, white or red).

The marketplace for today's wine industry is image conscious and price sensitive; the rules have changed to

the degree that *quality* is defined as *sustainable customer and consumer satisfaction* (1). It is a market that demands products with strong brand names and continuous renewal with regard to wine style, quality, purity, uniqueness and diversity. The successful and enterprising winemaker has become consumer driven and customer responsive, striving for products of outstanding quality that can be offered at every price point. Innovation at all levels of the total value chain is no longer an option for the wine industry, but a necessity; it is the only route to the consumers, who relentlessly vote with their wallets. A profitable and socially responsible wine industry will make a total commitment to quality, style and innovation from the vineyard to the consumer's palate.

It is clear that technological innovation is one of the cornerstones on which the successful wine industries of the 21st century will build toward global influence and sustainable profitability. Market-oriented, biotechnological innovation will focus on overcoming problems in the wine industry and creating and realizing new, strategically important opportunities. Biotechnological innovations can harmonize meaningfully with a complex of market, cultural, social, environmental and technical factors, without stripping the ancient art of winemaking of its charming mysticism and romanticism.

Despite the current scepticism of some consumer groups about genetically modified organisms (GMOs) and GM products, there is no doubt that the application of gene technology in the wine industry holds great potential. To be technologically equal to the tremendous consumer challenge, the world's pacesetting wine industries increasingly are focusing on the genetic programming and improvement of the three main organisms involved in the production of wine, namely grapevine, wine yeast and malolactic bacteria.

This overview highlights the most important examples of the way in which *Vitis vinifera* grape varieties, *Saccharomyces cerevisiae* wine yeast strains and *Oenococcus oeni* malolactic bacterial strains are currently being designed with surgical precision to meet market demand for the cost-effective, sustainable and environmentally friendly production of healthy, top-quality grapes and wine.

II. THE POTENTIAL OF GENETICALLY IMPROVED GRAPEVINE CULTIVARS

A. Grapevine Species and Cultivars

Economically, the grapevine constitutes the most important fruit species globally and has been linked to agricultural and religious activities in the earliest writings and chronicles. This ancient species has evolved over the ages from a bushy, sun-loving plant to a trailing climber. The grapevine has been domesticated with ease, giving rise to approximately 8 million hectares of intensely pruned and manicured grapevines that are typical of vineyards across the world (3,4).

Grapevines are classified into the genus *Vitis*, consisting of two sub-genera, *Euvitis* and *Muscadinia*, of which the former comprises the bulk of the *Vitis* species. A single *Vitis* species, *Vitis vinifera*, originated in Europe, whereas more than 30 species are native to China and a further ~34 species have been characterized in North and Central America. The scientific record of the origin of grapevine cultivars is at best rather fragmentary, but it is generally accepted that *V. vinifera* (the most cultivated *Vitis* species) comprises approximately 5000 true cultivars used in the wine, table and dried-grape industries of the world (6). Improvements to these cultivars initially relied largely on arbitrary selections of natural mutations that enhanced cultivation or some aspect of fruit and/or wine quality and were later followed by the more directed, clonal selection schemes. Grapevine improvement has curiously been "untouched" by classical breeding programs, in the sense that relatively few new cultivars became commercial successes, especially in the wine industry, where a few select and ancient cultivars are relied on for commercial production. However, breeding programs significantly impacted on the development of rootstock varieties resistant to soil-borne pests and pathogens, as well as to negative abiotic conditions (7).

When cultivar improvement is considered, the table/dried-grape and wine industries have different goals. The former industries market their products directly and have to provide the consumer with new, exciting and excellent-quality products, whereas the wine industry typically relies on established varietal names and predictable wine styles to sell its products. Genetic transformation technology has been heralded as having high potential in grapevine improvement programs in all three of these industries. Some of the advantages linked to this technology and its application in grapevine production will be discussed in the following sections.

B. Genetic Features and Techniques for the Analysis and Development of Grapevine Varieties

The fact that several plant genomes have been fully sequenced and that genome-wide, proteomic and metabolomic analyses are becoming more accessible confirms that a more advanced phase of plant improvement through molecular biology and genetic transformation is dawning. The accessibility of the grapevine genome in terms of molecular biology applications is currently much more restricted than that of wine yeast due to the size of the genome (ca. 470–483 mb divided into 38–40 chromosomes) and its complexity (only 4% of the

genome is transcribed) (4). The grapevine genome, however, is currently targeted for intense study, with multinational consortia collaborating in several initiatives to render molecular markers as well as the complete sequencing of the *Vitis* genome (8).

The technology to add genes of interest under the control of regulatory elements of choice into plant genomes has opened up various possibilities for plant improvement, and a wide range of economically important plant species have been targeted in this regard. *Agrobacterium*-mediated and biolistic bombardment technologies have ensured that an ever-growing list of plant species are accessible for genetic transformation. Noteworthy, however, is the fact that the grapevine has been considered recalcitrant to genetic transformation due to various difficulties, amongst others in obtaining regenerable tissue-culture systems that can withstand *Agrobacterium* or biolistic transformation and the subsequent selection regimes (3,4,9).

The first significant progress was made when embryonic cell lines were used as target tissue for grapevine transformations, leading to several laboratories (both private and public) routinely producing transgenic grapevines. In this regard, the term ''routinely'' includes only a few commercially important grapevine scion and rootstock cultivars. Since 1989, when the first successful grapevine transformations were performed, the focus has gradually shifted from the development of grapevine transformation technology to the implementation of the technology in the generation of useful plant lines.

C. Targets for the Genetic Improvement of Grapevine Varieties

Integrally linked to the prospect of rendering genetically improved grapevines is the use of molecular biology to study the fundamental processes in grapevine that underpin the physiological responses targeted for improvement. Initially, when limited genetic resources were available, genes with known function were introduced into plant species in the hope of developing ''improved'' phenotypes. This shotgun approach has taught us valuable lessons, especially about complications regarding transgene silencing, but has also proven that true and sustainable progress can only be made when basic knowledge is combined with application. Grapevine transformations are co-entering an exciting era with the plant sciences, as a growing list of genes and their regulatory sequences are becoming available from economically important species, including grapevine. Table 174.1 lists important focus areas of studies relevant to the potential targets for the grapevine improvement.

1. Improving Grapevine Health

It is generally accepted that plant disease is the exception rather than the rule, due to the very efficient mechanisms of plants defending themselves against pests and pathogens (10). Agricultural monoculture, however, is under constant threat by various pathogens and pests, and mechanisms to curb viral, bacterial, fungal and insect pathogens remain the major focus of the genetic engineering of crop plants. The current approach of single-gene transfers into plant genomes is perhaps also best-suited to the aim of enhanced disease tolerance, since single genes can confer disease resistance to plants.

Several different approaches have been used to enhance disease tolerance in plants, but almost all of them make use of some part of the natural interaction between host and pathogen (11). This interaction is complex and highly fluid due to the fact that the host and pathogen coevolve in the battle for survival. Most transformation strategies involve a gene product with known antipathogen activity that is introduced at high copies or in an inducible manner into the host of choice in an attempt to optimize parts of the plant's innate defence response. Examples of pathogenesis-related defence proteins in plants are glucanases, chitinases, thaumatin-like proteins, defensins, cyclophilin-like proteins, polygalacturonase-inhibiting proteins (PGIPs) and ribosome-inactivating proteins (RIPs) (12–14). Obtaining transgenic plants resistant to pathogenic bacteria has been less successful; the expression of the lytic peptide Shiva-1 has been reported (15), and induced expression of several defence genes have been detected in response to bacterial pathogens (13,16).

The other major approach of manipulated disease tolerance in grapevine (and other plants) relies on pathogen-derived resistance (PDR) and various applications thereof. In this approach, a pathogen-derived gene and its encoding product is expressed at an inappropriate time or in an inappropriate form or amount during the infection cycle, thus preventing the pathogen from maintaining infection (10). Most of the antiviral strategies rely on some aspect of PDR and constitute a major portion of the activity in the genetic transformation of grapevine varieties. One example of the PDR approach is the expression of a Closteroviral coat protein in grapevine in an attempt to combat leafroll disease (17). Some research groups are also endeavoring to express antisense to viral movement and replicase proteins to curtail the spread of viral infection in plants (18).

A range of transgenic plant species has been developed by this approach, with varying success. Some of the first transgenic grapevines expressing heterologous antifungal and antiviral genes are currently undergoing field-testing (19). These first "prototypes" of manipulated disease tolerance in grapevine, as in other plant species, are the beginning of a new era in plant cultivation, as old problems are being addressed in new ways. The technology will undoubtedly improve in sophistication, with the possibility of multiple gene transfers and the long-term and stable expression of transgenes, with the use of highly specific inducible regulatory sequences.

Targets for the Genetic Improvement of Grapevine Cultivars and Rootstocks

Desirable Properties	Focus Area	Examples of Current and Potential Target Genes
Improving Grapevine Health		
Fungal tolerance	Grapevine defense and defense signaling in response to fungal pathogens; pathology of the various fungal pathogens; innate resistances (molecular basis) of various species towards fungal pathogens	Glucanase- and chitinase-encoding genes from fungi, yeast and plants; ribosome inactivating proteins (RIPs); thaumatin-like protein (*Vvtl1*); antifungal peptide encoding genes from plants and insects; genes encoding polygalacturonase-inhibiting proteins (PGIPs), stilbene phytoalexins (stilbene synthases*: stsy*, *vst1, vst2*); phenylalanine ammonia lyase *(pal) CuZnSOD* (putative CuZn superoxide dismutase); detoxification enzyme-producing genes (NADPH-dependent aldehyde reductase, *Vigna radiata*-Eutypine reducing enzyme)
Bacterial tolerance	Grapevine defense and defense signaling in response to bacterial pathogens; pathology of the various bacterial pathogens; innate resistances (molecular basis) of various species towards bacterial pathogens	Anti-microbial peptides (lytic peptide, Shiva-I, defensins); dysfunctional import and integration protein encoding gene (*virE2delB*) from *Agrobacterium*
Viral tolerance	Epidemiology of virus infections and vectors; molecular biology on infecting virus; pathogen-derived resistance strategies (coat-proteins; movement proteins)	Virus coat proteins (translatable, anti-sense, non-translatable); virus movement proteins (anti-sense); replicase (RNA-dependent RNA polymerase), proteinases (2,5 oligoadenylate synthase)
Improving Grapevine Cultivation		
Resistance to water stress	Aquaporins; isolation of root-specific promoters	TIPs (tonoplast integral proteins); PIPs (plasma membrane integral proteins)
Oxidative damage	Carotenoid biosynthesis and control (several putative genes and promoters have been cloned); anaerobiosis	Carotenoid biosynthetic genes; *Adh* (alcohol dehydrogenase) genes; SODs (cystosolic CuZnSOD, chloroplast-residing CuZnSOD, mitochondrial-residing MnSOD)
Osmotic stress and other abiotic stresses	Proline accumulation; polyamines and their role in stress	*Vvp5cs* (Δ^1-pyrroline-5-carboxylate); *Vvoat* (δ-ornithine aminotransferase); FeSOD, glycine betaine, antifreeze genes from Antarctic fish (freezing tolerance)
Improving Grape Quality		
Color development	Ripening-related processes and signals, anthocyanin biosynthesis and control (several genes and some promoters have been cloned); isolation of berry-specific promoters	*ufgt* (UDP-glucose:flavanoid 3-*O*-glucosyltransferase) and/or regulatory sequences of *ufgt*; production of pelargonidin-based anthocyanins for novel berry color; anthocyanin methyl-transferases
Sugar accumulation and transport	Phloem loading/unloading; invertases; sugar transporters; isolation of berry-specific promoters	Invertases from plants and yeast to study phloem loading/unloading; sucrose transporters (*Vvsuc11, Vvsuc12*,*Vvsuc27); h*exose transporters (*Vvht1*, *Vvht2*)
Reduced browning (table and dried grapes)	Oxidation reactions	Silencing of polyphenol oxidase
Seedlessness (table grapes)	Seed-formation; isolation of seed-specific promoters	Baranase gene

Much knowledge has been gained about the nature of plant-pathogen interactions and the disease resistance pathways that operate in plants by generating and analysing transgenic plants. Model plants transformed with the various targeted genes become important resources if the nature of the manipulations and their effect *in planta* are further analysed with state-of-the art technologies, such as proteomics and microarray chips (20). A range of *Arabidopsis thaliana* mutants blocked in certain pathways of pathogen defence also provide extremely valuable information regarding the functions of genes (21). The research has developed to the point where the disease pathways are fairly well characterized and much emphasis is currently placed on the elucidation of the trigger systems of defence and the subsequent signal transduction processes leading to the various forms of defense.

2. Improving Grapevine Cultivation

Genetic transformation technology carries with it the tantalizing prospect of developing plant lines able to adapt to adverse climatic conditions, enhanced by greater understanding of stress tolerance in plants and basic knowledge of key aspects of plant growth and development. Ongoing efforts to develop transgenic grapevines with improved cultivation prospects are focusing on processes such as carbon-partitioning, modes of sugar translocation, water transport and the role of aquaporins, as well as the regulation of these processes. These efforts also deal with important limitations to cultivation such as drought and salt stress, photo-damage and freezing tolerance (22).

To date, a transgenic grapevine expressing antifreeze genes from Antarctic fish has been reported as a mechanism to provide cold tolerance (22). However, plant stress responses are complex pathways of interacting proteins driven by a range of signals attenuated or amplified by equally complex processes. This biological interaction is more difficult to manipulate with single or even multiple gene additions; knowledge of the control mechanisms and alterations thereof might prove more feasible. With this view, the accumulation of proline and polyamines are two examples in grapevine that have been studied. The regulation of key genes in these biosynthetic pathways is providing insight into their involvement in abiotic stress (23,24). Furthermore, the expression of several stress-related genes has been shown to be activated during grape ripening (25,26).

Crop prediction is another area of attention. One of the most difficult issues facing viticultural production is the understanding and management of crop load and quality in the face of seasonal and environmental variation and change in market demand. Most recently, a study of how related genes in grapevine are organized and interact was made possible by the identification of the genes involved in flowering and fruitfulness in *A. thaliana*. For example, the chimera that results in pinot meunier can be separated into a conventional pinot and a mutant pinot form in which fruitfulness is dramatically increased even in juvenile plants. This dramatic change is the result of a single DNA base change in a single gene affecting vegetative and floral development of the vine (27).

3. Improving Grape Quality

The description of quality in grapevine products differs in the three grapevine industries. The wine industry regards small, well-colored fruit complying with optimal ripeness indicators (sugars/acids/phenolics) as desirable, whereas the appearance and optimal size of table grape bunches are of prime importance. Basic quality factors, such as good color and sugar development, are of generic importance and are currently targeted in grapevine molecular biology. The basic processes of berry ripening and, more importantly, the elusive ripening signal(s) are being researched (28,29). The hormonal, environmental and biochemical signals impacting on the key ripening processes, such as pigment production, sugar accumulation and transport, as well as aroma component formation, are studied in grapevine as an example of a non-climacteric fruit. The ultimate aim of this type of approach is to change the metabolic flux through the important biosynthetic pathways that are active in the ripening berry to increase the formation of desirable or novel metabolites linked to the quality parameters of grapes.

The means of glucose/fructose accumulation during ripening is coming to light with the identification and analysis of grape berry genes encoding invertases and sugar transporters (30). The expression of flavenoid biosynthetic genes, responsible for color development, coincide with hexose accumulation in berries (31–33). The importance of UDP glucose flavonoid-3-glucosyl transferase (UFGT) in the control of berry color has been highlighted by comparison of gene expression in red and white grapes (34,35), and recent results indicate that Myb genes are involved in regulating UFGT (36). A number of genes that influence grape berry softening have also been isolated (37–39). Auxin and abscisic acid (natural hormones regulating growth and physiology) affect the expression of genes involved in the ripening process and have been implicated in the control of grape berry ripening (40). The aim of this approach is to meet the quality parameters of grapes with the formation of desirable or novel products by changing the metabolic flux through the important biosynthetic pathways active in the ripening berry.

Grapevine biotechnology, however, is in its infancy in this regard (as in most other crops) and will have to draw on significant elucidation of the underpinning physiological processes as well as improvements in transformation technology to reach these goals. Targeted gene insertion and deletion technologies are some of the tools that would make these and other innovative prospects, such as the manipulation of biochemical pathways to produce novel products and metabolites, more feasible.

III. THE POTENTIAL OF GENETICALLY IMPROVED WINE YEAST STRAINS

A. Yeast Species and Strains

Yeasts are predominant during wine fermentation. In spontaneous fermentations, there is a progressive growth pattern of indigenous yeasts originating from the surfaces of grape berries and the winery equipment (41–43). Yeasts of the genera *Kloeckera*, *Hanseniaspora* and *Candida* predominate in the early stages, followed by several species of *Metschnikowia* and *Pichia* in the middle stages,

when the ethanol rises to 3–4%. The latter stages of spontaneous wine fermentations are invariably dominated by the alcohol-tolerant strains of *Saccharomyces cerevisiae,* which therefore is known universally as the "wine yeast" (41,44). The indigenous yeasts present in spontaneous wine fermentations are thought to produce wines with a fuller, rounder palate structure. However, spontaneous fermentations are usually protracted and the outcome is highly unpredictable. Therefore, spontaneous fermentations are most often used in some Old World and *boutique* wineries that depend more on vintage variability and that are willing to accept these risks to achieve distinct styles of wines that reflect the yeast diversity of that specific region.

In modern, large-scale wineries, where rapid and reliable fermentations are essential for consistent wine flavor and predictable quality, specially selected starter culture strains of *S. cerevisiae* with known ability are used (41). In addition to the primary function of these active dried wine yeast starter culture strains to catalyze the rapid, efficient and complete conversion of grape sugars to alcohol without the development of off-flavors, today's pioneering winemakers demand starter culture strains with a whole range of specialized properties that can add value to the final product. This quest for wine yeast strains that are optimized for specific tasks set by winemakers has led to dedicated yeast breeding and genetic engineering. For reviews see (1,2,41,42,45–58).

B. The Genetic Features and Techniques for the Analysis and Improvement of Wine Yeast Strains

The majority of laboratory-bred strains of *S. cerevisiae* are either haploid or diploid, whereas industrial wine yeast strains are predominantly diploid or aneuploid, and occasionally polyploid. The nucleotide sequence of the entire genome of *S. cerevisiae* is known. It has a relatively small, compact genome (ca. 13 000 kb), a large number of chromosomes (16 linear chromosomes varying in length from 200 to 2200 kb), a small number of genes (ca. 6000 protein-encoding genes), little repetitive DNA and few introns (59–62).

Powerful classical and molecular genetic methods exist with which wine yeast strains can be analyzed and modified. Initially, tetrad analysis with the aid of a micromanipulator was used for the genetic identification, characterization and mapping of yeast genes. Recently, technology has been developed to provide a direct link between the genome (full set of genes) and the transcriptome (full set of transcripts) of a wine yeast strain. The genomic sequence has been used to design and synthesize high-density oligonucleotide arrays to monitor the levels of expression of nearly all the genes of yeast cells grown under fermentation conditions (reviewed in (63)). Furthermore, when the current deciphering of the function of the 6000 *S. cerevisiae* genes is completed in the near future, the entire proteome (full set of proteins) will become accessible for the unlocking of wine yeast's complex metabolome (metabolic activities and metabolites) (50,64–67).

The information obtained from the analysis of the entire genomes, transcriptomes, proteomes and metabolomes of wine yeasts undoubtedly will increase the specificity of the current methods with which starter strains are genetically selected and tailored for the production of particular types and styles of wine. At the moment, the classical strain selection and modification methods, such as variant selection, mutagenesis, hybridization (mating, spore-cell mating, rare mating, cytoduction and spheroplast fusion), are based mainly on a "shotgun" approach (68). With this approach, random genes are affected in an unpredictable way, or large genomic regions or entire genomes are recombined or rearranged. These methods, therefore, are not specific enough to modify wine yeasts in a well-controlled manner and they may bring an improvement in some of the yeast strain's properties, while compromising other desired traits. The only advantages of these methods are that they can be used to improve and combine traits under polygenic control and that they do not give rise to products that are included in the statutory definition of GMOs. Therefore, variants, mutants, hybrids, cytoductants and fusants are not subject to the same strict statutory regulations that pertain to GMOs and are also not treated with the same level of public suspicion as are wine yeasts that have been transformed with a single gene. However, genetic engineering remains the only reliable method that offers the possibility to modify an existing property, to introduce a new characteristic and to eliminate an unwanted trait without adversely affecting other desirable properties. Several effective transformation methods and plasmid vectors, as well as expression and secretion cassettes for the expression of heterologous genes and the secretion of their encoded proteins, have been developed for *S. cerevisiae*. This has offered wider applicability and a higher degree of specificity in the development of improved wine yeasts (2).

C. Targets for the Genetic Improvement of Wine Yeasts

Generally, the targets of yeast strain development all relate to improved economics of production and wine quality. Table 174.2 highlights some of the improvements that can be achieved using genetically engineered wine yeasts. These targets include increasing the efficiency of the fermentation process, the processing of wine and control of microbial spoilage, as well as enhancement of the wholesomeness and sensory quality of wine (2,54,55).

TABLE 174.2
Targets for the Genetic Improvement of Wine Yeast Strains

Desirable Properties	Focus Areas	Examples of Potential Target Genes
Improving Fermentation Performance		
Improved general resilience and stress tolerance	Stress response, sterol, glycogen and trehalose accumulation	Modification of glycogen or trehalose metabolism [for example acting on *GSY1* and *GSY2* (glycogen synthase), *TPS1* (trehalose-6-phosphate synthase), *TPS2* (trehalose-6-phosphate phosphatase)]
Improved efficiency of sugar utilisation	Hexose transporters, hexose kinases	Overexpression and modification of *HXT1-HXT18*, *SNF3*, *FSY1* and use of heterologous transporters and kinases
Improved efficiency of nitrogen assimilation	Improved utilisation of less efficient N-sources	Proline catabolism [*PUT1* (proline oxidase) and *PUT2* (pyrroline-5-carboxylate dehydrogenase)] and use of heterologous catabolic genes
Improved ethanol tolerance	Sterol formation, membrane ATPase activity	Modification of the expression of *PMA1* and *PMA2* (ATPase), sterol anabolic genes
Increased tolerance to antimicrobial compounds	Resistance to killer toxins, sulfur dioxide, agrochemicals	Inclusion of *KIL2* (zymocin and immunity factor), overexpression of *CUP1* (copper chelatin)
Reduced foam formation	Cell surface proteins	Deletion of *FRO1* and *FRO2* (froth proteins)
Improved Wine Processing		
Improved protein clarification	Proteases	Overexpression of *PEP4* (protease A) and secretion of other proteases
Improved polysaccharide clarification	Glucanases, pectinases, xylanases, arabinofuranosidases	Overexpression of *END1* (endoglucanase), *EXG1* (exoglucanase), *CacEL1* (cellodextrinase), *BGL1* (β-glucosidase, cellobiase), *PEL5* (pectate lyase) and *PEH1* (polygalacturonase), *XYN1-5* (xylanases), *ABF2* (arabinofuranosidase)
Controlled cell sedimentation and flocculation	Flocculins	Late expression of flocculation genes (*FLO1, FLO5, MUC1*/*FLO11)* under control of promoters (*HSP30*) imparting desired expression
Controlled cell flotation and flor formation	Cell wall hydrophobic proteins	Late expression of *MUC1*/*FLO11* under control of promoters (*HSP30*) imparting desired expression pattern
Improving Wine Preservation		
Wine yeasts producing antimicrobial enzymes	Lysozyme, glucanases, chitinases	Expression of *HEL1* (hen egg white lysozyme), *CTS1* (chitinase), *EXG1* (exoglucanase) and other antimicrobial enzymes
Wine yeasts producing antimicrobial peptides	Bacteriocins	Expression of *PED1* (pediocin), *LCA1* (leucocin) and other heterologous bacteriocin and zymocin genes
Wine yeasts producing sulfur dioxide	Sulfur metabolism and SO_2 formation	Overexpression of *MET14* (adenosylphosphosulfate kinase) and *MET16* (phospho adenosylphosphosulfate reductase), and deletion of *MET10* (sulfite reductase)
Improving Wine Wholesomeness		
Increased production of resveratrol	Stilbene synthesis	Expression of *4CL9/216* (co-enzyme A ligase), *VST1* (stilbene synthase)
Reduced formation of ethyl carbamate	Amino acid metabolism, urea formation	Deletion of *CAR1* (arginase) or expression of *URE1* (urease)
Reduced formation of biogenic amines	Bacteriolytic enzymes, bacteriocins	Expression of *HEL1* (hen egg white lysozyme), *PED1* (pediocin), *LCA1* (leucocin) and other bacteriocins
Decreased levels of alcohol	Carbon flux, glycerol metabolism and glucose oxidation	Overexpression of *GPD1* and *GPD2* (glycerol-3-phosphate dehydrogenase), modification of *FPS1* (glycerol transport facilitator), expression of *GOX1* (glucose oxidase)
Improving Wine Sensory Attributes		
Enhanced liberation of grape terpenoids	Glycosidases, glucanases, arabinofuranosidases	Overexpression of *END1* (endoglucanase), *EXG1* (exoglucanase), *CEL1* (cellodextrinase), *BGL1* (β-glucosidase, cellobiase), *PEL5* (pectate lyase) and *PEH1* (polygalacturonase), *ABF2* (arabinofuranosidase)

(*Continued*)

TABLE 174.2
(*Continued*)

Desirable Properties	Focus Areas	Examples of Potential Target Genes
Enhanced production of desirable volatile esters	Esterases	Modified expression of *ATF1* (alcohol acetyl transferase) and other alcohol transferases, *IAH1* (esterase) and other esterases
Optimized fusel oil production	Amino acid metabolism	Deletion of the *ILE*, *LEU* and *VAL* genes
Enhanced glycerol production	Glycerol metabolism	Overexpression of *GPD1* and *GPD2* (glycerol-3-phosphate dehydrogenase), *FPS1* (glycerol transport facilitator), and deletion of *ALD6*
Bio-adjustment of wine acidity	Maloethanolic and malolactic fermentation, lactic acid production	Expression of *MAE1* (malate permease), together with *MAE2* (malic enzyme) or *mleS* (malolactic enzyme), or *LDH1* (lacticodehydrogenase)
Optimization of phenolics	Phenolic acid metabolism	Modified expression of *PAD1* (phenyl acrylic acid decarboxylase), *pdc* (ρ-coumaric acid decarboxylase), *padc* (phenolic acid decarboxylase)
Reduced sulfite and sulfide production	Sulfur metabolism, hydrogen sulfide formation	Deletion of *MET14* (adenosylphosphosulphate kinase) and *MRX1* (methionine sulfoxide reductase)

1. Improving Fermentation Performance

Wine fermentations generally proceed at a rate greater than desired and are usually controlled by lowering the fermentation temperature. "Runaway" fermentations have a commercial implication, as fermentor space is reduced because of foaming and volatile aroma compounds are lost by entrainment with the evolving carbon dioxide. On the other hand, wine fermentation sometimes ceases prematurely or proceeds too slowly. The financial losses caused by "stuck," "sluggish" or "incomplete" wine fermentations are usually attributed to inefficient utilization of fermentor space and wine spoilage as a result of the low rate of protective carbon dioxide evolution and high residual sugar content (41). Therefore, the predictability of fermentation and the quality of the wine are directly dependent on wine yeast attributes that assist in the rapid establishment of numerical and metabolic dominance in the early phase of wine fermentation and that determine the ability to conduct an even and efficient fermentation with a desirable residual sugar level. Many factors affect the fermentation performance of wine yeasts. Among the general targets for the improvement of fermentation performance are increased resilience and stress resistance of active dried yeast cells; improved grape sugar and nitrogen uptake and assimilation; enhanced resistance to ethanol and other microbial metabolites and toxins; resistance to sulfite, heavy metals and agrochemical residues; and reduced foam formation (2).

As sterols, trehalose, glycogen and aquaporins fulfil multiple roles in increasing the survival of *S. cerevisiae* cells exposed to several physical and chemical stresses, they have important implications for the general stress tolerance, resilience, fitness and vigour of active dried wine yeast starter cultures upon reactivation (69). As a result, there is a strong incentive to develop wine yeast strains with a superior ability to accumulate these compounds and proteins. However, due to the complex stress response mechanisms in yeasts, it is not yet clear whether the deletion of the *ATH1* trehalase gene and the modification of the expression levels of the genes involved in the metabolism of trehalose (*TPS1, TPS2, ATH1*) (70,71), glycogen (*GSY1, GSY2*) (72) and sterols (*ERG1*, *ERG11*, *SUT1, SUT2*) (73), and in the synthesis of aquaporins (*AQY1, AQY2*) (74) will result in an improvement in yeast viability and vitality.

An imbalance in the high levels of carbon and low levels of nitrogen in grape must is the most common cause of poor fermentative performance (41). Sluggish or stuck fermentations occur because nitrogen depletion irreversibly arrests hexose transport. The main focus to ensure the efficient utilization of grape sugar (glucose and fructose) under conditions of nitrogen limitation is to increase the rate of glycolytic flux by replacing any nonfunctional mutant alleles of genes encoding the key glycolytic enzymes, to enhance the efficiency of hexose (especially fructose) uptake, and to alleviate the assimilation of proline and arginine (accounting for 30 to 65% of the total amino acid content of grape juice) from nitrogen catabolite repression (2,54,55). In the case of incomplete fermentations, the preference of wine yeasts for glucose over fructose can lead to excessive residual fructose levels that compromise the quality of the wine. It is hypothesized that the rate of alcohol production by wine yeast is limited primarily by the rate of sugar uptake, especially the uptake of fructose in the presence of high sugar levels during the early phase of fermentation and during the final stages of nitrogen depletion coupled to nutrient limitation. Therefore, the research of several laboratories focus on phosphorylation by the *HXK1*- and *HXK2*-encoded hexokinases and the *GLK1*-encoded glucokinase, as well as on hexose transporters encoded by *HXT1-HXT18* and *SNF3*. The low affinity hexose transporter Hxt3p and high

affinity transporters Hxt6p and Hxt7p play particularly important roles in wine fermentation (75). It is possible that increased expression of these transporters will decrease the occurrence of stuck fermentation. Two hexose transporter homologues, Snf3p and Rgt2p, are required for glucose sensing. Snf3 is specifically required for inducing a number of *HXT* genes under low glucose conditions. Dominant *SNF3* mutants constitutively express hexose transporters and are resistant to translational inhibition upon glucose withdrawal, providing a potential mechanism for wine yeast improvement (76,77). Furthermore, genes encoding fructose-specific transporters could also be sourced from other yeasts, such as *S. pastorianus, S. bayanus* and *Zygosaccharomyces bailii.* For instance, the *S. pastorianus FSY1*-encoded fructose/H^+ symporter could be overexpressed in wine yeast together with the other *HXT3, HXT6, HXT7* and *SNF3*-encoded hexose transporters and the *HXK1*-encoded hexokinase (with the highest affinity for fructose, but still a significantly lower affinity than for glucose), thereby attempting to improve glucose and fructose uptake during wine fermentations. Regarding nitrogen assimilation during wine fermentations, the deletion of the *URE2*-encoded repressor of the *PUT1*-encoded proline oxidase and *PUT2*-encoded pyrroline-5-carboxylate dehydrogenase represents the first step towards the development of wine yeasts that can efficiently assimilate the abundant supply of proline and arginine in grape juice under fermentative conditions (78–80).

Another thrust to improve the fermentation performance of wine yeasts is to increase their resistance to toxic microbial metabolites (e.g., ethanol, acetic acid, medium chain fatty acids, etc.), zymocins (yeast-derived killer toxins), chemical preservatives (e.g., sulfite) and agrochemicals containing heavy metals (e.g., copper). For example, modification of the expression of the *SUT1*, *SUT2*, *PMA1* and *PMA2* genes results in increased sterol accumulation and cell membrane ATPase activity, thereby increasing the resistance to ethanol. Also, the mycoviral determinants and other genes encoding killer toxins (zymocidal peptides) and immunity factors can be incorporated into wine yeasts to make them insensitive to the zymocins of contaminating wild yeasts (81–83). With respect to resistance to agrochemicals, an increase in the copy number of the *CUP1* copper chelatin gene enables wine yeasts to tolerate higher levels of copper residues in the grape must (2,54,55).

2. Improving Wine Processing

The main objectives of fining (addition of an adsorptive compounds followed by settling or precipitation) and clarification (e.g., sedimentation, racking, centrifugation, filtration, etc.) during wine processing include the removal of excess amounts of certain components and microbial cells to achieve clarity and to ensure the physicochemical stability of the end product (2). The fining and clarification of wine often includes expensive and laborious practices that generate large volumes of lees for disposal, thereby causing a loss of wine and removing important aroma and flavor compounds from the remaining wine. To minimize the disadvantages of these harsh fining and clarification practices, an increasing spectrum of relatively expensive commercial enzyme preparations (e.g., proteases, pectinases, glucanases, xylanases, arabinofuranosidases, etc.) are frequently added to the grape must and wine (84,85). As an alternative strategy to the addition of costly enzyme preparations that often contain unwanted contaminating or side activities, wine yeasts are being developed to secrete proteolytic and polysaccharolytic enzymes that would remove haze-forming proteins and filter-clogging polysaccharides, respectively. To this end, the overexpression of several bacterial, fungal and yeast genes resulted in the development of proteolytic, pectinolytic, glucanolytic and xylanolytic wine yeast strains. Under winemaking conditions, proteases have been unsuccessful in degrading haze proteins (86). However, a number of glycoproteins have been found to visibly reduce haze formation in wine, including yeast invertase (*SUC2*) (87) and two mannoproteins from *S. cerevisiae* known as haze protection factors (*HPF1* and *HPF2*) (88).

A second target for the improvement of clarification and filtration aims at efficiently removing all yeast cells from the liquid phase of the tank or barrel. Regulated expression of the flocculation genes is important to guarantee a high suspended yeast count for a rapid fermentation rate during the fermentation process, while efficient settling is needed to minimize problems with wine clarification at the end of sugar conversion. Yeast flocculation is especially important for the production of bottle-fermented sparkling wine, and the controlled onset of yeast flocculation at the appropriate time during sparkling wine production can simplify this costly process. The expression of the *FLO1* flocculin gene, linked to the late-fermentation *HSP30* promoter, can be induced by a heat-shock treatment (89), confirming that controlled flocculation is indeed possible during fermentation. Cell aggregation also plays a key role in the production of flor sherry, during which a related cellular process results in the flotation of the yeast cells, thereby forming a velum (biofilm) on the surface of the wine. By placing the *MUC1* (also known as *FLO11*) mucin gene under the control of the *HSP30* promoter, the formation of the biofilm can be promoted at the end of fermentation, thereby simplifying the development of the flor (90,91).

3. Improving Wine Preservation

Uncontrolled microbial growth before, during or after wine fermentation, can alter the chemical composition of the end

product, thereby detracting from its sensory properties of appearance, aroma and flavor. Healthy grapes, cellar hygiene and sound oenological practices are the cornerstones of the winemaker's strategy against the uncontrolled proliferation of spoilage microbes. Added safety is provided by the addition of chemical preservatives, such as sulfur dioxide, dimethyl dicarbonate, benzoic acid, fumaric acid and sorbic acid, which control the growth of unwanted microbial contaminants. However, excessive use of these chemical preservatives is harmful to the quality of the wine and is confronted by mounting consumer resistance. Consumer preferences have shifted to products that are less heavily preserved with chemicals, less processed, of higher quality, more natural and healthier. Therefore, biopreservation with yeast-derived metabolites (e.g., formation of sulfite or hydrogen peroxide during wine fermentations), antimicrobial enzymes (e.g., lysozyme, chitinases, endoglucanases, etc.) and peptides (zymocins and bacteriocins) is currently being considered as an alternative strategy to chemical preservation (92). However, the use of purified antimicrobial enzymes and bacteriocins is expensive, resulting in an increase in retail costs. This problem might be circumvented by expressing effective antimicrobial enzymes and peptides in wine yeast starter culture strains, thereby addressing the wine industry's call for wines of higher quality and purity. To this end, the hen egg white lysozyme gene (*HEL1*), the *Pediococcus acidilactici* pediocin gene (*PED1*) and the *Leuconostoc carnosum* leucocin gene (*LCA1*) have been used to engineer bactericidal yeasts (93–95). The antifungal yeast *CTS1*-encoded chitinase and *EXG1*-encoded exoglucanase have also been overexpressed in *S. cerevisiae* (96). The main approach in the construction of zymocidal strains entails the inclusion of a combination of mycoviral killer toxin determinants of *S. cerevisiae* (e.g., a K_1/K_2 double killer) and zymocin-encoding genes from other yeasts (e.g., *Hanseniaspora, Kluyveromyces, Pichia, Willopsis*, etc.) (97) into wine yeasts. The ideal would be to incorprate all of these antimicrobial activities into a single wine yeast, thereby counteracting all contaminating spoilage bacteria (e.g., *Acetobacter, Gluconobacter, Lactobacillus, Pediococcus*, etc.), yeasts (e.g., *Brettanomyces/Dekkera, Pichia, Zygosaccharomyces*, etc.) and molds (*Aspergillus, Botrytis, Penicillium, Trichoderma*, etc.) in winemaking.

4. Improving Wine Wholesomeness

It is generally accepted that moderate wine drinking can be socially beneficial and can be effective in the management of stress and the reduction of coronary heart disease. The principal protective compounds found in wine include the phenolic compounds, resveratrol, salicylic acid and alcohol (98). However, prudent wine drinkers are increasingly fastidious about the presence of undesirable compounds in wine. These unwanted compounds include ethyl carbamate, biogenic amines, and chemical preservatives (92). The most finicky among these fussy wine drinkers are even concerned about high levels of alcohol in wine. When wine yeast strains are developed, it therefore is of the utmost importance to focus on these health aspects and to develop yeasts that may enhance the benefits (e.g., production of resveratrol, carnitine, etc.) and reduce the risks (e.g., eliminating ethyl carbamate and biogenic amines, and reducing the levels of alcohol) associated with moderate wine consumption.

With regard to the production of resveratrol during fermentation, progress has already been made by constructing a wine yeast that expresses the *4CL9/216* co-enzyme A ligase and *VST1* stilbene synthase genes (99). The development of a bactericidal yeast, which is deleted for the *CAR1* arginase gene (blocking the secretion of urea, the precursor for the formation of ethyl carbamate) (100) or which is transformed with heterologous urease genes (enabling the degradation of urease) would reduce the requirement for added sulfite, yeast-derived ethyl carbamate and bioamines formed by bacterial contaminants (101,102). The bioreduction of the levels of alcohol in fermented beverages can be achieved by redirecting the carbon flux away from ethanol formation and towards the production of glycerol and gluconic acid. A significant increase in the level of extracellularly accumulated glycerol and concomitant decreases in ethanol concentrations have been achieved by the overexpression of the endogenous *GPD1* and *GPD2*-encoded glycerol-3-phosphate dehydrogenase isozymes of *S. cerevisiae* (103–105), together with the constitutive expression of its *FPS1*-encoded glycerol transport facilitator. Similar decreases in ethanol levels have been achieved by the expression of the *Aspergillus niger GOX1* glucose oxidase gene in *S. cerevisiae* (106).

5. Improving Wine Sensory Attributes

The single most important factor in winemaking is the organoleptic quality (appearance, aroma and flavor) of the final product. The endless variety of flavours stem from a complex, completely non-linear system of interactions among many hundreds of compounds. The bouquet of a wine is determined by the presence of a well-balanced ratio of desirable flavor compounds and metabolites and the absence of undesirable ones (107). With the exception of terpenes in the aromatic grape varieties and alkoxypyrazines in the herbaceous cultivars, perceived flavor is the result of absolute amounts and specific ratios of many of these interactive compounds, rather than being attributable to a single "impact" compound. Subtle combinations of trace components (accumulated secondary metabolites) derived from the grapes usually elicit the characteristic flavor and aroma notes of wine, whereas the products of yeast fermentation (e.g., esters, alcohols, etc.) contribute to the generic background flavor and aroma, as well as to the complexity and

intensity of the aroma and taste of the final product (5). Yeast can also be responsible for the production of unwanted byproducts, such as hydrogen sulfide.

There is an obvious need for the development of wine yeasts that could impart specific desirable characteristics to a wine. To this end, significant progress has been made in the construction of yeasts producing color- and aroma-liberating enzymes (e.g., pectinases, glycosidases, glucanases, arabinofuranosidases, etc.) (85,108) and ester-modifying enzymes (e.g., alcohol acetyl transferases, esterases, isoamyl acetate hydrolysing enzyme, lyases, etc.) (109–111). Furthermore, yeasts producing optimal levels of glycerol (the overexpression of *GPD1*, *GPD2* and *FPS1*, together with the deletion of the *ALD6* acetaldehyde dehydrogenase gene) (112), fusel oils (e.g., isobutyl alcohol, isoamyl alcohol, etc.), and phenolic acids (modified expression of the yeast *PAD1* phenyl acrylic acid decarboxylase gene, as well as the expression of bacterial *pdc p*-coumaric acid decarboxylase and *padc* phenolic acid decarboxylase genes) have been developed (113). In addition, wine yeasts carrying disrupted alleles of the *MET14* adenosylphosphosulfate kinase or *MRX1* methionine sulfoxide reductase have been constructed (114).

The bioadjustment of acidity in wine can be achieved by recombinant wine yeasts containing combinations of genes cloned from *Schizosaccharomyces pombe* and lactic acid bacteria. A wine yeast that contains the *S. pombe mae1* malate permease gene and the *mae2* malic enzyme gene converts malic acid to ethanol (maloethanolic fermentation) (115), whereas a transformant carrying the *mae1* gene together with the *Oenococcus oeni* (*mleA*), *Lactococcus lactis* (*mleS*) or *Lactobacillus delbrueckii* (*mleS*) malolactic enzyme gene converts malic acid into lactic acid (malolactic fermentation) (116). The maloethanolic wine yeast would be preferred for low pH wines from the cooler wine-producing regions, while the malolactic wine yeast would provide the best solution for high pH wines from the warmer regions. In the case of high pH wines, the production of additional lactic acid during fermentation can be achieved by incorporating the *Lactobacillus casei LDH1* lacticodehydrogenase gene into the malolactic wine yeast strain (117). These yeasts also preclude the requirement for the use of bioamine-forming malolactic bacteria in red wine and certain styles of white wine that are required to undergo malolactic fermentation.

IV. THE POTENTIAL OF GENETICALLY IMPROVED MALOLACTIC BACTERIA

A. Lactic Acid Bacterial Species and Strains

Malolactic fermentation, conducted by malolactic bacteria, is an important step in the grape vinification process, particularly in red wines. Most often malolactic fermentation will occur after the alcoholic fermentation; however, it is not limited to this stage of winemaking. The role of malolactic fermentation is threefold: wine deacidification by the conversion of L-malic acid to the ''softer'' L-lactic acid, microbial stability and wine flavor modification.

The wine bacteria associated with spontaneous malolactic fermentation belong to the family of lactic acid bacteria, encompassing four genera, *Lactobacillus* (*Lb.*), *Leuconostoc* (*Lc.*), *Oenococcus* (*O.*) and *Pediococcus* (*P.*). The species in these genera can be characterized by their ability to tolerate low pH, high ethanol concentration and to grow in wine. Those most commonly associated with wine are *Lb. brevis*, *Lb. plantarum*, *Lb. hilgardii*, *Lc. mesenteroides*, *O. oeni, P. damnosus* and *P. pentosaceus*. Even though it is postulated that species of *Lactobacillus* and to a lesser extent *Pediococcus* species may conduct the deacidification reaction in spontaneous malolactic fermentation, species of these two genera are more likely to be associated with spoilage of wine than with positive sensory attributes. *Oenococcus oeni*, formerly known as *Leuconostoc oenos* (118), is the species most commonly responsible for malolactic fermentation, as it is particularly well adapted to the harsh wine environment (low pH, high ethanol content, low nutrients) (119). Several selected strains of *O. oeni* have been commercialized to initiate malolactic fermentation.

B. Genetic Features and Techniques for the Analysis and Development of Malolactic Bacteria

The sequence of the *O. oeni* genome is almost complete, adding to the limited number of genes that have been characterized (120–123). Though *O. oeni* is an important organism in winemaking, knowledge of its genetics is limited. To date, however, a genetic transfer mechanism into *O. oeni* does not exist.

Considerable research has been done on other lactic acid bacteria, particularly those from the dairy industry. Substantial work has been devoted to the genetics of *Lactobacillus* species but to a lesser extent in *Pediococcus* species. Numerous vectors have been constructed to introduce modified genes into *Lactobacillus* species and strains. These vectors are designed to enable easy movement between Gram-positive and Gram-negative organisms utilizing dual replicons (origin of replication) and antibiotic markers. Also available are temperature sensitive features on a few of these plasmids. Some of these plasmids/vectors also function in *Leuconostoc* species, which is the closest lactic acid bacterial genus to *Oenococcus*. Many of these vectors may be suitable for *O. oeni*.

Another approach to improving industrially important *O. oeni* strains is the use of a new technology known as genome shuffling (124,125). This technique involves using a classical strain improvement method to generate populations with subtle improvements. Next, these populations are shuffled by recursive pool-wise protoplast

fusions. Genome shuffling has been successfully applied to improve acid tolerance in a poorly characterized industrial *Lactobacillus* strain (126) and appears to be broadly useful for the rapid development of tolerance and other complex phenotypes in industrial organisms.

C. Targets for the Genetic Improvement of Malolactic Bacteria

The ability to genetically alter the malolactic bacterial genome will depend upon the development of a suitable genetic transfer system (transformation, conjugation or transduction), which currently is unavailable. Potential improvements to malolactic fermentation by the genetic modification of *O. oeni* are summarized in Table 174.3. It would be of obvious interest to construct an *O. oeni* strain which is able to ward off potential competitors, improve its ability to cope with the harsh wine environment, increase its efficiency in the bioacidification of wine - conversion of malic acid to lactic acid, and/or to provide mechanisms to improve the organoleptic qualities of wine. Such an organism would not necessarily possess all these attributes, but generating a selection of improved *O. oeni* would be of great benefit to the wine industry.

1. Improving Malolactic Fermentation Performance

It has been demonstrated that *O. oeni* responds to various environmental stresses, such as high alcohol, acid and sulfur dioxide concentrations, by producing heat shock and stress proteins (*hsp18*, *clpX* and *trxA*) (127), as well

TABLE 174.3
Targets for the Genetic Improvement of Malolactic Bacteria

Desirable Properties	Focus Area	Examples of Potential Target Genes
Improved Fermentation Performance		
Increased ethanol, low pH, non-optimal temperature resistance	Protease associated with the ATPase complex, heat shock proteins and stress proteins	*hsp 18, clpX, trxA, fstH*
Efficient malic acid degradation	Malolactic fermentation and increased strain viability	*mleA, mleR, mleP* and genes involved in oleic acid assimilation
Improved tolerance to antibacterial compounds	Resistance against bacteriocins, sulfur dioxide, agrochemicals	Desired bacteriocin resistance gene
Improved tolerance against growth-inhibitory compounds such as tannins, fatty acids	Protease associated with the ATPase complex	*ftsH*
Improved Processing Efficiency		
Improved protein clarification	Proteases	Target genes not yet identified
Improved polysaccharide clarification	Glucanases, pectinases, arabinofuranosidases	Target genes not yet identified
Improved Wine Flavor or Other Sensory Attributes		
Optimized production of glycerol	Glycerol metabolisms	Glycerol dehydratase enzyme
Enhanced liberation of monoterpenes	β-glycosidases, glucanases, arabinofuranosidases	*bgl* (β-glycosidases) and other genes required for sequential release of monoterpenes from glycoside
Optimized levels of aldehydes	Enzymes involved in acetaldehyde metabolism and catabolism	Target genes not yet identified
Optimized levels of phenolics	Phenolic acid metabolism	Modified expression of *pdc*
Optimized levels of diacetyl	Enzymes involved in citrate fermentation	*alsS*, *alsD* (α-acetolactate synthase and decarboxylase), diacetyl reductase, citrate permease (*citP*), citrate lyase
Optimized levels of esters	Lipases and esterases	Increase in acyl transferases and decrease in esterase activities
Improved Wine Wholesomeness		
Reduced formation of biogenic amines	Amino acid decarboxylases	Deletion of *hdc* and *tdc* genes
Reduced formation of ethyl carbamate	Arginine degradation	Deletion of the arginine deiminase and ornithine carbamyl transferase
Reduced formation of glyoxal and methylglyoxal levels	Metabolism of glyoxal and methylglyoxal	Target genes not yet identified

as the protease-associated with the ATPase complex (*fstH*) (128). The manipulation of these genes could lead to improved tolerance of *O. oeni* to wines with conditions at the upper limit of *O. oeni* tolerance. The elevated expression of these stress proteins may also aid the commercial production of *O. oeni* for direct inoculation into wine, by better preparing the bacterial cells for the harsh wine environment.

The genes for malate metabolism have been cloned from *O. oeni* and three genes *mleR* (regulator), *mleA* (enzyme) and *mleP* (permease), have been identified (115). In order for malate metabolism to be initiated and to proceed efficiently in wine, a bacterial population density of at least one million cells/mL is needed. To increase the conversion efficiency of L-malate to L-lactate, it is necessary to understand the regulation of *mleA* by *mleR* and determine the rate-limiting step for malate metabolism, especially important at low cell density. A rapid adaptation of the *O. oeni* cell to its harsh wine environment may also ultimately enhance the catabolism of L-malate.

2. Improving Wine Wholesomeness

The role that malolactic fermentation plays in ethyl carbamate formation remains unclear. Arginine, a quantitatively important amino acid of grape must and wine, is a precursor to ethyl carbamate. Lactic acid bacteria vary in their ability to degrade arginine; experiments conducted in a synthetic and a laboratory vinified wine demonstrated a correlation between arginine degradation, citrulline production and ethyl carbamate formation during malolactic fermentation conducted by an *O. oeni* and *Lb. buchneri* strain (129–131). The arginine catabolism (*arc*) gene cluster of *O. oeni* has been cloned and characterized, thus providing a basis for manipulating the *arc* genes and reducing the potential of ethyl carbamate production (132).

Biogenic amines have undesirable physiological effects when consumed at high concentrations. The major biogenic amines in wine are histamine, phenylethylamine, putrescine and tyramine (133–135). Their concentration is lowest after alcoholic fermentation and increases variably in most wines during malolactic fermentation (136). Wine-associated lactic acid bacteria, including *O. oeni,* have been shown to decarboxylate amino acids to their corresponding amines. This decarboxylation reaction is purported to favor growth and survival in acidic media, since it induces an increase in pH and can also provide energy to the lactic acid bacteria (102,137). Lactic acid bacteria vary in their ability to produce the various amines.

The *O. oeni* histidine decarboxylase gene (*hdc*) has been cloned and characterized (138). A PCR-based test has also been developed for the detection of amino acid decarboxylating genes in lactic acid bacteria (139). The manipulation of the *hdc* gene in *O. oeni* strains with other desirable characteristics would ensure that reduced concentrations of histidine are present in wine.

The removal or reduction of spoilage bacteria (in particular *Lactobacillus* and *Pediococcus* species) which can potentially produce off-flavors and undesirable biogenic amines during grape vinification could be beneficial to the final wine product. The use of bacteriocin-producing species/strains of lactic acid bacteria in other food industries, especially the dairy industry, has met with considerable success. A pediocin producing *Lb. plantarum* strain was shown to efficiently combat the spoilage of cheese by *Listeria monocytogenes* (140). Furthermore, the expression of pediocin PA-1 from *Pediococcus acidilactici* or plantaricin 423 from *Lb. plantarum* by the introduction of the respective genes into *S. cerevisiae* has been shown to effectively eliminate lactic acid bacteria from an alcoholic fermentation (94). A similar strategy could be used to introduce the necessary genes into *O. oeni*.

3. Improving Wine Sensory Attributes

One of the most important flavor compounds associated with malolactic fermentation is diacetyl (a diketone, 2,3-butanedione), which can impart a ''buttery'' or ''butterscotch'' flavor to wine (141–143). Diacetyl is principally formed during malolactic fermentation by the bacterial metabolism of citric acid. This diketone is also an important flavor compound in the dairy industry, providing the characteristic ''buttery'' flavor of many fermented milk products.

The metabolism of diacetyl is well understood (144–146) and the environmental factors that influence its formation and degradation in wine have been established (147,148). The diacetyl pathway has been amenable to genetic manipulation in *Lactococcus lactis*, leading to overproduction of diacetyl (149). With the inactivation of the lactate dehydrogenase gene (*ldh*) in *L. lactis*, there was an accompanying alteration to the metabolic flux, eliminating lactic acid as a metabolic end product and producing ethanol, formate and acetoin. Acetoin is a degradation product of diacetyl and is considered flavorless in wine because of its high aroma threshold. The over expression of α-acetolactate synthase (*ilvBN* genes in *L. lactis*) leads to an increased production of acetoin (the reaction is driven towards acetoin and away from diacetyl), whereas the inactivation of the *aldB* gene (encoding α-acetolactate decarboxylase) resulted in an increased production of α-acetolactate and diacetyl at the expense of acetoin. The latter scenario is quite desirable in the dairy industry. The analogous genes [*alsS* (α-acetolactate synthase) and *alsD* (α-acetolactate decarboxylase)] have been cloned and sequenced from *O. oeni* (150) providing a means of altering diacetyl concentrations in wine. An alternative strategy would be to inactivate the citrate permease gene (*citP*), thus removing the

initial substrate for diacetyl. Such a natural mutant of *O. oeni* has been isolated and is commercially available.

Many potential aroma and flavor compounds are found in grapes and wine as glycosidically bound aglycons (monoterpenes, norisoprenoids, benzene derivatives and aliphates). Though β-glucosidase activity has been demonstrated in *S. cerevisiae* and *O. oeni* (151), both have limited ability to release the disaccharide glycosides. Improving release of glycosides in *O. oeni* strains following malolactic fermentation using similar methods to those described in yeast could lead to enhanced grape variety aroma in the wine.

Various sensory studies pre- and postmalolactic fermentation have shown that the fruity qualities of a wine may be enhanced after malolactic fermentation (152,153). An improved understanding of the formation and further metabolism of esters [acyl alcoholtransferase (ester synthesizing enzymes) and esterases (ester catabolizing enzymes)] in *O. oeni* could lead to the enhancement of specific, desirable esters.

Bitterness is a spoilage problem, primarily in red wine, which can be associated with lactic acid bacteria, including *O. oeni* strains. The fermentation of glycerol can lead to the formation of acrolein, which when it reacts with phenolic hydroxyl groups, results in wine bitterness. The manipulation of glycerol catabolism, for example the glycerol dehydratase, may lead to reduced acrolein formation. The presence of certain peptides is also a potential cause of bitterness in wine. Bitterness due to proteolytic action and formation of short peptides has been studied extensively in dairy-associated lactic acid bacteria. There appears to be minimal proteolytic activity associated with *O. oeni* and the peptide transport system of *O. oeni* is poorly understood. A better understanding of potential bitter wine peptides and their formation could reduce the occurrence of bitterness in some wines.

Numerous malolactic fermentation sensory studies and anecdotal evidence point to changes in the texture and body of the wine following malolactic fermentation, with reports indicating a fuller, richer, longer aftertaste (152). The chemical changes contributing to these favorable mouth-feel properties are poorly understood. The deacidification process itself contributes substantially to changes in mouth-feel, with the consequent increase of pH and decrease in titratable acidity. In addition, lactic acid feels softer than malic acid. Other contributors to wine mouth-feel or taste perception have been suggested, including polysaccharides, glycerol and mannoproteins. The contribution of malolactic fermentation in this area remains to be studied.

Malolactic fermentation has great potential to further enhance wine qualities by retaining or altering the aroma/flavor profile of the wine as well as by conferring microbial stability. However, the genetics of *O. oeni* for all these processes are still not well understood. With the availability of the complete *O. oeni* genome sequence, the development of an efficient gene transfer system into *O. oeni* and the understanding of the various pathways, "tailor made" *O. oeni* strains will become possible.

V. CHALLENGES FACING THE COMMERCIALIZATION OF GENETICALLY IMPROVED GRAPEVINE CULTIVARS AND MICROBIAL STARTER STRAINS

A. Scientific and Technical Hurdles

Despite the strong and persuasive scientific case for the use of gene technology in the improvement of grapes and wine, the wine industry has entered the 21st century without a transgenic grapevine variety or a recombinant microbial starter strain being used on a commercial scale (4). This is partially due to the complex chemical origins of wine quality, which has made the definition of specific and detectable genetic quality improvements difficult. An additional complexity in improving grapevine and wine yeast and bacteria entails the kaleidoscopic sequences of metabolic changes that occur throughout the successive stages of grape ripening and fermentation, respectively. However, considerable progress has been made over the last few years to overcome the technical hurdles in defining the wine industry's requirements genetically and improving grapevine varieties, wine yeast strains and strains of malolactic bacteria accordingly. The development of genetic transformation methods for *S. cerevisiae* (in 1978) and *V. vinifera* (in 1989), and the advent of technology with which entire genomes, transcriptomes, proteomes and metabolomes can be analyzed, have undoubtedly opened up new horizons for the wine industry. However, it is important to note that the information and technology that currently exist for model plant, yeast and bacterial systems have yet to be expanded to the much more complex genomes of grapevine and industrial strains of wine yeast and malolactic bacteria before all of the requirements and concerns of the producers, consumers and regulatory authorities can be addressed satisfactorily (4). The recent promising "prototypes" of genetically engineered grapevine cultivars and microbial starter strains have brought these objectives within the realms of possibility.

B. Legal and Regulatory Hurdles

The initial problems with statutory approval for the use of genetically engineered plants and organisms in the agro-industry are now slowly being dissolved by a growing consensus that risk is primarily a function of the characteristics of a product, rather than the use of genetic modification *per se* (2). The concept of "substantial equivalence" is widely used in the determination of safety by comparison with analogous conventional food and beverage products. When substantial equivalence can be

demonstrated, no further safety considerations usually are necessary. When substantial equivalence is not convincingly shown, the points of difference must be subjected to further safety scrutiny.

The legislation and regulations, although differing in detail, are broadly similar in most countries. Guidelines for the approval of GM products and the release of GMOs usually require a number of obvious guarantees. These include a complete definition of the DNA sequence introduced and the elimination of any sequence that is not indispensable for expression of the desired property; the absence of any selective advantage conferred on the transgenic organism that could allow it to become dominant in natural habitats; no danger to human health and/or the environment from the transformed DNA; and a clear advantage to both the producer and the consumer (2).

C. Intellectual Property and Patenting Hurdles

Patents covering many of the genetic tools (e.g., DNA sequences, gene promoters, marker genes, vectors, etc.) and methods (e.g., transformation protocols) commonly used in genetic engineering leave little ''freedom to operate'' (3,4). It is therefore imperative to address intellectual property issues such as patents or other forms of protection of genes, promoters and technologies through formal agreements (19). If ownership of a genetically improved grapevine, wine yeast or malolactic bacterium is in dispute, the release of such genetically improved grapevine plantlets and microbial strains might cause serious impediment to the commercialization process. On the other hand, genetically tailored grapevines, wine yeasts and malolactic bacteria (with "sufficiently distinct" properties) must also be protected in some way by the developer. However, whether improved grapevine varieties or strains of wine yeast and malolactic bacteria can be patented itself or protected in other ways may also depend on the legislation and regulations in each wine-producing country (19).

D. Political and Economic Hurdles

It is well known that economies are driven by different forces and therefore go through life cycles (54,55). For example, in terms of resources, the *Industrial Economy* was ''the economics of scarcity,'' because everything that fueled the economy was in short supply and available to only a few nations. The current *Information Economy*, which was built on the successes of the *Industrial Economy*, is driven by "the economics of plenty" and, thanks to communications, computer technologies and the Internet, information is no longer a scarce resource. Furthermore, it is already being speculated that the *Information Economy* is only the first phase of the *Bioeconomy*, which rests on the pillars of both Information Technology and Biotechnology (4). There is ample evidence that the *Info-Bioeconomy* has already brought about more economic transformation in the past few decades than was brought by the *Industrial Economy* in the previous centuries. Not everybody perceives all of these transformations as positive changes. Some critics and activists are whipping up public alarm and fueling political agendas and protests against globalization and a universal "borderless" economy. Certain lobby groups also claim that patents on genetically engineered organisms confer an unfair advantage to certain producers, thereby concentrating economic power in the hands of a few large multinational producers (2). Therefore, it can be expected that the commercialization of genetically improved grapevines and wine yeasts would not escape political meddling from the vested interests of economic and agricultural protectionism. The swelling tide in an overflowing ocean of wine is likely to increase the temptation for some to twist scientific data and misuse consumer confusion to justify trade bans and technical barriers to free trade.

E. Marketing Hurdles

The marketing of wine relies a great deal on label integrity and product identity. Therefore, it is of the utmost importance that genetically improved grapevines and yeasts do not interfere with the established varietal names and predictable wine styles. For example, the wine industry relies heavily on a few select cultivars and would therefore be very hesitant to introduce new varietal names (3,4,19). In the most profitable market segments, the varietal name (especially the names of the so-called "Big Five," namely Cabernet Sauvignon, Shiraz, Merlot, Chardonnay and Sauvignon Blanc), together with the origin of production and the vintage, form the cornerstones of the information that is presented on the bottle label to the increasingly brand-conscious customers and consumers. The outcome of the current debate on the description and naming of transgenic grapevines therefore will determine not only the procedure for the description of genetically modified grape varieties, but also, to a large extent, their acceptance by grapegrowers and winemakers and their commercial value in the marketplace (3,4).

This debate on the naming issue entails a number of factors, such as the source of gene(s) introduced into a particular grapevine, the "true-to-typeness" of the transgenic vine when compared to the original cultivar/clone and the organoleptic and sensory qualities of the resulting wine (3,4). Given the immense marketing value contained in varietal names, there is an urgent need for consensus that genetically modified grapevines are little different to grapevine clonal selections, which have been selected on the basis of beneficial, spontaneous genetic variations (e.g., a change in plant performance). When clonal selections are used, the identity may be known to the grape

grower, but the wine is still marketed under the varietal, and not the clonal (typically specified by a clone number) name (19).

It is important to note that many of our modern and most highly regarded wine grapevine cultivars (e.g. Cabernet Sauvignon, Chardonnay, Syrah, etc.) are the product of accidental crosses between varieties grown close to each other, probably in the same vineyard, a common practice in medieval times. The parents of many of today's cultivars are often obscure and sometimes humble varieties. Therefore, we do well to remember that much of the wine that we drink and value today is made from varieties that were already "genetically modified" many centuries ago. However, it remains to be seen whether transgenic grapevines with altered fruit qualities, such as improved color and flavour compound composition, will have to be assigned a new varietal name or just a new clonal number. These uncertainties, together with the impractical, but strong, calls for all products that are produced by gene technology to be labelled specifically, aggravate the wine industry's hesitance to adopt transgenic grapevines and recombinant strains of wine yeast and malolactic bacteria in the face of those who cannot resist riding the dangerous "backlash" market with labels stating that a particular wine product is "GM free" (2,4).

F. Traditional and Cultural Hurdles

The future application of gene technology in the wine industry will have to overcome some more specific hurdles. Foremost, national and, even more relevant, regional wine industries possess strong identities and deep cultural roots, as illustrated by proudly maintained local traditions. Furthermore, wine is generally viewed as a natural beverage produced by time-honored procedures. As a consequence, the industry is less receptive to technologies that promise revolutionary changes. In this context, it is also feared that gene technology may accelerate the tendency to standardize wines to satisfy large supermarket chains and the "average" international consumer, leading to loss of local identity, variety and uniqueness (4). The successful application of recombinant DNA technology in the wine industry will depend on assuring commercial users of transgenic grapevines and recombinant microbial starter strains that existing, desirable characteristics have not been damaged, that the requirements of beverage legislation are met and that the engineered cultivar and strain will be stable in practice, with suitable procedures for monitoring. Once the traditionalists are convinced of a clear organoleptic, hygienic or economic benefit of a transgenic grapevine variety or recombinant microbial starter strain, they would be in a strong position to implement such a vine or yeast, because most of the wine enterprises are fully integrated agro-industries that could exert direct control over the development of new, specialized niche markets for "GM wine products." Wine consumers in such types of niche markets are frequently passionate, well informed, well educated and, above all, very curious. Therefore, GM wines produced by a limited number of interested producers would certainly attract widespread attention and could possibly create a new, successful niche market. Based on such small beginnings, the broader benefits conferred by GM technologies could become apparent to grapegrowers and winemakers, and the technology could move rapidly from satisfying niche markets to general acceptance (4).

G. Public Perception Hurdles

The emotive, fear-mongering qualms and myths of the immorality of "unnatural" genetic interference with Nature, of unsafe "Frankenfood" and global havoc caused by GMOs have spread more readily than good sense or wise science, and far enough to masquerade in the cultural folklore as truth (2). Therefore, public perception of risk with regard to GM food has, so far, outweighed its view of possible benefits. Regulatory authorities appear more willing to approve the use of GMOs than the public is to use them. A significant proportion of the public still suspects that GM food will prove unhealthy in the long term and that the escape of GMOs will damage the environment and result in a loss of biodiversity (154). They also doubt that there is sufficient legal and practical protection against accidents involving GMOs.

It is clear that consumer education is essential to remove this fear of the unknown. Scientists must consistently inform the public and remain open about experiments, research and products. The consumer should be reassured of first-class, transparent regulatory systems and the meticulous implementation of biosafety legislation with clear technical standards and definitions with respect to GM products. The consumer should be persuaded by proper risk assessment and clear demonstration of safety, and thus be empowered to make informed decisions. Assurance must be given that GM wine and other grape-derived products will not be "force-fed" to consumers' for profit when there is no clear advantage for the consumer (4).

VI. CONCLUSIONS AND FUTURE OUTLOOK

The image of wine is romantic and appealing, a harmonious blend of nature, art and science. Wine has been called bottled poetry. But underneath the romance is tension, brought about by the classic clash between tradition and innovation, and no tension in the business of making wine is greater than that created by 21st century grape and wine biotechnology (5).

The production of wine requires a unique integration of artistic, scientific and economic aspects, individual creativeness and innovative technology pursuing perfection

(5). Most modern beverages rely upon bold, consistent flavors to attract and maintain a customer base; by contrast wine's attraction is a subtle assortment of changing sensations that makes its charming romanticism difficult to define (5). Historically the definition of wine quality has been the prerogative of the wine producer, but, in the modern globalized market, the control of this definition has shifted to the consumer. Consumers are purchasing *sensory experiences* when they buy wine, not standardized commodities; the winemaker with the best understanding of the biology of human perception and flavor and olfactory preferences will be most able to satisfy the consumer (5). There is even increasing evidence that different evolutionary pressures have shaped the chemosensory repertoire of the various human population groups (155). This will become an important factor for the exploration of untapped markets, Asia in particular, and for winemakers to offer styles customised for the different "noses and tongues" of the emerging markets.

In addition to wanting a product that is enjoyable in all its sensory aspects, today's consumers increasingly expect wines to be healthful and produced in an environmentally sustainable manner (5). The wine producers of the third millennium must understand the fundamental motivation that underpins consumer choice, and to produce wines of enhanced attractiveness while simultaneously developing and implementing sustainable production practices for both grapegrowing and winemaking. The stakes of success in meeting these consumer expectations are high; wine exports are crucial to the economies of many wine-producing countries.

As winemaking continues to evolve from cottage industries in a few countries into today's global network of producers, ultimate success (read profitability) will increasingly become reliant on biotechnological innovations (54,55). Expanding knowledge of senso-chemistry, fundamental molecular genetics and bioinformatics (including genomics, transcriptomics, proteomics and metabolomics) will continue to accelerate the pace of improving grapevines and microbial starter strains for a market-driven and quality-focused industry. Genetically tailored grapevine cultivars, wine yeast and malolactic bacteria promise to help the wine industry meet the consumers' demand for nutritional benefits and sound environmental practices.

There is a multitude of complex scientific, technical, economic, marketing, safety, legal and ethical issues to be overcome (2,4). To our knowledge, no transgenic grapevine, wine yeast or malolactic bacterium has been used for the production of commercial wine; this will continue to be the case until both consumers and industry are satisfied that GM products are safe, of high quality and beneficial. Given current concerns, it is perceived as commercial suicide to prematurely market the first wine made from transgenic grapes or fermented with recombinant yeast.

It would, however, be crippling to the entire wine sector to ignore the phenomenal potential of gene technology; it could propel the wine industry with quantum leaps into the era of "*designer*" products. That benefit will be realized, however, only if the application is judicious, systematic, and done with high regard for the unique nature of the product. The first GM wine products should unequivocally demonstrate minimal resource inputs, low environmental impact and organoleptic, hygienic and economic advantages for the wine producer and the consumer (54,55). Furthermore, wine's most enthralling and fascinating aspect, its diversity of style, should never be threatened by the use of tailored grapevines and wine yeasts. In fact, gene technology should rather be harnessed to *expand* the diversity of high quality wines. These are very large challenges that will require a substantial and sustained effort to overcome. The rewards for success in this endeavour, however, are correspondingly large (54,55).

175 Manufacture of Whisky

Takefumi Yoneya
Faculty of Cultural Policy and Management, Shizuoka University of Art and Culture

CONTENTS

I. INTRODUCTION

Whisky is one of the world's most loved alcoholic drinks. The word 'whisky' itself derives from the Gaelic '*uisge beatha*,' or 'water of life.' The traditional Latin name for a distilled spirit is aqua vitae, 'water of life' is equivalent to the Gaelic '*uisge beatha.*' Before the 11th century, alchemists invented by accident and gave this name (1).

The Irish were drinking a form of whisky in the 12th century. Henry II of England said that the distillation of the spirit 'usquebaugh' was well established in Ireland when he invaded there in 1172 (2). Distilling was certainly then brought from Ireland to Scotland in the early Middle Ages, although it seems to have been known in the Far East at a very early date among alchemists (3).

Scotch whisky was well established in Scotland by the end of the 15th century. The first record of a commercial transaction involving the supply of whisky (aqua vitae) was in the year 1494. The manufacture of whisky was brought to America in the 17th to 18th century and further developed to the manufacture in Canada. The whisky manufacture was also brought to Japan in the early 20th century. These five countries produce about 95% of the total production in the world and, therefore, they are known to be the five largest international whisky-distilling countries (4,5).

The appellation of whisky, spelled without an 'e' in Scotland, Canada and Japan but with an 'e' in Ireland and America, is the generic name for a distilled product made from saccharified and fermented cereal extracts.

Figure 175.1 is an exhibition of the tools used by the alchemists to make whisky.

II. SCOTTISH MALT WHISKY

The word 'Scotch' is, of course, a contraction of 'Scottish.' It was first used in the mid-19th century (6). Scotch whisky is a spirit produced by human art well established in Scotland by the end of the 15th century and now sold in vast quantities all over the world (2).

Barley, water and peat are the materials to produce the malt whisky of Scotland. Local barley grown in the north-east of the country was originally used and some of the greatest Highland distilleries today use the imported barley. Barley with high starch and low protein is preferred.

FIGURE 175.1 Exhibition room of alchemists in Suntory Whisky Museum (Japan). (Courtesy of Suntory Hakushu Distillery.)

The first process in making the whisky is malting, the turning of barley into malt. Malt is essentially barley that has been promoted to germinate by soaking in water and has then been dried by the application of heat (2). The soaking period in the tank named 'steep' is usually 2 to 3 days, then the water is drained off and the grain is spread out to a depth of 20 to 30 cm on a concrete floor in the malting house. Water content of barley raises to approximately 43% by this soaking. Barley starts to develop the germination on the malting floor and generates energy that rises the temperature. Maltman turned the barley every 4 or 6 hours in order to maintain temperature to be approximately 16°C and to prevent growing roots tangling each other. After 7 to 10 days, the growing stem of the barley becomes half to five-eighths of the length of the seed (4). Some distilleries now adopt huge revolving drums with which aeration and temperature are automatically controlled by computer. These labor-saving drums hold 10 to 50 tons of barley (in case of floor malting 8 to 12 tons).

The germinated green malt is transferred to the drying kiln that has a unique chimney-like oriental pagoda. The floor of the kiln is a drain board made of perforated iron or wire mesh. The green malt is spread on this floor at a depth of 70 cm to 1 m and dried in the smoke arising from a peat fire below the floor (4). Figure 175.2 is a sample of the peat to dry malt.

Besides peat, anthracite and coke are also often used for the fuel and the barley is dried for 40 to 55 hours until the moisture content becomes 3 to 4%. The peat smoke gives a special smoky flavor to the malt and to the final product mature whisky.

A growing number of distilleries no longer do their own malting, but buy their malt ready-made from maltsters, peated to the desired degree. The building of kiln is kept for the symbol of such distilleries (7).

The dried malt is moved to the maltmill and ground to fine grist that consists of husk, grits and flour in the ratio of 2:7:1, respectively (4). The malt grist is placed in a container known as a mash tun and hot water is added. The shape and size of mash tuns vary and they are made from stainless steel, copper and cast iron and usually have a lid (Figure 175.3). The malt is extracted for three or sometimes four times with hot water, each time at a different temperature, ranging from about 60°C, for the first to 100°C for the last (2). Mashing with hot water dissolves the starch from the malt and also activates the amylase that decomposes the starch to maltose.

The resultant liquid, wort, is drawn off from the base of the mash tun through the finely slotted bottom, cooled, and passed into fermentation vessels, or washbacks. The solids, draff, are removed from the mash tun and used as cattle feed (8). Mashing technology has made considerable advances in the brewing industry where the factors of conversion and filtration have tended to become distinct processes (7). The wort is run into a refrigerator and immediately cooled to about 21°C. If the wort is not cooled properly, the maltose would be decomposed and the yeast used in the next process, fermentation, would be killed by the heat.

FIGURE 175.3 Mash tun made from stainless steel. (Courtesy of Suntory Yamazaki Distillery.)

FIGURE 175.2 Peat used to dry malt. (Courtesy of Suntory Yamazaki Distillery.)

FIGURE 175.4 Wooden fermentation vessel, washback. (Courtesy of Suntory Yamazaki Distillery.)

Yeast is added in liquid or solid form to the liquid wort and fermentation takes place at 17 to 35°C for an average of 48 hours in large wooden or stainless steel washbacks (Figure 175.4). The lid of washback incorporates a rotating blade that prevents the foam pouring over the sides.

The inoculated yeast converts maltose into glucose, and then alcohol and carbon dioxide are produced from glucose. Yeast also produce small amounts of other compounds such as wide range of esters, aldehydes, acids and higher alcohols. Many of these are flavor elements. The fermented wort, wash, is a sweet peaty beer with an alcoholic content of 7 to 8% (4). The next process, distillation, is what actually produces the whisky.

Scotland malt whisky has been traditionally distilled in pear-shaped stills (pot stills) which are large copper kettles with narrow necks called lyne arms or lyne pipes that curved and enter the condenser. The shape and size of the pot still affect the quality of the whisky produced. Stills come in three basic designs; the 'onion' being the most common, the 'boil-ball' and the 'lantern' shape (Figure 175.5). The way these designs are interpreted - as to capacity, height, method of heating, angle of the lyne arm etc. differs from one distillery to another, and varies on the quantity of volatiles that will end up in the spirits (9,10). While many distilleries have retained or even switched back to direct firing either by coal or gas, a large number of distilleries now heat the stills by means of internal steam exchangers (7).

Another key aspect of still design is the area of copper that comes into contact with the wash and low wines. Copper dissolves easily and has an important influence on the quality of the spirit, since it removes sulfury or vegetable aromas by chemical reaction (10).

Since malt whisky is usually produced after two times distillation (occasionally a third still is installed), every distillery must have at least two such stills.

After fermentation, the wash passes through the wash charger, into the wash still (or singling still) for the first distillation. The charged volume is between half and two-thirds capacity, in order to allow for the expansion of the wash and the froth which builds up as it heated (10). In the still, the wash is heated and the alcoholic vapors that are boiling at a lower temperature (78.3°C) than water pass up the neck of the still and down through the worm (coiled copper pipe) within a water jacket (worm tub or condenser). The distillate from the wash, low wines, consists of 21 to 24% by volume of alcohol (ABV). A wash still of 30 000 liters capacity, charged with 20 000 liters, will remove alcohol and water at about 1,000 to 1,500 liters per hour. At the end of the run about a third of the wash will have become low wines (10).

This distillation process is repeated in the low wine still (or double still) which is smaller than wash still. During the second distillation, the stillman monitors its progress carefully as it runs through the spirit safe (Figure 175.6). The spirit safe contains several glass bowls into which the spirit can be directed using external faucets by the stillman. The stillman will start to test the spirit as soon as the condensed vapors pass through the spirit safe. The first liquid to the glass bowls, known as foreshots or head, turns cloudy when water is added (called demisting test) as they are still impure. The aldehyde, esters, furfural and other compounds of hydrogen, oxygen and carbon formed in the process of distilling the wash and known generally as congeneric are present in excess in the foreshots but they also give pot-still malt whisky its special bouquet and flavor (2). The foreshots are directed into the low wine charger to be redistilled in the low wine still. The stillman will continue to test the spirit in the spirit safe by adding water at regular intervals and checking the specific gravity.

As soon as the spirit ceases to turn cloudy with the addition of water, the stillman will immediately turn the faucets on the outside of the spirit safe and direct the spirit into the spirit receiver (8). When the spirit starts to weaken, this weakened spirit, called feints or tail, is run into the feints receiver. Stillmans stop collecting the spirit at the point when the alcohol content is as high as 69% by

FIGURE 175.5 Pot stills with various shape and size. (Courtesy of Suntory Yamazaki Distillery.)

FIGURE 175.6 The spirit safe — the apparatus to control the distillation. (Courtesy of Suntory Yamazaki Distillery.)

volume of alcohol for the lighter whisky character while as low as 60% for the heavier whisky character (10). The collected foreshots and feints will be added to the next wash for the distillation. The residue in the low wine still, spent lees, is little more than water, with a very small amount of copper from the still in solution: it is of no use or value and is gone to waste (10).

The spirit directed to the spirit receiver is called hearts or middle cut which consists of about 70% by volume of alcohol. The amount of the hearts is approximately a third of the spirit distilled. The immature spirit, called new pot or new spirit, is piped to the filling station, where it is diluted with water until its strength is reduced to 63.5% by volume of alcohol (4), prior to being run into casks which are made from American white oak (*Quercus alba*) or European oak (*Quercus robur*). Oakwood is thought to be desirable for maturing whisky because of its chemical complexity. The casks are second-hand that have once stored mainly either sherry or bourbon, and in rare cases port or other wines.

New spirits filled in casks are matured in bonded warehouses called 'dunnage' warehouses at least three years and after that they can be legally called Scotch whisky. If they are to be used for 'single malt' or for 'deluxe blend,' the cask will be stored for at least 10 to 15 years (8). But there is always the danger of the whisky acquiring a slightly 'woody' flavor after 15 years (2).

Whisky maturation is influenced by the factors such as the nature and history of the cask, the style of warehouse and its location, the outside microclimate of casks and maturation period. Oak casks that have previously been filled with sherry give a splendid mellowing effect (color, softness, richness, and smoothness) to the mature whisky while bourbon casks give a typically vanilla-like aroma. The process of charring the inside walls of bourbon cask prior to their first use also contributes to the flavor of malt whisky. This releases vanillin into the spirits and assists in removing undesirable off-notes. Oakwood also facilitates oxidation, which remove harshness, increases fruitiness and adds complexity (10).

The smaller the cask, the faster the maturing and the larger the amount of whisky lost through absorption by the porosity of the wood of cask. The degree of humidity in the warehouse where the casks lie during the maturation also affects the degree the loss of maturing whisky both its volume and its strength: the greater the humidity the more it loses strength, and the drier the more it loses volume (2). This is known as "angel's share," losing 1 to 3% every year (4). After ten year's maturation, alcohol content decreases to around 60%; the volume becomes 80% of the initial filling. The longer whisky is matured in the cask, the more changes of color and flavor will take place. Whisky is further diluted with water until its strength is reduced to 40 to 60% by volume of alcohol, prior to being run into bottles. Soft water free from organic and mineral impurity is the preferred water used for the whisky production.

Once run into the bottles, whisky does not further mature but some chemical changes will occur.

Since whisky when distilled is almost colorless, some degree of coloring is often added. Although malt whisky may acquire a certain amount of color while it is being matured in old oak sherry casks, it is an open secret that this can also be due to caramel or even sherry (11). Recently, a light colored whisky is becoming popular in the United States and Japanese markets. The manufacturer will also bear in mind the color of whisky preferred by the consumer.

Single malt whisky is the product of the single distillery. The age shown on the bottle label means the length of the youngest whisky's maturation period.

A vatted malt whisky is the product that is married together with various malt whiskies from different distilleries. A vatted malt whisky is labeled 'Pure Malt' or 'Scotch Malt Whisky.' It is impossible to determine the optimum age for whisky in general terms; so much depends on the individual case.

There are about 110 malt whisky distilleries in Scotland and about 80 to 90 distilleries are now in operation (12–14).

The traditional division of Scotch whisky is into Highland Malts, Lowland Malts, Campbeltown and Islays (15–18).

III. SCOTTISH GRAIN WHISKY

Scottish grain whisky is produced largely from maize with a small amount of malted barley that is not dried over peat fires. (The unmalted barley is also sometimes used with the maize.) The unmalted cereal is crushed and then pressure-cooked in batch cookers to gelatinize the starch so that it can be released and solubilized. Wet ground malted barley is added one-fifth of the amount of the unmalted cereal, then hot water; and the mixture is stirred (2). Amylase from malted barley converts the starch to fermentable sugars, maltose.

While many distillers retain this system, there is an increasing use of continuous operation for the cooking and conversion process (7). Fermentation of the wort is done in the same way by the action of inoculated yeast as the case of the making of malt whisky. The fermented wort, wash, is pumped into the patent still or Coffey still which can distillate with a different system from the distillation with pot still.

The patent still was first invented by Robert Stein in 1826 and was improved by Aeneas Coffey in 1831. According to the invention of patent still, making whisky has become quicker, cheaper, and in greater amounts. Its product has no peaty flavor, for the malt has not been dried over peat fires (2,4). The patent still basically consists of two linked copper columns, 12 to 15 m high; these are the analyzer and the rectifier. Each is divided horizontally into tens of chambers by perforated copper plates (Figure 175.7). Steam is led into the analyzer and proceeds up the

FIGURE 175.7 A copper plate of patent still. (Courtesy of Suntory Hakushu Distillery.)

FIGURE 175.8 A large plant of patent still. (Courtesy of Sun Grain Ltd.)

analyzer and then through the linking pipe into the rectifier.

The wash is continuously pumped into the rectifier that comes down in a coiled copper pipe and then by the connecting wash pipe into the top of the analyzer. The heated wash moves down, chamber by chamber in the analyzer and all the alcohol contained is vaporized before the wash reaches to the base of the analyzer. The steam and alcohol vapors, which rise up through the analyzer, go down the connecting vapor pipe (which emerges from the top of the analyzer) into the base of rectifier. As the alcohol vapor and the steam come more up to the rectifier, chamber by chamber, the new incomes wash, coming down the rectifier in its winding pipe, is then cooled, so that condensation takes place (2,16). Around 95% alcohol can be obtained when the vapor is drawn off through a cooling worm to the stainless steel spirit receivers. [Alcohol strength for making whisky is regulated below 94.8% by the law of Scotland (4).] Figure 175.8 shows one of the modern plants of patent still which uses more than two columns.

The spirit is then diluted with water around 70% by volume of alcohol, prior to being run into the secondhand oak casks that were previously used for the mature of malt whisky. The spirit-filled casks are stored in the warehouse for at least 3 years, the same as malt whisky (4). The grain whisky, being nearer neutral spirits than pot-still malt whisky, takes less time to mature and changes less in maturing. There are two types of grain whisky, one is single grain whisky produced in one distiller and the other is that produced by vatting the whiskies distilled in different distilleries. Only eight grain-distilleries are in operation and seven distilleries among these are located in Lowland (6).

IV. SCOTTISH BLEND WHISKY

Blending can involve combining around 20 to 50 different malt whiskies with 2 to 5 grain whiskies to produce a whisky with a more rounded character (2,16). Blends are central to the Scotch whisky market, outselling malt whiskies at a ratio of around nine bottles of blended whisky to one bottle of malt whisky. Andrew Usher, in Edinburgh pioneered blending in the early 1860s (4). Today, blending provides the distiller with an opportunity to create a product with unique and recognizable flavor attributes. It also enables product consistency. The proportion is 60 grain to 40 malt, and that the proportion of grain has risen since the earlier day of blending, when it was more likely to be 50:50 (2). Deluxe blended whiskies generally contain a higher ratio of malt to grain than standard blends (1).

The blended whisky is stored in oak casks (generally plain oak) for between 6 months and a year in order to optimize the product quality. Some blenders ‘marry’ the malts and the grains separately and bring them together only in bottling. Prior to bottling, the whisky is usually diluted to market strength, caramel is added to ensure continuity of coloring, and finally the spirit is filtered to prevent cloudiness from developing when water is added by the consumer (1). As for blends, the age (if any) stated on the label is the age of the youngest whisky in the blend. A flow diagram for the production of Scotch whisky is shown in Figure 175.9.

V. IRISH WHISKEY

Irish whiskey is whiskey distilled in Ireland. It is well known that the whiskey distilling originated in Ireland. The Irish were drinking a form of whiskey in the 12th century and the skills of whiskey making were brought to Scotland (1,2,16). The extra ‘e’ in the name is traditional, but gives no special meaning (6).

Malt and unmalted barley are what is needed to produce the malt whiskey of Ireland. Much of the current productions also use oats, wheat, and rye with barley. The

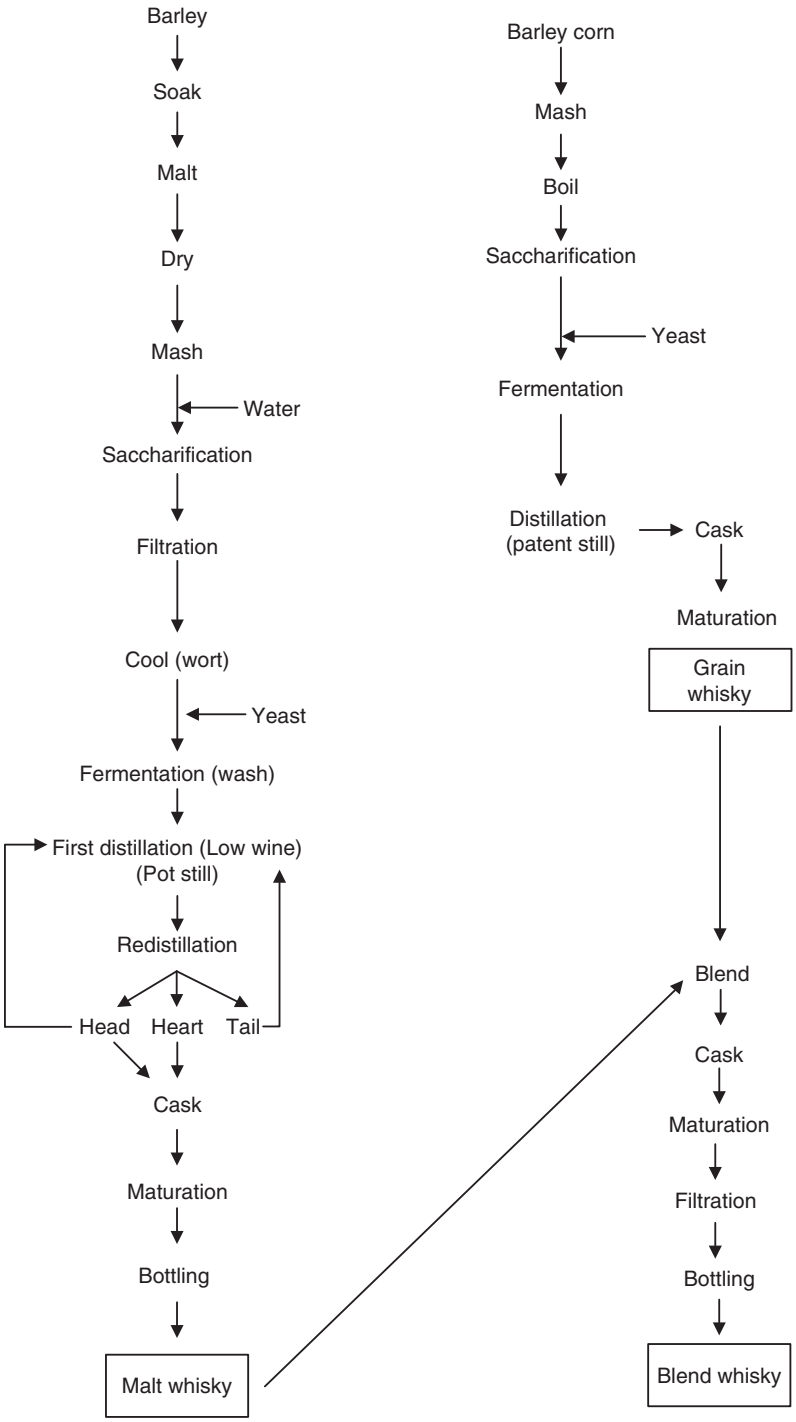

FIGURE 175.9 Flow diagram for the production of Scotch whisky.

size and design of Irish pot stills are quite different from Scottish pot stills. The size of pot stills in Scotland is in the range of 2,000 to 30,000 liters, while Irish stills are in the range of 50,000 to 150,000 liters. Irish stills are attached with the purifiers that remove congenerics such as the aldehydes, esters, furfural and other compounds of hydrogen, oxygen and carbon formed in the process of distilling of wash (2).

The distillation profiles of Irish whiskey are also different from that of Scotch whisky. The low wines obtained from the wash still are separated into two fractions according to the difference of alcohol concentration. The

weak low wines are distilled in a low wines still to obtain further fractionation, strong and weak feints. The weak feints are redistilled with the next batch of weak low wines, while the strong feints are added to the strong low wines for the third distillation (Figure 175.10).

The alcohol concentration (about 80% ABV) of the new spirit is much higher than the equivalent Scottish malt (6). New spirits that are reduced to 63.5% ABV are filled into secondhand casks of bourbon, rum and sherry for at least 3 years (usually 5 to 7 years). These straight Irish whiskeys are blended with grain whiskey before bottling. The more temperate climate of Ireland produces whiskeys with a slightly spicier taste and a crisp finish (8). Although the market of Irish whiskey is limited, it is internationally recognized as a distinct generic brand (5).

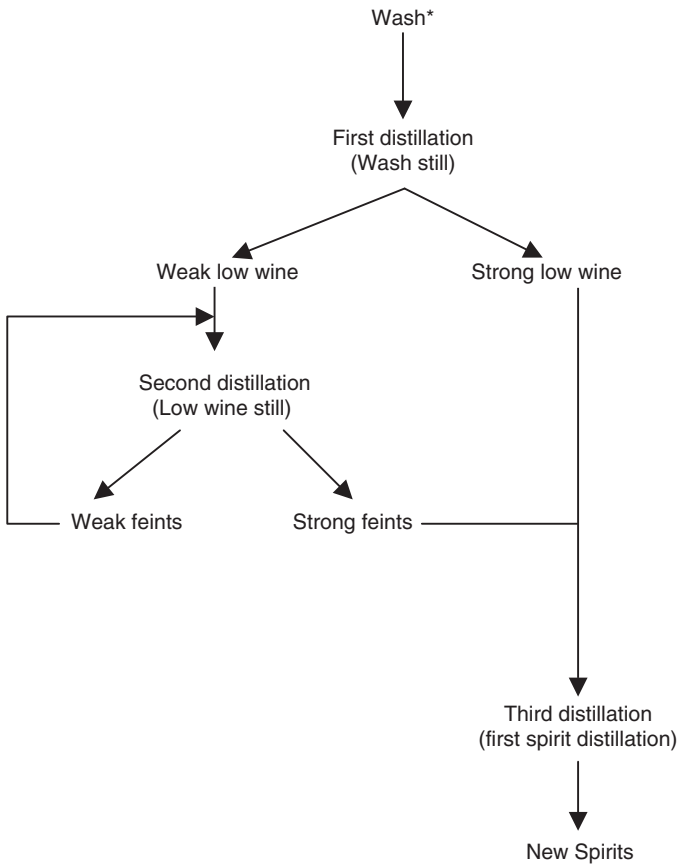
VI. AMERICAN WHISKEY

Contrary to what many people believe, Bourbon is one of a number of American whiskeys and its name was taken from Bourbon County in the state of Kentucky. By law, Bourbon must be produced from a mash of not less than 51% corn grain, and is usually made from between 70% and 90% corn, with some barley malt and rye or wheat (6,19).

The sour mash technique is one of the distinctive styles of American whiskey. The lactic acid bacteria is inoculated in order to prevent the bacterial contamination, then the residue (called backset or setback) of former distillation is added prior to yeast fermentation. If no sour mash is added at the start of fermentation, the result is called sweet-mash straight whiskey (6).

The distillation is done in column stills (patent stills) which is in common with nearly all American whiskeys. Spirits are collected at relatively low alcohol concentrations from 64 to 70% by volume. Therefore various flavor components are also included, hence the product has distinct aroma. The spirit is matured at least for 2 years in new white-oak barrels that have been charred. Charring has been used as a means of disinfecting barrels since the early 19th century. In bourbons, the definite characteristics are the tones of vanillin and caramel that the whiskey takes from the wood. It is bottled at over 40% by volume of alcohol (Figure 175.11).

Tennessee whiskey, which is legally classified as bourbon, is produced in the state of Tennessee in the same way as the method of Kentucky bourbon. The new spirit is filtered through the maple charcoal, prior to the maturation in the barrel. It has a mellow taste.



* See Figure 175.9 on flow sheet of Scotch whisky making for production of Wash.

FIGURE 175.10 Flow diagram for the production of new spirits for Irish whiskey.

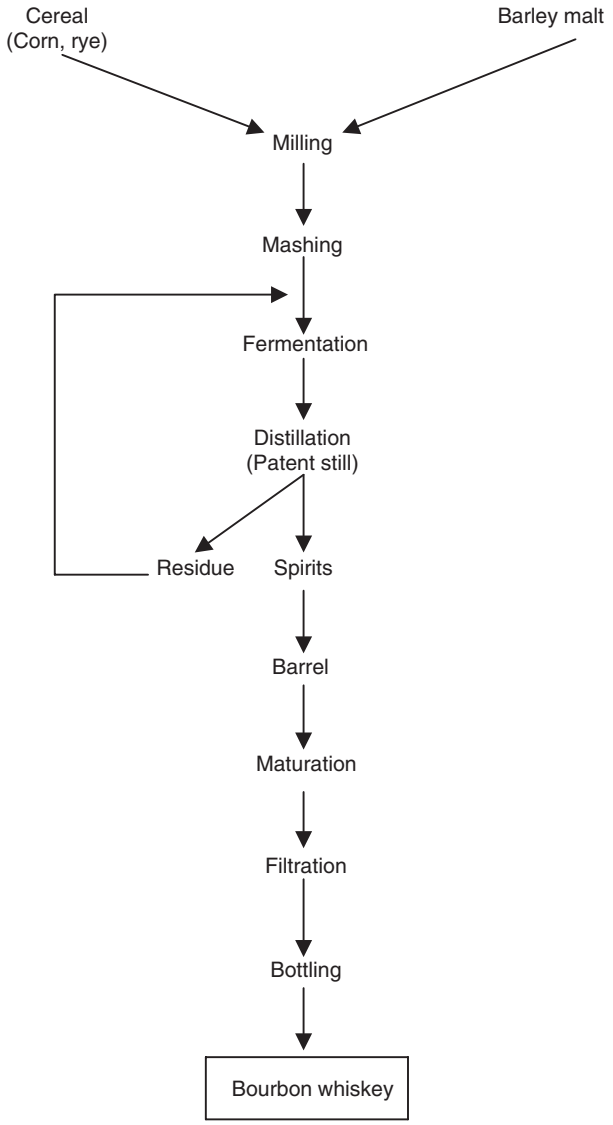


FIGURE 175.11 Flow diagram for the production of bourbon whiskey.

Rye whiskey is made from a mix of grains containing a minimum of 51% rye and straight rye is matured at least for 2 years in the charred white-oak barrels.

Corn whiskey is made from a mixture of grains containing a minimum of 80% corn. The product matured at least for 2 years in the oak barrels is called straight corn whiskey (16).

A neutral grain spirit is also made in the United States and it is exclusively used in blends.

VII. CANADIAN WHISKY

Canadian whisky is the whisky that is distilled in Canada. Hiram Walker in 1858 founded the first distillery and the product was launched as Canadian Club brand in 1884 (6). It is produced from corn, rye and barley malt. When rye is used over 51%, its product can be named 'rye whisky.'

There are two types: one is the flavoring whisky that is produced mainly from rye and the other is the base whisky that is made mainly from corn. Both are distilled in column stills. Flavoring whisky is matured in a charred barrel (new or old) and the base whisky is matured in regenerated bourbon barrels. Both are matured in the small barrels (smaller than 180 liters) for at least 3 years, then blended to make various brands. Canadian whisky is characteristic as flavory, light and mild, as compared to other whiskies (17).

Canadian whisky has been industrially developed to supply mainly the USA market. Today, there are a dozen or so distilleries across the country (6).

VIII. JAPANESE WHISKY

Although the whisky industry of Japan was not founded by Scottish/Irish immigrants, Japanese and Scottish distillers have strong ties. The first distillers were trained in Scotland and took their newly found knowledge to traditional sake distilleries in Japan (Figure 175.12) (5,8).

The first Japanese distillery was established in 1923 in the valley of Yamazaki on the outskirts of Kyoto. Its first whisky was launched in 1929. This whisky was a blended product of malt and unmatured neutral spirit and the neutral spirit has been replaced with a matured grain whisky made from North American maize.

The Japanese distilling industry have renewed their bonds with Scotland by buying into Scottish distillery operations. Other Japanese businesses and trading houses have also participated in the growth of whisky distilling, either by setting up joint venture companies or by importing Scotch whisky. They set out to produce the best raw materials, distilling technology, and maturing conditions required in producing a 'Scotch malt' type of whisky.

FIGURE 175.12 Suntory Whisky Building in Yamazaki Distillery (Japan). (Courtesy of Suntory Yamazaki Distillery.)

The landscape of the northern island, Hokkaido, is very similar to that of the Highland of Scotland with peat bogs, mountains, and cool, fresh streams, which flow over granite rocks (5,7). The peat produces a less intensive aroma than Scotland peat. Yoichi distillery of Nikka Company on the island Hokkaido east of the city Sapporo makes the most peaty of Japanese single malts (6).

Malt is imported, with a large proportion coming from Scotland and an increasing amount from Australia. Malt whisky was (and still is) fermented in wooden wash backs with cultured yeast, and distilled in traditional copper wash and spirit pot stills.

The grain whisky is made using North American maize, which is mashed and distilled conventionally. As in Scotland, malt and grain whiskies are matured in oak casks before blending (Figure 175.13).

The most popular brands are blends, but the Suntory and Nikka companies have been successfully developed single malts. They are indeed whiskies in their own right, not just as copies of Scotch as some people claim, even if a small number of Japanese blends and pure malts are based on Scotch single malts (6).

Most Japanese whisky businesses now fully own distilling, maturation and blending facilities in Scotland, setting a consumer trend that will continue into the future (Figure 175.14) (5).

IX. CONCLUSION

Whisky is world's most consistently successful and popular alcoholic drink that was commenced in Scotland in 1494 according to documentary records. Scotland, Ireland, the United States, Canada and Japan are now considered to be the five major whisky-producing countries. They developed their own individual style of whisky into something approaching a fine art.

FIGURE 175.14 A display of the whisky made in the five major whisky-producing countries. (Courtesy of Suntory Yamazaki Distillery.)

Recently the 'light' whiskies that have light flavor, color and body are pushed mainly in the United States and Japanese markets. And the proportion of single malts to blends consumed, even in Scotland, is very small; but there is nevertheless a steady rise in the availability and the consumption of single malts both in Britain and in certain overseas countries (2). The marketer must have eyes to lookout the consumer trends and make an effort to meet their needs. However, each country's particular style will remain basically unchanged.

Food Fermentation

176 Fermentation: Principles and Microorganisms

Ken-Yuon Li
Department of Food Science, Tung-Hai University

CONTENTS

I. INTRODUCTION

The use of microorganisms to process or preserve foods is an ancient technique. Yeast was the first microorganism used in the production of wine, beer and the leavening of dough. These techniques have been known for at least 4,000–5,000 years. When these processes are underway, bubbles form as in gentle boiling. This bubbling is due to the liberation of carbon dioxide gas from the degradation of sugar. The word fermentation signifies the gentle bubbling or boiling condition in these processes.

The nature of the fermentation reaction did not become clearly understood until the late part of the 19th century when Louis Pasteur discovered the relationship between living cells and fermentation. In 1854, Pasteur demonstrated the relationship between yeast and this reaction. The word fermentation became associated with microorganisms. Pasteur also showed that true

fermentation occurs only in the absence of free oxygen. He called life without air anaerobiosis. Actually, the definition of fermentation in biochemistry is the extraction of energy from carbohydrates and other organic substrates without using O_2 as an electron acceptor. Hence fermentation is an energy-yielding catabolic pathway that proceeds with no net change in the oxidation state of the products compared to that of the substrate. The common usage of the word fermentation frequently overlooks the strict biochemistry definition. A broad sense was adopted, that is, a process in which microorganisms produce chemical changes in organic substrates through the action of enzymes produced by these microorganisms. According to the common usage, the term "fermented foods" is used to describe a special class of foods that contain a complex mixture of carbohydrates, proteins, fats, etc., undergoing simultaneous modification under the action of a variety of microorganisms and enzymes. Reactions involving carbohydrates and carbohydrate-like materials are referred to as "fermentative." Changes in proteinaceous materials are designated "proteolytic," and the breakdown of fatty substances are described as "lipolytic." When complex foods are "fermented" under natural conditions, they invariably undergo different degrees of each type of change. Whether fermentative, proteolytic, or lipolytic end products dominate will depend upon the nature of the food, the types of microorganisms present and the environmental conditions affecting their growth and metabolic patterns.

The basic concept of fermentation is to facilitate the proliferation and predomination of desirable microorganism in the raw plant materials. The desirable microorganisms will metabolize sugars into chemicals such as lactate, ethanol and acetate that infuse the plant materials with various characteristics. The addition of salt and the inoculation of a defined microbial culture are the two basic methods for controlling the growth of microorganisms during fermentation. In this chapter, we will describe the predominant bacterial strains occurring in some popular fermented vegetables, illustrate their sugar metabolic reactions, and discuss how fermentation is manipulated with these organisms.

II. THE FERMENTATION OF VEGETABLES

At present only cabbage (sauerkraut and Korean kimchi), cucumbers (pickles), and olives are of real economic importance. In this chapter, the discussion is focused on these vegetable products. In addition to these vegetables, fermented carrots, the potential new products, and fermented bamboo shoots will be described.

A. Cabbage Fermentation

Sauerkraut is a fermented product made from fresh cabbage. In the cabbage fermentation process lactic acid bacteria are favored. The addition of 2.25–2.5% salt restricts the activities of undesirable gram-negative bacteria. The fermentation is started by *Leuconostoc mensenteroids*. This bacterium converts sugar to lactic acid, acetic acid, alcohol, CO_2, and other products that contribute to the flavor of sauerkraut. CO_2 helps maintain the anaerobic conditions necessary in fermenting cabbage. As the acids accumulate, *Leu. mensenteroids* is inhibited, but the fermentation continues with *Lactobacillus brevis, Pediococcus cerevisiae*, and finally, *Lactobacillus plantarum*. *Lb. plantarum* and *Lb. brevis* effect the final stages of sauerkraut production. *P. cerevisiae* and *Enterococcus faecalis* may also contribute to product development (1).

Kimchi is a traditional Korean fermented vegetable product. Kimchi fermentation is the Korean method for preserving a fresh and crispy vegetable texture for consumption during the winter when fresh vegetables are not available. Although the history of kimchi fermentation in Korea can be traced to the 3rd and 4th centuries, the earliest description of the processing methods is found in 17th century works of literature (2). The fresh cabbage is cut in half or shredded, soaked in brine with an approximately 10% salt concentration overnight and then washed and drained. The minor ingredients (garlic, red pepper, green onion, ginger) are chopped and mixed with shredded radish and stuffed between the salted cabbage leaves. The kimchi is packed in an earthen jar, buried in the ground, and pressed with a stone placed inside in order to keep the ingredients immersed in the juice. Before ripening, *Leu. mensenteroides* is the dominant microorganism, while *Lactobacillus* spp. are the major organisms in overripened kimchi. *Lactobacillus* species may be dominant in the later stages of kimchi fermentation depending on the temperature (2).

The difference between sauerkraut and kimchi is the of fermentation end-point. The best-tasting kimchi is attained before *Lb. brevis* and *Lb. plantarum* overgrowth occurs with an optimal pH of 4.5. The *Lb. brevis* and *Lb. plantarum* overgrowth diminishes the product quality, but sauerkraut production depends on these organisms.

B. Cucumber Fermentation

In the natural fermentation of pickles, selected cucumbers are placed in brine with about 5% NaCl. The brine strength is gradually increased during fermentation until it reaches around 16% NaCl. The sugars that diffuse from the cucumbers are fermented sequentially by *Leu. mensenteroides*, *P. cerevisiae*, *Lb. brevis*, and *Lb. plantarum*. Depending on the of fermentation condition, about 0.6 to 1.2 % lactic acid is formed in about 7 to 14 days. When the pH is lowered to 3.2, the metabolism of *Lb. plantarum* is inhibited and the fermentation is completed. In this process, the high salt level is used to protect against spoilage. The fermented cucumber must be desalted before being used in products.

However, the NaCl level in the desalting solution creates a serious dumping problem. Procedures have been developed for brining cucumbers in closed anaerobic tanks at substantially lower salt concentrations (3). This approach to fermentation has the potential to allow cucumber fermentation and storage at sufficiently low salt concentrations that require no desalting.

In natural fermentation, bloating in defective pickles often occurs. Bloating is due to the accumulation of CO_2 gas inside the cucumber during fermentation. The respiration of cucumber tissue and fermentation by *P. cerevisiae* and *Lb. plantarum* produce sufficient CO_2 to cause bloating (4). The degradation of malic acid to lactic acid is a major source of CO_2 when *Lb. plantarum* ferments brined cucumbers. Research has demonstrated that using a mixed culture with a malolactic-deficient mutant and normal malolactic strain of *Lb. plantarum* in brined cucumber fermentation could reduce the level of released CO_2 (5).

In cucumber fermentation, yeast has conventionally been viewed as undesirable because it produces CO_2. However, when N_2 is used in purging cucumber fermentation tanks to prevent bloater damage, using yeast (*Saccharomyces cerevisiae* or *S. rosei*) in the mixed culture can facilitate complete sugar metabolization (6).

Softening in defective pickles is another problem. Softening is attributed to pectinolytic enzymes that degrade the cucumber tissue. The source of these enzymes may be the microorganisms growing in or on the cucumbers. To reduce fermentation defects, a controlled fermentation process is used. The controlled fermentation method employs a chlorinated brine with 25° salinometer, acidification with acetic acid, the addition of sodium acetate, and inoculation with *P. cerevisiae*, and *Lb. plantarum* (7).

C. Olive Fermentation

Olive fermentation is similar to that in sauerkraut except that the olives are soaked in a 1.6 to 2.0% lye solution before brining. The lye treatment is necessary to remove oleuropein, a bitter factor in the olives. The olives are brined in containers following the complete removal of lye by rinsing the olives in fresh water. The brine concentration varies from 5 to 15%, depending on the variety and size of the olives (8). Lactic acid bacteria become prominent during the intermediate stage of fermentation. *Leu. mensenteroides* and *P. cerevisiae* are the first lactic acid bacteria to become prominent. These bacteria are followed by lactobacilli, with *Lb. plantarum* and *Lb. brevis* being the most important (9). The lye treatment may affect the microbial flora. Inoculation with *Lb. plantarum* may be required. A study has showed that using a strain of *Lb. plantarum* with the capability to produce bacteriocin as a starter controls lactic acid fermentation much better (10). The entire fermentation process may take two weeks to several months. The acid content of the final product varies from 0.18 to 1.27% (11).

D. Carrot Fermentation

Carrots are not a traditional vegetable for fermentation. Until 1969, carrots were fermented using a home-based process (12). Fermentation provides a simple method to preserve raw carrots. The raw carrot slices contain a high level of reducing sugar that might cause Maillard reactions and produces dark compounds with a burnt smell during thermal processes. Using lactic acid fermentation, the reducing sugar content in the raw carrot can be decreased to a level that allow the carrot slices to be processed using high temperature deep-frying to yield chips. The deep-fried carrot chips have a light red-yellow color and pleasant taste that makes them a potential new product (13).

A mixed culture of *Lb. plantarum*, *Lb. brevis*, *P. cerevisiae* and *Leu. mesenteriodes* is used to ferment carrots (14). Use of carrot-adapted inocula significantly reduced the lag period for early acid production despite the salt concentration. The repressive effects of increased salt concentrations on the rate of fermentation is that carrots treated with the lowest level of salt, 1.5%, require only 10 days incubation to produce a 1.0% acid level, whereas a 3.0% salt concentration requires 18 days incubation to reach a similar acid value. The acidic properties of fermented brines resemble the fermentation properties of the cabbage head brining solution (15).

A new process for carrot fermentation using an alkaline treatment with lye before inoculating a pure culture of *Lb. plantarum* was developed (16). The alkaline treatment helps inoculum establishment over the natural flora in the fermentation. However, most of the sucrose remains unmetabolized after 7 days of fermentation. Thus, long-term stability in the fermented carrots is not ensured. A high risk of secondary fermentation may present in the package product. This process was further modified using a mixed culture of *Lb. plantarum* and *S. cerevisiae* to replace the single culture of *Lb. plantarum*. The result indicated that the mixed culture was able to completely use up all of the sugars and, at same time, improve the flavor of the fermented carrots (17).

E. Bamboo Shoot Fermentation

People in the bamboo-growing regions of Asia have traditionally consumed fermented bamboo shoots. Dried Ma-bamboo (*Dendrocalamus latiflorus*) shoot is a special product of Taiwan (18). Mesu is a similar product from India (19). Both are produced by using non-salted fermentation with natural cultures.

Using mesu as a pickle and as the base for curry is a tradition in the Darjeeling hills and Sikkim area of India. A study has shown that a total of 327 strains of lactic acid

bacteria, representing *Lb. plantarum, Lb. pentosaceus* were isolated from 30 samples of mesu. These species were present in all of the raw bamboo shoot samples tested. Mesu is dominated by *Lb. plantarum* followed by *L. brevis*. *P. pentosaceus* was isolated less frequently and recovered from only 40–50% of the mesu samples. Fermentation is initiated by *P. pentosaceus*, followed by *L. brevis*, and finally succeeded by *L. plantarum* species. During the fermentation, the titrable acidity increased from 0.04 to 0.95%, resulting in a decline in pH from 6.4 to 3.8 (20). Ma-bamboo shoots are fermented using a traditional natural culture. After 10 days of fermentation, the fermented bamboo shoots contain about 10^9 cfu/g of lactic acid bacteria, and 10^4–10^6 cells/g of yeast and mold. The final pH was 3.3 to 4.1, and the titrable acid was 1.05–1.20% (19).

III. FERMENTATION TECHNIQUES

The procedures for vegetable fermentation are varied and complicated. Basically, vegetable fermentation can be considered as a three-staged process.

A. Stage 1 Consists of the Pretreatment Steps

In this stage, the common operations include sorting and grading raw vegetables, cleaning the selected vegetables, specific pretreatment, such as peeling carrots, blanching green beans, shredding cabbage, or lye-treating olives.

B. Stage 2 Is the Fermentation Environment Adjustment Operation

Adding salt and inoculating the defined starter culture are two methods to set up a suitable environment around the vegetables to allow the desirable microflora proliferate and predominate.

Salt addition is necessary in most kinds of vegetable fermentation. The major contributions of salt are: to inhibit the growth of pathogens and destroy spoilage microorganisms; to exert a selective effect on the microorganisms present on vegetables; to enhance the release of tissue fluids from the fermenting vegetables, and to impose a special flavor on the fermented vegetables. The amount of salt used depends on the particular vegetables. In the fermentation of cucumbers and olives, the salt concentration is 5–8% at equilibrium. For cabbages the salt concentration is less than 2.5% at equilibrium. The difference in salt concentration between that used in sauerkraut fermentation and pickle fermentation probably accounts for the difference in the types of lactic acid bacteria that grow in each fermentation environment (21).

The application of a defined starter culture is an another method to facilitate the predomination of desirable microflora in the fermenting vegetables. The lactic acid bacteria used for this purpose include *Lactobacillus* species (*Lb. plantarum* and *Lb. casei* are the most often used.), *Lactococcus lactis*, and *Leu. mensenteroides*. The defined starter cultures are capable of growing rapidly and are highly competitive under the environmental conditions used to ferment products.

C. Stage 3 Is the Vegetable Fermentation Process

Temperature, pH value and anaerobiosis maintenance are major factors that influence the course of fermentation. The temperature range for vegetable fermentation is 16 to 35°C. Vegetables fermenting at 10°C lead to good-quality products. Usually, the optimal temperature is between 15 and 20°C. Various microorganisms may dominate a mixed fermentation depending on the temperature. For sauerkraut fermentation, the preferred temperature is 18°C or lower. The predominant strain *Leu. mensenteroides* grows optimally at a lower temperature than the homofermentative *Lb. plantarum*, presumably resulting in a higher ratio of volatile/nonvolatile acids than at higher temperatures. For cucumber fermentation, the predominant cultures of *P. pentosaceus* and *Lb. plantarum* are capable of rapid growth at 18°C (22). The optimal temperature for vegetable fermentation depends on the predominant cultures during the fermentation.

The buffering capacity of the vegetable affects the extent of proliferation of the predominant culture used to ferment the natural sugars. Several methods have been adopted to maintain the pH during fermentation. Sodium acetate (23) and calcium acetate (24) have been used as buffering agents to assure complete sugar utilization during the primary fermentation of cucumbers. Acid neutralization during fermentation with a pH controller has also been used to assure complete sugar utilization (25). In the fermentation of carrots, sodium hydroxide treatment of peeled and trimmed carrots is a useful alternative to pasteurization to achieve controlled fermentation. Subsequent neutralization of the NaOH by adding acetic acid to the brine could lead to the formation of a buffer system in the brine. The buffer system benefits greater utilization of the fermentable sugars by the starter culture (26). For preserving fermented vegetables for long periods of time, the pH should be controlled below 4.0 (27).

During fermentation, to maintain anaerobic conditions the plant materials must be totally covered by the brine in the vessels. Open filled vessels are normally covered with plastic sheets or wooden plates weighted down with stones or heavy matter to exclude oxygen from the air. For cucumber fermentation, anaerobic tanks provide more suitable anaerobic conditions (23). Anaerobic tanks replaced open tanks in the olive fermentation industry of the USA and Spain many years ago (28).

IV. VEGETABLE FERMENTATION MICROORGANISMS

Fresh plant material harbors numerous and varied types of microorganisms. The microflora in vegetables and fruits is largely made up of *Pseudomonas* spp., *Erwinia herbicola*, *Flaeobacterium*, *Xanthomonas*, and *Enterobacter agglomerans* as well as various molds. Lactic acid bacteria, such as *Leu. mesenteroids* and *Lactobacillus* spp., are also commonly found, as are several species of yeasts (29). Between 40% and 75% of the bacterial flora in peas, snap beans and corn was shown to consist of leuconostocs and streptococci, whereas many of the gram-positive, catalase-positive rods resembled corynebacteria (30,31). An analysis of 30 different samples of white cabbage from four growing seasons has shown that the microflora normally is dominated by aerobic bacteria(e.g., pseudomonads, enterobacteria, and coryneforms) and yeasts, while lactic acid bacteria represent 0.15 to 1.5% of the total bacterial population (32). Vegetable fermentation involves controlling specific microorganisms or a succession of microorganisms that dominate the microflora in vegetables. Although lactic acid bacteria are present as a small population, the metabolic activities of this microorganism are indispensable in the vegetable fermentation process. Lactic acid fermentation is the most important contribution to the fermentation of vegetables.

A. The Major Lactic Acid Bacteria in Vegetable Fermentation

The major lactic acid bacteria involved in vegetable fermentation are located in three genera, *Lactobacillus*, *Leuconostoc*, and *Pediococcus*. Among the lactobacilli, several species and strains have been isolated from fresh vegetables. These include the homofermentative species *Lb. plantarum*, *Lb. casei, Lb. arabinosus*, and *Lb. homohiochii*, and the heterofermenters *Lb. brevis*, *Lb. fermentum*, and *Lb. buchneri.* The genus *Pediococcus* comprises two species, *P. pentosaceus* and *P. acidilactici.* Currently, *Leuconostoc* comprises a single species, *Leu. mensenteroides* (33).

The lactic acid bacteria share some common features: Gram positive; mesophilic but some can grow at temperatures as low as 5°C or as high as 45°C; growing at pH 4.0–4.5, some are active at pH 9.6 and others at pH 3.2; generally weakly proteolytic and lipolytic and require preformed amino acids, purine and pyrimidine bases and B vitamins for growth; do not contain a citric acid cycle or a cytochrome system no energy derived from oxidative phosphorylation, but energy is obtained via substrate level phosphorylation during the fermentation of sugars into lactic acid, ethanol or acetate, and CO_2.

There are four important species of lactic acid bacteria associated with vegetable fermentation: *Leu. mensenteroides, Lb. brevis, P. pentosaceus*, and *Lb. plantarum.* These species are successively predominant during sauerkraut fermentation in the approximate order listed (7). *Lb. brevis, P. pentosaceus*, and *Lb. plantarum* have also been reported to ferment cucumbers (34) and olives (35). The properties of these four species are described as follows.

1. *Leu. mensenteroides*

The colorless bacterial cell is spherical or egg-shaped and appears usually in pairs. The size of the bacterium is 0.5–0.7 μm. *Leuconostoc* is distinguished among the lactic acid bacteria in being heterofermentative and also in lacking aldolase, a key enzyme in glycolysis. Under anaerobic condition, this bacterium metabolizes glucose via phosphoketolase pathway, and produces D-lactate. At the temperature range of 20 to 25°C, this bacterium produces dextrans from sucrose. This bacterium is capable of metabolizing citrate into CO_2 and diacetyl, which is an important flavor component in many dairy products.

2. *Lb. plantarum*

Lb. plantarum is the final and predominant lactic acid bacterium species at the completion of fermentation in many vegetables. This is attributed to its metabolic diversity and tolerance for low pH conditions. The optimal growth temperature for this bacteria is 30°C. The bacterial cell is a short to medium rod usually in single, but sometimes in pairs or short chains. The size of the bacterium is 0.9–1.2 (width) × 3–8 (length) μm. This bacterium is classified as a facultative heterofermenter according to the metabolism of hexoses (36). This bacterium possesses both aldolase and phosphoketolase. Its homofermentative action on glucose with aldolase results in producing up to 1.5% DL-lactate. The lactate can be further metabolized to acetoin, formate, and acetate under certain conditions. In the heterofermantation of pentose via the phosphoketolase pathway, this bacterium produces lactate, acetate and CO_2. Strains are often adopted as acid producers in starter cultures. This bacterium is the first species recognized to possess the unique ability to protect against oxygen-free radicals by a nonenzymatic superoxide reduction mediated by manganese (37).

3. *Lb. brevis*

This bacterium has a short rod shape, occurring singly or in short chains. The size of the rod cell is 0.7–1.0 (width)× 2.0–4.0 (length)μm. The optimal temperature for growth is 30°C. This bacterium is heterofermentative, and metabolizes glucose to DL-lactate, ethanol, acetate, and CO_2. This bacterium is able to reduce fructose to mannitol.

4. *P. pentosaceus*

This is a spherical bacterium, occurring in pairs, tetrads, or cluster. The size of the coccus is 0.8–1.0 μm in diameter.

This bacterium cannot grow at temperatures over 45°C. The optimum growth temperature is in the range of 28–30°C. The optimum and final pHs are 6.5–6.0 and 4,0 respectively. This bacterium is homofermentative and produces DL-lactate from glucose. Most strains ferment arabinose, ribose, maltose, fructose, galactose and glucose to produce DL-lactate. Strains that are capable of fermenting xylose and lactose are known. Some strains produce bacteriocins during fermentation.

B. The Lactococci in Vegetable Fermentation

Although lactococci are not major lactic acid bacteria in the fermentation of vegetables, this bacteria support the fermentation with proteolytic activity (38) and the capability to break down citrate (39). Recently, some strains of *Lactococcus lactis* subsp. *lactis* with the capability of producing bacteriocin were isolated from minimally processed fresh vegetable and fruit products. Some researches have used these bacteriocin-producing lactococcal cultures as biopreservative in minimally processed fresh vegetables and fruits (40,41). Lactococci are spherical or ovoid cells that occur singly, in pairs, or as chains. They grow at 10°C but not at 45°C. They are homofermentative and produce L-lactate as the predominant end product of sugar fermentation.

C. The Yeasts in Vegetable Fermentation

Various groups of yeast are present at the beginning of vegetable fermentation. Sometimes, these yeasts become predominant in the fermentation. For example, in the fermentation of olives, yeasts are the predominant microorganisms in spontaneous fermentation, because the polyphenol compounds in olives affect the microflora by inhibiting the growth of lactic acid bacteria but not yeasts (42). As a result, the final product has a shriveled form, a high salt content and the principle bitterness does not disappear completely from the product. To limit the negative effects of yeast on the product quality, it is necessary to remove the polyphenols, acidify the cover brine and lower the salt content to enhance lactic acid bacterial growth (43). It is well known that yeast can proliferate under low pH conditions which usually inhibits the growth of lactic acid bacteria. In the spontaneous fermentation of tart carambola, which contains affluent organic acid with a pH is as low as 1.37–2.01, the yeasts *Candida pelliculosa, C. inconspicua, C. ciferrii,* and *S. cerevisiae* become predominant in the brine with 7–10% salt (44). In the cucumber fermentation, yeasts can affect the fermentation by utilizing sugars that would otherwise be metabolized to lactic acid by the lactic acid bacteria. The yeasts can also utilize the produced lactic acid, raise the pH, and allow other microorganisms to grow. The yeasts produce large amounts of gas. This is associated with pickles that bloated or have hollow defects. Although fermentative yeasts have been viewed as undesirable in vegetable fermentation, yeasts may facilitate the removal of fermentable sugars. In the cucumber fermentation, when N_2 is used to purge the cucumber fermentation tanks to prevent bloater damage, a selected yeast (*S. cerevisiae* or *S. rosei*) in a mixed culture with *Lb. plantarum* can help to exhaust the fermentable sugars rapidly and improve the quality of the products (6).

V. FERMENTATION BIOCHEMISTRY

Lactic acid bacteria are the dominant microflora in most fermented vegetables. Under normal food fermentation conditions, the main product from lactic acid bacteria metabolism is lactic acid with other products formed as by-products, such as acetic acid, acetaldehyde, ethanol, and diacetyl. All of these products contribute to control the growth of spoilage microorganisms and the specific flavor of the fermented products. Lactic acid bacteria are divided into two groups based on glucose metabolism end products. Those that produce lactic acid as the major or sole product of glucose fermentation are designated homofermentative. *Pediococcus, Lactococcus*, and some lactobacilli belong to this group (homolactics). Those organisms that produce equal molar amounts of lactate, carbon dioxide and ethanol from hexoses are designated heterofermentative. *Leuconostoc* and some lactobacilli are heterofermentative (heterolactics). The major metabolitic pathways of these organisms are described as follows.

A. Carbohydrates Metabolism

In general, approximately 75% of the solids in plants are carbohydrates. Total carbohydrates generally consist of simple sugars, starches, pectic substances, lignin and cellulose. Cellulose, pectic substances and lignin occur in all plants as the principal structural component of the cell walls. These structural polysaccharides contribute greatly to the characteristic texture of plant foods. These structural polysaccharides are usually not fermentable. The most common fermentable carbohydrates in vegetables are glucose, fructose, sucrose and starch.

1. Glucose Metabolism

Glucose is the major fermentable sugar in vegetables. Homolactics metabolize glucose via the glycolytic pathway to yield pyruvate. Pyruvate is further reduced to lactic acid via the enzyme lactate dehydrogenase. The pathway that converts glucose to lactic acid is called lactic acid fermentation.

Heterolactics produce lactic acid via the phosphoketolase pathway. This pathway involves the initial splitting of CO_2 from the glucose molecule, followed by a further splitting of the resulting pentose (xylulose-5-phosphate) into two-carbon and three-carbon fragments in a phosphoroclastic reaction catalyzed by phosphoketolase, yielding glyceraldehyde-3-phosphate and acetylphosphate respectively. The three-carbon fragment is eventually

reduced to lactate in the same way as homolactics, and the two-carbon fragment is reduced to ethanol. Products other than lactate are generated, the pathway is, therefore, called the heterofermentative pathway. Because lactic acid bacteria lack functional heme-linked electron transport chains and a functional Krebs cycle, they obtain energy via substrate level phosphorylation. In the heterofermentative pathway, 1 mole of ATP is produced per mole of glucose metabolized compared with 2 mol in the homofermentative pathway. Thus, the fermentation of glucose via the heterofermentative pathway is only half as efficient as in the homofermentative pathway.

2. Fructose Metabolism

Fructose is the second major sugar substrate for lactic acid fermentation in vegetables. Lactic acid bacteria contain fructokinase and phosphoglucoisomerase to phosphorylate fructose to fructose-6-phosphate and then isomerize to glucose-6-phosphate. In the homofermentative pathway, glucose-6-phosphate is further metabolized to pyruvate via glycolysis. The pyruvate is then reduced to lactate via lactate dehydrogenase. In contrast to homolactics, heterolactics contain mannitol dehydrogenas which catalyze the reduction of fructose to mannitol and oxidize NADH under anaerobic conditions (45). In this reaction a small amount of fructose is used as an electron acceptor with the remaining fructose converted to lactate, ethanol, acetate, and CO_2 (46).

3. Sucrose Metabolism

The sucrose content is less than the glucose and fructose content in most vegetables. The metabolism of sucrose in vegetable fermentation is usually incomplete in the final stage. For example, when beets containing 3.8% sucrose were fermented using *Lb. plantarum* for 12 days, the fermented beets still contain 2.8% residual sucrose. Using the same starter to ferment carrots for 35 days, 1.96% of the sucrose was reduced to 0.91% but the glucose and fructose in the fermented carrots were exhausted at the same time (47). Sucrose does not seem to be an optimal fermentable sugar for lactic acid bacteria. Actually, only a few lactic acid bacteria possess the ability to ferment sucrose. A screen test report showed that among 14 strains of lactic acid bacteria *Lb. cellobiosus* appeared to be the only species that metabolizes all of the sucrose in green bean juice. Under the same conditions, *Lb. buchnerii, Lb. fermentum,* and *Leu. mensenteroides* ferment about half of the sucrose in green bean juice (48). These lactic acid bacteria are able to hydrolyze sucrose with β-glucosidase. These products, glucose and fructose, can be metabolized via the pathways previously mentioned.

4. Starch Metabolism

The starch content in most fermented vegetables is limited, hence the amylolytic ability of lactic acid bacteria is a characteristic with little demand. Although hydrolyzing starch to simple sugars is not important in traditional fermented vegetables, a few amylolytic lactic acid bacteria have been isolated from starchy raw materials. An investigation of Mexican pozol, a fermented maize dough, indicates that lactic acid bacteria accounted for 90–97% of the total active microflora. Strains of lactic acid bacteria were isolated and identified including *Leu. mesenteroides*, *Lb. plantarum*, *Lb. confusus, L. lactis* and *L. raffinolactis* (49). From sour cassava starch fermentation *Lb. plantarum* and *Lb. manihotivorans* were isolated. *Lb. manihotivorans* grow and convert starch into lactic acid more rapidly and efficiently than *Lb. plantarum* (50) (51). During fermentation, these amylolytic lactic acid bacteria degrade the starch first, and then the resulting sugars allow a secondary flora to develop. An acidophilic starch-hydrolysing enzyme secreted from a strain of *L. plantarum* was isolated and partially purified. This enzyme has a molecular mass of approx. 230 kDa and is capable of hydrolysing soluble starch, amylopectin, glycogen and pullan. The major reaction products from soluble starch were maltotriose, maltotetraose and maltopentaose. These reaction products suggest that this enzyme may hydrolyses both α-1,6- and α-1,4-glucosidic linkages (52).

B. Organic Acids Metabolism

Citrate and malate are the most abundant organic acids in plants. Citrate metabolism is important in fermented dairy products while malate metabolism is important in wine.

The organisms responsible for citrate metabolism in starter cultures are leuconostoc and Cit^+ lactococci. Citrate is hydrolyzed to oxaloacetate and acetate by citrate lyase. Citrate lyase is inducible in leuconostocs and constitutive in Cit^+ lactococci (53). The oxaloacetate is decarboxylated to pyruvate, which can undergo several further transformations to diacetyl, acetoin, and 2,3-butylene glycol (54).

Malic acid is fermentable by lactic acid bacteria. Both homolactics and heterolactics are able to decarboxylate malic acid to lactic acid and CO_2. Minimal CO_2 production has been ascribed a beneficial role in maintaining anaerobiosis in sauerkraut. In cucumber fermentation, CO_2 production causes bloater damage. The decarboxylation of malic acid is undesirable in cucumber fermentation. *Lb. plantarum* produces most of CO_2 during cucumber juice fermentation via the decarboxylation of malic acid (55). Strains of *L. plantarum* that do not decarboxylate malic acid (MDC^-) might improve cucumber fermentation. Some MDC^- mutants have been obtained through N-methyl- N′-nitro-N-nitrosoguanidine mutagenesis of MDC^+ parent strains. These mutants did not produce significant amounts of CO_2 when they fermented cucumber juice containing native malate (56).

C. Biogenic Amines Biosynthesis

Fermented vegetables usually contain small amounts of biogenic amines. An excessive intake of biogenic amines may

cause food poisoning. Biogenic amines may also be considered carcinogens because of their ability to react with nitrites to form potentially carcinogenic nitrosamines (57). Most biogenic amines present in fermented vegetables are formed by the action of microorganisms through the decarboxylation of amino acids during fermentation. Sauerkrauts and sauerkraut-like products are popular fermented vegetables in many countries. Thus, sauerkraut could represent an important source of biogenic amines in daily diets. The biogenic amine content in commercial sauerkraut products is approximate 540 mg/kg (58). The main biogenic amines in sauerkraut are histamine, tyramine, putrescine and cadaverine derived from histidine, tyrosine, ornithine, and lysine, respectively. Biogenic amine formation in the initial stage of a spontaneous fermentation is correlated with the growth of *Leu. mensenteroides. Pedicoccus* species are also responsible for the formation of biogenic amines. It was observed that the production of histamine was associated with the vigorous growth of the *Pedicoccus* species (32). *Lb. plantarum* starter cultures were able to suppress the formation of tyramine, putrescine, and cadaverine by raising the pH to impede the growth of biogenic amine producers (59). Hence, it is possible to decrease the biogenic amine content in fermented vegetables by using lactic acid bacteria inoculates.

VI. STARTER CULTURE IMPROVEMENT

In vegetable fermentation starter cultures with certain beneficial bacteria are desirable. Cultures with desirable characteristics can be achieved through genetic modifications. Artificial mutagenesis and DNA recombination techniques are two available methods to generate genetically modified strains.

References on using mutagenesis to improve starter cultures for the vegetable fermentation are rare. One (60) of these researches describes procedures to obtain *L. plantarum* mutants that have lost the ability to decarboxylate malic acid (MDC^-) from the parent strain (MDC^+). In this research, the parent strain was mutagenized with N-methyl-N′-nitro-N-nitrosoguanidine, and the derived mutants were then screened with designed media to select the MDC^- mutants (60). The MDC^- mutants do not produce CO_2 from the degradation of malic acid. When using MDC^- culture in cucumber fermentation, the cucumbers were shown to be less susceptible to bloating (61). Another research involving mutation involved cultivating variant *L. delbrueckii* strains that were able to tolerate high concentration of lactic acid (62). Treatment with ethyl methanesulfonate mutated the parent strain. The lactic acid tolerant mutants were then selected using an acclimation and selection procedure. This procedure was reported to be successful in consistently producing stable mutants with enhanced lactic acid production capacity.

Recently the DNA recombinant technique has superseded classic mutagenesis in the field of industrial strain improvement. In industrial food fermentation, new genetic techniques have already been applied to lactic acid bacteria to generate desirable starter cultures (63). No customized genetically modified strains for vegetable fermentation have yet been developed. However, some *Lb. plantarum* strains used as grass silage starters have been genetically modified by introducing heterologous genes to gain desirable attributes. Because *Lb. plantarum* is also a dominant microorganism in the fermentation of vegetables the genetic modification of the silage starter *Lb. plantarum* will be a useful model for cultivating desirable vegetable fermentation cultures in the future.

It has been customary to add soluble carbohydrate to silage to facilitate rapid fermentation. If a starter with the ability to hydrolyze cellulose was used in the fermentation of silage, rapid fermentation might be achieved even without adding carbohydrates. According to this thinking, a genetically modified *Lb. plantarum* with the ability to degrade cellulose was cultivated. An *Lb. plantarum* strain was transformed by inserting the *cel*E gene coding endoglucanase from *Clostridium thermocellum* (64). A transformed *Lb. plantarum* strain possessing endoglucanase activity may be useful in improving the fermentation of olives and cabbage by producing acids rapidly, because this strain is able to supply mono- and disaccharides through the hydrolysis of cellulose.

A combination of polysaccharides metabolism and lactic acid fermentation trait is desirable for a starter strain to ferment plant material. For this objective, an *Lb. plantarum* silage starter strain was transformed by electroporation with plasmids containing an α-amylase gene from *Bacillus stearothermophilus* and an endoglucanase gene from *Clostridium thermocellum* (65). The transformed *Lb. plantarum* is a turely cellulolytic and amylolytic silage starter bacterium with the ability to produce lactic acid from the fermentation of cellulose and starch materials.

Increasing ethanol levels in lactic acid fermentation may be valuable in developing vegetable juice products. A strain of *Lb. plantarum* deficient in both D- and L-lactate dehydrogenase activity was constructed by using a two homologous recombination processes (66). Following cloning a alcohol dehydrogenase gene and pyruvate decarboxylase gene originating from *Zymomonas mobilis* in this lactate dehydrogenase-negative strain resulted in an ethanol production of more than 400 mM (almost 2%).

177 Fermented Food and Starter Cultures

Jytte Josephsen and Lene Jespersen
Department of Food Science, Food Microbiology, The Royal Veterinary and Agricultural University

CONTENTS

I. INTRODUCTION

Fermentation is a process in which microorganisms, in the absence of oxygen, generate energy by oxidizing carbohydrates and related compounds. It has been used since ancient times as an important method for preserving food. Vegetables, fruits, cereals, milk and other raw materials have been treated in special ways in order to promote the growth of beneficial microorganisms while inhibiting the growth of deteriorating and pathogenic microorganisms. Fermentation will preserve the food and enhance the taste, aroma, texture and nutritional value of the product. The preservation effect is the result of synthesis of lactic acid and by heterofermentation also, acetic acids and, some times, antimicrobial substances. Besides lowering the pH level, the organic acids are also toxic for many microorganisms. It is also important that the fermentable carbohydrates are completely utilized by the fermenting microorganisms and thereby made unavailable for the undesirable microorganisms. In some product the addition of salt will increase the shelf life of the products by lowering of the water activity. The natural habitats of lactic acid bacteria, yeast and mold are most often plant materials. However, the type of organisms can vary considerably [1], depending on type of plant, climatic conditions, and available nutrients in the raw material. During some fermentation (e.g., fermentation of plant material such as cabbage, cucumbers, olives, soya beans, and coffee), several different types of microorganisms are required at the various stages of the fermentation process. In other fermentations (e.g., production of yogurt and beer), only a few different microorganisms are required.

Even though the involvement of microorganisms and their importance for the fermentation process was not

known until relatively recently, it was found by practice that for some fermentations the addition of a portion of a previous fermentation was beneficial for the process. With the utilization of pasteurization of the milk in the late 19th century, it was discovered that bacteria was necessary for the souring of milk for production of butter. In 1878, Joseph Lister isolated a pure culture from sour milk and named it *Bacterium lactis* [2]. Later Sigurd Orla-Jensen (see Figure 177.1) classified this bacteria bacterium as *Streptococcus lactis* (see Figure 177.2) [3]; today it is classified as *Lactococcus lactis* subsp. *Lactis* [4]. In the late 19th century Vilhelm Storch (see Figure 177.1) in Denmark, Herman Weigmann in Germany and H.W. Conn in USA [5] independently introduced the addition of pure cultures to milk in order to improve fermentation. In 1896 Storch was granted a USA patent on production of starter cultures. The Danish pharmacist Chr. D. A. Hansen (see Figure 177.1) pioneered the production of commercial starter cultures as he initiated the production of liquid and dried cultures as early as the late 1880s. Most of the bacteria used for milk fermentations were named lactic acid bacteria (LAB) because they mainly produce lactic acid by their catabolism of the milk sugar (lactose) and because they were used to start or begin the fermentation, they were termed starters or starter cultures [6].

A breakthrough in the history of wine occurred when Louis Pasteur described "life without oxygen" and of brewing fermentation when Emil Christian Hansen (see Figure 177.3) at Carlsberg brewery (Copenhagen) in the late 19th century isolated a pure yeast culture from single cells. Alfred Jørgensen (see Figure 177.3), another Dane, managed to introduce pure yeast cultures as starter cultures in brewing all over the world. For wine making the concept of inoculating wine fermentations with pure yeast starter cultures was introduced by Müller-Thurgau in 1890 and in 1965 the first commercial dried starter cultures were produced for a large Californian winery [7]. In 1920 the "fed-batch" process was introduced for the production of baker's yeast and that resulted in a significant increase in the industrialised production of baker's yeast [8]. The involvement of molds (mycelial fungi) in food fermentation goes back to the first records on blue and white molded cheeses. The first records for the production of well-known cheeses such as Gorgonzola and Roquefort

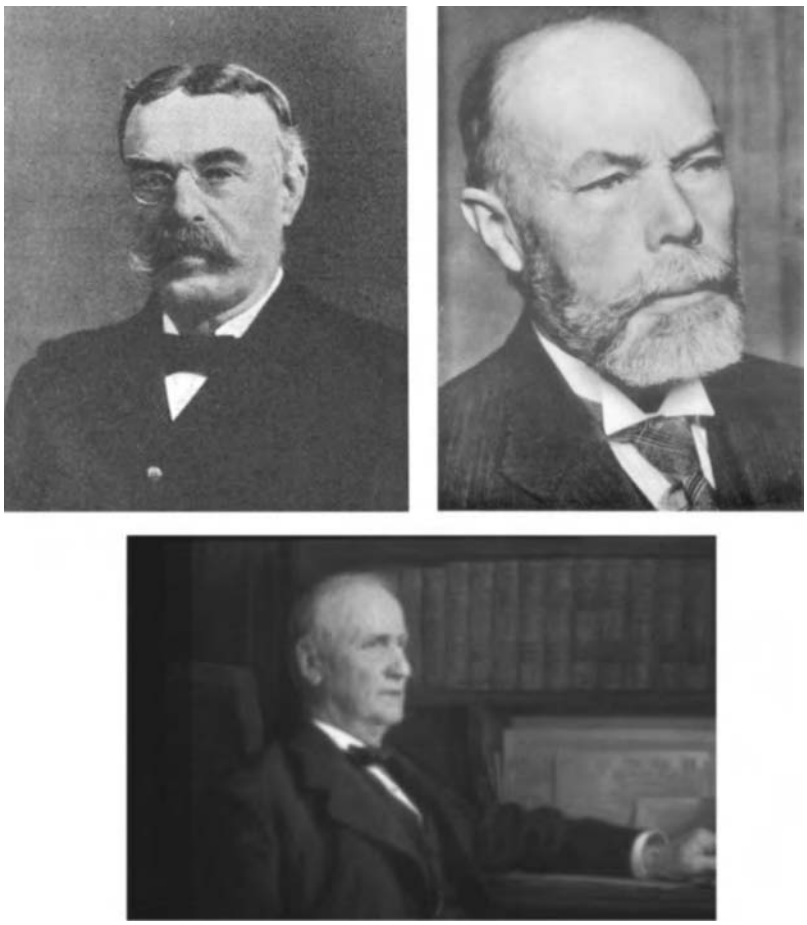

FIGURE 177.1 Photos of the Danish scientists Vilhelm Storch (1837–1918), Sigurd Orla-Jensen (1870–1949), and Chr. D.A. Hansen (1843–1916) important for isolation, identification and classification of lactic acid bacteria and their utilization as starter cultures.

FIGURE 177.2 Micrographs of different lactic acid bacteria made by S. Orla-Jensen in 1919 (From ref. [3]). The magnification is 1000 times.

is dated to 879 and 1070 respectively [8]. Eventually, the cultures involved in the fermentation were purified and starter cultures are now commercially available for cheese and meat even though not developed to a great extent.

Over the years the concept of utilization of starter cultures for the production of fermented food, especially of bread, beer, fermented milk products and cheeses, and for the production of sausages has gained increased attention.

II. FERMENTATION PROCESSES

Fermentations can basically be performed either by spontaneous fermentation, by back-slopping or by addition of starter cultures. By spontaneous fermentation the raw material, and its initial treatment, will encourage the growth of an indigenous flora [9]. For most spontaneous fermentations a microbial succession takes place, quite often LAB will initially dominate followed by various species of yeasts. Molds will only grow aerobically which limits their occurrence in certain types of fermented products. LAB produce lactic acid and other antimicrobial substances that will inhibit the growth of harmful bacteria, along with reducing the sugar content and, thereby, prolonging the shelf-life of the product. Yeasts mostly produce aroma components and alcohols [10]. When molds are involved in the fermentation they generally contribute by producing both intra- and extracellular proteolytic and lipolytic enzymes which highly influence the flavour and texture of the product [8].

In back-slopping, a part of a previous batch of a fermented product is used to inoculate the new batch. This procedure produces a higher initial number of beneficial microorganisms than found in raw material and ensures a

Emil Chr. Hansen

Alfred Jørgensen

FIGURE 177.3 Photos of the Danish scientists Chr. Emil Hansen (1842–1909) and Alfred Jørgensen (1848–1925) significant for isolation of a pure culture of yeast and its utilization as starter cultures within brewing.

faster and more reliable fermentation than occurs in spontaneous fermentation. This procedure probably also favors the growth of bacteria producing antimicrobial substances, ensuring the growth of the same bacteria every time. Examples of back-slopping are home-made fermentation of milk, vegetables and cereals. Industrial production of sourdough bread is often also done by back-slopping; a sample of the previous days sourdough is used to inoculate a new batch of dough [8].

Addition of starter cultures is most often used when it is possible to inactivate the indigenous flora by heat treatment of the raw material, permitting the growth of only the added starter microorganisms. However, it is not always possible to heat treat the raw material (e.g., fruits and vegetables) without influencing the texture of the final product [11]. Nevertheless, the addition of starter cultures—especially those containing a bacteriocin-producing strain alone or in combination with selected bacteriocin-resistant strains—may in fermentations of plants yield a greater possibility that the desirable flora will dominate in the fermentation [12–14]. Starter cultures can basically be classified as shown in Table 177.1.

Single strain starter cultures are primarily used for yeasts and molds in the production of beer and wine, and LAB for the production of a few dairy products, sausages and sauerkraut. Multiple starter cultures are used for dairy products, sourdough, sausages and wine. Mixed undefined bacterial starter cultures, also called traditional or artisanal starters [15], are primarily used in the dairy industry and in sourdough production.

III. BACTERIAL STARTER CULTURES

A. Introduction

Starter cultures can also be classified according to their optimal growth temperature as shown in Table 177.2. The most important bacteria for food fermentation are designated lactic acid bacteria (LAB). They are gram-positive rods or cocci, non-spore formers, catalase negative, obligatory fermentative, microaerophilic, usually non-motile bacteria having extensive growth requirements. They produce mainly lactic acid from glucose fermentation. The first classification of LAB was made in 1919 made by S. Orla-Jensen (see Figure 177.2) [3]. However, utilization of DNA technology and molecular typing methods has had a great impact on the taxonomy of bacteria and has led to a great deal of taxonomic revision. Table 177.3 shows a list of common LAB which have received new names within the last two decades. Table 177.4 shows the genera into which the LAB are presently divided. Table 177.4 also shows which pathways LAB use for fermentation of glucose.

Homofermentative LAB mainly makes lactic acid as their final product, whereas heterofermentative LAB makes equal amounts of lactic acid, acetic acid and CO_2. Other bacteria like *Acetobacter, Bifidobacterium, Micrococcus,* and *Staphylococcus* are also used as starter cultures for food and beverage fermentations; *Brevibacterium* and *Propionibacterium* are used as secondary or adjunct cultures. Some *Lactobacillus* species are also used as adjunct cultures.

TABLE 177.1
Definitions of Starter Cultures

Name	Contains
Single strain starter	A single well defined strain with known technological properties
Multiple starter cultures	2–6 well defined strains with known technological properties
Mixed strain starter	An unknown number of undefined strains

TABLE 177.2
Types of Starter Cultures

Type	Optimum Temperature	Typical Growth Temperature
Mesophilic	25–34°C	18 to 30°C
Thermophilic	37–44°C	40 to 44°C

TABLE 177.3
Name Changes of Common Lactic Acid Bacteria Resulting from Taxonomic Reversions*

New Names	Old Names
Carnobacterium divergens	*Lactobacillus divergens*
Carnobacterium piscicola	*Lactobacillus carnis*
Lactobacillus delbrueckii subsp. *bulgaricus*	*Lactobacillus bulgaricus*
Lactobacillus delbrueckii subsp. *lactis*	*Lactobacillus lactis*
Lactobacillus rhamnosus	*Lactobacillus casei* subsp. *rhamnosus*
Lactobacillus sakei	*Lactobacillus sake* and most strains of *Lactobacillus bavaricus*
Lactobacillus sanfranciscensis	*Lactobacillus sanfrancisco*
Lactococcus lactis subsp. *cremoris*	*Streptococcus cremoris*
Lactococcus lactis subsp. *lactis*	*Streptococcus lactis*
Lactococcus lactis subsp. *lactis* biovar. diacetylactis	*Streptococcus diacetylactis*
Leuconostoc mesenteroides subsp. *cremoris*	*Leuconostoc citrovorum*
Leuconostoc mesenteroides subsp. *dextranicum*	*Leuconostoc dextranicum*
Oenococcus oeni	*Leuconostoc oeni*
Streptococcus thermophilus	*Streptococcus salivarius subsp. thermophilus*
Tetragenococcus halophilus	*Pediococcus halophilus*
Weissella confusa	*Lactobacillus confusus*
Weissella paramesenteroides	*Leuconostoc paramesenteroides*

* Not all of these listed bacteria are used as starter or adjunct cultures; some have only been isolated from fermented food and beverage products. An updated list is present on http://www.bacterio.cict.fr.

[3] Ferment glucose by the homofermentative pathway and pentoses and 6-P-glyconate by the heterofermentative pathway.

B. Cultures for Milk Fermentation

The utilization of starter cultures in industrial milk fermentation is widespread. The most important starter cultures are the LAB. These cultures often consist only of mesophilic or thermophilic LAB, however, mixtures can also occur. Mesophilic starter cultures originate from North and East Europe. They consist primarily of *Lactococcus lactis* subsp. *cremoris* (*L. cremoris*), *Lactococcus lactis* subsp. *lactis* (*L. lactis*), *Lactococcus lactis* subsp. *lactis* biovar. *diacetylactis* (*L. diacetylactis*), *Leuconostoc mesenteroides* subsp. *cremoris* and *Leuconostoc lacti*s. Especially, *L. cremoris and L. cremoris* are capable of rapid acidification of milk. *L. diacetylactis*, *Leuconostoc mesenteroides* subsp. *cremoris* and *Leuconostoc lactis* can catabolize citrate into CO_2 and diacetyl. CO_2 is responsible for the production of holes in the cheeses, while diacetyl, the characteristic flavor of butter, is important for the flavor of many cheeses and fermented milk products. The diacetyl producing organisms are often called the aroma producers or *L. lactis* subsp. *lactis* (citrate +). *Lactobacillus paracasei* and *Lactobacillus casei* are the most frequent mesophilic lactobacilli found in many cheeses and are in some cases used as adjunct cultures [16–19]. *Lactobacillus rhamnosus, Lactobacillus plantarum* and *Lactobacillus curvatus* are also found in many chesses [17,18,20]. The dairy propionibacteria *Propionibacterium shermanii* and *Propionibacterium freudenreichii* are used in some Swiss type cheeses such as Emmental, Gruyère and Comté, in which they slowly catabolize lactate to propionate, acetate and CO_2. This is important for the production of holes and taste of the cheeses [20,21]. *Micrococcacaceae* and

Brevibacterium are used as surface flora in various chesses [22], they are important for cheese ripening.

Different types of mixed starter cultures have been developed. The composition of the different mesophilic starter cultures, and examples of products for which they are used is shown in Table 177.5. The most abundant cheese produced is cheddar cheese. It is commonly produced by the use of a multiple strain starter culture of *Lactococcus lactis* subsp. *cremoris* and *Lactococcus lactis* subsp. *lactis* with or without *Streptococcus thermophilus*. However, a mixed O-culture, TK5, has also been developed [23,24].

Thermophilic cultures originate from South and East Europe. They consist mainly of *Streptococcus thermophilus, Lactobacillus delbrueckii* subsp. *bulgaricus* and *lactis, and Lactobacillus helveticus.* The thermophilic LAB are used for rapid acidification or as adjuncts in cheeses. *Streptococcus thermophilus, Lactobacillus delbrueckii* subsp. *bulgaricus* and some *Lactobacillus delbrueckii* subsp. *lactis* catabolize lactose into lactate and galactose, which may be secreted. The residual galactose can give problems (e.g., growth of undesirable bacteria) in cheese and influences the browning of pizza cheese. *Lactobacillus helveticus* can use galactose as a carbon source and thereby remove the residual galactose. Furthermore, some strains of *Lactobacillus helveticus* are very proteolytic, thereby influencing the taste and texture of cheese [25,26]. Thermophilic LAB can also produce acetaldehyde, which is the characteristic flavor of yogurt. The composition of these starter cultures varies. Both defined single or multiple starter strain cultures and mixed undefined cultures are used. Mozzarella and yogurt is commonly produced by single or multiple strain starters which contain one or more *S. thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* strains, but many cooked cheeses are produced with mixed cultures. They are used either as milk cultures or whey cultures, with or without rennet. Thermophilic cultures and some examples of their products are shown in Table 177.6.

Other cheeses or fermented milk products are made with both mesophilic or thermophilic LAB starter cultures, or by addition of other LAB such as *Enterococcus faecium, Lactobacillus acidophilus* or other genera of bacteria (e.g., *Bifidobacterium*). Yeast and mold can also be added. Table 177.7 gives examples of dairy products provided with different combinations of microor-ganisms.

TABLE 177.5
Composition of Different Types of Mesophilic Starter Cultures and Some Examples of Their Products

Type	Organisms	Composition	Products
O	*Lactococcus lactis* subsp. *lactis*	5–10%	Cheddar
	Lactococcus lactis subsp. *cremoris*	90–95%	Cottage cheese

	Lactococcus lactis subsp. *lactis* biovar. *diacetylactis*	10–20%	
DL	*Lactococcus lactis* subsp. *lactis*	5–10%	Continental cheese
	Lactococcus lactis subsp. *cremoris*	60–80%	(with eyes)
	Lactococcus lactis subsp. *lactis* biovar. *diacetylactis*	10–20%	Mold ripened cheese
			Lactic butter
	Leuconostoc mesenteroides subsp. *cremoris* + *Leuconostoc lactis*	5–10%	Cultured buttermilk
			Creme fraiche, ymer

1. Starter Culture and Bacterophage

One of the disadvantages of using pure bacterial starter cultures is that they are more sensitive to bacteriophages than undefined mixed starters [23] or indigenous flora, where there will always be strains present that can survive phage attack and continue fermentation. Lactic acid fermentations of milk for cheese production are especially susceptible to

Yakult	*Lb. casei*

phages and special precautions have to be taken in order to exclude them. The use of phage resistant starter cultures, a high level of cleaning and sanitation, use of closed vats equipped with filters, specially designed pipelines, equipments and facilities, minimal access of persons and high personal hygiene are all recommended to achieve this. In this way it was possible to use a mixed O-culture, TK5, for production of cheddar cheese in Denmark for 11 years before bacteriophages able to inhibit acidification appeared [27,28]. Unfortunately, the phages became so virulent that after 12 years of production it was not possible to use the TK5 starter culture any longer in the dairy [23].

C. Cultures for Fermentation of Vegetables, Fruits and Grains

Plant fermentations involve either lactic acid, acetic acid or alcoholic fermentation or a combination of these fermentation types. In alcoholic fermentation it is mainly yeast (*Saccharomyces cerevisiae*) and fungi (*Aspergillus oryzae*) that participate; however, lactobacilli and *Pediococcus* can also be involved. This fermentation is described in more detail in this chapter section IV. Acetic acid fermentation, used for production of vinegar, is a two stage fermentation process, in which the first stage includes an alcoholic fermentation followed by the oxidization of ethanol via acetaldehyd to acetic acid [29]. The typical raw materials are grapes, potatoes or rice. Different subspecies of *Acetobacter* (*A. acati, A. pasteurianus* and *A. hansenii*) and *Gluconobacter oxydans* are used for vinegar production. Pure cultures are not widely employed in the acetic acid fermentation industry [29,30]. Interestingly, Nanda et al. [31] found that the *Acetobacter* strain responsible for the rice vinegar "Komesu" and "Kurosu" spontaneously established an almost pure culture during its long production time.

Traditional fermentations of vegetables, fruits and grains most often include a lactic acid fermentation involving many different species of LAB which are active at different stages of the fermentation process; this is followed by fermentation by yeast and mold [30,32–34]. *Lactobacillus plantarum* and *Leuconostoc mesenteroides* are the major microorganisms, however, many other LAB e.g. *Lactobacillus species* and *Pediococcus* may be involved.

Fermentation of vegetables is difficult to control [35] because it depends on the quality of the raw material, the harvesting condition and the temperature, which are vital in providing the optimal conditions for growth of the desirable microorganisms. The addition of salt, either as dry salt (2–3% w/v) or in solution (4–10% w/v) (called brining) and the creation of an anaerobic condition is commonly the initial step in fermentation of vegetables. One obstacle is that raw vegetables cannot normally be pasteurized without adverse influence on the product texture [11]. Another issue is that vegetable fermentation often relies on a very complex process in which many different bacteria succeed each other in very specific ways.

Many different plant fermentations are commercially produced [35] and most often on a small scale. Currently only olives, pickled cucumbers, sauerkraut and kimchi are industrially produced in economically important large amounts [36]. Commonly, the fermentations are performed by spontaneous fermentation or back-slopping. In a few cases utilization of LAB as single-strain cultures has been tried successfully. For production of sauerkraut, *Lactobacillus plantarum* [37,38], *Lactobacillus curvatus* [37], and *Leuconostoc mesenteries* alone [30] or combined with *Lactococcus lactis* [39] have been tried. *Lactobacillus plantarum* and *Lactobacillus pentosus* have been used in olive fermentation [40–44]; *Lactobacillus plantarum* [45–48], *Lactobacillus pentosus* [48], *Pediococcus pentosaceus* [48] successfully for pickled cucumbers. Examples of plant fermentations in which starter cultures have been used are shown Table 177.8.

Different grains (e.g., maize, rice, sorghum [49–64]) and legumes (e.g., soybeans, lupins, peas, lentils [65] can be fermented and most do not involve addition of starter cultures, but are fermented by spontaneous fermentation or back-slopping. However, starter cultures are used for production of sourdough from wheat or rye [30]. They are used as either single- or multiple-strains starters, with or without the addition of yeast. The LAB used in starter cultures are shown in Table 177.8. However, back-slopping using a batch of dough derived from a previous fermentation to inoculate the next batch of dough is still a common practice in industrial production in Denmark, Finland and Germany. Another way to start the fermentation is by addition of dried dough [66]. Many different LAB (especially *Lactobacillus* species) have been isolated from sour dough [67–69].

D. Cultures for Meat Fermentation

Starter cultures for meat fermentation are mainly used in the production of fermented sausages. These cultures are either single- or multiple-strain cultures of LAB and/or

+/-, with or without.

staphylococci. However, sausages may also be produced without the addition of starter cultures and rely instead on the indigenous microflora in the meat [70]. However, starter cultures provide technological advantages such as rapid and uniform acidification, good texture and sliceability, production of desirable flavor compounds, enhanced safety [71,72], good color formation and stability, and better control over the fermentation process. Staphylococci are important for the aroma and color formation and stability; LAB are central for the other properties. Because meat contains extremely low amounts of sugar, the addition of carbohydrate influences the final pH. There are two main types of sausages, the northern European type in which the sausages are smoked and dried, and the southern European sausages that are dried with or without mold present [35]. Generally the sausages from southern Europe are drier than the sausages from northern Europe (semidry). Most fermentations are carried out at 17–24°C, although variations occur. For example, the American pepperoni sausages are fermented at 40°C. Table 177.9 shows which microorganisms are used as starter cultures for the production of sausages.

IV. YEASTS USED AS STARTER CULTURES

A. Introduction

Yeasts are involved in both spontaneous and controlled fermentations. For spontaneous fermentation processes the yeasts are introduced by either the raw materials or via the process equipment [74–76]. When yeast are used as starter cultures, they are in general used as single cultures and may be introduced either to initiate the fermentation process or at a later stage in the fermentation to ensure optimal aroma production and so forth. Most yeast species are able to grow under both aerobic and anaerobic conditions. However, some yeast species are specifically respiratory yeasts whereas others are fermentative yeasts for which respiration is repressed even at aerobic conditions. Primarily, yeasts utilize carbohydrates as carbon source, which are converted into alcohols and CO_2 as well as a number of secondary metabolites such as esters, organic acids, aldehydes, ketones a.o. [77].

Yeasts involved in the fermentation of foods and beverages belong primarily to the ascomycetous yeasts. Among these, the most well described yeast species is undoubtedly *Saccharomyces cerevisiae*. This species is used worldwide for the production of bread, wine, beer, cheese etc. and is overall the predominant starter culture in use. Other important yeast species are *Saccharomyces pastorianus,* used for production of lager beer, and *Debaryomyces hansenii*, used for production of cheese and fermented meat products. A microscopic picture of *D. hansenii* cells is shown in Figure 177.4. Yeast species other than the above mentioned are potential starter cultures and do often occur in high numbers during spontaneous fermentations (Table 177.10). The evolvements of DNA technologies and molecular typing techniques have over the recent decades influenced significantly the taxonomic position of many yeast genera and further reorganizations are expected in the future. For a current taxonomic description of yeast species the taxonomic keys of Kurtzman and Fell [78] and Barnett et al. [79] should be consulted.

The benefits obtained by moving from spontaneous fermentations to controlled fermentations are many and, therefore, there seems to be a growing interest in the use

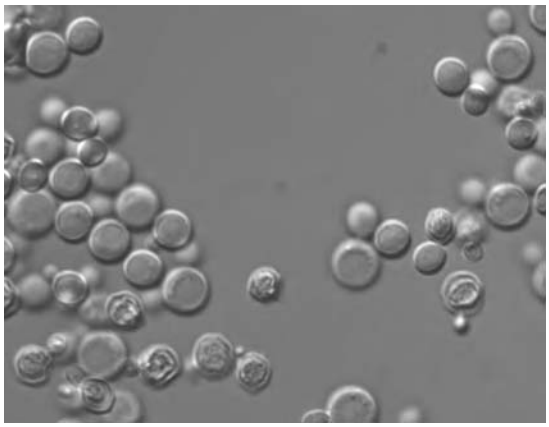

FIGURE 177.4 Cells of *Debaryomyces hansenii.* The magnification is 1000 times.

of yeasts as purified starter cultures, not only in the control of existing fermentation processes but also in the development of new food products. In controlled fermentation, the habitat of the yeast species as well as the various functions of different yeast species should be taken into consideration as well as any probiotic property [80] [81] or possible pathogenic hazard [82] [83]. Also the taxonomic position of the starter cultures must be clarified and methods for typing at subspecies level introduced.

Especially for brewing, wine and baker's yeasts, efforts have been made to improve the technological properties of the strains by formation of genetic modified organisms (GMO). However, in most cases the GMOs have not been used in industrial food fermentations due to consumer resistance and statutory regulations [7].

B. Brewing Yeasts

The brewing industry has a long tradition of the use of single starter cultures of brewing yeast based on single cell cultures. Worldwide, up to a thousand different brewing yeast cultures have been described. The brewing yeast strains vary in their technological properties including aroma production, rate and degree of attenuation, flocculation, oxygen requirement and reproduction [84]. During brewing fermentation maltose is the most dominant carbon source but sucrose, glucose, fructose and maltotriose will also be present and utilized. Brewing yeast strains have been shown to vary in their ability to utilize maltose and genotypic variations in their number of maltose transporter genes have been reported [85].

Two types of *Saccharomyces* yeasts are involved in beer fermentation: ale yeasts (also known as top fermenting yeasts) and lager yeasts (also known as bottom fermenting yeasts) [84]. Ale yeasts have, since the last century, been classified as *S. cerevisiae,* whereas lager yeasts have been known under a variety of names such as *Saccharomyces carlsbergensis, Saccharomyces uvarum* and *S. cerevisiae*. The development of molecular typing techniques has revealed several genetic differences between ale and lager brewing yeasts [86–90], and according to recent classifications, lager yeasts are now considered to belong to *Saccharomyces pastorianus* [91] even though they often are still referred to as *Saccharomyces carlsbergensis* [92]. However, some confusion still exists regarding the phylogenetic relationship between lager yeasts and other yeast within the genus *Saccharomyces*. It appears to be generally accepted that lager yeasts are alloploid and contain parts of two divergent genomes [93,94], one from *S. cerevisiae* and one from another *Saccharomyces* species, most likely *S. bayanus* [88,95,96] or to a specific strain of *Saccharomyces monacensis* [92,97], which according to recent taxonomic keys, now also belongs to *S. pastorianus* [91].

Starter cultures of *S. cerevisiae* have also been reported to be used in the production of South African sorghum beer [98] and in addition to its use as an industrial starter culture *S. cerevisiae* has been isolated from a variety of different indigenous spontaneously fermented beers or beer-like beverages [75].

C. Winery Yeasts and Yeasts Used for the Production of Distilled Alcohols

Traditionally, wine is produced by spontaneous fermentation and several yeast species have been reported to be involved in the fermentation. The predominant microorganisms on the grapes vary according to the grape variety, climatic conditions, soil quality, development and physical quality of the grapes as well as the amount of fungicides applied to the vineyards. Nevertheless, the predominant yeast genera on grapes are reported to be *Kloeckera* and *Hanseniaspora,* whereas *Saccharomyces cerevisiae* is not observed or observed at only very low concentrations on healthy undamaged berries. The yeast genera associated with wine making include: *Candida*, *Cryptococcus*, *Debaryomyces*, *Dekkera* (teleomorphic form of *Brettanomyces*), *Hanseniaspora* (teleomorphic form of *Kloeckera*), *Kluyveromyces*, *Metschnikowia*, *Pichia*, *Rhodotorula*, *Saccharomyces*, *Saccharomycodes*, *Schizosaccharomyces* and *Zygosaccharomyces*. Some of these yeast genera are thought to be essential for the wine fermentation, while others are regarded as transient organisms. Due to the low pH and high sugar content of grape juice a natural yeast selection will take place during spontaneous wine fermentation. At the early stages of the fermentation yeast of the genera *Candida*, *Hanseniaspora* and *Kloeckera* will dominate, followed by species of *Metschnikowia* and *Pichia.* The latter stages of the fermentation will be dominated by alcohol-tolerant strains of *S. cerevisiae* [7].

TABLE 177.10
Examples on Yeast Species Used as Starter Cultures or Occurring Spontaneously at High Numbers in Fermented Products

Fermented Foods and Beverages	Yeast Species[a]	Products
Beer	*Saccharomyces cerevisiae**	Ale, stout, porter,

	Pichia guilliermondii (*C. guilliermondii*)	
	Pichia membranifaciens (*C. valida*)	
	Cryptococcus spp.	

[a] * indicate that commercial starter cultures are available; anamorph form is given in parentheses.

Within the last decades there has been in wine-making an increasing interest in the use of starter cultures and today most large-scale productions are carried with starter cultures of primarily *S. cerevisiae.* Several different physiological variants of *S. cerevisiae* have been reported for the production of different types of wine and *S. bayanus* has been used as a starter culture especially for wine partially produced at low temperatures (e.g., Sauternes, Tokay, Muscat and Amarone) [99,100]. Recently, genera other than *Saccharomyces* have been reported to be beneficial in the production of wine in order to enhance the taste and flavor of the wine [101] [102].

Yeasts are involved in the production of several special other types of alcoholic beverages, besides wine, including a large number of indigenous alcoholic beverages produced by spontaneous fermentation [9]. In most cases, the yeast species responsible for the fermentation is *S. cerevisiae.* However, yeast species belonging to genera

other than *Saccharomyces* have been reported – for example, for the production of sherry where a secondary fermentation by so-called flor yeast occurs. At the early stage of the secondary fermentation the yeast forms a surface film on the top of the wine; several yeast species, including *Pichia anomala* and *Pichia membranifaciens* yeast have been reported to be involved in this secondary fermentation. However, during the fermentation a microbial succession takes place and *S. cerevisiae* is now believed to be the most important flor yeast for sherry production [103]. Non-*Saccharomyces* yeasts have been reported to be especially involved in the early stages of indigenous, spontaneously fermented beverages [104]. But, at the later stages of the fermentations *S. cerevisiae* will nearly always dominate, as is the case for brewing of sake where isolates of *S. cerevisiae*, previously known as *Saccharomyces saké,* is used [105]. For distilled alcohols the vast majority of modern distilleries use starter cultures of *S. cerevisiae*; exceptions are *Schizosaccharomyces pombe,* used for production of specific spirits and lactose-fermenting yeasts, used in the production of neutral spirit from whey [106].

D. Baker's Yeast

Baker's yeast is traditionally used throughout Europe and the United States as starter culture for the production of a large variety of wheat-based breads. In Scandinavia and the northern part of Europe, sourdough bread made from rye by back-slopping is also popular. The European tradition for production of bread seems to have spread now all over the world, including Southeast Asia and Africa [8]. In all cases the dominant yeast used as starter culture is *Saccharomyces cerevisiae* Meyen ex. E.C. Hansen, as described by Vaughan-Martini and Martini [91] and Barnett et al. [79]. As an alternative baker's yeast *Saccharomyces exiguus* has been used [107].

Baker's yeast is produced as a bulk product. The global yearly production amount to 2 million tons and a yearly growth of approximately 4% has been reported [108]. The propagation of baker's yeast is based on a fed-batch process characterized by aerobic conditions and low carbohydrate concentrations [109]. Except for the utilisation of carbohydrates, optimization of baker's yeasts seems to focus on other aspects quite different from those of brewing yeasts. Also, the number of commercially available baker's yeast appears to be limited compared to brewing yeasts. Beside efficient utilization of maltose, maltotriose and other fermentable carbohydrates present in the dough, the important technological properties of baker's yeasts appear to be biomass yield, formation of CO_2, influence on dough structure, aroma formation and a high resistance to stress conditions such as oxidative stress, drying, freezing and thawing [8,110,111]. The latter results in a demand for high yeast concentrations of trehalose as a protective agent [112]. Also, the ability of the yeast strains to adapt, from the conditions during propagation and production, to the conditions in the dough needs to be considered [109].

Types of fermented cereals other than traditional wheat bread are seen especially in areas where European style bread is not traditionally produced as e.g. in a great part of Africa. Examples of indigenous fermented cereals are products based on fermented maize, millet and sorghum. These products are most often produced by spontaneous fermentation where *S. cerevisiae* is the dominant yeast species, in co-existence with LAB especially [9,50,74,113].

E. Yeasts Used for Dairy Products

For dairy products yeasts are mainly used in cheese production but may also be involved in the production of fermented milk. Yeasts are primarily used as single-starter cultures but many products are still produced by back-slopping or spontaneous fermentation. A mixture between the used starter culture and a dominant indigenous flora is also seen in many dairy products. Yeasts are in most cases used as secondary starter cultures in order to enhance the aroma production or to facilitate the growth of other microorganisms. In general the functions of yeasts during cheese production and their influence on the cheese quality are poorly investigated [114].

The occurrence and functions of yeasts have been especially studied for the production of surface ripened cheeses such as Brick, Limburger, Port Salut, Taleggio, Tilsitter, Trappist, and the Danish Danbo cheese. The surface smear of these cheeses is found to consist of a mixed flora comprising both yeasts and bacteria. For cheese such as the Danish Danbo, the osmotolerant yeast *Debaryomyces hansenii* has been found almost exclusively [76], whereas in other types of surface ripened cheeses, yeasts such as *Candida zeylanoides*, *Yarrowia lipolytica, Kluyveromyces lactis* and others have been found [115–117]. The yeasts initiate the ripening process by degradation of lactate, thereby increasing the pH on the cheese surface and allowing the growth of a more acid-sensitive bacterial flora comprising, amongst others, *Brevibacterium linens* [118]. It should be mentioned that the species *D. hansenii* has been divided into two varieties, *D. hansenii* var. *hansenii* and *D. hansenii* var. *fabryii* [119]; apparently the predominant variety seen in cheese production is *D. hansenii* var. *hansenii* and isolates of this variety have been introduced as starter culture [76,118]. *K. lactis* has further been found to occur in high numbers in soft cheeses such as Camembert [20]. *S. cerevisiae* has also been used as a starter culture in the production of especially Gorgonzola, but it apparently also occurs spontaneously, together with other yeasts, as an integral part of the

microflora of both blue-veined cheeses and some types of soft cheeses [20,120]. *Saccharomyces cerevisiae* has been reported to stimulate mycelial growth and conidia formation of *Penicillium roqueforti* as well as influencing aroma formation and having some proteolytic activity [120,121].

Even though previously considered as a mold, *Galactomyces geotrichum* (*Geotrichum candidum*) is now considered as a yeast species [122] and will be considered as such in the following. *G. geotrichum* is associated with milk and the dairy environment. It is known as a starter culture for several types of mold-ripened cheeses (e.g., Camembert), surface ripened cheeses and cheeses as the French St. Albray. On the other hand, *G. geotrichum* has also been shown to be a potential spoilage organism. *G. geotrichum* is sometimes used in combination with other microorganisms such as *Penicillium camemberti* or *Brevibacterium linens* for the production of surface-ripened cheeses.

Even though not used as a starter culture in the dairy industry, *Yarrowia lipolytica* is often found in soft, blue veined and surface-ripened cheeses. *Y. lipolytica* is characterized by having a quite pronounced lipolytic and proteolytic activity [123] that might be difficult to control if used as a starter culture for cheese production. Furthermore, *Y. lipolytica* is known to produce brownish pigments in cheeses.

For fermented milk yeasts within the genera *Candida*, *Galactomyces*, *Kluyveromyces*, *Saccharomyces* and *Torulaspora* are generally used [124]. *G. geotrichum* (*G. candidum*) is used as commercial starter culture in the production of viili, a Scandinavian fermented milk product and *Saccharomyces unisporus* and *Kluyveromyces marxianus* (*Candida kefyr*) are used as commercial starter cultures in the production of milky kefir. *S. cerevisiae* has also been reported to be involved in the fermentation of a number of indigenous African fermented milk products known under names such as *amasi*, *nono* and *rob* [125,127].

F. Yeasts Used for Meat Products

The use of yeasts in the fermentation of meat products is not well developed. An exception is the use of the osmotolerant yeast *D. hansenii* for the production of sausages and a few other meat products [128]. *D. hansenii* is aerobic and, therefore, primarily found on the outer parts of the fermented meat products; its depletion of oxygen has a color stabilizing effect. Further, *D. hansenii* is reported to have proteolytic activity against sarcoplasmic proteins and several peptides [128] and to have lipolytic activity against pork fat [129]. Several meat products, including high quality products such as Parma and Serano ham, are still spontaneously fermented and yeasts are also involved in these types of fermentation. In addition to *D. hansenii*, *Candida zeylanoides* has been found to be involved in the ripening of Iberian dry-cured ham [130], *C. zeylanoides* and *Pichia membranifaciens* in British sausages [131] and *Cryptococcus laurentii*, *Cryptococcus humicolus*, *Debaryomyces polymorphus* and *Pichia guilliermondii* in Portugese cured ham and bacon [132].

V. MOLDS USED AS STARTER CULTURES

A. Introduction

In Europe starter cultures of molds are primarily used for the production of cheese and meat, and worldwide the production of a variety of indigenous foods is based on spontaneous mold fermentations (Table 177.11). Molds only grow in the presence of oxygen which limit their

TABLE 177.11
Examples of Mold Species Used as Starter Cultures or Occurring Spontaneously at High Numbers in Fermented Products

Fermented Foods and Beverages	Mold Species[a]	Products
Cheese	*Penicillium roqueforti**	Roqueforti, gorgonzola, Danish blue, camembert
	*Penicillium camemberti**	
Meat	*Penicillium camemberti**	Meat sausage, dry cured ham
	*Penicillium chrysogenum**	
	*Penicillium nalgiovense**	
	Penicillium aurantiogriseum	
	Penicillium commune	
	Penicillium olsonii	
	Penicillium solitum	
	Eurotium rubrum	
Wine	*Botrytis cinerea*	Sauternes, Tokay
Indigenous fermented foods	*Aspergillus oryzae**	Soy sauce, tempe, Chinese soybean paste ("sufu" or "furu"), Japanese "miso" and "shoyu"
	*Aspergillus sojae**	
	Actinomucor spp.	
	Mucor spp.	
	Rhizopus oligosporus	
	Rhizopus oryzea	
	Rhizopus spp.	
Fermented fish	*Aspergillus penicillioides*	Indonesian dried salted fish
	Aspergillus wentii	
	Eurotium rubrum	
Indigenous fermented beverages	*Aspergillus oryzae*	Sake, Chinese, Indian and Thai spirits, wine and beers
	Aspergillus spp.	
	Mucor spp.	
	Rhizupus spp.	

[a,*] indicate that commercial starter cultures are available.

applications. In general molds are known as effective producers of enzymes and their proteolytic and lipolytic activities are often high; several molds also have extracellular glycoamylase activity. Furthermore, molds are known to produce a variety of different aroma compounds of which the best known are alcohols and organic acids. Molds preferentially grow on carbohydrates but may also grow in protein-rich media without carbohydrates in which they use amino acids as carbon source [133]. The taxonomy of molds is primarily based on their micromorphology and growth characteristics on different media, but their production of secondary metabolites can also be used as taxonomic characters [134]. Unfortunately, DNA technology and the use of molecular typing techniques have not developed as fast for molds as for yeasts and the typing of molds used as starter cultures is still based primarily on phenotypic criteria. A taxonomic description of food borne fungi is given by Samson et al. [135].

B. Molds Used for Dairy Products

The use of such molds as *Penicillium roqueforti* and *Penicillium camemberti* has a long history in the production of cheese and their use as starter cultures goes back to the beginning of 19th century. *Penicillium roqueforti* is used as a secondary starter culture in the production of blue-veined cheeses but it may also occur spontaneously in a number of other foods and for some types of cheeses it is regarded as a contaminant. The fact that *P. roqueforti* is able to grow at high NaCl and low O_2 concentration and at a relative high CO_2 concentration makes it suitable for the production of blue-veined cheese. During cheese maturation *P. roqueforti* produces a number of extracellular peptidases and proteinases that are mainly responsible for the extensive proteolysis of blue-veined cheese. Large differences in proteolytic [136] and lipolytic activity [137] have been reported between different commercial strains of *P. roqueforti*. The lipolytic enzymes especially seem to be responsible for the characteristic flavor and taste of blue-veined cheeses through their production of high concentrations of methyl ketones [137]. *P. camemberti* is used as a starter culture for the production of Camembert and similar types of surface-ripened cheeses, and is highly restricted to the production of cheese and is seldom observed in other foods or in the environment [8]. *P. camemberti* is able to grow on the cheese surface due to its high NaCl tolerance. On the cheese surface, it degrades lactate, resulting in an increased pH. When the lactate is depleted, the proteinases from *P. camemberti* then degrade casein, resulting in a further increase in pH and the release of ammonia. Besides its pronounced proteolytic activity, *P. camemberti* also produces lipases that are involved in aroma formation. Figure 177.5 shows the mycelial growth of *P. camemberti* on a soft cheese surface.

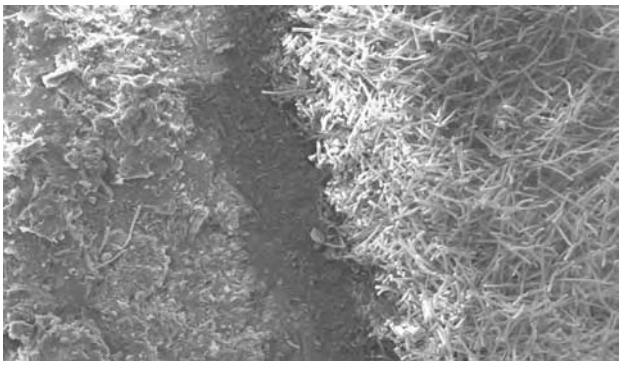

FIGURE 177.5 Growth of *Penicillium camemberti* on a soft cheese surface. The magnification is 250 times.

C. Molds Used for Meat Products

The use of molds as starter cultures for fermentation of meat is mainly concentrated in such European regions as Italy, Spain, France, Germany and Hungary. *Penicillium* spp. are mainly involved in the fermentation and the meat products produced typically are sausages and ham. Common molds used for fermentation of meat include *Penicillium nalgiovense*, *Penicillium chrysogenum* and *Penicillium camemberti* [8,138,139]; but also other species might be used. *Penicillium commune* and *Penicillium olsonii* have been reported to be involved in the spontaneous fermentation of Spanish meat sausage [140], *Penicillium aurantiogriseum* in the fermentation of dry sausages [141] and a variety of *Penicillium* spp. including *Penicillium aurantiogriseum*, *P. chrysogenum*, *P. commune*, *Penicillium echinulatum* and *Penicillium expansum* have been found during spontaneous fermentation of dry-cured Iberian ham [142]. For the latter, nontoxigenic strains of *P. chrysogenum* have been recommended as starter cultures [142]. *Eurotium rubrum* and *Penicillium solitum* were found to be the dominant species during production of traditional Tyrolean smoked and cured ham [143]. *Aspergillus* spp. are not used as starter cultures for meat fermentation but may be observed during production of cured ham where they can grow at low water activity.

Besides influencing the appearance, molds contribute to the characteristic aroma and flavor of the product by production of extracellular proteinases and lipases [144]. Also, the molds inhibit the growth of unwanted microorganisms and have an antioxidative effect. Strains of both *P. chrysogenum* and *P. nalgiovense* are known penicillin producers and the latter, at least, has been shown to be able to produce penicillin when growing on meat surfaces and to secrete it into the product [145]. Therefore, starter cultures of molds must be carefully analyzed by both chemical and biological tests to ensure that they do not form neither penicillin nor mycotoxins in the product [139].

D. Molds in Wine Production

Molds are not used as starter culture for wine production, but the growth of *Botrytis cinerea* may be required for the production of certain types of wine. In general the growth of *B. cinerea* is unwanted, as it will rot the grapes. However, for the production of sweet white wine such as French Sauternes and Hungarian Tokay, the development of *B. cinerea* on the matured grapes is required and known as "noble or vulgar rot;" this results in overripening and dehydration leading to increased sugar content in the grapes. Also, the growth of *B. cinerea* adds a characteristic flavor to the wine produced from these grapes. Specific environmental conditions such as alternating dry and humid periods are required for reaching the perfect stage of maturation and the development of *B. cinerea* [146,147]. Biological control of the growth of *B. cinerea* on matured grapes has been obtained by use of the yeast *Pichia membranifaciens*; its antagonistic effect against *B. cinerea* appears to be related to its secretion of exo- and endo-β-1,3-glucanases [148].

E. Molds Used for Fermentation of Indigenous Fermented Foods and Beverages

The most well known indigenous fermented products, where molds are involved in the fermentation, are probably soy sauce and tempeh. Soy sauce is of Chinese or Japanese origin and is produced by an initial solid stage mold fermentation of equal parts of cooked soybeans and roasted and crushed wheat, inoculated with conidia of *Aspergillus oryzae* and *Aspergillus sojae*. After fermentation for 3 days the material is placed in brine (22–25% (w/v) NaCl) for 6–8 month. During this phase halophilic LAB and yeasts (*Zygosaccharomyces rouxii*) occur either spontaneously or are added as starter cultures. Finally, the soy sauce is harvested by pressing and is then pasteurized. Tempeh originates from Java and Indonesia and is a solid-stage mold fermentation of soaked and cooked soybeans or other leguminous seeds or cereals. After boiling and cooling, the beans are inoculated with *Rhizopus oligosporus* and *Rhizopus oryzae* and packed. After fermentation for 24–48 hr the beans are tighten together due to mycelial growth. The fresh tempeh can be eaten after cooking or frying [146]. Other examples of indigenous mold fermented foods are *sufu* or *furu*, a Chinese soybean pasta produced by *Actinomucor* spp., *Mucor* spp. or *Rhizopus* spp. [149], and Japanese *miso* and *shoyu* produced by *Aspergillus oryzae* and *Aspergillus sojae* [150]. Xerophilic molds such as *Eurotium rubrum*, *Aspergillus wentii* and *Aspergillus penicillioides* have also been reported to be involved in the fermentation of Indonesian dry salted fish [151].

Especially in the Asia, species of *Aspergillus*, *Mucor* and *Rhizopus* are used as amylase producers for fermented beverages that are based on rice or wheat [150]. An example is the production of sake in which spores of *Aspergillus oryzae* are used to breakdown starch to fermentable carbohydrates that are then converted to alcohol by *S. cerevisiae.* Similarly, *Aspergillus* spp., *Mucor* spp. and *Rhizopus* spp are used in the production of Chinese, Indian and Thai spirits, wines and beers [152].

ACKNOWLEDGMENT

The information in this chapter has been modified from "Fermented food and starter cultures," by J. Josephsen and L. Jespersen, in *Handbook of Food and Beverage Fermentation Technology*, Editors: Y. H. Hui et al., Marcel Dekker, New York, 2004.

178 Manufacture of Fermented Product

Wai-Kit Nip
Department of Molecular Biosciences and Bioengineering, University of Hawaii at Manoa

CONTENTS

I. INTRODUCTION

The availability of fermented foods has a long history among the different cultures. Acceptability of fermented foods also differs because of cultural habits. A product highly acceptable in one culture may not be so acceptable by consumers in another culture. The number of fermented food products is countless. Manufacturing processes of fermented products vary considerably owing to variables such as food group, form, and characteristics of final products; kind of ingredients used; and cultural diversity. It is beyond the scope of this chapter to address all the manufacturing processes used to produce fermented foods. Instead, this chapter is organized to address fermented food products based on food groups such as dairy, meat, cereal, soy, and vegetables. Within each food group, manufacturing processes of typical products are addressed. This chapter is only an introduction to manufacturing processes for selected fermented food products. Readers should consult the references below and other available literature for detailed information.

II. FERMENTED DAIRY PRODUCTS

A. Ingredients and Kinds of Products

Fermented dairy products are commonly produced in milk-producing countries and by nomadic peoples. These products are highly acceptable in these cultures. They have been gradually accepted by other cultures because of cultural exchange. It is generally accepted that most fermented dairy products were first discovered and developed by nomadic peoples. The production of a fermented dairy product nowadays can be a highly sophisticated process. However, the production of another fermented dairy product can still be conducted in a fairly primitive manner in another location. The quality of a fermented dairy product varies due to the milk, microorganisms, and other ingredients used in the manufacturing process. Many factors affect the gross composition of milk (15, 32, 34, 55, 62). The factors most significant to the processing of milk products are breed, feed, season, region, and herb health. Reviews of animals' milk are available in the literature. Table 178.1 lists the approximate composition of cow's milk (15, 32, 34, 48, 55, 62). In industrial countries, milk composition is standardized to meet a country's requirements. However, it is understood that the requirements in one country may not be the same as those in another; thus, the composition may vary for the same product. International agreements to standardize some products are now available. However, products produced in different locations still can vary because of microorganisms and culturing practices used in their production.

Fermented dairy products can be grossly divided into three big categories: cheeses, yogurts, and fermented liquid milks. Within each of these categories, there are

TABLE 178.1
Approximate Composition of Milk

Components	Average Content in Milk (% w/w)	Range (% w/w)	Average Content in Dry Matter (% w/w)
Water	87.1	85.3–88.7	
Solid-not-fat	8.9	7.9–10.0	(69)
Fat in dry matter	31	22–38	(31)
Lactose	4.6	3.8–5.3	36
Fat	4	2.5–5.5	31
Protein	3.25	2.3–4.4	25
Caesin	2.6	1.7–3.5	20
Mineral substances	0.7	0.57–0.83	5.4
Organic acids	0.17	0.12–0.21	1.3
Miscellaneous	0.15		1.2

TABLE 178.2
Kinds of Fermented Dairy Products with Examples

Kinds	Examples
Fermented Liquid Milks	
Lactic fermentation	Buttermilk, Acidophillus,
With alcohol and lactic acid	Kefir, Koumiss
With mold and lactic acid	Villi
Concentrated	Ymer, Skyr, Chakka
Yogurts	
Viscous/liquid	Yogurt
Semisolid	Strained yogurt
Solid	Soft/hard frozen yogurt
Powder	Dried yogurt
Cheeses	
Extra hard	Parmesan, Romano, Sbrinz
Hard with eyes	Emmental, Gruyere, Swiss
Hard without eyes	Cheddar, Chester, Provolone
Semi-hard	Gouda, Edam, Caerphilly
Semi-hard, internally mold ripened	Roquefort, Blue, Gorgonzola
Semi-soft, surface-ripened with bacteria	Limburger, Brick, Munster
Soft, surface mold ripened	Brie, Camebert, Neufchatel
Soft, unripened	Cream, Mozzarella, US-Cottage

subcategories. Table 178.2 presents examples for each of these categories (15, 32, 34, 48, 55, 62).

In the manufacturing of fermented dairy products, various ingredients such as the milk itself, microorganism(s), coagulants, salt, sugar, vitamins, buffering salts, bleaching (decolorizing) agents, dyes (coloring agents), flavoring compounds, stabilizers, and emulsifiers may be used. The use of these ingredients in fermented liquid milks, yogurts, and natural and processed cheeses are summarized in Table 178.3 (15, 32, 34, 48, 55, 62).

Various microorganisms such as lactic acid bacteria, yeasts, and molds are used in the manufacturing of fermented dairy products to produce the various characteristics in these products. Table 178.4 lists some of the more common dairy microorganisms and their uses in fermented liquid dairy products, yogurts, and cheeses (12, 31, 49).

Cultures of the different microorganisms are available in various forms, such as liquid, frozen, or freeze-dried. Examples of their usage in the manufacturing of fer mented dairy products are listed in Table 178.5 (15, 32, 34, 48, 55, 62).

Because the starter cultures are available in various forms, the preparation steps for these cultures, before inoculation, are different. Table 178.6 lists some of the preparation procedures used in the industry for different forms of starter cultures (15, 32, 34, 48, 55, 62).

Different microorganisms have different temperature requirements for their optimum growth and functioning. Some fermented dairy products, such as mold-ripened cheeses, may require more than one microorganism to complete the manufacturing process. These molds function best during the long ripening period and therefore have standard incubation temperatures in the refrigerated range. This is also true for some cheeses that require long ripening periods. Microorganisms requiring higher incubation temperatures are used in the production of fermented liquid milks that require only a short incubation time. Table 178.7 lists some of the dairy microorganisms used in some products and their incubation temperatures (12, 17, 31, 35, 42, 52, 54).

B. Cheeses

Cheeses can be classified into different categories based on their moisture, the way the milk is processed, and the types of microorganisms used for the ripening process (Table 178.8) (15, 32, 48).

[a] Product group: 1 = yogurt, 2 = fermented liquid milk, 3 = cheese.

In the processing of cheese, the amount of curd used for each block of cheese to be made differs considerably, (Table 178.9) (15, 32, 34, 35, 42, 48, 52, 54). Harder cheeses have much larger blocks than the soft cheeses. This may be due to the ease of handling after ripening.

Cheeses are packaged in different forms to satisfy consumer consumption patterns and, to some extent, to be compatible with the way the cheese is ripened and for marketing purposes. The various packaging materials are selected to protect the cheeses in a sanitary condition, extend shelf life, and delay the deterioration of the final products. Table 178.10 lists some of the requirements of cheese packaging materials (15, 17, 34, 42, 48, 52, 54, 55, 62).

All cheeses produced must be coagulated from acceptable milk to form curd, followed by removal of the whey. Most cheeses are made from standardized and pasteurized milk. Nonpasteurized milk is also used in some exceptional cases, provided they do not carry pathogens. The majority of cheeses are made from cow's milk. Milks from other animals are also used for specialty products. The coagulation process is conducted through the addition of coagulant (rennin or chymosin) and incubation of appropriate lactic acid bacteria in milk to produce enough acid and appropriate pH

TABLE 178.8
Classification of Cheese According to Moisture Content, Scald Temperature, and Method of Ripening

Hard Cheese (Moisture 20–42%; Fat in Dry Matter, 32–50%, Minimum)				
Low Scald, Lactic Starter	*Medium Scald, Lactic Starter*	*High Scald, Propionic Eyes*	*Plastic Curd, Lactic Starter or Propionic Eyes*	
Gouda	Cheddar	Parmesan	Provolone	
Cheshire	Svecia	Beaufort	Mozzarella	
Semi-Hard Cheese (Moisture 45–55%; Fat in Dry Matter, 40–50%, Minimium)				
Lactic Starter	*Smear Coat*	*Blue-Veined Mold*		
St. Paul	Limburg	Roquefort		
Lanchester	Munster	Danablue		
Soft Cheese (Moisture >55%; Fat in Dry Matter, 4–51%, Minimum)				
Acid-Coagulated	*Smear Coat or Surface Mold*	*Surface Mold*	*Normal Lactic Starter*	*Unripened Fresh*
Cottage cheese (USA)	Brie	Camembert	Quarg	Cottage (UK)

TABLE 178.10
Requirements of Cheese Packaging Materials

Low permeability to oxygen, carbon dioxide, and water vapor
Strength and thickness of film
Stability under cold or warm conditions
Stability to fats and lactic acid
Resistance to light, especially ultraviolet
Ease of application, stiffness, elasticity
Ability to seal and accept adhesives
Laminated films to retain laminated
Low shrinkage or aging unless shrinkage is a requisite
Ability to take printed matter
Should not impart odors to the cheese
Suitability for mechanization of packaging
Hygienic considerations in storage and use
Cost effectiveness as a protective wrapping

for curdling the milk. After the casein is recovered, it is salted and subjected to fermentation, with or without inoculation with other microorganisms to produce the desirable characteristics of the various cheeses. Variations in the different manufacturing steps a wide variety of cheeses with various characteristics. Table 178.11 summarizes the basic steps in the cheese manufacturing process (12, 15, 31, 32, 34, 42, 48, 52, 54, 55, 62). Table 178.12 summarizes the ripening conditions for various cheeses. Selected examples are introduced below to provide an overview of the complexity of cheese manufacturing (12, 15, 31, 32, 34, 42, 48, 49, 50, 52, 54, 55, 62).

1. Cottage Cheese Manufacturing

Cottage cheese is a product with very mild fermentation treatment. It is produced by incubating (fermenting) the standardized and pasteurized skim milk with the starter

TABLE 178.11
Basic Cheese Making Steps

Standardize cheese milks
Homogenize cheese milks
Heat-treat or pasteurize cheese milks
Add starter
Add color and additives
Coagulation/Curdling:
Cut coagulum/curd
Stir and scald
Wash curd cheese
Salt cheese
Press cheese
Coat, bandage, and wrap cheese
Let cheese ripen
Package for retail
Store

TABLE 178.12
Cheese Ripening Conditions

Types of Cheese	Storage Period (days)	Temperature (°C)	Relative Humidity (%)
Soft	12–30	10–14	90–95
Mold ripened	15–60	4–12	85–95
Cooked, e.g., Emmental			
Cold room	7–25	10–15	80–85
Warm room	25–60	18–25	80–85
Hard, e.g., Cheddar	45–360	5–12	87–95

Sources: References 12, 15, 31, 32, 34, 42, 48–50, 52, 54, 55, 62.

lactic acid bacteria to produce enough acid and appropriate pH for the curdling of milk. The curd is then recovered and washed, followed by optional salting and creaming. The product is then packed and ready for marketing. No further ripening is required for this product. This is different from most fermented cheeses that require a ripening process. Table 178.13 lists the various steps involved in the production of cottage cheese (15, 34, 42, 48, 52, 55, 62).

2. Cheddar Cheese Manufacturing

Cheddar cheese is a common hard cheese without eyes used in the fast-food industry and in the household. Its production process is characterized by a requirement for milling and cheddaring of the curd. This cheese can be ripened with a wax rind or rindless (sealed under vacuum in plastic bags.) It is also categorized into regular, mild, or sharp based on the aging period (45–360 days). The longer the aging period, the sharper the flavor. It is packaged as a large block or in slices. Table 178.14 lists the basic steps in the manufacturing of cheddar cheese (15, 34, 42, 48, 52, 55, 62).

TABLE 178.13
Basic Steps in Making Cottage Cheese

Standardize skim milk			
Pasteurize milk with standard procedure and cool to 32°C			
Inoculate with Active Lactic Starter, Add Rennet, and Set Curd:			
Rennet addition—at 2 ml single strength (prediluted, 1:40) per 1000 kg milk within 30 minutes of starter addition			
Specifications	Short Set	Medium Set	Long Set
Starter concentration	5%	3%	0.5%
Temperature of milk set	32°C	27°C	22°C
Time from setting to cutting	5 hr	8 hr	14–16 hr
Final pH and whey titratable acidity—4.6 and 0.52%, respectively			
Cut curd with 1.3, 1.6, or 1.9 cm wire cheese knife			
Cook Curd:			
Let curd cubes stand for 15–30 minutes and cook to 51–54°C at 1.7°C per 10 minutes			
Roll the curds gently every 10 minutes after initial 15–30 minute wait			
Test curd firmness and hold 10–30 minutes longer to obtain proper firmness			
Wash Curd:			
First wash with 29°C water temperature			
Second wash with 16°C water temperature			
Third wash with 4°C water temperature			
Drain washed curd (by gravity) for about 2.5 hours			
Salt and cream at 152 kg creaming mixture per 454 kg with final 0.5–0.75% salt content and 4% fat content (varies with products and optional)			
Package in containers			
Storage at refrigerated temperature			

Source: References 15, 34, 42, 48, 52, 55, 62.

3. Swiss Cheese Manufacturing

Swiss cheese is also a common cheese used in the fast-food industry and in the household. It is characterized by having irregular eyes inside the cheese. These eyes are produced by *Propionicbacterium freudenreichii* subsp. *shermanii,* which produces gases trapped inside the block of cheese during fermentation and ripening. A cheese with eyes like Swiss cheese has become the icon for cheese in graphics. Swiss cheese is also characterized by its propionic acid odor. The salting process for Swiss cheese utilizes both the dry- and brine-salting processes. Like cheddar cheese, it can be categorized into regular, mild, and sharp, depending on the length of the curing process. Table 178.15 lists the basic steps in the manufacture of Swiss cheese (15, 34, 42, 48, 52, 55, 62).

4. Blue Cheese

Blue cheese is characterized by its strong flavor and by blue mold filaments from *Penicillium roqueforti* inside the cheese. It is commonly consumed as cheese or made into a salad dressing. In the manufacturing of blue cheese, as in that of Swiss cheese, salting is accomplished by the application of dry-salting and brining processes. It is characterized by a cream bleaching step to show off the blue

TABLE 178.14
Basic Steps in Making Cheddar Cheese

Standardize cheese milk.
Homogenize milk.
Pasteurization and additional heating of milk.
Cool milk to 31°C.
Inoculate milk with lactic starter (0.5–2% active mesophilic lactic starter).
Add rennet or other protease(s)—198 ml single strength (1:15,000) rennet per 1000 kg milk. Dilute the measured rennet 1:40 before use.
Agitate at medium speed.
Set the milk to proper acidity—25 minutes.
Cut the curd using 0.64 cm or wider wire knife. Stir for 5 minutes at slow speed.
Cook the curd at 38°C for 30 minutes with 1°C for every 5 minute increment. Maintain temperature for another 4–5 minutes and agitate periodically at medium speed.
Drain the curd at 38°C.
Cheddar the curd at pH 5.2–5.3.
Mill the curd slabs.
Salt the curd at 2.3–3.5 kg salt per 100 kg curd in three portions in 30 minutes.
Waxed Cheddar Cheese:
Hoop and press at 172 kPa for 30–60 seconds then 172–344 kPa overnight.
Dry the cheese at 13°C at 70% RH for 2–3 days.
Paraffin the whole cheese at 118°C for 6 seconds.
Rindless Cheddar Cheese:
Press at 276 kPa for 6–18 hours.
Prepress for 1 minute, followed by 45 minutes under 686 mm vacuum.
Remove and press at 345 kPa for 60 minutes.
Remove and vacuum seal in bags with hot water shrinkage at 93°C for 2 seconds.
Ripen at 85% RH at 4°C for 60 days or longer, up to 9–12 months, or at 3°C for 2 months then 10°C for 4–7 months, up to 6–9 months.

Source: References 15, 34, 42, 48, 52, 55, 62.

TABLE 178.15
Basic Steps in Making Swiss Cheese

Standardize cheese milk to 3% milk fat—treatment with H_2O_2-catalase optional.
Pasteurize of the milk.
Inoculate with Starters:
Streptococcus thermophilus, 330 ml per 1000 kg milk
Lactobacillus delbruechii subsp. *bulgaricus,* 330 ml per 1000 kg milk
Propionibacterium freudenreichii subsp. *shermanii,* 55 ml per 1000 kg milk
Add rennet, 10–20 minutes after inoculation—154 ml single-strength (1:15,000) rennet extract per 1000 kg milk, prediluted 1:40 with tap water before addition. Stir for 3 minutes.
Let milk set (coagulate) for 25–30 minutes.
Cut the curd with 0.64 wire knife; let stand undisturbed for 5 minutes; stir at medium speed for 40 minutes.
Cook the curd slowly to 50–53°C for about 30 minutes and stir at medium speed, then turn off steam and continue stirring for 30–60 minutes with pH reaching 6.3–6.4.
Allow the curd to drip for 30 minutes.
Press the curd—with preliminary pressing, then at 69 kPa overnight.
Salt the Curd:
First salting—in 23% salt brine for 2–3 days at 10°C
Second salting—at 10–16°C, 90% RH. Wipe the cheese surface from the brine soaking, then sprinkle salt over cheese surface daily for 10–14 days
Third salting—at 20–24°C, 80–85% RH. Wash cheese surface with salt water and sprinkle with dry salt 2–3 times weekly for 2–3 weeks
Rinded Block Swiss Cheese:
Cure—at 7°C or lower (USA) or 10–25°C (Europe) for 4–12 months.
Package in container and store at cool temperature.
Rindless Block Swiss Cheese:
Wrap or vacuum pack the blocks.
Cure stacked cheese at 3–4°C for 3–6 weeks.
Store at cool temperature.

Sources: References 15, 34, 42, 48, 52, 55, 62.

mold filament with a lighter background and by needling the block of curd to spread the blue mold filaments. It also has a soft and crummy texture due to the needling process and to the gravity draining procedure used to drain the curd. The curing period of two to four months is shorter than for hard cheeses. Its shelf life of two months is also shorter than that of its harder counterparts. Table 178.16 lists the basic steps in the manufacture of blue cheese (15, 34, 42, 48, 52, 55, 62).

5. American Style Camembert Cheese

American style camembert cheese is categorized as a soft cheese. It is characterized by a shell of mold filament on the surface produced by *Penicillium camembertii*. Brie cheese is a similar product. Addition of annatto color is optional. Like blue cheese, it is gravity drained. Therefore it has a soft, smooth texture. This cheese is surface salted and has a total curing period of three weeks before distribution. It is usually cut into wedges and wrapped individually for direct consumption. Table 178.17 lists the basic steps in the manufacture of American style camembert cheese (15, 34, 42, 48, 52, 55, 62).

6. Feta Cheese Manufacturing

Feta cheese is a common cheese in the Mediterranean countries. It is a soft cheese characterized by its brine curing (maturation) process, which is not common in cheese making. Instead, it has a similarity to the manufacture of sufu (Chinese fermented tofu, see below in this chapter). Like other soft cheese, the curing period is only two to three months. Table 178.18 lists the basic steps in the manufacture of Feta cheese (50).

C. YOGURT

Yogurt can be considered as a curdled milk product. Plain yogurt is yogurt without added flavor, stabilizer, or

TABLE 178.16
Basic Steps in Making Blue Cheese

Milk Preparation:
- Separate cream and skim milk.
- Pasteurize skim milk by HTST, cool to 30°C.
- Bleach cream with benzoyl peroxide (optional) and heat to 63°C for 30 seconds.
- Homogenize hot cream at 6–9 mPa and then 3.5 mPa, cool, and mix with pasteurized skim milk.

Inoculate milk at 30°C with 0.5% active lactic starter. Let stand for 1 hour.
Add rennet—158 ml single strength (prediluted 1:40) per 1000 kg milk. Mix well.
Let Coagulate or set, 30 minutes.
Cut curd with 1.6 cm standard wire knife.
Cook curd at 30°C, let stand 5 minutes, and then agitate every 5 minutes for 1 hour. Whey should have 0.11 to 0.14 titratable acidity.
Drain whey by gravity for 15 minutes.
Inoculate with *Penicillium roqueforti* spores—2 kg coarse salt and 28 g *P. requeforti* spore powder per 100 kg curd followed by thorough mixing. Add food grade lipase (optional).

Salting:
- First salting—dip the curd in 23% brine for 15 minutes, then press or mold at 22°C, turning every 15 minutes for 2 hours and every 90 minutes for rest of day.
- Second salting—salt cheese surface everyday for 5 days at 16°C, 85% RH.
- Final dry salting or brine salting in 23% brine for 24–48 hours. Final salt concentration about 4%.

Incubate for 6 days at 16°C, RH
Wax and needle air holes or vacuum pack and need air holes.
Mold filament development in air holes at 16°C for 6–8 days.
Cure at 11°C and 95% RH for 60–120 days.

Cleaning and Storing:
- Strip off the wax or vacuum packaging bag.
- Clean cheese, dry, and repack in aluminum foil or vacuum packaging bags.
- Store at 2°C.

Product shelf life—2 months.

Source: References 15, 34, 42, 48, 52, 55, 62.

TABLE 178.17
Basic Steps in Making American Style Camembert Cheese

Standardize milk.
Homogenize milk.
Pasteurize milk at 72°C for 6 seconds.
Cool milk to 32°C.
Inoculate with 2% active lactic starter followed by 15–30 minutes acid ripening to 0.22% titratable acidity.
Add annatto color at 15.4 ml per 1000 kg milk (optional).
Add rennet —220 ml single-strength (prediluted 1:40) rennet per 1000 ml, then mix for 3 minutes and let stand for 45 minutes.
Cut curd with 1.6 cm standard wire knife.
Cook curd at 32°C for 15 minutes with medium speed stirring.
Drain curd at 22°C for 6 hours with occasional turning.
Inoculate with *Penicillium camemberti* spores by spray gun on both sides of cheese once.
Press and mold curd by pressing for 5–6 hours at 22°C without any weight on surface.
Surface salt cheese; let cheese stand for about 9 hours.
Cure—at 10°C, 95% RH for 5 days undisturbed, then turn once and continue curing for 14 days.

Packaging, Storage, and Distribution:
- Wrap cheese and store at 10°C, 95–98% RH for another 7 days.
- Move to cold room at 4°C and cut into wedges, if required, and rewrap.
- Distribute immediately.

Source: References 15, 34, 42, 48, 52, 55, 62.

TABLE 178.18
Basic Steps in Making Feta Cheese

Standardize milk with 5% fat, enzyme treated and decolorized.
Homogenize milk.
Pasteurize by standard procedure and cool to 32°C.
Inoculate with 2% active lactic starter as cheddar cheese and allow to ripen for 1 hour.
Add rennet at 198 ml single-strength rennet (prediluted, 1:40) per 1000 kg milk and let set for 30–40 minutes.
Cut the curd with 1.6 cm standard wire knife and let stand 15–20 minutes.
Allow curd to drip for 18–20 hour at 12–18 kg on 2000 cm^2, with pH and titratable acidity developed to 4.6 and 0.55%, respectively.
Prepare cheese blocks of 13 × 13 × 10 cm each.
Salt in 23% salt brine for 1 day at 10°C.
Can and box cheese blocks in 14% salt brine (sealed container).
Cure for 2–3 months at 10°C.
Soak cured cheese in skim milk for 1–2 days before consumption to reduce salt.
Yield—15 kg/100 kg of 5% fat milk.

Source: Reference 50.

coagulant. Its acceptance is limited to those who really enjoy eating it. With the development of technology, other forms of yogurt, such as flavored and sweetened yogurt, stirred yogurt, yogurt drinks, and frozen yogurt, are now available. Its popularity varies from location to location. It is considered as a health food when active or live cultures are added to the final product. Table 178.19 lists the basic steps involved in the manufacture of yogurt. Table 178.3, presented earlier, should also be consulted for reference to other ingredients (9, 58).

Most commercially produced yogurt and its products contain sweeteners, stabilizers, or gums (Table 178.20); fruit pieces; natural and synthetic flavors (Table 178.21); and coloring compound (Table 178.22) (9, 58).

Different countries also have different standards on the percent fat and percent solids-not-fat (SNF) contents in their yogurt products (Table 178.23) (9, 58).

The different variables described above make the situation complicated. The term "yogurt" in one country may not have the same meaning in another country. This creates difficulties for international trade. Consensus or agreement among countries, and proper labeling are needed to identify the products properly.

TABLE 178.19
Basic Steps in the Production of Yogurt

Standardize liquid milk.
Homogenize liquid milk.
Heat-treat or pasteurize liquid milk at 90°C for 5 minutes or equivalent.
Cool pasteurized milk to 1–2°C above inoculation temperature.
Add starter (inoculation), 1–3% operational culture.
Add flavor, sweetener, gums, and/or color (optional).
Incubate at 40–45°C for 2.5–3.0 hours for standard cultures.
Break curd (optional).
Cool to 15–20°C in 1–1.5 hours.
Add live culture (optional).
Package.
Store at ≤10°C.

D. Fermented Liquid Milks

In milk-producing countries, it is common to have fermented milk products. These products were first discovered or developed by accident. Later, the process was modified for commercial production. Fermented liquid milks are similar to plain yogurt drinks. It is basically milk that has gone through an acid and or alcoholic fermentation. The final product is maintained in the liquid form rather than in the usual soft-gel form of yogurt. There are different fermented liquid milks available, but only sour milk, kefir, and acidophilus milk are discussed below. Readers should refer to the references listed below and other available literature on related products.

1. Sour Milk Manufacturing

Table 178.24 presents the basic steps in the manufacturing of the most basic fermented liquid milk, sour milk. The milk is standardized, pasteurized, inoculated, incubated, homogenized, and packaged. It is a very straightforward procedure compared to those for the other two products, kefir and acidophilus milk (12, 15, 31, 32, 34, 49, 55, 62).

TABLE 178.20
Some Common Gums that Could Be Used in Yogurt Manufacturing

Kind	Name of Gum
Natural	Agar
	Alginates
	Carrageenan
	Carob gum
	Corn starch
	Casein
	Furcelleran
	Gelatin
	Gum arabic
	Guar gum
	Karaya gum
	Pectins
	Soy protein
	Tragacanth gum
	Wheat starch
Modified gums	Cellulose derivatives
	Dextran
	Low-methoxy pectin
	Modified starches
	Pregelatinized starches
	Propylene glycole alginate
	Xanthin
Synthetic gums	Polyethylene derivatives
	Polyvinyl derivatives

Sources: References 9 and 58.

2. Kefir Manufacturing

Kefir is a fermented liquid milk product characterized by the small amount of alcohol it contains and its inoculant, the kefir grains. It is a common product in the Eastern

European countries and is considered to have health benefits. Among all the fermented dairy products, only this and similar products contain small amounts of alcohol. Also, in all the other fermented dairy products, pure cultures of bacteria, yeasts, and/or molds are used, but in kefir, the kefir grains are used and recycled. Kefir grains are masses of bacteria, yeasts, polysaccharides, and other

TABLE 178.25
Basic Steps in Kefir Processing

Preparation of Mother "Kefir"
Standardize milk for preparation of mother "kefir."
Pasteurize milk at 90–95°C for 15 minutes and cool to 18–22°C.
Spread kefir grains at the bottom of a container (5–10 cm thick) and add pasteurized milk (20–30 times the amount of kefir grains).
Ferment for 18–24 hours, mixing 2–3 times. Kefirs grains float to the surface.
Filter out the kefir grains with a fine sieve, wash the grains with water, and save for the next fermentation.
Save the fermented milk for the next-step inoculation.

Preparation of Drinkable Kefir
Blend fermented milk from above with 8–10 times fresh, pasteurized, untreated milk.
Pour into bottles, then close the bottles and ferment mixture for 1–3 days at 18–22°C.
[Another option is to mix the fermented milk with fresh milk at 1–5% and ferment at 20–25°C for 12–15 hours (until pH 4.4–4.5 is reached), then ripen in storage tanks 1–3 days at 10°C. Product is not as traditional but is acceptable.]
Cool to refrigerated temperature.
Store and distribute.

Source: References 12, 15, 18, 31, 32, 34, 48, 49, 55, 62.

products of bacterial metabolism, together with curds of milk protein. Production of kefir is a two-step process: (1) the production of mother kefir and (2) the production of the kefir drink. Table 178.25 lists the basic steps in kefir manufacturing (12, 15, 18, 31, 32, 34, 48, 49, 55, 62).

3. Acidophilus Milk

Acidophilus milk is considered to have probiotic benefits. Like yogurt, it is advertised as having live cultures of *Lactobacillus acidophilus* and *Bifidobacterium bifidum* (optional). These live cultures are claimed to provide the benefit of maintaining a healthy intestinal microflora. Traditional acidophilus milk has a considerable amount of lactic acid and is considered to be too sour for the regular consumers in some locations. Therefore, a small amount of sugar is added to the final product to make it more palatable. This later product is called sweet acidophilus milk. Table 178.26 lists the basic steps in the manufacture of acidophilus milk (12, 15, 31, 32, 34, 48, 49, 55, 62).

III. MEAT PRODUCTS

A. Ingredients and Types

Fermented meat products such as ham and sausages have been available to different cultures for centuries. It is interesting to learn that the ways these products are produced are basically very similar in different cultures. Besides the meat, nitrite and salt, and sugar (optional), pure cultures are

TABLE 178.26
Basic Steps for Sweet Acidophilus Milk Processing

Procedure 1:
Standardize milk.
Heat milk to 95°C for 60 minutes, cool to 37°C, and hold for 3–4 hours; reheat to 95°C for 10–15 minutes, then cool to 37°C.
Inoculate with 2–5% bulk starter.
Incubate for up to 24 hours or to 1% lactic acid.
Cool to 5°C.
Pack and distribute.
Procedure 2:
Standardize milk.
Homogenize milk at 14.5 MPa.
Heat to 95°C for 60 minutes.
Cool to 37°C.
Inoculate with direct vat inoculation (DVI) starter.
Incubate for 12–16 hours or to about 0.65% lactic acid.
Heat at ultra high temperature (UHT), 140–145°C for 2–3 seconds to eliminate undesirable contaminants.
Cool to 10°C or lower.
Package and distribute.

Source: References 12, 15, 31, 32, 34, 48, 49, 55, 62.

sometimes used, especially in fermented sausages. Microorganisms do not merely provide the characteristic flavor for the products; the lactic acid bacteria also produce lactic and other acids that can lower the pH of the products. Pure cultures are sometimes used in hams to lower the pH and thus inhibit the growth of *Clostridium botulinum.* The raw meat for ham manufacturing is basically a large chunk of meat, and it is difficult for microorganisms to penetrate into the center, unless they are injected into the interior. Microbial growth is mainly on the surface, and the microbial enzymes are gradually diffused into the center. By contrast, in sausages the cultures, if used, are mixed with the ingredients at the beginning, and the fermentation is carried out without difficulty. Besides, sausages are much smaller than hams. Table 178.27 lists some of the ingredients used in the manufacture of hams and sausages (6, 24, 28, 29, 51, 53, 60, 61, 64).

TABLE 178.27
Raw Ingredients for Fermented Meat Products

Ingredient	Ham	Sausage
Meat		
Pork	Yes	Yes

TABLE 178.28
Basic Steps in Dry Cured Ham Processing

Prepare pork for dry curing.
Mix the proper ratio of ingredients [salt, sugar, nitrite, and inocula (optional)].
Rub the curing mixture into the meat.
Stack the green ham for initial dry curing at 36–40°C.
Rerub the green ham and stack for additional curing at 36–40°C.
[The ham should be left in the cure for the equivalent of 3days per pound of meat.]
Soak the cured ham for 2–3 hours, then thoroughly scrub.
Place green ham in tight-fitting stockinette and hang in smokehouse to dry overnight.
Smoke at about 60 or 80°C with 60% RH for 12–36 hours.
Cool.
Vacuum pack and place in cool storage.

Source: References 6 and 61.

B. HAMS

Hams, as indicated earlier, are made from large chunks of meat. Western cultures manufacture ham using either a dry cure and or a brine cure process, sometimes followed by a smoking process. Tables 178.28 and 178.29 list the basic steps involved with the dry cure and brine cure of hams, respectively. These two processes are similar except for the salting step (6, 61).

Chinese hams are basically manufactured using a dry curing process. Procedures differ slightly, depending on

TABLE 178.29
Basic Steps in Brine Cured Ham Processing

Prepare pork for brine curing.
Mix the proper ratio of ingredients (salt, sugar, and nitrite with inocula optional): 5 gallons of brine for 100 pounds meat.
Soak the meat in the prepared brine, or stitch pump the brine into the meat (10% of the original weight of the meat) followed by soaking in the brine for 3–7 days vacuum tumbling or massaging (optional).
Remove the meat from the cover brine and wash.
Place green ham in tight-fitting stockinette and hang in smokehouse to dry overnight.
Smoke at about 60 or 80°C and 60% RH for 12–36 hours.
Cool.
Vacuum pack and place in cool storage.

Source: References 6 and 61.

TABLE 178.30
Basic Steps in Chinese Jinghua Ham Processing

Select pork hind leg, 5–7.5 kg.
Trim.
Salt, 7–8 kg salt per 10 kg ham.
Stack and overhaul at 0–10°C for 33–40 days.
Wash with cold water and brush.
Dry in the sun for 5–6 days.
Ferment (cure) for 2–3 months at 0–10°C (harmless green mold will develop on surface).
Brush off the mold and trim.
Age for 3–4 months, maximum 9 months; alternate aging process in temperature-programmable room with 60% RH for 1–2 months.
Grade.
Package and distribute.
(Yield: about 55–60%.)

Source: References 28 and 64.

the regions where the hams are made. The most famous Chinese ham is the Jinghua ham made in central China. Yunan ham, from southern China, also has a good reputation. In the old days, without refrigeration facilities during processing, transportation, and storage, it is believed that the ham completed its aging process during the transportation and storage stages. Today, with controlled temperature and relative humidity rooms, the hams are produced under controlled conditions. Table 178.30 lists the current process used in China for Jinghua ham (28, 64).

C. Sausages

Many European-type sausages are manufactured using a fermentation process. These sausages have their own characteristic flavors due to the formulations and curing processes used. It is not the intent of this chapter to list the various formulations. Readers should consult the references in this chapter and other references available elsewhere. Commercial inocula are available. Bacteria and some yeasts grow inside the sausage during the ripening period, producing the characteristic flavor. Molds can grow on the surface during storage if sausages are not properly packaged and stored in the refrigerator. Because these sausages are not sterilized, fermentation is an ongoing process, and the aged sausages carry a stronger flavor. Table 178.31 lists the basic steps in the manufacture of dry fermented sausages (24, 29, 51, 60).

IV. FERMENTED CEREAL PRODUCTS (BREADS AND RELATED PRODUCTS)

A. Kinds of Products and Ingredients

In wheat-producing countries or areas, baked yeast bread is a major staple in people's diets. This is common in the major developed countries. In other countries, other forms of bread may be the major staple. Baked bread may come in different forms such as regular yeast breads, flat breads, and specialty breads. Today, even retarded (chilled or frozen) doughs are available to meet consumers' preference for a semblance of home-cooked food. For countries or areas with less available energy, other forms of bread such as steamed bread and boiled breads are available. Fried breads are consumed mainly as breakfast or snack items. Table 178.32 lists some examples of different types of breads (8, 22, 27, 45–47).

Today, as a result of centuries of breeding selection, there are different types of wheat available to suit production environments in various regions with diverse climatic conditions. Wheat used for making bread is hard wheat, soft wheat, or a combination of both to meet product specifications. Wheat kernels are milled with removal of the bran and germ and further processed into wheat flour. Traditionally, this flour is the major ingredient for baking bread. For some health conscious consumers, whole wheat flour is the flour of choice for making bread nowadays. Wheat bran is also added to increase the fiber content of the product. Table 178.33 lists the proximate

TABLE 178.31
Basic Steps in Dry (Fermented) Sausage Processing

Select meat for processing.
Chop and mix chopped meat with spices, seasonings, and inocula at temperature of about 10°C.
Stuff the mixture in suitable casings.
Make links.
Cure or dry for 1–3 months in rooms with temperature, relative humidity, and air circulation regulated according to the type of sausage being produced.
Package and place in cool storage.

composition of wheat and some of their common wheat products (8, 22, 45).

In the manufacture of various wheat-based breads and related products, the major ingredients are wheat flour, yeast, sourdough bacteria (optional), salt, and water. Other ingredients vary considerably with the types of products produced. These may be grossly classified as optional ingredients, additives, or processing aids. Each country has its own regulations and requirements. Table 178.34 lists basic ingredients, optional ingredients, additives, and processing aids used in the manufacturing of bread and related products (8, 22, 45).

B. Regular Bread

Table 178.35 lists the basic steps in bread manufacturing (8, 22, 45).

There are three basic processes in commercial bread making: straight dough process, sponge-and-dough process, and continuous-baking process. The process to be used is determined by the manufacturer and the equipment available in the baking plant. Table 178.36 lists the basic steps in the different processes. The major difference is in the way the dough is prepared and handled (8, 22, 45).

Because the dough may be prepared in various ways, the amounts of ingredients used differ accordingly. Table 178.37 lists two formulations, comparing the differences in ingredients that arise from differences in the dough preparation processes (8, 22, 45).

C. Retarded Dough

As indicated earlier, retarded dough is also available to some consumers. This type of dough is more accessible where refrigerators and freezers are more common. Dough is prepared so that the fermentation is carefully controlled, and the dough is packed inside the container. Storage of

TABLE 178.34
Bread Making—Functional Ingredients

Kind	Examples
Basic Ingredient	
Wheat flour	Bread flour, whole wheat flour
Yeast	Compressed yeast, granular yeast, cream yeast, dried yeast, instant yeast, encapsulated yeast, frozen yeast, pizza yeast, deactivated yeast *Saccharomyces cervisiae, S. carlsburgenis, S. exisguus*
Salt	
Water	
Optional Ingredients	Whole wheat flour, gluten, soya flour, wheat bran, other cereals or seeds, milk powder, fat, malt flour, egg, dried fruit, vitamins Sourdough bacteria: *Lactobacillus plantarum, L. brevis, L. fermentum, L. sanfrancisco* Other yeasts
Additives	
Emulsifier	Diacetylated tartaric acid esters of mono- and di- glycerides of fatty acids (DATA esters), Sodium stearyl-2-lactylate (SSL), distlled monoglyceride, lecithin
Flour treatment agents	Ascorbic acid, L-cysteine, potassium bromate, potassium iodate, azodicarbonamide
Preservatives	Acetic acid, potassium acetate, sodium diacetate, sorbic acid, potassium sorbate, calcium sorbate, propionic acid, sodium propionate, calcium propionate, potassium propionate
Processing Aids	Alpha-amylase, hemicellulose, proteinase, novel enzyme systems (lipases, oxidases, peroxidases)

TABLE 178.35
Basic Steps in Regular or Common Bread Making

Prepare basic and optional ingredients.
Prepare yeast or sourdough for inoculation.
Mix proper ingredients to make dough.
Allow to ferment.
Remix dough (optional).
Sheet.
Mold and pan.
Proof in a temperature and relative humidity controlled chamber.
Decoratively cut dough surface (optional).
Bake, steam, fry, or boil.
Cool.
Package.
Store.

Source: References 8, 22, 45.

TABLE 178.36
Various Bread Making Processes

Straight Dough Baking Process:
Weigh out all ingredients.
Add all ingredients to mixing bowl.
Mix to optimum development.
Allow first fermentation, 100 minutes, room temperature, or at 27°C for 1.5 hours.
Punch.
Allow second fermentation, 55 minutes, room temperature, or at 27°C for 1.5 hours.
Divide.
Allow intermediate proofing, 25 minutes, 30–35°C, 85% RH
Mold and pan.
Allow final proofing, 55 minutes at 30–35°C, 85% RH
Bake at 191–232°C for 18–35 minutes to approximately 100°C internal temperature.

Sponge-and-Dough Baking Process:
Weigh out all ingredients.
Mix part of flour, part of water, yeast, and yeast food to a loose dough (not developed).
Ferment 3–5 hours at room temperature, or at 21°C for 12–16 hours.
Add other ingredients and mix to optimum development.
Allow fermentation (floor time), 40 minutes.
Divide.
Allow intermediate proofing, 20 minutes, 30–35°C, 85% RH, or 27°C for 30 minutes.
Mold and pan.
Allow final proofing, 55 minutes, 30–35°C, 85% RH
Bake at 191–232°C for 18–35 minutes to approximately 100°C internal temperature.

Continuous-Baking Process:
Weigh out all ingredients.
Mix yeast, water, and maybe part of flour to form liquid sponge.
Add remaining flour and other dry ingredients.
Mix in dough incorporator.
Allow fermentation, 2–4 hours, 27°C.
Pump dough to development chamber.
Allow dough development under pressure at 80 psi.
Extrude within 1 minute at 14.5°C and pan.
Proof for 90 minutes.
Bake at 191–232°C for 18–35 minutes to approximately 100°C internal temperature.

Source: References 8, 22, 45.

this package is also carefully controlled. When the package is open, consumers can just follow the instructions on the package to bake their own bread. The technology is proprietary to the manufacturers, but there are some guidelines available (Table 178.38) (8, 22, 45).

D. Flat (Layered) Bread

Flat bread is a general term for bread products that do not rise to the same extent as regular bread. Flat breads are common commodities in Middle Eastern countries and in

TABLE 178.37
Sample Bread Recipes

White Pan Bread (Bulk Fermentation or Straight Dough Process):

Ingredients	Percent of Flour Weight
Flour	100.0
Yeast	1.0
Salt	2.0
Water	57.0

TABLE 178.38
General Guidelines for Retarded Dough Production

Reduce yeast levels as storage times increase.
Keep yeast levels constant when using separate retarders and provers.
Reduce yeast levels as the dough radius increases.
Reduce yeast levels with higher storage temperatures.
The lower the yeast level used, the longer the proof time will be to a given dough piece volume.
Yeast levels should not normally be less than 50% of the level used in scratch production.
For dough stored below −5°C, the yeast level may need to be increased.
Reduce the storage temperature to reduce expansion and weight loss from all dough pieces.
Lower the yeast levels to reduce expansion and weight losses at all storage temperatures.
Dough pieces of large radius are more susceptible to the effects of storage temperatures.
The lower freezing rate achieved in most retarder-provers, combined with the poor thermal conductivity of dough, can cause quality losses.
Proof dough pieces of large radius at a lower temperature than those of small radius.
Lower the yeast level in the dough to lengthen the final proof time and to help minimize temperature differentials.
Maintain a high relative humidity in proofing to prevent skinning.

countries or areas with less accessible energy. In developed countries, flat breads are considered specialty breads. The making of the dough is similar to that of regular bread. But, the dough is flattened and sometimes layered before it is baked directly inside the hearth or in an oven. Table 178.39 lists the general production scheme for flat breads (46, 47).

E. Croissants and Danish Pastries

Croissants and Danish pastries can be considered as products that result from modifications of the basic bread making process. The dough preparation steps are similar, but the ingredients are different. Table 178.40 compares the ingredients used in making croissants and Danish pastries. From this table, it is clear that even within each group, the ingredient formulation can vary considerably, producing a wide variety of products available in the market (8, 22, 45).

F. Steamed Bread (Mantou)

Steamed bread is common in the Chinese community. Plain steamed bread is consumed as the major staple in the northern provinces of China. However, stuffed steamed breads are consumed as specialty items in various parts of China. Manufacture of steamed bread differs from that of regular bread mainly in the dough solidification process. Regular bread uses a baking process, whereas in steamed bread, steaming is used instead of baking. Consequently, in steamed bread, there is no brown crust on the bread surface because the temperature used is not high enough to cause the browning reaction. Steamed bread is always consumed hot or held in a steamer because the bread is soft at this temperature. Sometimes the bread is deep-fried before consumption. Steamed bread hardens when it cools down, making it less palatable. Various procedures are available for the production of steamed bread. Table 178.41 lists the basic steps in steamed bread processing in China (27).

TABLE 178.40
Formulations for Croissant and Danish Pastries

Ingredients	Croissant	Danish Pastries
Flour	100	100
Salt	1.8–2.0	1.1–1.56
Water	52–55.4	43.6–52
Yeast (compressed)	4–5.5	6–7.6
Shortening	2–9.7	6.3–12.5
Sugar	2–10	9.2–25
Egg	0–24	5–25
Skimmed milk powder	3–6.5	4–6.25
Laminating margarine/butter	32–57	50–64

V. FERMENTED SOY PRODUCTS

A. Kinds of Products and Ingredients

Soybeans have been available to the Chinese for centuries, and various fermented soy products were developed and spread to neighboring countries. These countries further developed their own fermented soy products. Soy sauce originating in China probably is the most famous and widely accepted fermented soy product. The credit for this wide acceptance also goes to the Kikkoman Company from Japan, which has helped spread soy sauce worldwide through their marketing strategy. Fermented whole soybeans such as ordinary natto, salted soybeans (e.g., Japanese Hama-natto and Chinese dou-chi), and tempe (Indonesia); fermented soy pastes (e.g., Japanese miso and Chinese dou-pan-chiang); and fermented tofus (e.g., sufu and stinky tofu or chao-tofu of Chinese origin) are

TABLE 178.41
Basic Steps in Steamed Bread Processing

Selecting flour and ingredients such as milk powder and sugar (optional).
Mixing dough.
Fermentation:
Full fermentation—1–3 hours
Partial fermentation—0.5–1.5 hours
No-time fermentation—0 hours
Remixed fermentation dough—remixing of fully fermented dough with up to 40% of flour by weight.
Neutralizating with 40% sodium bicarbonate and remixing.
Molding.
Proofing at 40°C for 30–40 minutes (no-time dough).
Steaming for about 20 minutes.
Steamed bread is maintained at least warm to preserve quality.

more acceptable to ethnic groups. Consumers worldwide are gradually accepting these products through cultural exchange activities. The manufacturing of these products varies widely. Table 178.42 summarizes the ingredients needed for the manufacture of common fermented soy products (16, 37–39, 56, 57, 59, 63, 65).

B. Soy Sauce

There are many types of soy sauce, depending on the ratio of ingredients (wheat and soybeans), the fermentation and extraction procedures, and the flavoring ingredients (caramel and others) used. However, the procedures for manufacturing are similar. Basically, soy sauce is made by fermenting cooked soybeans in salt or brine under controlled conditions to hydrolyze the soy proteins and starches into smaller flavoring components. The soy sauce is then extracted from the fermented soybeans for standardization and packaging. Table 178.43 lists a generalized scheme for the manufacture of soy sauce. More detailed information is presented in references listed in this chapter and available literature elsewhere (16, 37–39, 57, 65).

C. Fermented Whole Soybeans

1. Ordinary (Itohiki) Natto

Ordinary natto is a typical Japanese fermented whole soybean product. The sticky mucilaginous substance on the surface of soybeans is its characteristic. It is produced by a brief fermentation of cooked soybeans with *Bacillus natto*, and it has a short shelf life. Table 178.44 lists the basic steps in the manufacture of ordinary natto. For

TABLE 178.43
Production Scheme for Soy Sauce

Select and soak beans.
Cook clean or defatted soybean under pressurized steam at 1.8 kg/cm^2 for 5 minutes.
Cool cooked bean to 40°C.
Roast and crush wheat.
Mix prepared soybeans and wheat.
Inoculate with *Aspergillus oryzae* or *sojae.*
Incubate mixture to make starter koji at 28–40°C.
Add brine (23% saltwater) to make moromi (mash).
Inoculate with halophilic yeasts and lactic acid bacteria (optional).
Brine fermentation at 15–28°C.
Add saccharified rice koji (optional).
Age moromi (optional).
Separate raw soy sauce by pressing or natural gravity.
Refine soy sauce.
Add preservative and caramel (option).
Package and store.

Source: References 16, 37–39, 57, 65.

TABLE 178.44
Production Scheme for Itohiki (Ordinary) Natto

Start with clean, whole soybeans.
Wash and soak at 21–25°C for 10–30 hours.
Cook soybean under pressurized steam at 1–1.5 kg/cm^2 for 20–30 minutes.
Drain and cool soybean at 80°C.
Inoculate with *Bacillus natto*.
Mix and package in small packages.
Incubation:
40–43°C for 12–20 hours, or 38°C for 20 hours plus 5°C for 24 hours.
Final product.
Refrigerate to prolong shelf life.

Source: References 38 and 39.

detailed information on ordinary natto, please refer to the references in this chapter (38, 39, 65).

2. Hama-natto and Dou-chi

Hama-natto is fermented whole soybeans produced in the Hama-matsu area of Japan. Similar products are produced in Japan, prefixed with different names taken from the production location. A very similar product in the Chinese culture is "tou-chi" or "dou-chi." It is produced by fermenting the cooked soybeans in salt, brine, or soy sauce, and then drying them as individual beans. Hama-natto includes ginger in its flavoring, whereas the inclusion of ginger flavoring is optional in dou-chi. Table 178.45 lists the basic steps in the production of Hama-natto and dou-chi. For further information, readers should refer to the references in this chapter and other available literature (37–39, 65).

TABLE 178.45
Production Scheme for Soy Nuggets (Hama-natto and Dou-chi)

Start with clean, whole soybeans.
Wash and soak for 3–4 hours at 20°C.
Steam cook soybean at ambient pressure for 5–6 hours or at 0.81.0 kg/cm^2 for 30–40 minutes.
Drain and cool soybean to 40°C.
Add alum (optional for douchi).
Mix with wheat flour (optional for Hama-natto).
Inoculate with *Aspergillus oryzae.*
Procedure 1 (Hama-natto):
Incubate for 50 hours at 30–33°C.
Soak inoculated soybean in flavoring solution for 8 months.
Incubate under slight pressure in closed containers.
Procedure 2 (dou-chi):
Incubate at 35–40°C for 5 days.
Wash.
Incubate for 5–6 days at 35°C.
Remove beans from liquid for drying.
Mix with ginger soaked in soy sauce (Hama-natto only).
Package final product (soy nuggets).
Refrigerate to prolong shelf-life (optional).

Source: References 37–39, 65.

D. Fermented Soy Pastes

Both the Chinese and Japanese have fermented soy pastes available in their cultures, and they are made in similar manner. However, the usage of these two products is quite different. The Japanese use their fermented soy paste, miso, in making miso soup, and to a lesser extent, for example, in marinating/flavoring of fish. Miso soup is common in traditional Japanese meals. The Chinese use their fermented soy paste, dou-pan-chiang, mainly as condiment in food preparation. Dou-pan-chiang can also be made from wing beans, and this is beyond the scope of this chapter. Table 178.46 lists the basic steps in the manufacture of miso. For detail information on miso and dou-pan-chiang, readers should consult the references for this chapter and other literature available elsewhere (16, 37–39, 56, 57, 65).

E. Fermented Tofu

1. Fermented Soy Cheese

Sufu, or fermented soy cheese, is made by fermenting tofu that is made by coagulating the soy protein in soy milk with calcium and/or magnesium sulfate. It is similar to feta cheese in its fermentation process. Both products are matured in brine in sealed containers. Some packed sufu contains flavoring ingredients. Table 178.47 lists the basic steps in the manufacture of sufu. For detail information, readers should refer to the list of references in this chapter and the other available literature (37–39, 59).

TABLE 178.46
Production Scheme of Fermented Soybean Pastes (Miso)

Start with whole, clean soybeans.
Wash and soak at 15°C for 8 hours.
Cook at 121°C for 45–50 minutes or equivalent.
Cool and mash the soybeans.
Prepare soaked, cooked, and cooled rice (optional).
Prepare parched barley (optional).
Inoculate rice or barley with *Aspergillus oryzae* (tane-koji, optional).
Mix koji and rice or barley mixture.
Add salt to koji and rice or barley mixture and mix.
Inoculate halophilic yeasts and lactic acid bacteria (optional).
Pack mixture (mashed soybean and koji) into fermenting vat with 20–21% salt brine.
Ferment at 25–30°C for 50–70 days.
Blend and crush ripened miso.
Add preservative and colorant (optional).
Pasteurize (optional).
Package and store.

Source: References 16, 37–39, 56, 57, 65.

2. Stinky Tofu

Stinky tofu is a traditional Chinese food made by fermenting tofu briefly in "stinky brine." The tofu is hydrolyzed slightly during this brief fermentation and develops its characteristic flavoring compounds. When this raw stinky tofu is deep-fried, these compounds volatilize and produce the characteristic stinky odor, thus the name "stinky tofu." It is usually consumed with chili and soy sauces. Stinky tofu is also steamed with condiments for consumption. Table 178.48 lists the basic steps in the manufacture of stinky tofu. Readers should consult the references in this chapter for further reading (37–39, 59).

TABLE 178.47
Production Scheme for Sufu (Chinese Soy Cheese)

Clean whole soybeans.
Soak.
Grind with water.
Strain through cheesecloth to recover soymilk.
Heat to boiling and then cool.
Coagulate soymilk with calcium and/or magnesium sulfate.
Cool to 50°C.
Press to remove water (formation of tofu).
Sterilize at 100°C for 10 minutes in hot-air oven.
Inoculate with *Mucor*, *Actinomucor*, and/or *Rhizopus* sp.
Procedure 1:
Incubate in dry form for 2–7 days, depending on inocula.
Incubate (ferment in 25–30% salt brine) for 1 month or longer.
Brine and age in small containers with or without addition of alcohol or other flavoring ingredients.
Procedure 2:
Incubate at 35°C for 7 days until covered with yellow mold.
Pack in closed container with 8% brine and 3% alcohol.
Ferment at room temperature for 6–12 months.
Final product (sufu or Chinese soy cheese).

Source: References 37–39, 59.

TABLE 178.48
Production Scheme for Stinky Tofu

Clean whole soybeans.
Soak.
Grind with water.
Strain through cheesecloth to recover soymilk.
Heat to boiling and then cool.
Coagulate soymilk with calcium and/or magnesium sulfate.
Cool to 50°C.
Press to remove water (formation of tofu).
Press to remove additional water.
Soak in fermentation liquid for 4–20 hours at 5–30°C.
Fresh stinky tofu, ready for frying or steaming.
Refrigerate to prolong shelf life.

Source: References 37–39, 59.

F. Tempe (Tempeh)

Tempe is a traditional Indonesian food consumed commonly by its people. It is made by fermenting cooked soybeans wrapped in wilted banana leaves or plastic wraps. The mold *Rhizopus oligosporus* produces its mycelia, and these mycelia penetrate into the block of soybeans. The mold mycelia also surround the block. This kind of fermentation is similar to molded cheese fermentation. Tempe is gradually being accepted by vegetarians in the West as a nutritious and healthy food. It is generally consumed as a deep-fried product. Table 178.49 lists the basic steps in the production of tempe (38, 39, 63, 65).

TABLE 178.49
Production Scheme for Tempe

Start with whole, clean soybeans.
Rehydrate in hot water at 93°C for 10 minutes.
Dehull.
Soak with or without lactic acid overnight.
Boil for 68 minutes.
Drain and cool to 38°C.
Inoculate with *Rhizopus oligosporus* w/o *Klebsiella pneumonia.*
Incubate on trays at 35–38°C, 75–78% RH for 18 hours.
Dehydrate.
Wrap.

VI. FERMENTED VEGETABLES

A. Kinds of Products and Ingredients

Fermented vegetables were produced in different cultures in the old days to preserve the harvested vegetables when they are not available or due to climatic limitations. Some of these products started as traditional cultural foods but became widely accepted in other cultures. It is interesting that most of these processes are similar. Salt is used in the production of the product or the salt stock. Natural lactic acid fermentation, to produce enough lactic acid to lower product pH, is the major microbial activity in these processes. With the amount of salt added and lactic acid produced, these two ingredients create an environment that can inhibit the growth of spoilage microorganisms. Available leafy vegetables, fruits (commonly used as vegetables), and roots are used as the raw materials. Starter cultures are used occasionally. Vinegar is used in some products. Chili pepper and other spices are used in many products. Preservatives may also be used to extend shelf life after the package is opened. Table 178.50 compares the ingredients used in different fermented vegetable products (1, 3, 5, 10, 13, 14, 19, 25, 36, 43).

B. Sauerkraut

The term sauerkraut literally means sour (*sauer*) cabbage (*kraut*). It is a traditional German fermented vegetable product that has spread to other cultures; it is used on its own or in food preparations. Its sequential growth of lactic acid bacteria has long been recognized. Each lactic acid bacterium dominates the fermentation until its end product becomes inhibitory for its own development and creates another environment suitable for another lactic acid bacterium to take over. The fermentation continues until most of the available fermentable sugars are exhausted. The production of sauerkraut is not risk-free and sanitary: precautions must be taken to avoid spoilage. Table 178.51 presents the basic steps in sauerkraut processing (1, 13, 19, 25).

TABLE 178.51
Basic Steps in Sauerkraut Processing

Select and trim white head cabbage.
Core and shred head cabbage to 1/8 inch thick.
Salt with 2.25–2.50% salt by weight with thorough mixing.
Store salted cabbage in vats with plastic cover, weighed with water to exclude air in the cabbage.
Ferment at 7–23°C for 2–3 months or longer to achieve an acidity of 2.0% (lactic).
Heat kraut to 73.9°C before filling the cans or jars, then exhaust, seal, and cool.
Store and distribute.

Source: References 5, 13, 19, 25.

C. Pickles

Western-style pickles are produced by salting the pickling cucumbers in vats in salt stocks for long-term storage, followed by desalting, and bottling in sugar and vinegar, with or without spices. The fermentation is still lactic acid fermentation. However, it is more susceptible to spoilage because air may be trapped inside the slightly wax-coated cucumbers. In the salt curing of cucumbers, spoilage can occur, and precautions should be taken to avoid its occurrence. Because of their high acidity and low pH as well as their high salt content, the products are generally mildly

TABLE 178.52
Basic Steps in Fermented Pickles Processing

Size and clean cucumbers.
Prepare 5 (low salt) or 10% brine (salt stock).
Cure (ferment) cucumbers in brine for 1–6 weeks to 0.7–1.0% acidity (lactic) and pH of 3.4–3.6, dependent on temperature, with salinity maintained at a desirable level (15% for salt stock). Addition of sugar, starter culture, and spices is optional.
Recover pickles from brine, then rinse or desalt (salt stock).
Grade.
Pack pickles into jars filled with vinegar, sugar, spices, and alum, depending on formulation.
Pasteurize at 74°C for 15 minutes, followed by refrigerated storage; exhaust to 74°C at cold point, then seal and cool; or vacuum pack and heat at 74°C (cold point) for 15 minutes, then cool.
Store and distribute.

Source: References 1, 3, 5, 13, 14, 19.

heat-treated to sterilize or pasteurize them. Table 178.52 lists the basic steps in the production of Western-style pickles (1, 3, 5, 13, 14, 19).

D. KIMCHI

Kimchi is a traditional Korean fermented vegetable. Most kimchi is characterized by its hot taste because of the fairly high amount of chili pepper used in the product and its visibility. However, some kimchis are made without chili pepper, but with garlic and ginger as well as other vegetables and ingredients. Vegetables used in making kimchi vary with its formulation: Chinese cabbage, cucumber, and large turnip are more common. Either chili pepper, or garlic and ginger can be used to provide a hot sensation. Other ingredients may also be added to provide a typical flavor. The fermentation is still lactic acid fermentation. Traditionally, kimchi was made in every household in rural areas in Korea to provide vegetables for the winter, when other fresh vegetables were not readily available. Today, it is a big industry in Korea, and kimchi is available year-round. Even small kimchi refrigerators are now available to meet the demands of consumers living in cities. In other parts of the world where Koreans are residents, kimchi is available either as a household item or as a commercial product. Kimchi is usually not heat sterilized after packaging in jars. Pasteurization is optional. Kimchi is considered perishable and is stored refrigerated. Table 178.53 lists the basic steps in the manufacture of kimchi (36, 43).

TABLE 178.53
Basic Steps in Kimchi Processing

Select vegetables (Chinese cabbage, radish, cucumber, or others).
Wash vegetables.
Cut vegetables, if necessary.
Prepare 8–15% brine.
Immerse vegetables in brine for 2–7 hours to achieve 2–4% salt in vegetable.
Rinse and drain briefly.
Add seasoning.
Ferment at 0°C to room temperature for about 3 days.
Package (can also be done before fermentation).
Store at 3–4°C.

Source: References 36 and 43.

TABLE 178.54
Basic Steps in Fermented Chinese Vegetables

Select and clean vegetables.
Cut vegetables (optional).
Procedure 1:
Wilt vegetables for 1–2 days to remove moisture.
Dry salt vegetables in layers with weights on top (5–7.5% salt).
Ferment for 3–10 days.
Wash.
Dry or press fermented vegetables (optional).
Add spices and flavoring compounds.
Package.
Sterilize (optional).
Procedure 2:
Wilt cut vegetables.
Rinse fermentation container in hot water.
Fill the container with cut vegetables.
Add 2–3% brine and other flavoring compounds (optional).
Ferment at 20–25°C for 2–3 days.
Ready for direct consumption or packaging and cool storage.

Source: References 10 and 36.

E. CHINESE PICKLED VEGETABLES

The Chinese also manufacture a wide range of pickled vegetables. Various kinds of vegetables are used as raw materials. The fermentation can be either a dry-salting or a brining process, depending on the product to be manufactured. However, the fermentation is still lactic acid fermentation. The major difference between Chinese-style pickled vegetable products and Western-style pickles is that desalting is usually not practiced in the manufacture of Chinese-style pickled vegetables. The desalting process is left to the consumers, if needed. Also, some Chinese-style vegetables are made into intermediate moisture products that are not produced in their Western-style counterparts. Table 178.54 lists some of the basic steps in the manufacturing of selected Chinese pickled vegetables (10, 36).

VII. APPLICATION OF BIOTECHNOLOGY IN THE MANUFACTURING OF FERMENTED FOODS

With the advances in biotechnology, microorganisms with special characteristics for the manufacturing of fermented

foods have become available. The most significant example is the approval by the FDA of Chy-Max (chymosin produced by genetic manipulation) used in the production of cheese. Its availability greatly reduces the reliance on chymosin from young calves and produces economic savings. Other products with similar or other properties are also available in the market. Genetically modified lactic acid bacteria and yeasts used in fermented food production are also available nowadays to reduce production costs. Gradual acceptance by consumers is the key to the further development and success of biotechnology (2, 15, 20, 26, 31, 34, 52, 55, 62). Readers should refer to the references in this chapter and other references available for further information.

VIII. PROCESS MECHANIZATION IN THE MANUFACTURE OF FERMENTED FOODS

Fermented foods produced by traditional methods are labor intensive and rely a great deal on the experience of the manufacturers. The main drawback is product inconsistency. In most developed countries, products such as many cheeses, yogurts, breads, sausages, and soy sauce are now made by highly mechanized processes to standardize the products (4, 7, 11, 21, 23, 30, 33, 40, 41, 44). This not only provides product consistency, but also reduces production costs. Consumers benefit from these developments. However, some consumers, even in developed countries, still prefer the traditional products, even at an increased cost, because of their unique product characteristics. There are also fermented products that are still made by traditional or semimechanized processes because mechanization processes have not been developed for them.

179 Sour Cream and Crème Fraîche

Lisbeth Meunier Goddik
Oregon State University

CONTENTS

I. INTRODUCTION

Sour cream is a relatively heavy, viscous product with a glossy sheen. It has a delicate, lactic acid taste with a balanced, pleasant, buttery-like (diacetyl) aroma (1). Various types of sour cream are found in many regions of the world. The products vary in regard to fat content and by the presence or absence of non-dairy ingredients. Furthermore, both cultured and direct acidification is utilized to lower pH. This chapter will cover sour cream as it is produced in the US and its French counterpart — crème fraîche.

II. SOUR CREAM

A. Definition

The US Food and Drug Administration (21CFR 131.160) defines sour cream as follows (2): "Sour cream results from the souring, by lactic acid producing bacteria, of pasteurized cream. Sour cream contains not less than 18 percent milkfat; ……. Sour cream has a titratable acidity of not less than 0.5 percent, calculated as lactic acid." If stabilizers are used, the fat content of the dairy fraction must be at least 18 percent fat and above 14.4 percent of the entire product.

Consumers' desire for decreasing dietary fat content has created a market for low fat sour creams. Among these products, the reduced fat (at least 50% fat reduction), and non-fat are common**,** in part due to FDA's labeling requirements for low fat products (21CFR101). Sales data over the past 25 years for the US market (3) are illustrated in Figure 179.1. The trend clearly shows increased sales. In 2000, nearly 400 million kg of sour cream were sold. Per capita sales of sour cream and dips were 1.4 kg. In comparison, per capita sales for yogurt, heavy cream, and half and half were 2.1 kg, 0.9 kg, and 1.7 kg, respectively (3).

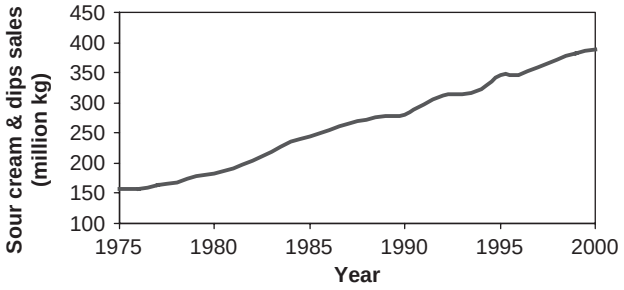

FIGURE 179.1 Sale, in million kg, of sour cream and dips in the US between 1975 and 2000.
Source: USDA, Agricultural Marketing Service.

B. Sensory Characteristics

Traditionally, the flavor of sour cream was well characterized by "sour." However, the trend for cultured dairy products is toward a milder flavor (4), which permits the sensation of aromatic compounds produced by lactic acid cultures. Lindsay et al. (5) found that important flavor compounds in sour cream include diacetyl, acetic acid, acetaldehyde, and dimethyl sulfide. Sour cream is highly viscous and should be smooth and free of particulate matter. As for appearance, a homogenous, glossy surface is preferred and no whey separation should be visible in the container (6).

C. Utilization

Sour cream is predominantly utilized as an accompaniment with warm entrees such as baked potatoes, burritos etc. This usage imposes certain demands on the sensory characteristics of the product, especially in regard to texture when in contact with warm surfaces. Sour cream must remain viscous without whey separation when placed on warm food. Some have even requested that baked potatoes can be reheated in the microwave with sour cream already added, and the sour cream should remain unaltered by this treatment. In addition, flavor characteristics become less significant when mixed with high intensity savory flavor notes such as those encountered in the Mexican cuisine. In fact, for some usages the absence of off-flavors may be considered as the primary flavor attribute. This general shift in emphasis away from flavor toward texture has led to a renewed interest in a "back to basics" sour cream such as crème fraîche, which is described later in this chapter.

III. FERMENTATION

As with all fermented dairy products, the choice of starter culture is crucial for the production of high quality sour cream (7). Mixed strains of mesophilic lactic acid bacteria are used for sour cream. In general, both acid and aroma producers are utilized. Acid producers include *Lactococcus (Lc) lactis* ssp. *lactic* and *Lc lactis* ssp. *cremoris. Lc lactis* ssp. *lactis* biovar *diacetylactis* (or *Cit*$^+$ *Lactococci*) and *Leuconostoc mesenteroides* ssp. *cremoris* are commonly used aroma producers.

The acid producers convert lactose into L-lactate through a homofermentative pathway. They can produce up to 0.8% lactic acid in milk (8) and are responsible for lowering pH in the fermented product.

In contrast, aroma producers are heterofermentative and can convert lactose into D-lactate, ethanol, acetate and CO_2. In addition, these strains convert citrate into diacetyl which is one of the major flavor compounds responsible for typical sour cream flavor. Diacetyl is subsequently partially converted into acetoin, which is a flavorless compound (9). Extensive research at starter culture companies have led to the development of *Leuconostoc* strains that show less of a tendency to convert diacetyl into acetoin**,** thus retaining high levels of diacetyl (D. Winters, personal communication. 2002). Use of such strains can extend the shelf-life of sour cream**,** as it takes longer for the product to turn stale. *Leuconostocs* also reduce acetaldehyde to ethanol (10,11). In fact, acetaldehyde has been shown to promote the growth of *Leuconostoc mesenteroides* ssp. *cremoris* (12,13). Acetaldehyde is typically associated with yogurt flavor (green apple), but is considered an off-flavor in sour cream.

The choice of starter cultures will affect product texture as well. Strains of acid producers have been developed which increase viscosity through the production of exopolysaccharides (14). These polysaccharide chains contain galactose, glucose, fructose, mannose and other sugars. Quantity and type depend on the bacteria strain and growth conditions (15,16). The exopolysaccharides interact with the protein matrix creating a firmer network and increasing water binding capacity. The importance of this behavior was confirmed by Adapa and Schmidt (17) who found that low fat sour cream, fermented by exopolysaccharide producing lactic acid bacteria, was less susceptible to syneresis and had a higher viscosity.

Production of high quality sour cream requires a fine balance of acid, viscosity, and flavor producing bacteria. While this balance varies among commercially available strains, a typical combination would be 60% acid producers, 25% acid and viscosity producers, and 15% flavor producers (D. Winters, personal communication, 2002).

IV. GEL FORMATION

Fermentation leads to a significant increase in viscosity. Two physicochemical changes cause this behavior (18,19). The casein submicelles disaggregate because of solubilization of colloidal calcium phosphate. In addition, the negative surface charge on the casein micelles decrease as pH approaches the isoelectric point. This creates the opportunity for casein micelles to enter into a more ordered system. Besides the protein network, cream gains viscosity from the formation of homogenization

clusters (20). Following single stage homogenization at room temperature, milk fat globules will cluster and these clusters may contain up to about 10^5 globules (21). Casein molecules adsorb onto newly formed fat globule membranes and, in the case of high fat content, form bridges between fat globules. Clustering increases viscosity because 1) serum is entrapped between the globules and 2) formation of irregular shaped clusters.

V. STABILIZERS

The gel structure may not be sufficiently firm to withstand abuse during transportation, handling, and storage. This could result in a weak bodied sour cream and whey syneresis in the container. These defects are especially noticeable for low fat products. To ensure consistent firm texture dairy processors often choose to add non-dairy stabilizers (22). Stabilizers commonly found in sour cream include polysaccharides and gelatin.

Stabilizers must be food grade and approved. The type and quantity used vary widely dependant on fat content, starter culture, and required sensory characteristics of the final product. Types and quantities of potential stabilizer mixtures used in sour cream are outlined in Table 179.1. Especially the non-fat formulation contains other ingredients such as emulsifiers, color, and protein.

Polysaccharides bind water and increase viscosity. Commonly used plant polysaccharides include carrageenans, guar gums and cellulose derivatives. Modified starches are frequently utilized as well. It is necessary to fully hydrate these polysaccharides to optimize their functionality. Depending on the ingredient, this may require efficient blending systems for incorporation of the ingredient into the cream, though care should be taken to avoid churning the cream. Complete hydration can sometimes only be accomplished following heating and cooling steps, which conveniently are done by the pasteurization process. Time may also be a factor for hydration to occur. Besides binding with water molecules, polysaccharides may also interact with milk proteins and form a network, which limits the movement of water and increases viscosity. A short description of the stabilizers is provided below:

a) Carrageenans: Extract of seaweed. Three types of carrageenans are commercially available, lambda, iota, and kappa, which differ based on the amount of sulfate. They have low viscosity at high temperature but viscosity increases during cooling. Lambda has the highest sulfate content, is soluble in cold milk, and forms weak gels. Iota is soluble in hot milk (55°C) and prevents syneresis. Kappa only dissolves in hot milk (<70°C) and forms brittle gels (23).
b) Guar gum: Endosperm of seed from Cyanopsis tetragonolobus plant. Different types of guar gum are available to fit processing conditions. Maximum viscosity develops over time. All are soluble in cold milk. The main component is mannose with attached galactose units.
c) Methylcellulose: A cellulose which improves freeze-thaw stability and prevents melt upon heating (22).
d) Gelatin: In contrast to the polysaccharides described above, gelatin consists primarily of protein (84–86%) and is derived from animal sources such as skin and bones (24). Gelatin is an excellent gelling agent but some off-flavors are perceived when used at excessive concentrations.

TABLE 179.1
Example of Stabilizer and other Ingredients Used in Sour Cream

Product	Ingredients	Usage Level
Sour Cream	Modified food starch, grade A whey, sodium phosphate, guar gum, sodium citrate, calcium sulfate, carrageenan, locust bean gum	1.5–1.8%
Low fat sour cream	Same as above	1.75–2.0%
Non-fat sour cream	Modified food starch, microcrystalline cellulose, propylene glycol monoester, gum Arabic, artificial color, cellulose gum	6.2–6.6%

VI. PROCESSING

Throughout the processing of sour cream, extra care should be taken to protect the cream. Prior to pasteurization, rough cream treatment could lead to rancid off flavors due to lipolysis. Following fermentation, it is important to treat the coagulum gently to retain body and texture. This includes use of positive displacement pumps instead of centrifugal pumps, round pipe elbows instead of 90° angles, and use of gravity feed wherever possible. In addition, special cream pasteurizers may be used (Figure 179.2).

Ingredients can be incorporated directly into standardized cream by mixing equipment such as a triblender. Another option is to incorporate the dry ingredients into the milk portion before standardizing the cream. The mix is preheated and homogenized (~ 65°C, 10–25 MPa) (25,26) immediately prior to pasteurization. Dairy homogenizers are normally double stage to prevent homogenization clusters. However, in sour cream production single stage homogenization is preferred to build up the body of the product. Additional viscosity is obtained if the cream is homogenized downstream from the pasteurizer though such a process increases the potential for postpasteurization contamination. Pasteurization is done at relatively

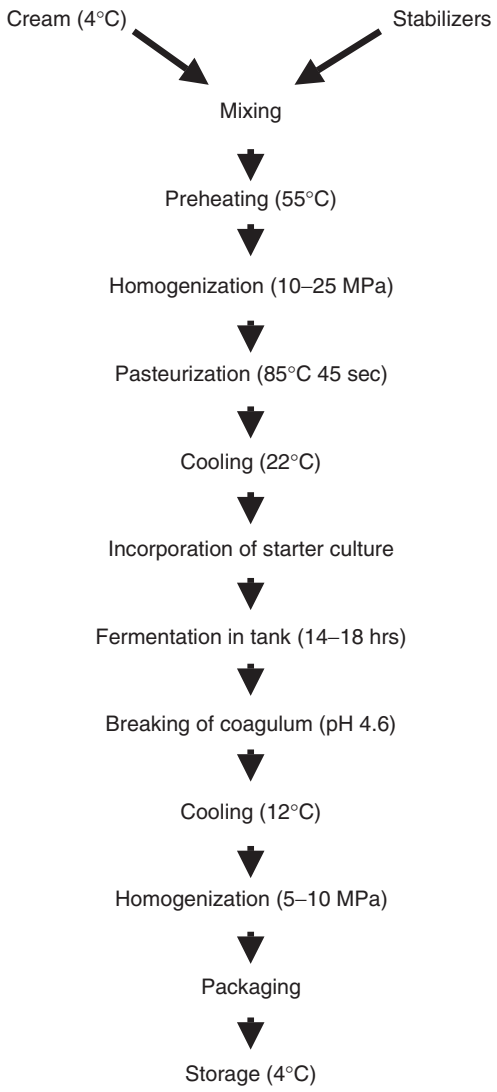

FIGURE 179.2 Process flow chart of typical sour cream process.

high temperatures (85–90°C for 10–45 sec), well above what is required for destruction of pathogens. The more severe heat treatment lowers the potential for oxidative and rancid off-flavors during storage as well as it may help improve product viscosity. The cream is cooled to 22–25°C, pumped into the fermentation tank and starter culture is added. Gentle mixing should continue until culture and cream are properly mixed (maximum 30 min). At this point mixing is stopped until fermentation is complete. The fermentation tank may be double-jacketed to allow for better temperature control. However, in reality this is not essential if the temperature of the processing room remains relatively constant around 22°C. Fermentation temperature may vary slightly from plant to plant. Higher temperatures lead to faster fermentation and potentially a more acidic product while lower fermentation temperatures may give a more flavorful product. The fermentation is slowed down/stopped by cooling when the desired acidity (~pH 4.5 or titratable acidity around 0.7% – 0.8%) is achieved. Typically this takes 14–18 hours. The coagulum is broken by gentle stirring and the product is cooled either by pumping cooling water into the double jacketed area of the tank or by pumping the cream through a special plate cooler. The cream should be cooled to around 8–12°C, which slows starter culture activity before packaging. Prior to packaging, it can also be passed through a homogenizer screen (smoothing plug) or similar type of flow restrictor to smooth and improve texture (27). The final cooling to around 4°C must occur slowly in the package in the cooler in order to allow the cream to obtain the appropriate viscosity. It is essential that the cream not be moved during this cooling step.

The above process assumes large-scale production. However, numerous process variations exist.

A. "Short Cuts"

Throughout the process described above, special attention is focused on gentle treatment of the product to assure proper body and texture. In reality, the stabilizers used today permit more flexibility in the process. A certain amount of product abuse can be tolerated without lowering the product quality because the stabilizers, when properly used, create a firm texture and prevent whey separation.

B. Low Quantity

It is possible to significantly simplify the process when producing small quantities of product. Sour cream can be made with a double-jacketed pasteurization tank, a pump, and a fermentation tank with gravity feed to the filler. The absence of a final in-line cooling step would require an efficient cooling procedure for the packaged product.

C. Chymosin Addition

Low quantities of chymosin may be added at the same time as the starter culture. This creates a more "spoonable" sour cream. Lee and White (28) found that chymosin addition (e.g. 0.066 ml/L) to low fat sour cream resulted in increased viscosity and whey separation. Sensory scores were lower for the chymosin containing sour cream in regard to flavor, body/texture, and appearance. This indicates that it may be preferable to modify the stabilizer mixture rather than to add chymosin when trying to increase product viscosity.

D. Set Sour Cream

The standardized, pasteurized cream can be mixed with starter culture and immediately filled into the package. The cream is then fermented within the final package which leaves the coagulum undisturbed. When the appropriate acidity is obtained, the products are cooled either by passing through a blast cooler or by placement in a cooler.

The advantage of this method is the possibility to lower or eliminate stabilizers and yet obtain excellent body and texture. The disadvantages are the large space requirement for fermenting the packaged product and the relatively slow cooling.

E. Direct Acidification

A product somewhat similar to sour cream can be obtained by direct acidification by organic acids such as lactic acid instead of fermentation. However, Kwan et al. (29) and Hempenius et al. (30) found that sensory panelists preferred cultured sour cream instead of chemically acidified cream. Product temperature at the time of acidification is critical and should be around 20–25°C. Higher temperatures increase the likelihood that graininess occurs and lower temperatures increase the time required for gel formation (27).

F. Low Fat and Non-fat Sour Cream

Vitamin A fortification is required in these products. The processes are often similar to traditional sour cream though non-fat sour cream mix should be homogenized at much lower pressure. The main difference is observed in the stabilizer mix as described above in section V.

VII. SHELF-LIFE

Sour cream should have a shelf-life around 25–45 days. One study documents that, when properly stored undisturbed at 4°C, sour cream has an acceptable shelf-life for up to 6 weeks (31). In another study, Folkenberg and Skriver (7) evaluated the change of sensory properties of sour cream during storage time. As storage time approached 28 days the intensity of prickling mouthfeel, sour odor, and bitter taste increased. The samples were stored under ideal conditions, which suggest that real life distribution and storage temperature abuse would likely decrease the shelf-life of this product below 28 days.

The single most important factor determining shelf-life remains cream quality. Unless the cream is of excellent quality, the sour cream quickly develops off-flavors. Two parameters that impact cream quality are 1) raw milk quality, and 2) pretreatment of milk. Good quality raw milk has a low bacterial content (low standard plate count) and comes from healthy cows (low somatic cell count). Even good quality raw milk spoils unless quickly cooled and kept at low temperatures until pasteurization. Furthermore, the time interval between milking and pasteurization should be as short as possible. Other factors to consider are proper cleaning and sanitation of all milk contact surfaces, well installed and sized pumps, and no unnecessary milk handling.

Assuming that high quality cream is utilized the parameters that limit shelf-life tend to be associated with either flavor defects or surface growth of yeast and molds. When using appropriate stabilizers the body and texture should remain adequate throughout the shelf-life. A guide on how to prevent flavor defects is included below. Yeasts and molds are controlled by improving sanitation throughout the process. As with many other dairy products sanitation trouble spots are often associated with the filler machines, which are difficult to clean.

VIII. SENSORY DEFECTS IN SOUR CREAM

A. Flavor

The high lipid content makes sour cream extremely vulnerable to lipid associated off flavors such as rancidity and oxidation. Other flavor defects include flat, lacks cultured flavor and high acid.

Rancid: Hydrolytic rancidity or lipolysis is caused by the release of free fatty acids from the glycerol backbone of triglycerides. The reaction is catalyzed by the lipase enzyme, which can be a native milk lipoprotein lipase or can originate from bacterial sources. Triglycerides are generally protected from lipase activity as long as the milk fat globule remains intact. However, damage to the globule will lead to rapid lipolysis because lipase, which is situated on the surface of the globule, can access the triglycerides. Therefore, precautions must be taken to prevent damage to the milkfat globule until pasteurization, which denatures most types of lipase. This means that raw milk/cream must be pasteurized before or immediately after homogenization to assure denaturation of lipase. Likewise, it is strongly recommended never to recycle pasteurized milk/cream back into raw milk/cream storage, which is essentially an issue of rework handling. Cream, from poor quality raw milk, can also develop rancid off-flavors during storage, as some bacterial lipases are quite heat stable and do not denature during pasteurization.

Oxidized: Autoxidation of milk fat is a reaction with oxygen that proceeds through a free radical mechanism. Unsaturated fatty acids and phospholipids are the prime substrates that are broken down into smaller molecular weight compounds such as aldehydes and ketones. Oxidized cream exhibits off flavors and aromas that have been characterized as cardboardy, metallic, oily, painty, fishy, and tallowy (6). Oxidation is catalyzed by divalent cations such as iron or copper. Thus, the best prevention is to avoid contact of milk/cream with these metals. This requires attention to details, as a single fitting or pipe made of these metals can cause significant autoxidation.

Lacks fine flavor/lacks cultured flavor: Both flavor defects tend to be associated with the choice of starter culture. It may be possible to improve flavor by switching to culture systems with more aroma producing capacity or to strains that retard the transfer of diacetyl into acetoin. It is also possible to add low concentrations of citric acid (below 0.1%), which is then converted to diacetyl by the aroma producing starter cultures. The defect can also result from

flavors imparted by stabilizers. Lowering the stabilizer dose or changing to another stabilizer system may be required.

High acid: If the final product pH is very low (e.g. around pH 4.0) the product gets an unpleasant sour flavor. While it is possible to stop the fermentation at a higher pH, this does not necessarily solve the problem because slow fermentation continues in the cooled and packaged product. Therefore, it is often preferable to change the starter culture mixture to lower the ratio of acid producing bacteria.

Bitter: Bitter off flavors are often indicators of excess proteolytic activity. Poor quality raw milk may contain heat stable proteases that remain active throughout storage. The defect is especially noticeable at the end of shelf life. Improving raw milk quality, increasing pasteurization temperature, or shortening code dates are possible solutions.

B. Body and Texture

As described above, texture is an essential quality parameter. Sour cream must remain highly viscous when in contact with warm food surfaces such as baked potatoes.

Too firm or weak: Improper choice of stabilizers can cause over-stabilized sour cream that clings to the spoon. Alternatively, the sour cream can be weak bodied and "melt" on the hot food surface.

Grainy: Grainy is primarily a mouthfeel problem, though it can be visually distracting as well in extreme cases. Grainy sour cream can be an indication of poor blending or incomplete hydration of ingredients. A different choice of stabilizers or a modification of incorporation procedure may improve the product. Another solution is to pass the product through a single stage homogenizer valve prior to packaging. Grains can also indicate that the fermentation was stopped at too high a pH and the caseins are at their isoelectric point around pH 4.6.

Free whey: Whey syneresis on top of the sour cream in the package is considered a significant quality defect. There are three solutions available to solving the problem. 1) Change or increase the concentration of stabilizer. 2) Increase fat content. Higher fat sour creams have a better water binding capacity. 3) Reevaluate the entire process and eliminate points of product abuse. This would primarily include all steps following fermentation.

IX. CRÈME FRAÎCHE

Crème fraîche or more correctly crème fraîche épaisse fermentée is the European counterpart to the US sour cream product. Crème fraîche has a fat content around 30–45% and has a mild, aromatic cream flavor. The differences between the two products originate in the manner of usage. The usage of sour cream is described above. Crème fraîche is used cold on desserts such as fruit or cakes, or warm as foundation in cream sauces which are commonly used in the French cuisine. This double usage creates a unique demand for specific product attributes. The dessert utilization requires a clean, not too sour (4), cultured flavor, that doesn't overpower flavors from other dessert components. The cultured flavor should be refreshing so that it covers the impression of fat in the product. This emphasis on flavor has led to significant research at starter culture companies and dairy processing companies to develop starter cultures that cause optimum flavor development. The body and texture should be smooth and less firm than sour cream. Crème fraîche should be "spoonable," not "pourable," and should spread slightly on the dessert without being a sauce.

The incorporation of crème fraîche into warm sauce requires thermostability, otherwise the protein would precipitate and flocculate in the sauce. For regular crème fraîche (>30% fat) flocculation is rarely a problem. In contrast, low fat crème fraîche (~15% fat) is less stable when heated. Addition of stabilizers such as xanthan gum can stabilize low fat crème fraîche. However, based on European labeling legislation a crème fraîche cannot contain stabilizers and a stabilized product would therefore need to be marketed under another name.

Crème fraîche is produced by a process similar to that of sour cream, with the exception that no ingredients are added. Without stabilizers, it becomes a challenge to obtain good body and texture. Each processing step requires attention to producing and maintaining high viscosity. In this case the homogenizer becomes an essential tool for building viscosity. Only single stage homogenization is utilized. The product is sometimes homogenized twice, either in subsequent runs before pasteurization, but more commonly both before and after pasteurization. Homogenization after pasteurization promotes better viscosity and, equally important, better thermostability. An additional homogenization following fermentation gives a homogeneous product with a smooth mouthfeel. Homogenization downstream from the pasteurizer (i.e. after pasteurization) should raise concerns in regard to post-pasteurization contamination. Ideally, an aseptic homogenizer should be used. However, the high price of such homogenizers makes this an unsuitable alternative. Instead, great emphasis must be placed on proper cleaning and sanitizing of the downstream homogenizer. In addition, food safety issues are normally controlled because of the high content of lactic acid bacteria and the low pH.

There is some discussion as to the final pH of crème fraîche fermentée. Kosikowski et al. (25) and Kurmann et al. (32) state that the cream is fermented to pH 6.2–6.3. However, commercially it is commonly fermented to an end pH around 4.5. The mild flavor is not obtained by a higher pH but rather through selection of aroma producing starter cultures. It is the combination of aroma compounds and the high fat content that mask the sour flavor in crème fraîche.

Crème fraîche is a new product on the US market. The high fat content and small scale processing contribute to a retail price which is at least twice as expensive as traditional sour cream. Nevertheless, sales are growing. Its increasing popularity is an indication of changing culinary habits promoted by growing population diversity and exposure to European culture. While crème fraîche is far from being a mainstream product on the US market, it is an interesting addition to the dairy case and can be found in many specialty stores.

ACKNOWLEDGMENT

The information in this chapter has been modified from "Sour cream and crème fraîche," by L.M. Goddik, in *Handbook of Food and Beverage Fermentation Technology*, Editors: Y. H. Hui et al., Marcel Dekker, NY 2004.

180 Quality Control and Sanitation of Cheese

Søren Lillevang
Arla Foods, Innovation Centre Brabrand

CONTENTS

I. INTRODUCTION

Production of cheese is a process of concentrating milk by the interaction of the milk, starter cultures and in most cases rennet. Traditionally cheese has been produced in small vats, but during the last 3 to 4 decades, processing has become increasingly industrialized. Before industrialisation, little attention was directed toward the hygienic aspects of cheesemaking, partly because the batch sizes were small and partly because methods of analysis were not well developed, consumption of cheese would normally cause only a few disease cases. In the recent years, more attention is being given to the hygienic aspects for several reasons: Methods for detecting pathogens have improved; more focus on emerging pathogens like *Listeria* and *E. coli* H7:O157; and the larger batch sizes increase risk to larger numbers of consumers, if pathogens are present. Furthermore, because of the large batches, economical losses will be substantial if the quality is not acceptable. Finally an unacceptable quality in just a few batches from a producer may lead to loss of market shares. All these reasons have led to a considerable increase in attention on the hygienic aspects of cheesemaking. These aspects include a range of factors such as

hygiene, environmental and technological factors, interactions between microorganisms, and the setting up control systems in order to prevent contamination, or at least inhibit the growth of pathogens.

Complications in doing this arise from the fact that there are many different cheese varieties, such as yellow- (with or without surface ripening), fresh-, blue veined-, white molded and cottage cheese, each with their own risks for the presence or growth of pathogens or spoilage microorganisms. In this chapter, the most important physical, chemical and microbiological factors required for inhibiting or avoiding pathogens or spoilage microorganisms are described. The creation of a comprehensive control system is discussed.

II. GENERAL ASPECTS OF CHEESE

Cheeses comprise a huge number of varieties and thus the composition also varies. The chemical composition of a cheese results from production under either high or low acidification, depending on the type of cheese, and the starter culture, which also plays a role in formation of the metabolic profile. As an example, the starter culture is able to form lactic acid as the major component, diacetyl, ethanol, acetic acid, benzoic acid and bacteriocine (1).

Depending on the type of cheese, the water content varies from very low in grana cheeses to very high in cottage cheese and the pH may vary from very low in blue veined cheeses and feta (4.6–4.8) to very high in queso fresco (6.2–6.5). As pH varies, so does the lactic acid content. The sodium chloride content varies from very high (4–6%) in some blue veined cheeses and feta to very low (0.8–1.0) in cottage cheese. The sodium chloride content, dry matter and other salts in cheese are responsible for the water activity, which is a very important growth determinant for microorganisms.

Regarding growth of microorganisms on the surface of cheeses, the packaging conditions are very important because the oxygen barrier varies, depending on the packaging material. The choice of packaging material depends on the type of cheese to be packed. Curing times for some cheeses may vary from short (1–6 days) or longer (up to 2 years) time intervals. This factor challenges the hygienic conditions in the curing rooms in relation to the chemical composition of the cheeses. Another challenge in this respect is the variation in temperatures that may occur in curing rooms. The temperature may vary from very high (20–22°C), for example for some Swiss type cheese varieties, to very low (2–5°C) for fresh cheeses or special varieties. During the curing time, temperature is elevated or lowered depending on the cheese type to be produced. Finally, the addition of nitrate or lysozyme to prevent growth of primarily *Clostridia* is an antimicrobial factor to be considered (2).

From a hygienic point of view, the cheese process in itself is a stabilizing factor. Starter culture is added to the cheese milk at 30°C and, together with the action of rennet, the milk coagulates to form a gel. As pH drops through the formation of lactic acid from the starter culture, the water binding capacity of the proteins drops. This, together with cutting of the formed gel, separates the milk into cheese and whey. After about 90 minutes, depending on type of cheese to be produced, the pH has dropped from 6.7 in fresh milk to about 6.0. After this initial cheese process, the cheese mass is pressed and anaerobic conditions are created. After pressing, the cheeses are left to complete acidification to the minimum pH (5.2), typically requiring 24 hours. Most cheese types are then cured in curing rooms at different temperatures and they may be ripened with or without a surface ripening culture. Some cheeses are packed in different foils in the curing room. Some fresh types of cheeses, however, are packed directly, then stored at 5°C and consumed within a few weeks.

III. ENVIRONMENTAL AND TECHNOLOGICAL FACTORS

A. Organic Acids and pH

The starter culture consists of lactic acid bacteria (LAB), and within 24 hours, the minimum pH is usually achieved. The minimum pH may vary, but in most cheeses the minimum pH is about 5.2 or lower; for cheddar pH 5.0 is normal, and in feta the pH may be as low as 4.6. While the buffer capacity in the cheeses is high due to the high protein content, the amount of lactic acid formed in the cheeses is also very high, up to 1.5% for some cheese types. This amount of lactic acid and the relatively low pH, achieves inhibition of many pathogens and spoilage microorganisms, especially gram negatives. However, the gram positives will also be inhibited under these conditions. Yeast and molds are only affected a little by the low pH and high amount of lactic acid. Depending on the type of starter culture, certain amounts of other organic compounds will also be formed (1). When gas producing mesophilic LAB are used as starters, diacetyl is formed in amounts that are able to cause a little inhibition of pathogens and spoilage microorganisms. Due to the metabolism occurring in the cheeses, the starters will also form acetic acid, up to 250 ppm is normal. This amount is not enough to prevent the growth of pathogens or spoilage microorganisms, and has a little impact. Other organic compounds like benzoic acid and ethanol may also have an impact on the growth of pathogens and spoilage microorganisms.

While the amounts of organic compounds formed are difficult to control, it is easy to control pH and it is important to keep it as low as possible without altering with the desirable organoleptic properties of the cheeses.

B. Temperature

Temperature and curing duration are important variables from a technological and hygienic point of view. While the curing temperature and time may improve the organoleptic properties of the cheese, it may also possibly lead to microbial growth. At 1°C, given the right conditions, *Listeria* is able to grow (3), while others such as *Clostridium tyrobutyricum* are not able to grow below 8°C (4). Therefore it is important to monitor the interaction between the curing temperature and time, in relation to the growth of selected microorganisms, and the cheese's organoleptic properties. From a hygienic point of view the temperature should be kept as low as possible.

C. NaCl and Water Activity

At a high NaCl content, and/or low water content, many microorganisms are prevented from growing (5). In such cheeses, *Staphylococci, Listeria* and yeast are chief concerns, as they are salt tolerant (6). In fresh cheeses of which the water activity is high and the NaCl content is about 0.8–1.0, the risk of growth is high these are physiological conditions. It is not possible to lower the NaCl amount because it originates from the milk, and, in many cases, it is not possible to elevate the amount due to changes in the organoleptic properties. In these cases, other means must be used to prevent growth of pathogens and spoilage microorganisms.

D. Nitrate and Lysozyme

Nitrate and lysozyme are often added to cheese milk in order to prevent late blowing from *Clostridium tyrobutyricum* (2–7). In most cases these additives also inhibit the growth of other microorganisms. But it is worth noting that the activity of the starter may also be slightly inhibited, causing a slower decrease in pH during the fermentation process, resulting in less inhibition of pathogens and spoilage microorganisms during the acidification process.

IV. ANTAGONISTIC/SYMBIOTIC ACTIONS IN CHEESES

For several years, nisin, a bacteriocin produced during fermentation has been recognized as preservative in a variety of cheeses. Nisin is produced by *Lactococcus lactis* subsp. *lactis*, one of the species used for acidification. The ability to produce nisin is strain dependant. Nisin can be added to cheese milk or processed cheese as a powder for inhibiting gram positives. Use of a living nisin producing *Lactococcus* in cheese production is not widespread because of inhibition of the starter culture may be a problem. Other bacteriocins are known (8–9). The starter culture used in the production of surface ripened cheeses, consists of a mixture of yeast, *Brevibacterium linens*, other coryneform bacteria, *Micrococcus, Staphylococcus* (primarily *equorum* and *xylosus*) and gram negatives in limited numbers (10). Bacteriocins from *B. linens* and *Staphyloccus* have been reported, and this is considered to be one way to control *Listeria* on surface ripened cheeses (11–13). *Enterococcus* sp. has also been reported to produce bacteriocins, and this production may also have an impact on the control of harmful gram positives on cheeses.

Apart from producing organic inhibitors and bacteriocins, the starter culture may also inhibit other microorganisms by direct competition for substrate. The starter culture ferments lactose into lactic acid/lactate, and thus inhibits the growth of harmful lactose fermenting microorganisms like coliforms or spoilage bacteria e.g. heterofermentative lactobacilli. Other substrates converted by the starter culture during cheesemaking are citrate and protein fragments, which mean that these compounds can't serve as substrate for pathogens. The formation of lactic acid/lactate will in turn promote the growth of lactate fermenting microorganisms (e.g. certain *Clostridia*). The best known is *Clostridium tyrobutyricum* which causes late blowing in cheeses; however, there are means available to prevent this (see Section VI.A).

V. HYGIENIC ASPECTS OF EQUIPMENT

A. Bactofugation

Bactofugation is widely used as a mean to remove sporeformers from the milk; well functioning bactofugation removes up to 98% of the spores (14). During the autumn and winter seasons, when cows are fed with silage, the spore content of *Clostridium tyrobutyricum* may be as high as 4000 per liter milk; As few as 10–20 spores per liter may cause late blowing in cheese. With a removal efficincy of 98% by bactofugation, the number of spore formers remaining is about 80 per liter, thus bactofugation is not completely effective in preventing late blowing. A relatively new process involving double bactofugation, is usually enough to prevent late blowing. Normally bactofugation is able to remove about 70% of the non-sporeforming flora, but this is far from sufficient removal of the non-sporeforming microorganisms.

B. Microfiltration

A better, but also more expensive, way to remove bacteria in general is microfiltration. Microfiltration will remove about 99.9% or more of the microbial flora present, including spore formers. By this the quality of the cheese milk is improved and the risk of the presence of microorganisms will decrease considerably. In cases where it is crucial that special spoilage microorganisms are absent, it is appropriate to perform microfiltration prior to pasteurization.

C. Pasteurization

Pasteurization is the ultimate step for removal of pathogens. Low pasteurization is defined as the combination of time and temperature and is sufficient to kill all vegetative pathogens. Still, it should be noted that not all microorganisms are killed by low pasteurisation. Spores of *Bacillus* and *Clostridium* sp. will survive along with a few spoilage microorganisms such as heterofermentative *Lactobacillus*.

In the pasteurization process it is important to control the temperature. During pasteurization the temperature will oscillate from the set point and it is crucial that the lower temperature be above 71.8°C. Controlling this requires an accurate temperature detection system. Such a system should be able to register the temperature rapidly and with high frequency. Another issue in pasteurization is the temperature differences between the components in the pasteurization unit. For example if the differences in the regenerative system are too big, fouling may occur, leading to lower efficiency in the pasteurization unit. The operation time for the pasteurization unit is also of importance. With the demands for high production efficiency, running times tend to increase, but this is often compromised due to biofilm formation. Finally of course, the cleaning of the pasteurization unit is important considering the concentration of the cleaning agents and the temperature used.

D. Cheese Vats

The cheese process is normally conducted at 30°C, with a cooking temperature range from 35–55°C. These temperatures are the normal interval in which pathogens or spoilage microorganisms are able to grow or survive. It is, therefore, necessary that the cheese vats are maintained in a high hygienic condition. There should not be any dead ends in the vats and the interfaces between the cheese vat and pumps, stirring systems, etc. should be secured properly. Finally, it is important that cleaning is easy to perform either as a "cleaning in place" (CIP) system or manually.

E. Brines

In most cases cheeses are subjected to brine with a NaCl content of about 21%. Direct salting may also be used, for example, in cheddar and cream cheeses. Due to the high salt content only a few microorganisms represent a risk; yeast (as spoilage microorganisms), *S. aureus* and *Listeria monocytogenes* are the only microorganisms of concern. It is also important to note that an infection in the brine leads only to surface contamination, as the cheese at this stage is already formed and the surface has been closed during pressing.

F. Curing and Packaging

There are three methods for curing cheeses: Packaged in bags or foil; unprotected on shelves with surface ripening; and unprotected on shelves without surface ripening. If the cheeses are packaged, the risk of contamination and/or growth is small. In general, packed and subsequently cured cheeses, keep their characteristic low pH, which along with the packaging protects against contamination.

Cheeses that are not packed, and without surface ripening, have a higher risk of contamination. For surface ripened cheeses the risk of contamination is higher than if they are also packed. The microorganisms used for surface ripening will develop into a thick layer and, hence, protect against contamination partly by producing antagonistic compounds such as methanthiol and bacteriocins, and substrate competition.

G. Distribution and Cheeses on the Market

Obviously the risk of contamination is very low when cheeses are distributed packaged and will only be contaminated by damaging the packaging. The risk is if pathogenic or spoiling microorganisms are already present in low amounts. They may grow if the cooling chain is broken. This factor is often seen in the cooling desks at the supermarkets especially, where the temperature often is as high as 15°C, 10°C above the required 5°C; precautions should be taken to keep the temperature at 5°C or below.

VI. IMPORTANT MICROORGANISMS

There are many species of pathogens or spoilage microorganisms in and on cheeses to be considered, in and on cheeses. However, many microorganisms are not found in cheese or will not grow during the cheese process. Absence of other microorganisms is controlled by veterinarian authorities in the primary (at the farmhouse) production. Among other *Brucella, Mycobacteria* and *Tuberculosis* are under veterinarian control in most countries.

A. Clostridia

Clostridia are widespread in nature and occur in raw milk. Only very few cases of illness due to *C. botulinum* can be attributed to cheese, thus the major concern is spoilage due to *C. tyrobutyricum* which causes late blowing of hard or semihard cheeses. Late blowing occurs when the number of *C. tyrobutyricum* in the cheese milk exceeds 10–50 spores per liter and the pH is 5.2 or higher (15). During late blowing lactate is converted into butyric acid, carbon dioxide and hydrogen; spoiling is characterized by extreme eye formation, split defects and off flavors. Prevention of spores in cheese milk can be achieved, to some extent, by bactofugation (16), but bactofugation is not adequate to prevent late blowing. Double bactofugation or microfiltration is, however sufficient to prevent late blowing. If it is not possible to bactofugate or microfiltrate, the addition of nitrate or lysozyme is an alternative, but the legal amounts

allowed of these compounds may not be sufficient to prevent late blowing. An effective alternative is to cool the cheese down below 8°C, at which the spores will not develop.

B. *E. coli*

Normally *E. coli* should not occur in cheeses, although 10–1000 *E. coli* per gram can be allowed from time to time depending on the cheese type. The major concerns are the pathogenic *E. coli* types. These are divided into enterohemorrhagic (EHEC), enteropathogenic (EPEC) enteroinvasive (EIEC) and enterotoxigenic (ETEC) (17). They can cause serious disease and have been reported to cause foodborne diseases in at least five outbreaks (18–20). Most concern is with the EHEC *E. coli H7:O157* that was involved in an outbreak in cheese produced from raw milk. In order to prevent pathogenic *E. coli* it is crucial to pasteurize the cheese milk. This will assure that they are not present in the milk, although postcontamination may occur. Good manufacturing practice is normally sufficient to prevent such contamination. If postcontamination does occur, it is important to prevent its growth. The activity of the primary starter should be controlled to assure a fast pH drop to below 5.5, which will inhibit *E. coli* growth. If hard cheeses are produced, the water activity should be held as low as possible, because growth of pathogenic *E. coli* does not occur at a water activity below 0.96. Such conditions are present in some blue veined cheeses like Danish blue and roquefort.

C. *Salmonella*

As for pathogenic *E. coli*, only a few cheese related *Salmonella* outbreaks have been reported (21–23). Because *Salmonella* are very heat and salt sensitive, they are not likely to grow in cheese. Thus, prevention of their contamination of cheese milk is crucial. Properly pasteurized milk is sufficient to eliminate *Salmonella* and the same precautions as described for control of *E. coli* should be taken. Fast acidification and good manufacturing practices along with maintaining as low water activity as possible is usually enough to produce safe *Salmonella* free cheeses.

D. *Listeria*

Listeria is widespread in nature and can be found in up to 50% of milk samples from raw milk silotanks, depending on geographical and seasonal variations. *Listeria monocytogenes*, a gram positive pathogen, has caused a few outbreaks of disease. Two of these outbreaks have caused higher rates of mortality (24,25). In 1985, 48 people died due to consumption of a Mexican style cheese (25). The reason for the contamination was a leak in the pasteurization equipment, resulting in a mixing of raw and pasteurized milk. In the mid-1980s 34 people died due to consumption of Vacherin Mont d'Or from Switzerland (24).

Listeria is difficult to control due to the relatively high heat stability (D10 at 69°C is about 15 sec). The temperature range for growth is 0–45°C, at pH 4.4–9.5, and up to 10% NaCl. In order to prevent growth it is important to pasteurize efficiently, which means ensuring that the cheese milk has been heated to at least 72°C for 15 sec. In the outbreaks, the products had characteristics that favored growth of *L. monocytogenes*. In the Mexican style cheese, for example only a weak acidification took place and the NaCl content was low. In the case with Vacherin Mont d'Or, insufficient hygiene, coupled with a rise in pH and a low NaCl also favored growth of *L. monocytogenes* (24). It is also worth noting that bacteriocin-producing starters and surface ripening cultures may inhibit the growth of *L. monocytogenes* (12). The infectious dose of *Listeria* is high compared to *Salmonella* and pathogenic *E. coli* which makes it easier to control it in the products. But on the other hand, *Listeria* is more likely to grow in the final product, depending on the type of cheese, because of its high resistance to low pH, NaCl and low temperature.

E. *Staphylococcus aureus*

S. aureus is associated with milk due to its close association with cows. It is relatively salt tolerant but sensitive to pH. The infectious dose is high about 10^5 pr ml. Disease arises from heat stable toxins, which means that even though no living *S. aureus* may be detected, the toxins may still be present (26). Thus, it must be assured that the number of *S. aureus* transferred from cow to product does not exceeded 10^5 pr ml, which is assured by a good manufacturing practice on the farms including assuring cooling in milk tankers and raw milk silotanks. Because *S. aureus* does not grow below about 8°C, the holding temperature should be held below 8°C, especially if the milk is stored for a long time in a silotank. *S. aureus* will only grow in cheeses with low acid content or if the cheese surface pH rises during curing. Good hygiene is normally enough to assure either the absence or low numbers in or on cheeses.

F. Others

Other microorganisms may cause spoilage or diseases in addition to the discussed above. Yeast and heterofermentative *Lactobacilli* may cause gas production or off flavors in cheeses, although the problem is generally easily solved by cleaning. In both cases, spoilage is due to heavy contamination in the dairy environments, and normally it is easy to control the environments to prevent heavy contamination. There is also the possibility for mold growth, which may be a problem on the surface of cheeses.

Formation of molds should be avoided partly because the damage to the product is severe and partly because formation of molds in some cases leads to formation of mycotoxins. Packaging in a modified atmosphere and in a material which creates a high oxygen barrier will prevent growth of molds. The risk from growth of molds is the formation of mycotoxins, but normally if molds become apparent, it will be destroyed. Mycotoxins are not able to penetrate the entire cheese, but are normally located in the outer rind, about 0.5–1.0 cm in depth depending on the cheese type and water activity.

VII. CONTROL SYSTEMS

In building up a control system, it is important to consider in each step of cheese production from the farm to the final product the microorganisms of concern. These steps are called critical control points and by introducing hazard analysis of critical control points (HACCP) it is possible to introduce a very high safety level of the products. Critical control points are production steps where some of the physiological or chemical conditions could cause a change conductive for growth of unwanted microorganisms. This means that careful evaluation should be performed if the microorganisms of concern can survive or grow at each control point. The most important parameters to evaluate are temperature; process time at the given temperature; pH and possibility of pH to change; water activity; and addition or formation of inhibitors.

There are different tools for determining whether a control point is critical. One is Predictive Modeling. Predictive Modeling is based on subjection of a large dataset on the growth of different microorganisms under different conditions into a database system. The growth data on the microorganisms derived from laboratory research, challenge tests and real product experiences are analyzed statistically and a program formed that predicts the microorganisms growth at selected temperatures, water activities, pH values, and often under other conditions such as the presence of additives.

Another critical point is the cleaning system. In most dairies, cleaning in place (CIP) is used. Sodium hydroxide with a pH of about 11 and a temperature at 70–80°C is used to wash away most of the milk components from the equipment followed by flushing with water. Nitric acid at pH about 2 is then used to remove acid soluble components from the equipment. It is expected that the strength of the CIP and the temperature will drop during the long transportation distances. In both cases, the cleaning efficiency and the direct killing effect on microorganisms will be less. Thus CIP is an important critical control point. Once the critical control points are established, limits for accepted values are determined and controlled with selected intervals.

VIII. CONCLUDING REMARKS

In order to control the presence and growth of pathogenic microorganisms, it is important to do whatever is possible to prevent their occurrence from farm to cheese product and to ensure that good manufacturing practice is implemented throughout the production. Implementation of HACCP is an excellent tool to control the pathogens or spoilage microorganisms. Raw milk should be of good quality, and its storage should be at low temperatures, especially if storage times are long. Pasteurization is also critical, thus the pasteurisation plant should be under careful control: The temperature must be stable and not below 72°C, the pasteurizer should be cleaned at required intervals and it must be assured that there are no dysfunctions such as mixing raw and pasteurized milk. The activity of the starter must be high; this will lead to a fast drop in pH, helping to control pathogens. If possible, the temperature should be kept as low as possible and the salt content as high as possible. During the process, hygienic precautions should include good personal hygiene, high water quality used for the production and adequate cleaning efficiency. It must be ensured that the CIP system be optimal with regard to strength of the sodium hydroxide and acid used, as well as the temperature employed during the cleaning step.

It should be emphasized that foodborne outbreaks in cheese consumption seldom occur. It is encouraging that considering the huge amount of cheeses consumed worldwide, only a few outbreaks have been documented. One of the reasons for this is that cheese is a well conserved system, creating a protective chain of hurdles against pathogenic and spoilage microorganisms.

ACKNOWLEDGMENT

181 Meat Fermentation

Fidel Toldrá
Instituto de Agroquímica y Tecnología de Alimentos (CSIC)

CONTENTS

I. INTRODUCTION

Fermentation is one of the oldest preservation practices used by man and is applied to a wide variety of foods. The term fermented meat is very generic and involves a wide variety of meat products based on a mixture of minced meat and fat, with salt and/or sugar, which is stuffed into a casing, fermented and dried or smoked (1). The evolution of fermented meats has followed a traditional route, with oral transmission from generation to generation over the centuries but very empirically, with a rather poor knowledge of the process technology (2). It was just in the latest decades of the 20th century when rapid advances in the scientific knowledge of the chemistry, biochemistry and microbiology involved in the process were reached (3). This knowledge prompted successful developments in technology and a significant progress in quality standardization.

There is a wide variety of processing technologies (with important variations in the conditions for drying, ripening, smoking, etc.) as well as an important influence of the meats used as raw materials (genetic type, feed, rearing system, etc.) and microorganisms selected for the fermentation, all of this giving important variations in quality, especially in sensory characteristics. Main types of fermented meats and the most important processing technologies are described in this chapter.

II. TYPES OF PRODUCTS

Some of the most important and well-known products are listed in Table 181.1. Based on the moisture content, most of fermented meat products may be classified as dry (weight loss higher than 30%), semi-dry (weight loss lower than 20%) or just fermented sausages when no drying is applied. Some of the typical Mediterranean sausages are French saucisson, Spanish chorizo or Italian salami. On the other hand, German or Hungarian style salamis represent some of the typical northern European products. There are basic differences between both groups of products (4). So, the Mediterranean sausages, which are not smoked, undergo a slow process with nitrate addition and very mild temperatures for both fermentation and drying. On the other hand, only nitrite is used in northern European sausages with faster processes and final smoking in most cases — i.e. up to 95% of German raw sausages are smoked (5). The pH drop, reduction in water activity and drying are main factors responsible for shelf-life of these products. In general, and depending on the total processing time, three main groups of fermented sausages can be established (4): Rapid (less than 7 days), regular (around 3 weeks) and slow (up to 3–4 months).

III. RAW MATERIALS

A. Ingredients

The main ingredients are chilled raw meat from skeletal muscle tissue, either porcine alone or mixed with bovine. Other species like chicken may be used. Frozen fat tissue, usually firm pork back fat, with low content of polyunsaturated fatty acids is preferred. Highly unsaturated fat may experience undesirable oxidations and result in off-flavors, color oxidation and an unpleasant melting fats appearance on the cut surface. Fat kept under frozen storage for long time may also experience an intense oxidation and thus must be rejected for the same reasons.

TABLE 181.1
Examples of Fermented Meats Based on the Extent of Drying (3,6,7)

Extent of Drying	Weight Loss (%)	Type	Examples
No drying	< 10	Spreadable	German teewurst
"	"		Frische mettwurst
Short drying	< 20	Sliceable	Summer sausage
"	"		Lebanon Bologna
			Saucisson d´Alsace
Long drying	> 30	Sliceable	Hungarian & Italian salami
"	"		Pepperoni
"	"		Spanish salchichón
"	"		French saucisson

B. Other Ingredients and Additives

Salt constitutes the most typical curing agent. It is added within the range 2–3% and plays several important functions: It exerts a partial bacteriostatic action, contributes to an initial reduction in a_w to 0.96 and to partial solubilization of the myofibrillar proteins and, finally, imparts a typical salty taste. Nitrite, and sometimes nitrate, are also added to the curing mixture. Nitrite is a well-known microbial preservative with a specific protection against pathogens, especially *Cl. botulinum*. Another important role of nitrite is the development of the typical cured meat color (8,9). In addition, nitrite also helps in preventing oxidation and contributes to cured meat flavor (10) although the full chemical mechanisms are not fullly understood due to the complex number of compounds in the sausage and the high reactivity of nitrite. Ascorbic and erythorbic acids or their sodium salts are used to favor nitrite reduction to nitric oxide, exert antioxidative action and inhibit the formation of nitrosamines (3). Carbohydrates are added as substrate for microbial growth and development. The choice of the carbohydrate and its amount depends on the type of desired fermentation and ripening time. The fermentation rate will be rather faster or slower depending on the type of carbohydrate. Monosaccharides are rapidly fermented while disaccharides and more complex polysacharides take longer and pH drop is thus delayed. Sometimes, glucono-delta-lactone, that hydrolyzes to gluconic acid, may be used as an alternative way for a non-microbial pH drop but the quality of the product is rather poor (11). Spices, like ground pepper, paprika, garlic, etc., are used to give a typical and characteristic flavor, and sometimes color, to the fermented meat (12). Most of them are also effective antioxidants (13).

C. Starters

Traditionally, the fermentation was held at mild temperatures with the selective growth of the indigenous flora or the inoculation of flora from a previous succesful fermentation, a technique known as back-slopping. But these practices resulted in a wide variability in both safety and quality of the final products. The use of micrbial starters had a rapid development and application in the second half of the last century. Most of these cultures are based on lactic acid bacteria (*Lactobacilli* or *Pediococcus* strains) to ensure a rapid acidulation and *Micrococcaeae (Kocuria* or *Staphylococcus* strains) to have a good sensory profile (14–18). Proteolytic and lipolytic enzyme activities are important for flavor development. Other important enzyme activity in *Micrococcaceae* are nitrate reductase which contributes to the reduction of nitrate to nitrite, and catalase that mediates the degradation of hydrogen peroxide (19–21). Yeast may be used as a complement in starter cultures due to its growth on the outer area of the sausage and its important deaminase/deamidase and lipolytic

activity. Certain molds may be used as starters for the external surface of the mold-ripened sausages (22).

D. Casings

Casings are available in many materials but all of them must exhibit a good permeability to water and air. Traditional sausages have typically used natural casings that are irregular in shape but give good elasticity, tensile strength and permeability. Collagen-based casings shrink with the sausage and have good permeability. Synthetic casings are usually based on cellulose and, although non-edible, they allow good standardization due to the uniform shape and controlled pore size (23).

IV. PROCESSING TECHNOLOGY

The main stages in the processing of fermented sausages are briefly described below.

A. Comminution or Chopping

Chilled meat pieces, usually from pork and beef, and frozen fat tissues are comminuted in a meat grinder, usually in a 2/1 ratio. The size of the particles may be regulated depending on the holes of the grinder (see Figure 181.1), Then, additives (salt, nitrate/nitrite, carbohydrates, microbial starters, spices and optionally sodium ascorbate or erythorbate) are added and the whole mass is mixed for homogenization. This operation is carried out under vacuum to remove as much oxygen as possible (see Figure 181.2). Once fully homogenized, the batter is stuffed into the casings by using vacuum filling devices. A general view of stuffing machines in a fermented sausage industry is shown in Figure 181.3. Once the sausages are stuffed, they are hung in racks and placed in air-conditioned rooms with computer control of temperature, relative humidity and air flow rate. Local traditional sausages, which are produced in an artisanal way, are stuffed in natural casings and placed in either natural or air-conditioned ripening rooms.

FIGURE 181.1 Grinding of meats and fats. There are many sizes of grinder plates in accordance to the required particle size.

FIGURE 181.2 Detail of the batter after mixing in a vacuum mixer massager.

FIGURE 181.3 General view of a sausage manufacturing plant. Stuffing machines and vacuum mixer massaging can be observed. Courtesy of Tabanera Company, Segovia, Spain.

B. Fermentation

The main goal of the fermentation stage consists in the growth and development of the microbial flora, either naturally present in the meat or added as starter in the mixing. Simultaneously, different biochemical changes consisting in the enzymatic breakdown of carbohydrates, proteins and lipids take place. Other changes consist in the acid gelation of meat proteins as a result of pH drop, an initial moisture loss as a consequence of water release from meat proteins and a reduction in the redox potential through the combined action of the muscle and lactic acid

bacteria enzymes (24). An example of fermentation in an industrial computer-controlled chamber is shown in Figure 181.4.

The time required for fermentation depends on the type of product but is mainly a function of temperature and specific microorganism used as starter. There are two clear technologies for meat fermentation that decide the type of starter to be used as well as fermentation conditions (2). In the USA fermentation, starters such as *L. plantarum* or *P. acidilactici* are used for fermenting at high temperatures, (i.e., up to 40°C). The result is a rapid lactic acid generation that accumulates and produces a pH drop below 5.0. The spoilage microorganisms are rapidly inhibited but flavor formation is somehow restricted by low pH values due to inhibition of exopeptidases and lipolytic enzymes, most of them active at neutral pH. In Europe, milder fermentation temperatures, around 22–26°C, are used although other differences may be found between Mediterranean and northern European countries. For instance, the use of nitrate and long ripening, with no smoking, are typical of Mediterranean sausages. The shelf life mainly depends on drying and low water activity. On the other hand, northern European countries use nitrite, short ripening and smoking (25).

FIGURE 181.4 Example of a fermentation chamber with computer control of temperature, relative humidity and air rate. Courtesy of Tabanera Company, Segovia, Spain.

C. Ripening and Drying

There are two main objectives in this stage: Drying and development of sensory properties. Sausages are hung in racks and placed in either natural or air-conditioned ripening rooms. Special care must be taken with relative humidity in the chamber as an excessive dryness in the environment may result in an excessive dehydration of the sausage surface, known as case hardening. Recommended relative humidity in the environment should not exceed in more than 0.1 units the water activity value in the sausage and air speed must be kept to values as low as 0.1 m/s which are enough for environment homogenization (2). A periodic change in the circulation of the air also allows a good exchange of the air between the sausages and the fresh blown-in air (26) The length of the ripening/drying period depends on the kind of product and its diameter, ranging from 7 days to 3–4 months. The length and conditions of the process, that allow for an intense and prolonged microbial and enzymatic action, as well as the optional smoking, have a strong influence on the sensory properties. In some Mediterranean dry fermented sausages, a mold layer is grown on the outer surface, giving a particular appearance and contributing to ammonia generation and pH increase through deamination of amino acids (see Figure 181.5).

D. Smoking

Traditionally, smoking has been applied in areas with cold and humid climates for preservation, due to its bacteriostactic effect on yeasts, molds and certain bacteria. In addition to its antimicrobial and antioxidative effects, its main role has changed to the development of sensory properties that are appreciated by consumers (27). Smoking has several advantages such as giving a characteristic color

FIGURE 181.5 Example of a ripening chamber with computer control of temperature, relative humidity and air rate. Courtesy of Tabanera Company, Segovia, Spain.

and flavor to the product, preservation due to the bactericide and bacteriostatic effect of smoke compounds and antioxidative properties due to the phenols in the smoke (28). Smoking can be applied, by controlled combustion of oak wood, before or after fermentation.

V. SAFETY

Preservation of fermented sausages is achieved through a chain of succesive events known as hurdle effect (29). Nitrite added to the mass exerts its bactericidal effect, reinforced by oxygen removal during the mixing under vacuum, being aerobic bacteria inhibited by low redox potential. Lactic acid bacteria grow during fermentation and generate large amounts of lactic acid, that produce a pH drop inhibitory of acid-sensitive spoilage microorganisms, and other metabolites like acetic acid or hydrogen peroxide that contribute to preservation (30). In addition, many strains of lactic acid bacteria, associated with meat fermentation, are producers of bacteriocins, which are biological active proteins or peptides, active at micromolar concentrations (31), with a bactericidal action against other microorganisms (32,33). These bacteriocins act by adsorption to specific or non-specific receptors on the cell surface resulting in cell death (34,35). Finally, the reduction in water activity values as a consequence of dehydration during the drying/ripening stage also contributes to the stability of the product, especially in dry fermented sausages. The combination of these hurdles restrict the activity of most food-borne pathogens although strict care must be taken. For instance, *Salmonella* can be inhibited by pH 5.0 and $a_w < 0.95$ (6,36). *Staphylococcus aureus* is sensitive to acid pH but its toxin, that is produced in aerobic conditions, might be produced in the elapsed time before pH drop depending on the conditions that need to be controlled (7). *Clostridium botulinum* is restricted by the presence of lactic acid bacteria and nitrite together with a rapid pH drop and low a_w (6). The combination of low pH, specific starter cultures and $a_w < 0.90$ limits the growth of *Listeria monocytogenes* (37) and *Escherichia coli* (38). It is important to adopt and implement a hazard analysis and critical control points (HACCP) plan as a system of preventive controls to improve the safety of fermented meats. Hazards would include both biological and chemical contaminants.

Biogenic amines constitute another group of toxic substances that can cause disease in humans. Several factors such as the presence of microorganisms with decarboxylase activity, favorable processing conditions for the growth of these microorganisms, the production of the enzyme involved in decarboxylation of amino acids and the availability of free amino acids as substrate, contribute to the generation of amines (39). Main amines are tyramine (from tyrosine), phenylethylamine (from phenyalanine), histamine (from histidine), tryptamine (from tryptophane), putrescine and cadaverine (from ornithine and lysine, respectively). The amine levels in different types of sausages were recently reported (40) but some variability was observed probably due to variations in the manufacturing process and the type and quality of meat used (41) but, in general, the concentrations were relatively low. Tyramine is the amine generated in larger amounts through the decarboxylation of tyrosine, activity found in strains of *Lactobacillus* and *Enterococcus* (42,43). This amine is involved in increased cardiac output and migraine (44) but, fortunately, the estimated tolerance level is higher than for other amines (45,46). Cadaverine and putrescine may appear when meats of poor hygienic quality have been used as raw materials (47). Reduced risk for amine generation implies the use of raw materials of high quality, good manufacturing practices during the whole process and the use of starter cultures with no decarboxylase activity but, if possible, competitive against amine-producing microorganisms (36). In general, the low amounts of nitrate and/or nitrite initially added to the mix and the low nitrite residual levels reduce the possibility for nitrosamines generation to negligible levels (48).

VI. CHANGES DURING THE PROCESS

Many biochemical changes have been reported along the processing of fermented meats, being most of them as a consequence of endogenous and/or microbial enzymatic reactions. Some of these changes are restricted to the beginning of the process which is the case of nucleotide breakdown reactions or the glycolysis-related enzymes and subsequent generation of lactic acid. Proteolysis and lipolysis constitute two of the most important enzymatic phenomena, responsible for the generation of compounds with direct influence on taste and aroma (3,24) (Figure 181.6).

A. Glycolysis

Lactic acid is the main product resulting from carbohydrate fermentation. Once the added carbohydrates (glucose, sucrose, etc.) are transported into the cell, they are metabolized via the glycolytic or Embden-Meyerhof pathway. The ratio of the enantiomers L and D lactic acid depends on the species of lactic acid bacteria present and, more specifically, on the action of the L and D lactate dehydrogenases, respectively, and the lactate racemase. There are some key enzymes in the carbohydrate metabolism like aldolases, that generates glyceraldehyde-3-phosphate, pyruvate kinase, that generates pyruvate from phosphoethanol pyruvate and lactate dehydrogenase that generates lactic acid from pyruvate (11). Glucose is mainly metabolized through a homofermentative way but some other end products like acetate, formate, ethanol and acetoin, with an impact on sausage aroma, may be produced in trace amounts from alternative heterofermentative pathways (25). The pH drops as a consequence of

lactic acid accumulation and contributes to the preservation of the sausage by preventing the growth of undesirable microorganisms (49). The generated lactic acid also contributes directly to acid taste and indirectly to aroma, due to the formation of metabolites, and sausage consistency due to protein coagulation as pH approaches the isoelectric point of most of the myofibrillar proteins (50).

B. Proteolysis

Proteolysis consists in the progressive degradation and breakdown of major meat proteins (sarcoplasmic and myofibrillar proteins) and the subsequent generation of peptides and free amino acids. The result is a weakening of the myofibrillar network and generation of taste compounds but its extent depends on many factors. One of the most important is the activity of endogenous muscle enzymes, which depends on the original crossbreeds (51,52) and the age of the pigs (53,54). Main muscle enzymes involved in these phenomena are cathepsins B, D and L that show a great stability in long term dry-curing processes, good activity at acid pH values and are able to act against myofibrillar proteins (55–57). Other important muscle endopeptidases like calpains exhibit poor stability and its optimal pH near 7.0 is far from that in the sausage (58). Muscle enzymes exert a combined action with microbial proteases although different enzymatic profiles may be found depending on the microorganisms used as starter cultures (59). One of the major challenges is just to establish the relative role or percentage of contribution of endogenous and microbial enzymes to proteolysis. The proteolytic system of different *Lactobacillus* has been studied and contains endopeptidases able to degrade sarcoplasmic and myofibrillar proteins (60–63) as well as exopeptidases like dipeptidylpeptidase (64), tripeptidase (65), dipeptidase (66) and aminopeptidases (67,68). However, some studies (40,69) revealed that protein degradation, especially myosin and actin, is initiated by cathepsin D, a muscle endopeptidase very active at pH values near 4,5 and able to degrade both proteins. Cathepsins B and L would be more restricted to actin and its degradation products. The latter stages of proteolysis would be predominantly by bacterial peptidases and exopeptidases.

Other important factors are related with the processing technology. For instance, the temperature and time of ripening will determine the major or minor action of the enzymes, the amount of added salt, which is a known inhibitor of cathepsins and other proteases, will also regulate the enzyme action (70,71) and thus the proteolysis and taste (72).

The generation of small peptides may be depressed by the level of salt which inhibits muscle peptidases (73–75) although intense levels of non-protein-nitrogen, up to 20% of the total nitrogen content, may be reached. Some of these peptides give characteristic tastes (76). Final proteolysis steps by aminopeptidases, especially from microbial origin, are very important (77,78). These enzymes release free amino acids along the process and a substantial increase in the concentration of free amino acids is usually observed (79,80).

C. Transformation of Amino Acids

The released free amino acids as a consequence of proteolyisis are then subject of a number of enzymatic and/or chemical transformations that produce different compounds that will affect the sensory characteristics of the product (12). So, microbial decarboxylation of amino acids may produce biogenic amines. Transamination consists in the transference of the α-amino group of the first amino acid to the α carbon atom from an α-keto acid generating a keto acid from the first amino acid and a new amino acid. Dehydrogenases transform the amino acid in the corresponding keto acid and ammonia. Deamidation also generates ammonia (81). The microbial degradation of the amino acid side chain by liases may lead to phenol and indole formation (82). The Strecker degradation of amino acids produces branched aldehydes, like 3-methylbutanal, 2-methylbutanal and phenylacetaldehyde from leucine, isoleucine and phenylalanine, respectively, through oxidative deamination-decarboxilation reactions (83).

D. Lipolysis

Lipolysis consists on the breakdown of tri-acylglycerols by lipases and phospholipids by phospholipases resulting in the generation of free fatty acids. These fatty acids may contribute directly to taste and, indirectly to the generation of aroma compounds through further oxidative reactions. Main lipolytic enzymes, located in muscle and adipose tissue, in combination with microbial lipases, are involved in these phenomena (84). Although it is difficult to establish a relative role of endogenous and microbial enzymes to lipolysis, the percentage of contribution of endogenous lipolytic enzymes to total fat hydrolysis is estimated around 60 to 80% with the rest due to microbial lipases (69). The most important lipases located in muscle are the lysosomal acid lipase and acid phospholipase while in adipose tissue are the hormone sensitive lipase and the monoacylglycerol lipase (85). These enzymes show good stability through the full process (86–88). Although their activity also depends on pH, salt concentration and water activity, the conditions found in the sausages favor their action (89). The generation rate of free fatty acids, especially oleic, linoleic, estearic and palmitic acids, increases during the process. Most of these fatty acids proceed from phospholipids degradation (3) although some of them generate volatile compounds through further oxidative reactions (90). In the case of adipose tissue, the rate of generation, especially of oleic, palmitic, linoleic, stearic, palmitoleic and myristic acids, is also high.

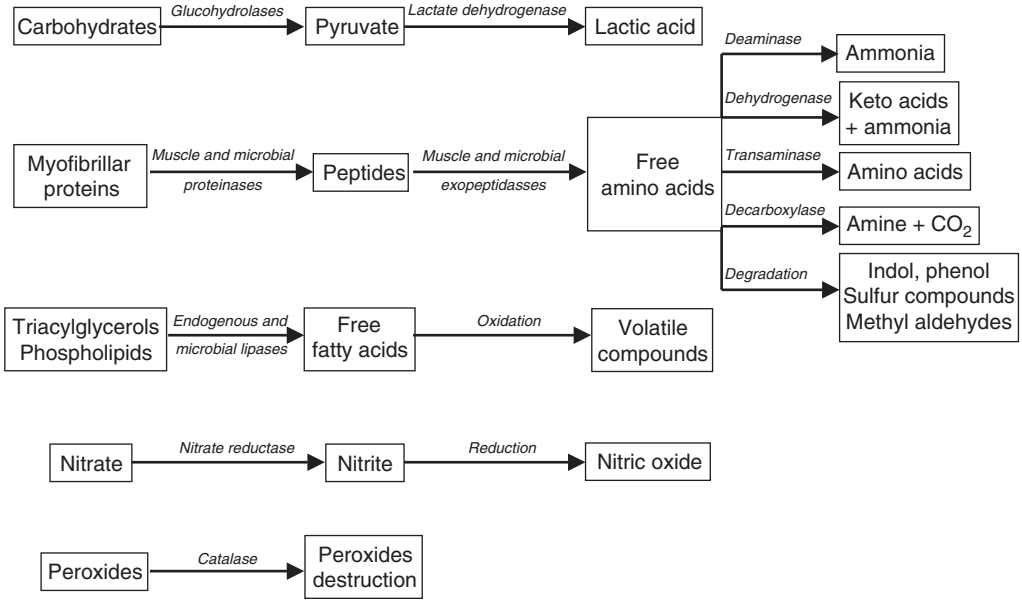

FIGURE 181.6 Scheme showing the most important reactions by muscle and microbial enzymes affecting sensory quality of fermented meats.

E. Oxidation

The generated mono and polyunsaturated fatty acids are susceptible to further oxidative reations to give volatile compounds. The beginning of lipid oxidation is correlated to an adequate flavor development. On the contrary, an excess of oxidation may lead to off-flavors (91). In fact, the generation of the characteristic aroma of dry-cured meat products is in agreement with the beginning of lipid oxidation. Free radical formation is catalyzed by muscle oxidative enzymes, like peroxydases and ciclooxygenases, external light, heating and the presence of moisture and/or metallic cations. The next step in oxidation is the formation of peroxide radicals (propagation) by reaction of free radicals with oxygen. The formed hydroxyperoxides (primary oxidation products) are flavorless but very reactive giving secondary oxidation products that contribute to flavor (92). The oxidation is finished when free radicals react each other. Main products from lipid oxidation are aliphatic hydrocarbons (poor contribution to flavor), alcohols (high odor threshold), aldehydes (low odor threshold) and ketones. Alcohols may interact with free carboxylic fatty acids giving esters, especially when nitrate is not used.

VII. DEVELOPMENT OF SENSORY CHARACTERISTICS

A. Color

The color mainly depends on the concentration of its natural pigment myoglobin, that depends on the type of muscle and the age of the animal (93,94). For instance, myoglobin concentration is higher in muscles with oxidative pattern and in older animals (94). The typical bright-red color is due to nitrosomyoglobin, compound formed after reaction of nitric oxide with myoglobin. About 10 to 40% of total myoglobin is transformed into nitrosomyoglobin (95). Nitric oxide is produced by reduction of nitrite and is favored by ascorbic acid. Those sausages made with nitrate need its reduction to nitrite by nitrate reductase activity in *Micrococcaeae*. However, this bacteria is inhibited at pH values below 5.2, being necessary to control the pH drop during fermentation to ensure that nitrate reductase can reduce nitrate to nitrite (2). Nitrosomyoglobin is susceptible to oxidation, especially at low pH and redox potential, conditions found in dry fermented sausages. So, it is very important to avoid oxidants (i.e.- peroxides) and thus the convenience of the presence of antioxidants to preserve color.

B. Texture

Texture depends on several factors like the extent of drying (loss of moisture), the extent of proteolysis, especially by cathepsin D (degree of myofibrillar protein breakdown) and the content in fat and connective tissue. The lactic acid accumulation produces the coagulation of myofibrillar proteins, the release of some water and the formation of a gel. The bonds are stabilized and the matrix of the sausage is developed (96). The consistency is accelerated during the drying period. The content in fat also exerts a positive influence on some texture and appearance traits. Textural characteristics such as firmness, hardness and cohesiveness of meat particles are continuously developed during drying. Shear values

are corelated with sausage diameter, moisture content, drying time and sometimes the initial grinding (97). In general, a good consistency is desired to facilitate the sliceability.

C. Flavor

1. Generation of Taste Compounds

Main contributors to taste are listed in Table 181.2. D and L lactic acid, especially the D enantiomer, and acetic acid are the main compounds responsible for the sour taste (43). The generation of free amino acids is the result of the combined action of muscle and microbial aminopeptidases. These enzymes are active at neutral pH, being partly inhibited at acid pH. This is the reason why those fermented meats with an intense pH drop lack significant generation of free amino acids (80). Salt is the main compound responsible for salty taste. Other compounds like glutamic and aspartic acids impart a sour taste while its sodium salts also impart a salty taste. Bitter taste is mainly associated with aromatic amino acids like phenylalanine, tryptophan and tyrosine and sweet taste with alanine, serine, proline, glycine and hydroxyproline (98,99). The generation of all these free amino acids is extremely important in fermented meats (55,79) and somehow the generation rate is affected by levels of salt as the involved enzymes (peptidases and aminopeptidases) are partly inhibited (73,74,100). Some taste enhancement may be expected from ATP-derived compounds like inosine monophosphate (IMP) and guanosin monophosphate (GMP).

2. Generation of Aroma Compounds

Aroma development is a very complex process involving numerous reactions like chemical or enzymatic oxidation of unsaturated fatty acids and further interactions with proteins, peptides and free amino acids (50). In fact, a substantial number of volatile compounds have been reported in fermented sausages (101–105). Main groups of volatile compounds are listed in Table 181.3 and a scheme of flavor generation routes is shown in Figure 181.7. Final flavor depends on the mixture of characteristic aromas and odor thresholds for each compound although, in general, ketones, esters, aromatic hydrocarbons and pyrazines are correlated with pleasant aromas (25). Aliphatic aldehydes, ketones, alcohols and esters are typical products of different lipid oxidation reactions. Some volatile compounds like 2-methyl propanal, 2-methyl butanal, and 3-methyl butanal arise from Strecker degradation of the amino acids valine, isoleucine and leucine, respectively (105). Branched-chain acids and alcohols are secondary products. Dimethyldisulfide proceed from the Strecker degradation of sulfur containing amino acids like methionine. Compounds like diacetyl, acetoin and acetaldehyde are typical products of pyruvate microbial metabolism (25). Some pyrazines are formed through Maillard reactions between sugars and free amino acids and, although generated in low amounts, they also impart some characteristic aromas like nutty, green, earthy, etc. The spices have an intense impact on aroma. Some sulphur compounds are derived from garlic, some terpenes from pepper, 3-hexenol in paprika, etc. (12). Ammonia is released through enzymatic deamidation and deamination reactions (81).

Several hundreds of volatile compounds have been identified in the aroma of fermented meats and several techniques have been used to estimate their relative importance (105). The most important compounds contributing to aroma may be determined by comparison of a certain amount with its sensory threshold value in a similar matrix, by correlation of the respective amounts to the sensory profile of the fermented meat or by gas chromatography coupled to olfactometry (104). Some interesting correlations have been found between some volatile compounds and specific characteristics of the process. For instance, a

stronger and typical flavor has been reported in nitrite-containing dry-fermented sausages (106). In small diameter sausages, with mild processing conditions and short ripening time, most of the volatiles are produced by lipid autooxidation (107). Ketones, aldehydes, esters and terpenes are the volatile compounds usually found in Spanish and Italian sausages (51). Medium aged Italian Milano salami with low production of lactic acid, and thus higher pH, is preferred (108). The type of starter also has a strong influence on flavor like a lower rancidity when using *S. saprophyticus*, curing odor correlated with 2-pentanone, 2-hexanone and 2-heptanone when using *S. carnosus* in combination with either *P. acidilactici*, *L. sakei* or *P. pentosaceus*, or butter odor correlated with acetoin, diacetyl, 1,3-butanediol and 2,3-butanediol when using *S. saprophyticus* and *S. warneri* (109). Many aroma volatile compounds have been reported to be produced by *S. xylosus* (110) and *S. carnosus* (111). Flavor may be affected not only by time of ripening but also by packaging (112). Pre-ripening exerts a beneficial sensory effect in dry fermented sausages (113).

182 Technologies for Jalapeño Pepper Preservation

Rosa María Galicia-Cabrera
Universidad Autónoma Metropolitana

CONTENTS

I. INTRODUCTION

Nutrition of Aztecs and other cultures living in prehispanic Mexico was based on corn, beans, hot pepper and a type of zucchini. Hot pepper (*Capsicum annuum*) is an excellent source of vitamins A and C; the compound responsible for irritation ("hotness") is capsaicin located in the fruit placenta. In addition to the pungent effect, capsaicin stimulates appetite, increases saliva secretion and is considered to have beneficial effects on gastric fluid production. Ever since the Aztec empire, chili is added to a number of Mexican traditional foods. This cultivar is widely acceptance in Europe, Asia and Africa where Spanish traders took it as commercial item after the conquest of Mexico. Today, chili is distributed and consumed worldwide (1–3).

The most important chili cultivars in Mexico are "ancho" (wide chili): poblano, mulatto and miahuateco; Jalapeño: classic Jalapeño, candelaria or peludo ("hairy") and espinalteco; serrano and mirasol (known as guajillo or cascabel when dried). These cultivars represent 70 to 80% of chili national production. Sweet peppers, those with low concentration or none of capsaicin, are exported. These are mainly moron, and in a lesser extent anaheim, caribe, fresno and cherry (4).

Asia was the main chili producer in 2001 (8,238,000 MT) followed by Mexico (1,961,000 MT) and the United States (885,630 MT). A high percentage of chili production undergoes processing such as freezing, canning, dehydration and pickling (5).

II. PROCESSING OF JALAPEÑO PEPPER

Jalapeño pepper is the most popular in North America. Its name, jalapeño, refers to the city of Xalapa, situated in the Mexican state of Veracruz. This is a fleshy, pungent fruit; harvested when unripened, with green bright color (Figure 182.1). Most of the harvest (60%) is pickled and canned; about 20% is consumed raw. If the fruits are harvested when ripened (red), they are dried and smoked; this product is known as chipotle (2,4,6).

FIGURE 182.1 Fresh Jalapeño pepper.

III. JALAPEÑO PEPPER PRESERVATION BY FERMENTATION OR PICKLING

Pickled Jalapeño pepper is widely consumed in Mexico. This is a scalded, pasteurized product, generally merchandized in cans or glass jars, with brine to which spice and vinegar have been added. However, Jalapeño pepper shelf-life extension by fermentation is carried out only at a very small industrial level. Information regarding fermented or pickled vegetables is scattered and there is no clear differentiation between pickled and fermented products (7). This section describes the processing of fermented and pickled Jalapeño pepper merchandised in cans or glass jars.

Pickling and fermentation are preservation methods extending fruit and vegetable shelf lives via a simple and

inexpensive technology. The processed material undergoes transformation resulting in a highly acceptable food to the consumer. Pederson (8) pointed out the various methods for fruit and vegetable preservation:

1. Pickling without undergoing fermentation
2. Fermentation in a low concentrated brine
3. Fermentation in a highly concentrated brine
4. Preservation by drying and salting at low salt concentration

However, there is a controversy regarding whether the terms "pickling" and "fermentation" are equivalent. According to Pederson and Luh (9) pickled products are those added with edible acids, either lactic or acetic (vinegar); on the other hand, fermented products are such that acid was produced from sugars by bacterial metabolism. Both pickled and fermented vegetables are mainly preserved by the action of acid, also improving sensory characteristics and possibly increasing its nutritive value. According to these definitions, Jalapeño pepper can be either fermented or pickled.

Undesirable microbial growth is inhibited by acid as well as by salt concentration (10). In addition of reducing populations of spoilage microorganisms shelf-life extension of fermented or pickled vegetables also depends on inhibition of plant enzymatic activity involved in the ripening process. Control of both spoilage mechanisms, microbial and enzymatic, in Jalapeño peppers is achieved by pickling and fermentation.

IV. FERMENTED JALAPEÑO PEPPER

Acid is produced by fermenting sugars through the action of lactic acid bacteria, such as *Lactobacillum plantarum,* although the presence of *Leuconostoc mesenteroides* also has a marked effect upon fermentation and product quality (11,12). In addition to lactic acid bacteria activity, other fermentative bacteria, such as acetic acid-producing microorganisms also carry out vegetable fermentation enhancing shelf life and sensory characteristics (12). Undesirable microorganisms are inhibited by various mechanisms. Salt addition allows the growth of naturally present lactic acid bacteria, but the combined salt and acid action allows the selection of microflora associated with vegetable preservation. In some cases, sugars are added to enhance the fermentation process (10). At the same time, fermentation reduces carbohydrate concentration and increases acid production (13). The most important conditions for an adequate vegetable fermentation are: anaerobiosis, salt concentration, temperature, and the used of suitable starters. Lactic acid bacteria can be present as native microflora in the pepper, but to assure a uniform fermentation, selected starters are usually added.

To obtain the best fermented jalapeño pepper quality, the raw material (*Capsicum annuum)* cv. Jalapeño must be recently harvested, still green, and without wounds or peduncle. Figure 182.2 shows the general flow diagram of fermented Jalapeño pepper processing (14).

A. Preliminary Operations

Raw Jalapeño peppers are selected according to their size and quality. They are washed, and small incisions are made in order to facilitate brine diffusion to the central part, and to eliminate gas formed during fermentation. Washing and blanching diminishes hot pepper fermentative ability; therefore it is necessary to add a starter culture (*Lactobacillum plantarum*).

V. FERMENTATION

Fermentation is carried out by facultative anaerobic homofermentative strains such as *Lactobacillum plantarum* and *Pediococcus cereviseae*. *L. plantarum* produces acetic acids as well as ethanol and gas (CO_2 and H_2). Peppers are immersed in 10% brine for 4 to 6 weeks, and 0.5 to 1% sucrose is added although pepper cell fluid contains carbohydrates as well as nitrogen compounds and minerals. The fruit cell fluid, however, tends to dilute the brine. For this reason, it is also necessary to add 1% salt daily during the first week, and three times a week during the rest of the immersion time in order to keep the desired brine concentration (18–20%). The peppers must be completely covered by the brine at all times.

Fermentation takes place in 4 to 6 weeks. It is carried out in closed tanks, with a vent to allow the gas formed during the process to dissipate. At the end of the fermentation period, the peppers, originally bright green, turn into olive green. The plant tissue also changes, taking a translucent aspect. Acid concentration increases from 0.8 to 1.5% (expressed as lactic acid) promoting a decrease in pH. The peppers are then washed to eliminate salt excess, classified according to their size, placed in glass jars or plastic bags, mixed with other vegetables, usually carrots and onions, and covered with vinegar.

Fermented Jalapeño peppers are highly perishable if the vinegar has less than 3% acetic acid. In this case, pasteurization is necessary. It is carried out over 30 min at 71°C (for glass jars containing 280 g of product). Finally, the product is labeled, packaged and stored in a similar way as for pickled (non-fermented) Jalapeño peppers.

VI. PICKLED (NON-FERMENTED) JALAPEÑO PEPPERS

The most widely merchandized Jalapeño peppers in producing countries such as Mexico, are pickled non-fermented products. They are sold in different can sizes and consist of whole cut peppers, mixed with scalded onions, carrots, mushrooms and vinegar to which spices have been added (Figures 182.3 and 182.4).

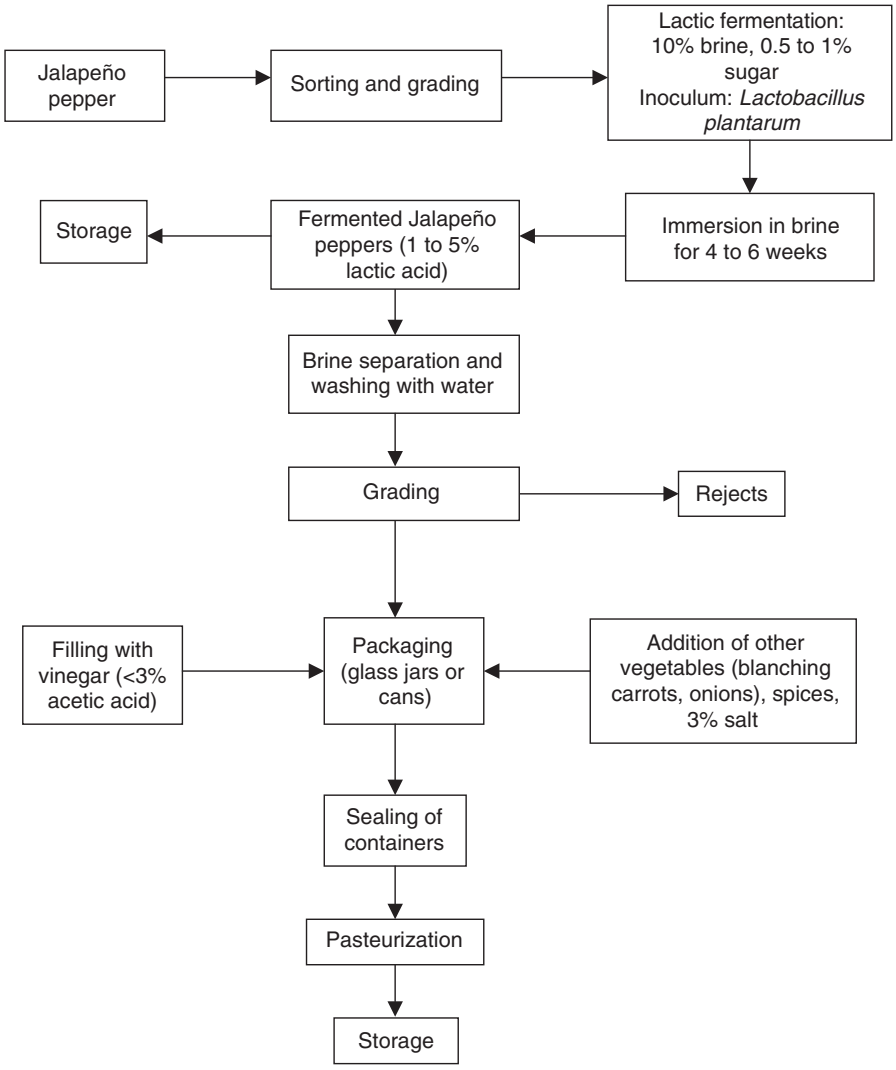

FIGURE 182.2 Fermented pickled Jalapeño pepper processing.

FIGURE 182.3 Pickled and sliced lengthwise Jalapeño peppers.

FIGURE 182.4 Pickled and sliced Jalapeño peppers ("nachos").

The main difference between this product and fermented peppers is that the raw material is fresh peppers or preserved with salt (brine). According to its acidity, the product is then heat-treated (15). As it is an acidic food spoilage can take place, therefore a further preservation method is necessary. The flow diagram for this process is shown in Figure 182.5. At domestic level or in small industries, pickled Jalapeño peppers are prepared by mixing scalded carrots, onions and other vegetables with Jalapeño peppers cut lengthwise, adding vinegar previously flavored with pepper, cinnamon, marjoram, thyme and clove, and other condiments (onion, garlic and laurel fried in vegetable oil) (16).

A. Preliminary Operations

Contaminants or inedible components can be present when Jalapeño peppers, carrots and onion are selected for this process. Added vegetables undergo following operations: washing, selection, classification, size reduction and scalding. Canning also ensures an adequate edible quality of the product.

Jalapeño peppers, carrots and onions are transported into the processing plant and selected for processing or storage, according to their quality and degree of ripeness. Washing by immersion, spraying, or combined methods are carried out in order to eliminate contaminants (17,18).

1. Washing

During immersion washing dirt adhering to the vegetable surface is softened and eliminated together with stones, sand and other abrasive material that may damage the equipment during further operations. Immersion tanks are made of metal, mortar or building materials suitable for easy cleaning and disinfection. In order to improve the washing efficiency, stirring is provided. Detergent or chlorine is also added to decrease the microbial load. During spray drying, vegetables are exposed to pressurized water applied if water supply is restricted.

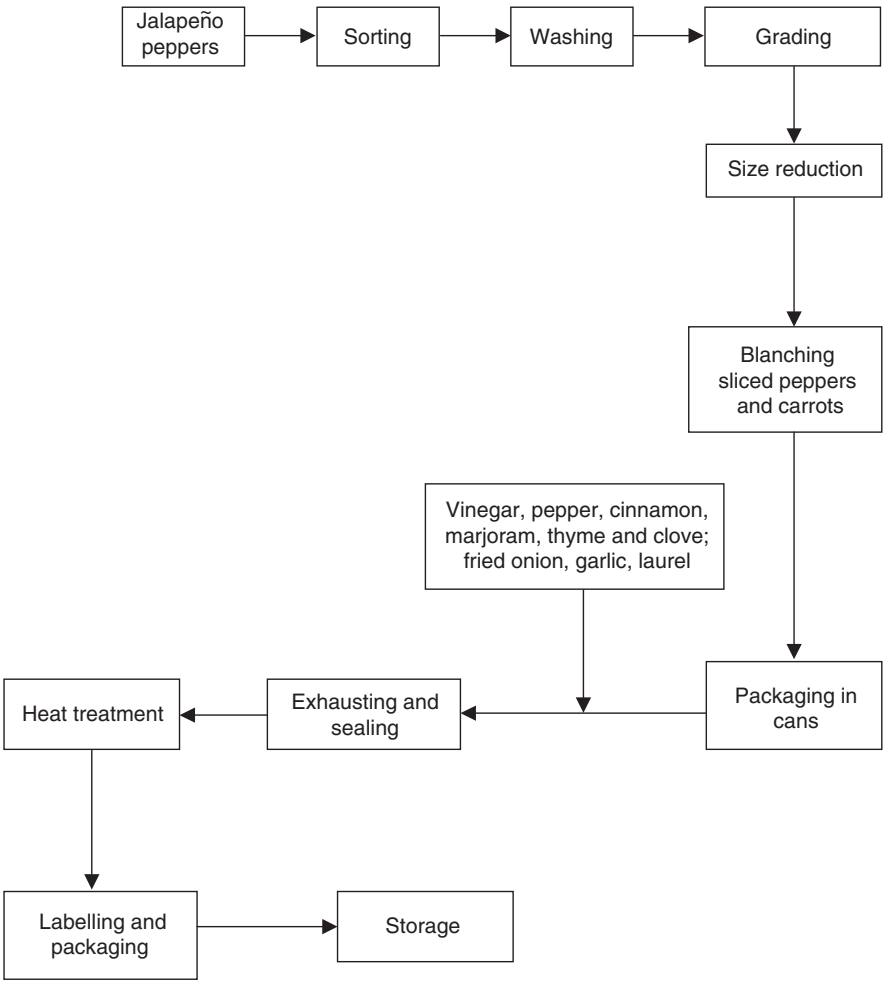

FIGURE 182.5 Non-fermented pickled Jalapeño pepper processing.

2. Sorting and Grading

Deterioration occurs during harvesting, transportation to the processing plant, or cleaning. These operations are carried out to discard products unsuitable for processing: damaged, unripe, overripe or deformed vegetables.

Vegetables are selected according to size and quality and are directed to processing or direct consumption. In general, classification consists in simultaneous evaluation of various physical properties. For hot peppers, onions, and carrots, classification is manually carried out. By this procedure simultaneous evaluation of several attributes is achieved, difficult in an automatic procedures. Classification renders having uniform material directed to a specific operation, such as peeling, size reduction, or blanching. Grading also homogenizes the product, improving heat-processing efficiency. Trained personnel generally carry out quality classification.

3. Peeling

Peeling is a necessary operation during carrot and onion processing to improve product appearance and to eliminate inedible parts, although it is important not to discard large portions of the vegetable. There are different peeling methods:

Abrasion: Carrot peeling is done by abrasion. Skin is removed by friction; the product is in contact with carborundum rollers or placed into containers coated in the inside with abrasive materials such as silicon or carbon. The abrasive surface detaches the carrot skin, later removed by a water stream.

Flame peeling: Applied mainly to onions, it consists of placing the vegetables on a conveyor moving through an oven at >1000°C. As vegetables pass, the outmost layer and fine roots are burnt and eliminated by high pressure water spraying.

4. Size Reduction

In this operation the average size of a solid food material is reduced by the application of external forces such as impact, compression or abrasion (17). In the case of Jalapeño peppers they are cut lengthwise into four parts and the peduncle and seeds eliminated. Cutters consist of a series of rotating blades, and centrifugal force holds the product against the blades.

5. Spoilage Enzymes

Enzymes, endocelular, exocelular or microbial, assume an active role in food deterioration. Microbial enzymes are also able to act on the food substrate even when the microbial cell is inactivated or dead (19). Insufficient scalding can result in an increase in food spoilage as heat applied can disrupt the tissues, liberating the substrate but not inactivating the enzymes. Scalding efficiency in vegetables is measured by inactivation of two enzymes: catalase and peroxidase. Jalapeño scalding in water is carried out for 8 to 10 min at 95°C; carrots are scalded for 6 to 8 min, water at 95°C (15).

6. Blanching

It is applied prior to processing in order to inhibit enzymatic activity and to decrease microbial populations. Blanching can be combined with other operations such as peeling or cleaning (17–19). Efficient enzyme inactivation is carried out by heating at given temperature-time conditions, and further fast cooling to room temperature. The two blanching methods commonly used are: applying saturated steam and immersion in hot water. At industrial levels, steam blanching is the most widely applied (17), it consists in applying steam to the vegetables placed on a conveyor moving through a steam tunnel. Varying the conveyor speed controls the residence time in the tunnel. In some cases water spray is applied at the start and end of the conveyor in order to condense excess steam. During hot water blanching vegetables are held for a given time at 70–100°C, with a further draining-cooling period.

B. Packaging

The aim of this operation is to keep the product, from processing to the consumer, in the same hygienic and quality conditions. Cans are made from three-piece tin sheets, coated on the inside with an epoxyphenolic enamel (Figure 182.6). The lids are also made of tinfoil and coated with the same material used in the can. The lid also has two or three circular expansion rings, providing resistance against deformation due to an increase in the internal pressure (20).

C. Pickle

According to Mexican regulations (21), pickle is a mixture of vinegar, vegetable oil, onion, carrots, laurel, garlic,

FIGURE 182.6 Three-sheet tin can, with internal porcelain enamel covering.

salt, sugar and optional spices. Vinegar has 2% acetic acid and 5% sodium chloride.

D. Blanching Vegetables

Cut peppers, carrots and onions must not be less than 60% total product weight, peppers must be included in a higher proportion.

E. Filling

Vegetable mix is first added to the can, previously washed with hot water; the brine (pickle) is then added at 82 to 86°C. Filling must be carefully controlled in order to assure that the correct amount of vegetable mix and pickle is added, and to fulfill specifications. Headspace must be 10% of total can volume. Filling is done when transported by the conveyors, which carry the cans to the vegetable mix filler and then to the liquid one.

F. Exhausting

When air is evacuated from the headspace before sealing internal pressure is decreased during sterilization. At the same time oxygen evacuation prevents tin corrosion and oxidation. During this operation air is replaced by vapor promoting a partial vacuum in the headspace after condensing. Exhaustion is carried out in tunnels (or exhausters), as shown in Figure 182.7. Another way to promote exhaustion is by using steaming equipment, which inject steam to the headspace before closing the cans (20).

G. Sealing

Sealing is carried out in steaming machine. According to the design and speed of the operation, the basic stages of the operations are: (a) folding edges; (b) pressing the folded tin to form an hermetic seal impermeable to air (22).

FIGURE 182.7 Vapor tunnel or exhauster.

H. Heat-Treatment

Cans or glass jars are subjected to heat treatment to sterilize or pasteurize their contents. It can be done in batches or by continuous retorting. Cans are heated at a time-temperature condition in vapor or hot water. Pasteurization of pickled Jalapeño peppers destroys microorganisms resistant to high acetic acid concentrations, able to promote product alteration. Heat treatment also inhibits vegetable or microbial enzymes (23). Heat treatment of 93.3°C and 10 min are recommended for acid pickles (pH 4.3 to 4.5). However, a time-temperature process depends on type of container, volume, and heat processing equipment.

1. Batch Processing

During this operation retorts are saturated with vapor and containers are placed in baskets. Retorts can be horizontal or vertical, and the cans can be still or rotating during the process. Can rotation promotes heat transfer, so that processing time is reduced and higher temperatures can be achieved.

2. Continuous Retorting

This type of equipment is fitted with hydrostatic closings before and after the pressurized sections. Processing can be also carried out by can rotation, where the cans move in and out of the pressurized section through hydrostatic column seals, equilibrating the internal pressure.

A variation of this equipment is the flame retort, operated at atmospheric pressure throughout the process. Flame retort equipment is fitted with direct heating, applied to the rotating retort. An advantage of this type of retorting is a high product quality due to mild heating conditions.

In all heat treatments the final part is can cooling with water to reach final temperatures not less than 38°C. Because the cans are not completely cooled down, water is eliminated from the outside, avoiding corrosion.

I. Marking, Labeling and Packaging

Once the containers undergo heat treatment, each can or jar is marked with a code, a production date, a batch number and a plant code. The label includes the product name, the commercial name, the drained and net weight, the ingredients and other specifications required by the country's regulations (21). Packing is automatically carried out in cardboard boxes or high-density polyethylene bags, or other suitable packaging material with enough resistance to protect the product and containers.

J. Storage

Heat-treated Jalapeño peppers keep their quality characteristics at 18 to 21°C. At a higher temperature, acid products in cans without inner coating consume oxygen in the

headspace faster than in coated cans. The result is a considerable loss in ascorbic acid content and fast product oxidation (23,24). On the other hand, canned Jalapeño peppers have a longer shelf life if stored at 0 to 5°C (23).

VII. REGULATIONS

A. Mexican Specifications

NMX-F-121-1982, 21 is Mexico's quality bylaw (Norma Mexicana) regulation for pickled Jalapeño or serrano peppers. This regulation includes six consumer presentations or styles and two quality levels.

The presentations are: whole peppers, peppers without seeds, peppers in halves, peppers cut lengthwise, pepper cut in rings and chopped peppers. There are two quality classifications for whole peppers only; for the rest of the presentations there is one quality classification. Table 182.1 shows physical and chemical specifications.

These specifications also include microbial characteristics, chemical contaminants, optional ingredients, sampling and specificity of quality degrees, labeling, containers and packaging. Among optional ingredients are: garlic, pepper, cinnamon, cloves, ginger, laurel, marjoram, thyme and nutmeg. In defining the Mexican official specifications the main Jalapeño pepper processing industries took part, such as Productos Del Monte, La Costeña, Hérdez, Conservas San Miguel, Conservas Guajardo and Elías Pando.

B. International Specifications

The processed fruit and vegetable Committee of the Codex Alimentarius Commission FAO/OMS, has elaborated a General Specification project for pickled products. At present, this project is at the sixth stage, that is revision by all member countries. However, the project does not include pickled cucumbers or kimchi (25).

During the 21st session of the Codex Committee on Processed Fruits and Vegetables, held in San Antonio, Texas on 2002, it was agreed to stop the draft Codex standard on the sixth stage of Codex Alimentarius normalization procedure. This decision was taken on the basis of the product nature, expressed by several member countries, with respect to the edible characteristics of the covering medium or if it should be eliminated, as well as pH, salt concentration and processing conditions (scalding, lactic fermentation, heat treatment before or after container filling, etc.) (25). The Draft Codex Standard for Pickled Products (26) includes the following specifications:

TABLE 182.1
Specification of Jalapeño Peppers (Mexican Legislation NMX-F-121-1982, 21)

Specification	Minimum	Maximum
Acidity (as acetic acid) (%)	0.75	2.0
Chloride (as sodium chloride)(%)	2.0	7.0
pH		4.3
Filling (%)	90	
Headspace (%)		10
Vacuum (mm Hg)	76.2	

1. Scope

This standard applies to edible fruits, vegetables, cereals, legumes, spices and condiments which have been cured, treated or processed to produce an acid product and which are offered for direct consumption in oil, brine or acidic media.

2. Product Definition

Due to the wide variety of pickled or fermented products, this chapter deals with a general definition.

Pickled products are:

a) Prepared from sound, clean and edible fruits, vegetables, cereals, legumes, spices and condiments.
b) Subjected to curing and processing with ingredients appropriate to the type in order to ensure preservation of the product and its quality.
c) Processed in an appropriate manner in order to ensure the quality and proper preservation of the product
d) Preserved in an appropriate manner in a suitable packing medium with ingredients appropriate to the type and variety of pickled product.

3. Essential Composition and Quality Factors

This section includes basic ingredients such as edible fruits, vegetables, cereals, legumes, spices and condiments in a liquid medium in a combination with one or more of the optional ingredients.

The optional ingredients are nutritive sweeteners, unrefined nutritive sweeteners, edible vegetables oils, vinegar, citrus juice, dried fruits, malt extract, salt, brine, chilies, seasoning (of plant origin and animal origin).

Some specific requirements are:

Pickled products in edible oils: Oil must not be less than 10% by weight.

Pickled products in brine: Salt in the covering liquid must not be less than 10% by weight, if salt is used as the main preservation agent.

Pickled products in acidic media: Acid must not be less than 2% by weight, expressed as acetic acid. Accepted food additives are shown in Table 182.2.

TABLE 182.2
Authorized Food Additives (Draft Codex Standard for Pickled Products, 26)

Preservatives	Maximum Level
220 Sulphur dioxide 221 Sodium sulphite 222 Sodium hydrogen sulphite 223 Sodium metabisulphite 224 Potassium metabisulphite	30 mg/kg (as sulphur dioxide)
211 Sodium benzoate 212 Potassium benzoate	250 mg/kg (as benzoic acid)
200 Sorbic acid 202 Potassium sorbate	1000 mg/kg as sorbate
Acidity Regulator	
260 Acetic acid (glacial)	Limited by GMP

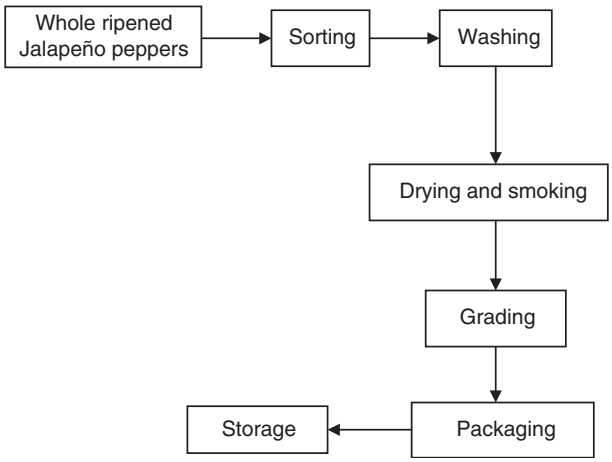

FIGURE 182.8 Drying of ripened Jalapeño pepper.

4. Weights and Measures

Pickled products in edible oil, in brine and in acid media: basic ingredient in the final product (drained weight) must not be less than 60% by weight.

This draft standard also includes other chapters on contaminants, hygiene, labeling and methods of analysis and sampling, referring to relevant legislations of other related Codex Committees.

VIII. RIPENED JALAPEÑO PEPPER DRYING (CHIPOTLE PEPPER)

Jalapeño pepper is a conic fruit of approximately 6 cm long, 4 cm width, tasty and consistently, in general the surface is scorched. This is a highly acceptable characteristic as it prevents cuticle removal during pickling. However, if it is excessive, the fruits are directed to chipotle fabrication (2,3). A flow diagram depicting this process is shown in Figure 182.8.

A. Preliminary Operations

1. Sorting

Jalapeño peppers, if directed to dehydration and smoking, must be healthy, ripened and showing intense red color.

2. Washing

Fruits are washed by immersion in tanks added with detergent or chlorine to reduce microbial loads.

3. Seed Removal

The fruits can be processed complete, with seeds, or once the seeds are removed, in this case the product has a higher commercial value. In addition, seeds are used for the next seeding season. Seed extraction is carried out before smoking; chilies without seeds are called "capones" (capons) (3).

B. Drying

This operation removes through evaporation by heating procedures most of the water present in fruits and vegetables. The main objective is to extend the shelf life by reducing water activity. Microbial growth and enzymatic activity is considerably reduced due to the reduction of available water. Drying also reduced food weight and volume; therefore transportation and storage costs are also reduced (17). Drying and smoking, or applying hot air carries out dehydration of Jalapeño peppers.

1. Drying and Smoking

It consists in applying hot smoke in ovens, located close to the producing area. In small processing plants, the oven consists of two brick chambers linked together with a tunnel; in one chamber smoke is generated by burning sawdust or wood, chilies are placed in a second chamber on a 1.5 to 2.5 cm thick, 2 × 2 m long rack made generally of bamboo, with 20 cm × 2 m wood supports (27). Chilies on the rack in 18 to 20 cm thick layers are in direct contact with the smoke; they are constantly turn over using a 1.5 m long shovel to reach homogeneous drying and smoking of the product. The combined effect of heat and smoke is an efficient drying. Process duration varies depending on the desired final moisture and smoke content, average duration is 3 to 6 days obtaining a dark brown product with smoke-like flavor taste (Figure 182.9) (2,27).

In large processing plants ovens can held 800 a 900 kg of raw peppers, producing a 60 to 70 kg dehydrated product. If more than 900 kg raw chilies are processed, fruits can be damaged or broken, reducing product quality (3).

FIGURE 182.9 Chipotles (dried and smoked Jalapeño peppers).

The final product quality (chipotle pepper) depends on ripening stage of the harvested raw material as well as drying conditions.

2. Hot Air Drying

In this method the fruits are dried in hot air tunnels with isolated walls, allowing continuous operations and high production capacity (18). Jalapeño peppers are placed in trays stocked in moving racks, with enough separation to allow drying air to circulate around them. The racks are introduced in the drying tunnel at suitable intervals. When one rack is introduced in the "wet" end of the tunnel, another is removed from the "dry" end. Air is forced by fans though heaters, producing forced convection; this sir is then horizontally fed into the tunnel and trays, although some turbulence is also produced by air circulating between trays. Air is applied at rates between 2.5 to 6 m/s; each rack contains 15 trays with a total of 350 to 400 kg raw pepper, following a 25 m total tunnel length with a rectangular or square 2 $\times$ 2 m transversal section and capacity for 22 moving racks; air counter currently fed. After 8 hours drying, the tunnel is at 55 to 60°C; drying of the first racks fed is achieved after 36 hours; after this time 2 to 3 racks are dried every 4 hours (18,27). Dried fruits should have 6% to 10% moisture content (2,17,23).

3. Grading

The dried product is classified into three categories:

First quality: Peppers of largest size, uniform color, without any deterioration or breakage

Second quality: Peppers of the same size as previous ones, but non-uniform color.

Third quality: Broken or damaged peppers, non-uniform color.

C. Packaging

In general, dried peppers are packaged in 55 to 60 kg sacks.

D. Storage

If the product has been properly packed and protected against oxygen humidity and light, it can reach 1 or 2 years shelf life (22). Oxygen presence deteriorates carotenoides present in the skin. Pigment oxidation increases if other extrinsic factors are present such as high storage temperature, light, metal ions, oxygen or peroxidases (28). These factors affect color, aroma and composition, and, consequently, considerably reduce the commercial quality.

IX. CANNED CHIPOTLE PEPPER IN "ADOBO" (SPICY SAUCE)

Canning, still as the main food preserving method, is based on the premise of microbial destruction by heat, and on recontamination prevention. With the exception of certain heat-tolerant bacteria, lethality starts at about 46–49°C. In conventional canning, food is placed inside containers, air is removed and cans are hermetically sealed and placed in a retort to be sterilized with steam. The rate at which heat penetrates into the canned product must be measured from the slowest-heating part of the can, or cold point. The basic heat penetration processes are convection and conduction, and a combination of the two (29).

The quality of canned fruits and vegetables is affected not only by the heat process but also by the method used to prepare the food material. Such preparation involves washing, trimming, sorting, blanching, filling into containers, and maintenance of the headspace in the can upon vacuum closing.

Canned chipotle peppers are of great demand in Mexico; they are consumed directly from the can or used as meat or sauce seasoning. Cans are merchandized in different sizes and formats; chipotle peppers are usually canned in a spicy sauce, or "adobo," made of other peppers (anchos, or "wide," and mulattos) tomato, garlic, onion, cumin, oregano, salt, sugar and vinegar (Figure 182.10).

FIGURE 182.10 Adobo ("spicy sauce") chipotle peppers.

A. Preliminary Operations

Canned chipotle pepper in "adobo" is shown in Figure 182.11. Whole dried chipotle peppers, as well as dried ancho and mulatto are transported to the processing plant in 50 to 60 kg sacks.

1. Sorting

Dried peppers are sorted in order to eliminate broken peppers, seeds or leaves. Tomatoes, onions, garlic are also sorted to remove any material, unsuitable for processing.

2. Washing

Pepper and other vegetables washing is carried out by immersion in stirred tanks, or by water spraying.

3. Grading

It is manually carried out.

4. Peeling

Garlic and onion peeling is carried out applying the flame method already described for non-fermented pickled peppers. Chipotle peppers peduncles are removed; seeds, veins and peduncles are also removed from ancho and mulatto peppers.

5. Blanching

Tomato blanching is carried out in water during 1 to 2 min at 95°C; blanching and peeling is carried out at the same time. Fast cooling at room temperature improves the efficiency of both operations.

Dried pepper scaling softens the disuse, reduces pungency, removes seeds, improves color and decreases microbial loads. Chipotle pepper is scalded in water during 10 to 15 min at 95°C; ancho and mulatto peppers are scalded in water at 95°C for 15 to 20 min. At the industrial level, scalding with steam is generally applied.

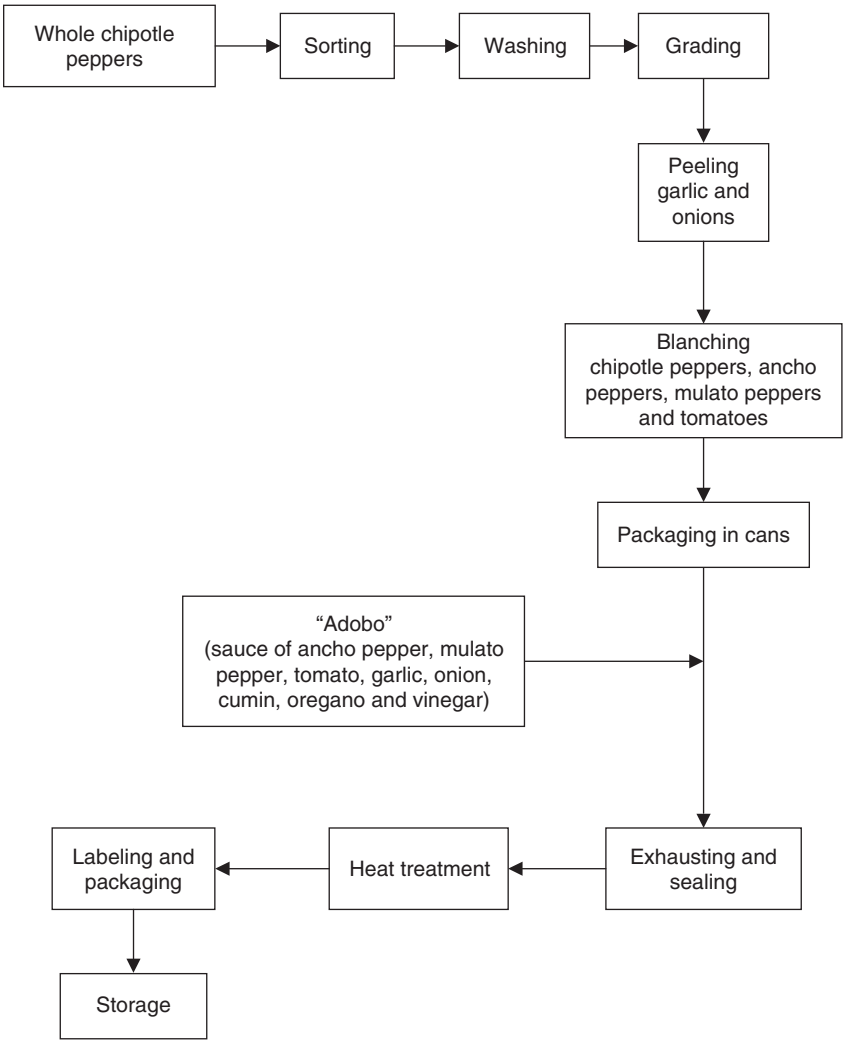

FIGURE 182.11 Canning of adobo ("spicy sauce") chipotle peppers.

B. Packing

Packaging is carried out in 3-piece tin cans with epoxy phenol enamel; lids are made of the same material, fitted with an easy-opening ring and three expansion moldings (Figure 182.12).

C. Adobo ("Spicy Sauce")

To date, there is no Mexican standard (NMX) for chipotle peppers in adobo. Therefore, adobo formulation varies from one food processor to other, mainly regarding the amount of mulatto pepper sometimes using other pepper (guajillo) as well as amount and type of spices included. Several industries buy the adobo from specialized plants that formulate and dry this sauce.

D. Blanching Vegetables

Whole chipotle peppers, as well as sliced onion must be 60% minimum weight of total net weight, although chipotle peppers must be the dominant vegetable present. The covering medium is adobo sauce.

E. Filling

Chipotle peppers and onion slices are placed in previously washed cans; adobo is then added at 82–86°C. Headspace must be 10% total can volume. Filled cans are exhausted, closed, pasteurized, marked, labeled, packed and stored in a similar way as with non-fermented pickled Jalapeño peppers.

FIGURE 182.12 Three-piece easy-opening can.

183 Sourdough Bread

Åse Hansen
Department of Food Science, Royal Veterinary and Agricultural University

CONTENTS

I. INTRODUCTION

Sourdough is used as an essential ingredient in the production of wheat and rye bread and mixtures hereof. Sourdough has been used for leavening of bread dough for several hundreds of years, and sourdough bread was made in Egypt as early as 3000 BC [1]. The sourdough was a piece of dough from the previous baking which was kept

until the next baking, where it was mixed with flour, salt and water to make the bread dough. The intervals between baking could be from one day in bakeries to one month in home baking. If the time between baking was long, salt could be added to the surface of the sourdough to avoid wrong fermentation. While this piece of dough was saved, lactic acid fermentation took place due to multiplication and metabolic activity of lactic acid bacteria (LAB) originally present in the flour. During this fermentation, selection and multiplication of yeasts from the flour also occurred. The natural content of LAB and yeasts from the sourdough was responsible for the leavening capacity of the bread dough primarily due to their production of carbon dioxide. Yeast from beer or wine production could also be added to the dough to increase the leavening capacity until production of commercial baker's yeast began during the 19th century [2]. The sourdough still holds a place of honour in many households throughout the world, and small portions are passed on to the daughters at marriage [2].

A. Wheat Sourdough

Sourdough is used as an important ingredient in the production of wheat bread [3,4] as well as crackers and the Italian sweet baked products as Pandoro, Colomba and Panatone [5,6]. The tradition of making wheat bread with the addition of sourdough is widely used in the Mediterranean area such as Italy [5,7], Greece [8,9], Spain [10], Egypt [11] and Morocco [12]. The tradition is also known from The Netherlands [13], Iran [14] and the San Francisco bay in the US [15,16].

The cereal intake in the traditional diet of Greece is mostly in the form of sourdough bread rather than pasta [8]. In Italy, sourdough is used in more than 30% of bakery products, which include more that 200 different types of sourdough bread. In some regions of southern Italy, most of the bread including sourdough bread is made from durum wheat instead of common bread wheat [7]. In Morocco, commercial bakeries supply only part of the population with bread, while most people eat homemade bread made with traditional sourdough, which has been carefully kept in every family. Addition of baker's yeast is used mainly in towns and villages where refrigeration can be employed [12].

B. Rye Sourdough

Sourdough is essential in rye bread making and the tradition of rye sourdough fermentation correspond to the rye-growing areas in the north, central and eastern European countries including the Baltic states, where rye bread constitutes a considerable amount of the bread consumption. Rye sourdoughs have been characterised from Finland [17], Sweden [18] and Denmark [19,20], Germany [21–23], Austria [24], Poland [25], Czechoslovakia [26], Russia [27] and Portugal [28].

Bread made from mixed wheat and rye is very common in many European countries, and sourdough should be used to enhance the sensory properties of the bread and prolong the microbial shelf life if more than 20% of the flour is from rye [29]. One of the most famous rye sourdough bread still produced today is the pumpernickel named after the Swiss baker Pumper Nickel. The bread originates from 1443, where there was a significant scarcity of wheat in Europe [2].

The tradition of production of rye bread without the addition of baker's yeast has continued even in large-scale bakeries until today, and the leavening capacity of the sourdough is still very important in rye bread production. In the sixties and seventies, the time between baking and consumption of bread increased due to changes in the society, and in some bakeries, preservative compounds such as vinegar, propionic acid or sorbic acid were added to the dough for the prevention of moulds. However, the natural content of yeasts from the sourdough is also inhibited by those preservatives, resulting in decreased leavening capacity, and it was necessary to add baker's yeast to increase the bread volume. The use of propionic acid as a preservative in bread is prohibited in many countries today. Stringent hygiene in bakeries makes it possible to produce bread with long shelf life without added preservatives, if sourdough is added.

C. Why Is Sourdough Used?

The advantages of using sourdough for bread production include the possibility of leavening bread dough with little or no baker's yeast added, improved dough properties, and the achievement of a better and more aromatic bread flavor and texture compared to bread only leavened by bakers yeast (Table 183.1). Sourdough flavor is developed by a long fermentation process that requires 12–24 hours, while fermentation by baker's yeast has to be finished within 1–2 hours. The addition of sourdough can also extend the shelf-life of bread by several days by increasing the mold-free period of bread and retarding the development of rope. The nutritional value of sourdough bread made from high extraction flour is enhanced

TABLE 183.1
The Advantages of Using Sourdough in Bread Making

Leavening of dough
Improved dough properties
- inhibition of α-amylase
Increased flavor and taste of bread
Improved nutritional value of sourdough bread
- higher bioavailability of minerals
- lower glycemic index
Extended shelf life of sourdough bread
- longer mold-free period
- prevention of rope in bread
- antistaling

compared to bread made without sourdough due to a higher content of free minerals, which are separated from phytic acid during the long fermentation processes.

Interest in using sourdough in bread production has increased considerably in many European countries during recent decades [4,30,31]. Today, a larger part of the consumers prefer healthy bread with aromatic taste, good texture, and long shelf-life without the addition of artificial preservatives. The demand for organic food is also on the rise, and a larger part of the bread made from organically grown cereals is made with sourdough due to its higher quality and better image. More consumers are also interested in food with history, and sourdough bread is related to traditional and original food.

II. CHARACTERIZATION OF SOURDOUGH

High quality sourdough bread is dependent on a consistent and microbial stable sourdough. Good fermentation capacity of the sourdough is influenced by the microbial flora (lactic acid bacteria and yeasts) in the sourdough, flour type (wheat/rye, flour extraction rate, activity of enzymes), flour/water ratio (dough yield), and the process parameters. The process parameters such as temperature, initial pH, quantity of added sourdough starter, time of fermentation, and type of production system (batch/continuous) have to be strictly controlled.

A. Definition of Sourdough

Sourdough is a mixture of flour and water, in which LAB have caused a lactic acid fermentation to occur. It is in general accepted that the LAB should still be able to produce acids, when flour and water are added (metabolically active). The sourdough also has a natural content of sourdough yeasts, which are important for the leavening capacity of the dough. However, no official definition of sourdough exists, but it should include all different types of sourdough products with "living" LAB and exclude artificial sourdough products. According to Lönner [32], a sourdough should contain more than 5×10^8 metabolically active LAB/g, and have a pH value below 4.5.

B. Types of Sourdoughs

Sourdoughs can be started as follows:

a) during spontaneous fermentation
b) by adding a piece of mature sourdough (mother sponge)
c) by adding a defined starter culture

Most sourdoughs used in both wheat and rye bread baking are still initiated by adding a piece of mature or ripe sourdough also called mother sponge, but there is a tendency to use defined starter cultures with specific fermentation patterns. This tendency increases as these cultures become commercially available.

1. Spontaneous Fermentation

When dough made from flour and water is left for one to two days at ambient temperature, a spontaneous fermentation will take place due to the naturally occurring microorganisms in the flour. The dough will become acidified due to lactic acid fermentation. During the fermentation there is a successive favoring of the Gram-positive LAB from the flour at the expense of the Gram-negative bacteria, which dominate the microflora of the flour [21,32]. The microflora of some spontaneously fermented rye sourdoughs were dominated by a homofermentative *Lactobacillus* spp. and *Pediococcus* spp. [32,33]. The level of LAB in sourdoughs was up to 3×10^9 colony forming units (CFU)/g and the number of yeasts about 10^6 to 10^7 CFU/g. However, spontaneous sourdoughs do not always succeed and may result in products with off-flavor.

2. Mature Sourdough

Sourdoughs used by artisan bakers and in bakeries have traditionally been based on spontaneous fermentation, during which the sourdough has been kept metabolically active and probably microbial stable for decades by the addition of flour and water daily, the so called "freshening" of the dough based on "back-sloping" (Figure 183.1). The fermented sourdough is used for bread production, but part of it is used as starter by initiating a new sourdough. The terminology for sourdough and starter in different countries is listed in Table 183.2.

In commercial rye bread baking, the bakeries can use their own adapted sourdough or, if they have quality

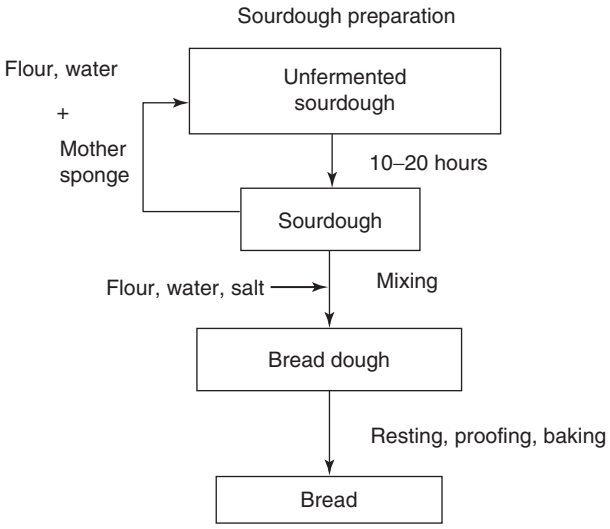

FIGURE 183.1 A schedule for production of sourdough.

TABLE 183.2
Terminology for Sourdough in Different Countries

Modified after [5].

problems due to unstable process control, they can add a commercial sourdough as a starter. Most bakeries in Germany and Denmark regularly add commercial sourdoughs composed of a well-adapted microflora derived from natural sourdough fermentation. Examples of commercial sourdoughs are the Sanfrancisco sour for wheat bread production [34] and the Böcker-Reinzucht-Sauer® for rye bread production. Some products sold as sourdough have no living microorganisms, and these products will not contribute to a natural acidification and development of flavor compounds in the dough.

3. Starter Cultures of Pure Strains of LAB

Starter cultures for sourdough fermentation are pure cultures of dried or freeze-dried LAB, or a mixture of LAB and sourdough yeast. They should be mixed with flour and water, and kept for several hours for multiplication and fermentation of the microflora. This fermented dough can then be used as a sourdough. The microorganisms have been selected due to their ability to acidify dough in a short time and result in acceptable bread flavor when used in bread baking. Cultures containing *Lactobacillus sanfranciscensis*, *L. plantarum*, *L. brevis* and *L. fructivorans* or *L. brevis*, *L. pontis* and *Saccharomyces cervisiae* are available [35]. Use of defined starter cultures with specific properties gives rise to new interesting opportunities for controlling and regulating of the sourdough fermentation. The term "starter culture" is sometimes used in the literature for a mature sourdough which has to be mixed with flour and water to ferment, or for commercial sourdoughs.

C. Sourdough Parameters

A sourdough can be characterized by the chemical parameters pH, content of total titratable acids (TTA), content of lactic and acetic acid, and the microbial parameters such as number and species of LAB and yeast. The microbial parameters are described in the following section.

The final pH of a mature sourdough is 3.5–3.8 in most rye and wheat sourdoughs [3,36,37]. Sourdough pH values show less variation and differences than TTA values. The TTA values in sourdoughs are dependent on the fermentation temperature, extraction rate of the flour, and the water content. In wheat sourdoughs, TTA has been found to vary between 8 and 11 in sourdoughs made from low extraction flour and 16 to 22 in wholemeal sourdoughs [3,38]. Rye sourdoughs are often made from flours with higher extraction rate than wheat flour and TTA values vary between 15 and 26 [21,36].

The content of lactic and acetic acid in sourdoughs is very important for the taste and flavor of the sourdough bread [31,39]. The fermentation quotient (FQ), the molar ratio between lactic and acetic acid, is used as a measure in German studies of sourdoughs for the balance in production of those acids. The FQ should be around 4 in sourdough to result in a harmonic taste of bread. A low content of acetic acid results in a high FQ with a too little flavor, whereas a low FQ results in too strong an acid flavor [21]. However, acetic acid has a more efficient antimicrobial effect against mold- and rope-producing bacteria compared to lactic acid [40].

III. MICROBIOLOGY OF SOURDOUGH

The microflora of the sourdoughs includes adapted LAB and yeasts that have optimal conditions for growth and fermentation similar to the conditions for the sourdough (temperature, water content, pH), and which probably produce antimicrobial compounds [41]. The microflora in bakery sourdoughs remains remarkably stable in spite of the use of non-aseptic fermentation conditions [20,23,34,42]. The LAB and yeasts isolated and identified from wheat and rye sourdoughs are listed in Tables 183.3 and 183.4, respectively.

Early systematic studies of the microflora responsible for the sourdough fermentation were made on sourdoughs from Germany by Hollinger in 1902, from Russia by Seliber in 1939 (cited in [43]), and from Denmark by Knudsen in 1924 [19]. Spicher and co-workers have carried out many profound investigations concerning the identification of the microflora from different types of sourdoughs, both adapted sourdoughs from bakeries and in commercial starter cultures for sourdough [4,21]. Recent investigations on sourdough fermentation have mainly dealt with interactions between sourdough microorganisms, identification of new species, inhibitory substances of sourdough LAB, and induced specific enzymatic activities.

LAB are mainly responsible for the acidification of the sourdough, whereas the sourdough yeasts are very

important for the production of flavor compounds and for a harmonic bread flavor in combination with the acids. The levels of LAB in sourdoughs are 10^8–10^9 cfu/g and yeasts are 10^6–10^7 cfu/g, respectively [4]. The LAB: yeast ratio in sourdoughs is generally 100:1.

A. Lactic acid Bacteria

1. Identification

LAB are a group of Gram-positive bacteria, which are catalase-negative, non-motile nonspore-forming rods or cocci which produce lactic acid as the major end product during the fermentation of carbohydrates. They are strictly fermentative, aero-tolerant or micro-aerofile, acidophilic, salt-tolerant and have complex nutritional requirements for carbohydrates, amino acids, peptides, fatty acids, salts, nucleic acids derivates and vitamins [44,45].

The LAB have traditionally been classified taxonomically into different genera based on colony and cell morphology, sugar fermentation, growth at different temperatures, configuration of lactic acid produced, ability to grow at high salt concentration, acid tolerance or cell wall analyses [46]. Genera of LAB identified from sourdoughs are *Lactobacillus*, *Leuconostoc, Pediococcus* and *Streptococcus*, and the majority of the sourdough LAB belongs to the genus *Lactobacillus*. The taxonomy of LAB is still under revision. *Lactobacillus* have been divided into three groups according to their carbohydrate fermentation patterns [46]:

- Obligately homofermentative LAB:
  Hexoses are almost completely fermented to lactic acid (>85%) by the Embden-Meyerhof-Parnas (EMP) pathway. Fructose is also fermented, but neither gluconate nor pentoses are fermented.
- Facultatively heterofermentative LAB:
  Hexoses are almost completely fermented to lactic acid by the EMP pathway. Pentoses are fermented to lactic acid and acetic acid by an inducible phosphoketolase.
- Obligately heterofermentative LAB:
  Hexoses are fermented to lactic acid, acetic acid (ethanol) and CO_2. Pentoses are fermented to lactic and acetic acid. In general, both pathways involve phosphoketolase.

Lactobacillus isolated from sourdoughs are divided into the three groups shown in Table 183.5. When the LAB are only divided as homofermentative or heterofermentative LAB, the facultative heterofermentative LAB are grouped as homofermentative due to the fermentation pathway of glucose (Tables 183.3 and 183.4).

In the presence of oxygen or other oxidants increased amounts of acetate may be produced at the expense of lactate or ethanol [45]. Various compounds such as citrate, malate, tartrate, quinolate and nitrate may also be metabolized and used as energy sources or electron acceptors [44,45].

The techniques used for classification of LAB are not reliable for many LAB, and they have often led to misidentification [47]. Some organisms badly grow on laboratory media and may escape isolation and can therefore not be identified by standard procedures. For rapid classification, a set of molecular probes was developed. These include hybridization- and PCR based techniques as well as recognizing specific sequences in the ribosomal genes [47]. Nevertheless, the use of probes at the species level is restricted, as their specificity may be lost during discovery of new species sharing the same part of an RNA sequence [48]. Alternatively, the taxonomic method Random Amplified Polymorphic DNA (RAPD) allows elucidation of strain biodiversity below the species level, and the resulting electrophoretic patterns can be clustered and compared to a database [48]. The consequent application of 16S rRNA sequence analysis and DNA-DNA hybridization experiments have led to identification of many new species. *L. pontis* [49] and *L. panis* [50] were isolated from rye sourdoughs, and *L. paralimentarius* [51] was isolated from wheat sourdough. Recently described species isolated from sourdoughs are *L. frumenti* [52] and *L. mindensis* sp. *nov* [53].

2. Occurrence

Heterofermentative LAB play a major role in sourdough fermentation compared to other fermented food systems. *L. sanfranciscensis* (former names *L. brevis var. lindneri* and *L. sanfrancisco*) is by far the most dominant LAB in both wheat and rye sourdoughs (Tables 183.3 and 183.4). *L. brevis* and *L. plantarum* also occur frequently in both types of sourdoughs. Some strains initially classified as *L. brevis* were renamed as *L. pontis* [49]. Several other *Lactobacilli* have been identified from rye sourdoughs e.g., the homofermentative *L. acidophilus, L. alimentarius*, *L. amylovorus*, *L. casei, L. delbrueckii, L. farciminis, L. leichmanii, L. rhamnosus*, and recently *L. mindensis*, and the heterofermentative *L. büchnerii, L. cellobiosus, L. curvatus, L. fructivorans, L. fermentum, L. viridescens* including the new identified species *L. panis*, *L. frumenti* and *L. pontis*. Strains of *L. pontis* utilize only a very limited number of carbohydrates and they are found in close association with *L. sanfranciscensis*, from which they are difficult to separate physically.

Fewer different *Lactobacilli* have been identified from wheat sourdoughs, such as *L. alimentarius, L. casei, L. cellobiosus, L. curvatus L. delbrueckii, L. farciminis, L. fermentum L. lactis* and the recently identified *L. paralimentarius* (Table 183.4). However, the homofermentative *Pediococcus* and *Weissella* and the heterofermentative *Leuconostoc* have also been isolated from wheat sourdoughs.

[a] when fermented; [b] FDP fructose-1,6-diphosphate; [c] inducible by pentoses.

The table is modified after Kandler and Weiss,1986 [46].

Former names of some of the bacteria: [d] *L. brevis* spp. *lindneri* and *L. sanfrancisco.*

The variation in the composition of the microflora depends on the fermentation conditions such as flour type, extraction rate, water content, fermentation temperature, fermentations time and how the sourdough is refreshed. Most sourdoughs are fermented about 30°C, but *L. delbrueckii* has been isolated from rye sourdoughs with a fermentation temperature above 50°C [18,27]. Hammes, Stolz, and Gänzle [35] found that the most predominant LAB in firm sourdoughs with fermentation temperature between 23 and 30°C are *L. sanfranciscensis* and *L. pontis*. However, *L. fructivorans*, *L. fermentum* and *L. brevis* were also identified from this type of sourdough.

Some industrial sourdoughs are characterized by high water content to fluid conditions (suitable for pumping), elevated fermentation temperature (>30°C), and shorter fermentation time (15–20 hours). Fluid sourdoughs can be produced in large volumes — often by continuous fermentation systems, and they can be cooled for storing in silos up to one week. The microflora in this type of sourdough is dominated by *L. panis* [50], *L. reuteri, L. sonfranciscensis* and *L. pontis* [35]. The development of sourdough yeast is poor in fluid sourdoughs and consequently it is necessary to add baker's yeast is to the bread dough.

Sourdoughs kept at ambient temperature will continue acidification. The LAB are sensitive to low pH in longer time and the LAB will thus die off. Therefore dried sourdough preparations are preferred for commercial sourdough samples. However, LAB are rather sensitive to preservation by drying, and LAB present in commercial sourdoughs must survive drying. *L. plantarum*, *L. brevis*, *Pediococcus pentosaceus* have been identified from dried commercial sourdough preparations, and dried starter cultures containing strains of *L. sanfranciscensis* have only recently become commercially available [35].

B. Yeast in Sourdoughs

Several species of yeasts have been isolated from bakery and commercial sourdoughs. However, the taxonomy of yeasts has been gradually changed since the 1970s, and various synonyms have been used (Table 183.6). The traditional systematization and identification of yeasts have been based on biochemical tests as well as morphological and physiological criteria [54], but imperfect fungi cannot be studied using traditional genetics. New molecular characteristics have defined and changed the taxonomy of yeasts [55]. The physiological features of industrial yeasts have been shown to alter when changes occur in growth conditions, and species of *Saccharomyces cerevisiae*, *S. exiguous* and *Torulopsis delbrueckii* have been found to intermix genetically with each other [55].

The most frequently isolated yeast species from rye and wheat sourdoughs are *S. cerevisiae* (Tables 183.3 and 183.4). Other yeast species often isolated from sourdoughs are *S. exiguus, Candida milleri (C. holmii)*, *C. krusei* (*Issatchenkia orientalis*). The yeast species *Pichia saitoi*, *P. norvegensis* and *Hansenula anomala* and some *Saccharomyces* spp. have occasionally been isolated from sourdoughs.

TABLE 183.6
Yeasts Isolated from Sourdoughs and Their Synonyms

Perfect Fungi	Imperfect Fungi	Synonyms
Saccharomyces cerevisiae		
S. exiguus	*Candida holmii*	*Torulopsis holmii*
		Torula holmii
		S. rosei
	Candida milleri	*Torulopsis holmii*
S. delbrueckii		*Torulaspora delbrueckii*
S. uvarum		*S. inusitatus*
Issatchenkia orientalis	*C. krusei*	*S. krusei*
		Endomyces krusei
Pichia anomala	*C. peliculosa*	*Hansenula anomala*
P. membrafaciens	*C. valida*	
P. norvegensis

P. satoi		
Endomycopsis fibuligera		*S. fibuliger*

C., Candida; P., Pichia; S., Saccharomyces.
The table is modified after Kurtzman and Fell [128] and Barnett, Payne and Yarrow [129].

Candida spp. are members of *Deuteromycetes* (fungi imperfect), because they have lost their ability to undergo sexual development. *C. milleri* is a non-sporulating form of *S. exiguous* and was first described by Yarrow in 1978 [56]. *C. milleri* is physiological similar to *C. holmii*, but is different according to DNA identification. Some strains identified as *Torulopsis holmii* in the literature before 1978 have subsequently been assigned to *C. milleri* [55].

T. holmii and *S. cerevisiae* were the dominating yeasts in bakery rye sourdoughs from Finland, whereas *S. cerevisiae* dominated in rye sourdoughs used for home baking [57]. A later study showed that the yeasts isolated from rye bakery sourdoughs in Finland were similar to *C. milleri* [55]. Wlodarczyk [25] found that *S. cerevisiae* accounted for 99% of all yeasts found in starters from three industrial rye bread bakeries in Poland, whereas the sourdoughs from the smaller bakeries contained a wider range of yeast strains.

Traditional Portuguese sourdoughs prepared from maize and rye were dominated by *S. cerevisiae* and *Torulaspora delbrueckii* [58], and *S. cerevisiae* and *C. pelliculosa* [28], respectively. *S. cerevisiae* was also the

dominating yeast in wheat sourdoughs from Italy, followed by *S. exiguous*, *C. krusei*, *P. norvegensis* and *Hansenula anomala* [59]. Addition of baker's yeast is widely used in some Italian wheat sourdoughs [7], whereas many sourdoughs are also prepared without sourdoughs [60].

The yeasts present in sourdoughs are generally acid-tolerant. Strains of baker's yeast *S. cerevisiae* have poor tolerance of acetic acid in sourdoughs [61], whereas strains of *S. cerevisiae* isolated from sourdoughs can grow on MYGP broth acidified with acetic acid to pH 3.5 [37].

C. Microbial Interactions

The high stability of sourdoughs used for a longer period might be caused by production of inhibitory substances [41], but also microbial interaction between the LAB and the sourdough yeasts are of importance. Several sourdough LAB produce inhibitory substances against spoiling microorganisms. These compounds are organic acids in particular acetic acid, carbon dioxide, ethanol, hydrogen peroxide, and diacetyl [62]. The inhibition, however, can also be caused by bacteriocins that are low molecule-mass peptides, or proteins, with a bactericidal or bacteriostatic mode of action, in particular against closely related species [41].

Microbial interaction was demonstrated early for the Sanfrancisco sourdough. The sourdough yeast *T. holmii (C. millery)* does not assimilate maltose [34,63], whereas *L. sanfrancisco* hydrolyses maltose and excretes one of the glucose molecules to be used for the sourdough yeast [64]. The glucose uptake of the yeast cell can induce an outflow of amino acids, and this liberation of amino acids has made growth of *L. sanfranciscensis* possible even in a medium initially deficient in essential amino acids [65]. Several LAB increase the acidification of sourdoughs when the sourdough are added to the sourdough yeasts *T. holmii* or *S. cerevisiae* [63,66]. However, LAB might also multiply more slowly and decrease the production of acids in mixtures with yeasts [67].

A real risk of bacteriophage contamination of sourdoughs exists as bacteriophages with activity against *L. fermentum* have been isolated from an Italian sourdough [68].

IV. TECHNOLOGICAL ASPECTS

A. Production of Sourdough

Sourdough can be made with variations in the following parameters: flour type — wheat/rye, flour extraction rate, flour/water ratio, temperature, time and amount of starter. Sourdough can also be made in one to three steps. The one-stage process is the basic way to make a sourdough and is widely used. Two- and three-step sourdoughs have traditionally been used in rye bread production in many German bakeries [21]. Industrialization in bakeries has also included the sourdough production, where the time consuming multiple-stage processes have changed to the work-saving one-stage process. Traditional rye sourdoughs have often been based on firm sourdoughs, but in automated large scale bakeries firm sourdoughs are difficult to handle, and they have been replaced by pumpable semi-fluid to fluid sourdoughs which are suitable for automated fermentation systems. Today, continuous fermentation plants are used in many bakeries in Europe. The following deals with how sourdough fermentation can be influenced by the flour type, flour extraction rate, fermentation temperature, water content in sourdough, and by the amount of added ripe sourdough.

B. Flour Type

The flour in the sourdough is the substrate for the fermenting microorganisms. Wheat and rye flour are mostly used for sourdough making, but maize flour can also be used [28,69]. The amount of fermentable carbohydrates in the flour varies with the type of cereal, but in particular with the activity of endogenous enzymes in the flour. The activities of amylases, xylanases and peptidases are important for liberation of the fermentable low molecular weight carbohydrates and amino acids. On dough stage, the α-amylase can not degrade intact starch granules, but some granules are damaged during the milling process and may be partly degraded in the dough.

Starch is generally not degraded by LAB, and the content of fermentable mono- and disaccharides in rye flour is up to 5% with maltose (3%) as the main part [70]. Savola found that this content of free sugars decreased by 3% during sourdough fermentation. However, Henry and Saini [71] found only small amounts of low molecular weight sugars in rye (0.7% sucrose and $< 0.1\%$ of glucose, fructose, raffinose and stachylose). The content of pentosans (arabinoxylans) in rye flour is high (6.5 to 12.2%) [72] compared to wheat flour (2–3%) [73], and they can be degraded to the pentoses xylose and arabinose by the corresponding enzymes during the bread making processes [74].

The content of fermentable carbohydrates in wheat flour is 1–2% [67,75]. The content of maltose increased during the sourdough fermentation from 1.5 to 2.4%, and the content of fructose from 0.05 to 0.45% in a sourdough fermented with *Lc. mesenteroides* [75]. The content of glucose was unchanged at the level of 0.17% as a result of a balance between bacterial consumption and hydrolysis by the enzymatic activity. No sucrose was detected in the samples, so the increase in fructose could not be caused by yeast invertase.

Most *Lactobacillus* isolated from sourdoughs are non-amylolytic, but amylolytic strains have been isolated from African fermented cereal products made from maize such as ogi, mawé and kunu-zakki [76].

1. Extraction Rate

The extraction rate of the flour is one of the most important factors for determining the character of sourdough [77,78]. With a high extraction rate (80–100%), the content of nutrients such as B-vitamins and minerals increases compared to low extraction rate flour (65–75%), as does the buffering capacity of the flour primarily due to the phytic acid from the aleurone layer of the cereals. These factors can stimulate the growth and biochemical activity of the microflora in the sourdough followed by a higher production of acids and flavor compounds. Rye flours have a generally higher extraction rate than wheat flours.

A linear relationship between ash content and TTA was found in wheat sourdough. The final TTA in sourdoughs made from wholemeal flour (ash 1.5%) was almost double the value compared to sourdoughs made from straight-grade flour (ash 0.55%), and the final pH was reached in less time in sourdoughs made from the low extraction flours [3].

C. Water Content

The water content in the sourdough determines the firmness of sourdoughs, and it can be expressed as the dough yield (DY), which is the amount of sourdough per kg per 100 kg flour. DY varies from 150 in firm sourdoughs to 300 in fluid sourdoughs. The development in TTA is lower in fluid rye sourdoughs compared to firm sourdoughs, but if the acidity is measured per gram dry matter it will be lower in firm sourdoughs [21,36]. This indicates that the nutrients are better used by the LAB in fluid sourdoughs compared to firm sourdoughs. The production of lactic acid is not influenced by the DY, whereas the production of acetic acid is generally lower in fluid sourdoughs [21,36]. The water content in sourdoughs influences the acidification of the dough more than the temperature [79].

The content of LAB was not influenced by the firmness of rye sourdoughs, whereas the yeast propagation was low in the firm sourdoughs with levels below 10^3 cfu/g in six of the seven sourdoughs [36]. However, a surface layer of yeast cells was seen on the firm sourdough fermented with *L. plantarum*.

D. Temperature

The temperature of the sourdough is influenced by the temperature of the flour, the water and the mother sponge, and it is often adjusted and regulated by the water temperature. In practice, the temperature increases 6 to 8°C during industrial fermentation, if the temperature is not thermostatically regulated. So it is important that the temperature of the water is not too high. The temperature of the sourdough greatly influences the microbial propagation and production of acids, as the optimal temperature for growth and acidification varies for the different species of LAB. Spicher [80] found that the lowest generation time was 20 min for *L. brevis* at 35°C and *L. plantarum* at 40°C, and 60 min for *L. fructivorans* at 30°C and *L. fermentum* at 40°C. Changes in the fermentation temperature from the optimal conditions increased the generation time considerably, and the generation time for *L. fermentum* was prolonged to 120 min at 40°C and 140 min at 25°C.

The optimum temperature for growth of the LAB is close to the optimal temperature for acid production, and most LAB have temperature optima between 30 and 35°C [21]. In general, the final pH is reached more quickly at higher temperatures (30–35°C) compared to lower temperatures (20–25°C) [21,79,81]. Some species, mostly heterofermentative, can grow below 15°C, such as *L. farciminis, L. plantarum, L. rhamnosus, L. brevis, L. fructivorans, Lb. sanfranciscensi*. The highest temperature for growth is between 45 and 55°C and most species which can tolerate high temperatures are homofermentative, such as *L. acidophilus, L. amylovorus, L. delbrueckii*. However, also the heterofermentative species of *L. pontis, L. rhamnosus, L. fermentum* and *L. reuteri* can grow above 45°C [45].

The optimum temperature for growth of sourdough yeasts has not been intensively investigated, but it seems to be lower than for the LAB. The optimum temperature for growth of *C. milleri* was determined to be 27°C [44], while *C. milleri* and *S. exiguous* do not grow at temperatures above 35°C [56]. The minimum temperatures for growth of LAB and yeast are important when sourdoughs are stored by cooling, as the sourdough should not develop during the storage. The minimum temperature for growth of most sourdough yeasts has been found to be 8°C [55].

The content of acids produced in sourdough increases with increased fermentation temperature due to higher production of lactic acid, whereas the production of acetic acid is only negligible influenced by the temperature [21,81]. This confirms the general rule that the relative content of acetic acid is higher in cold sourdoughs compared to warmer sourdoughs [21].

Investigation of the influence of the fermentation temperature on the production of flavor compounds in rye sourdoughs showed that the starter cultures themselves produced few volatile compounds, whereas the production of iso-alcohols and ethyl acetate increased considerably with higher temperature in sourdoughs fermented with homofermentative LAB due to activity by the propagating yeasts [81].

E. Amount of Mother Sponge

The amount of mother sponge to be mixed with flour and water for a new sourdough should be so high that the content of LAB in the sourdough is able quickly to decrease the pH to inhibit the growth of the gram-negative bacteria in the flour. The amount of mother sponge influences the pH-lowering capacity in a sourdough, as low pH is

reached more quickly when the amount of added mother sponge is high [79]. However, higher levels of acids are produced when a lower amount of mother sponge is added, as the fermentation time is longer before the pH drops to the critical pH level [20]. The recommended amount of mother sponge is generally 10–20% for both rye and wheat sourdoughs [21,79]. The Sanfrancisco sourdough is rebuilt every eight hours or at least two to three times a day, seven days a week. The amount of mother sponge used in preparing a new sourdough is 25–40% of the sourdough [15]. This high amount of mother sponge makes the sourdough very stable, and this sourdough has been continued for more than a century.

V. DOUGH PROPERTIES AND BREAD QUALITY

A. Dough Properties and Bread Texture

1. Wheat Dough and Bread

Incorporation of sourdoughs in wheat bread making influences the gluten proteins and the viscoelastic behavior of doughs due to the drop in pH value caused by the organic acids produced. Several investigations have shown that the addition of acid to wheat dough decreased the dough stability during mixing, and the acidified doughs became considerably softer than a non-acidified control dough [82–84].

Dough stability was also decreased when it was prepared with the addition of sourdough [85] [86]. The dough consistency was unchanged when the sourdough was fermented by a heterofermentative culture and softer if a homofermentative culture was used [86]. Proteolytic breakdown of proteins was enhanced at low pH during fermentation of wheat dough, and major effects were attributed to changes in pH rather than to microbial proteolytic activity from the sourdough [87].

In spite of the decreased stability in doughs with added sourdough increased bread volumes are reported for bread containing up to 20% sourdough [31,86]. The crumb structure of bread containing up to 20% sourdough has been comparable to standard bread without sourdough, whereas inferior crumb structure was observed in bread containing 40% sourdough [88].

2. Rye Dough and Bread

The main component of rye and wheat is starch, and its content has a crucial influence on the bread texture. It becomes sticky and pasty if the starch is degraded during the bread making due to too high activity of amylases. This problem is greater in rye bread making than for wheat bread, as the activity of the sprout-induced enzyme α-amylase is highest in rye [89]. This is caused by rainy summers in the rye-growing area. Furthermore, the period from harvest to possible sprouting is extremely short for rye; it can even sprout in the fields [89]. One of the main functions of sourdough in rye bread making is inactivation of the α-amylase activity, and a general rule in bakeries is to add a larger amount of sourdough when the activity of enzymes in the flour is high. Bread with a rye content of more than 20% normally require the addition of sourdough to prevent degradation of starch [88,90]. Rye starch begin to swell as low as 52°C and subsequently the α-amylase can degrade the starch until it will be heat-inactivated at 80°C [91] (s.169, 171). Rye α-amylase has pH-optimum at pH 5.5 [92] and the activity is totally inactivated in sourdough at pH below 4. Wassermann and Dörfner [93] found that the viscosity of rye doughs (rye flour and water) was lowest at pH 5.

The activity of α-amylase is not only reduced considerably in the sourdough, but also in the rye dough with added sourdough. The activity of α-amylase was totally inactivated in an imitated sourdough acidified to pH 3.5 (TTA 32) by lactic and acetic acid [94]. The activity of α-amylase in the bread dough after resting (pH 4.5), with 20% sourdough added, was about half the activity in the flour.

Pentosans (arabinoxylans) play a key role in the viscosity of rye doughs due to high water-binding capacity. The viscosity of sourdoughs decreases during the sourdough fermentation due to the activity of the pentosan-degrading enzymes at the beginning of the fermentation. However, those enzymes are inactivated in the fermented sourdough [94]. Rye proteins are different from wheat proteins, as they do not form gluten structure. Kratochvil and Holas [95] found that proteolytic activity in rye sourdough was caused by enzymes from the flour.

B. Flavor and Taste

The flavor of bread crumb depends mainly upon the flour type and the enzymatic reactions taking place due to yeast and sourdough fermentations, whereas the flavor of bread crust is more influenced by the thermal reactions during the baking process. Including sourdough in the bread recipe is recommended for a more aromatic bread flavour [31,96] and sourdough bread has higher content of volatile compounds [31,39,97–99] and higher scores in sensory tests [31,100,101]. The content of volatile compounds produced during sourdough fermentation depends on the flour type (wheat, rye, maize), the extraction rate of the flour, the fermentation temperature, the water content in the sourdough and the microorganisms in the sourdough. Generally, the LAB in the sourdough are mostly responsible for the acidification of the dough, and the sourdough yeasts for the production of flavor compounds. Factors that favor the propagation of yeasts will also result in higher content of yeast fermentation products.

The extraction rate of the flour and the water content in the sourdough mostly influences the acidification of the sourdough. Higher extraction rate of the flour results in

higher production of lactic and acetic acid [38,102], however, sourdoughs fermented with heterofermentative cultures have much higher content of ethyl acetate [38]. The production of acids calculated per gram dry matter is higher in fluid sourdoughs than in firm sourdoughs. Higher water content in the sourdough and increased fermentation temperature result in higher propagation of yeasts and in higher content of iso-alcohols [36,81,102].

Sourdoughs fermented with heterofermentative LAB have, aside from much higher content of acetic acid and ethanol, a higher content of ethylacetate and ethyl-hexanoate compared to sourdoughs fermented with homofermentative LAB, which have higher contents of diacetyl and some other carbonyls [36,81,102,103]. The production of acetic acid in sourdoughs can be increased in heterofermentative cultures with the addition of fructose as a hydrogen acceptor [102,104]. When sourdough yeasts are added in the preparation of the sourdough, the production of ethanol, iso-alcohols, esters and diacetyl increase considerably [37] [103].

In sourdough bread, the content of esters are very low compared to the corresponding sourdoughs [31,39]. Sensory evaluation of rye bread crumb shows that the most intense and bread-like flavor is associated with 2-propanone, 3-methyl-butanal, benzylalcohol and 2-phenylethanol [39]. However, vanillin, 2,3-butandione, 3-hydroxy-4,5-dimethyl-furanone and methylbutanoic acids also contribute to the overall crumb flavor [98]. The perceived taste of salt is enhanced in sourdough rye bread compared to wheat bread, so less salt can be added in sourdough rye bread [105].

Sensory evaluation of wheat bread crumb showed that bread made with sourdough fermented with the heterofermentative *L. sanfranciscensis* had a pleasant mild, sour odor and taste. Bread fermented with *L. plantarum* had an unpleasant metallic sour taste, but when the sourdough was also supplemented with the sourdough yeast *S. cerevisiae,* the bread acquired a more aromatic bread flavor. That bread had a higher content of methyl-butanol, methylpropanoic acids and 2-phenylethanol which may, in part, cause the more aromatic flavor [31]. Mixed cultures with both Lab and yeast are recommended for an aromatic and pleasant sourdough bread flavor [31,103,106]. A lexicon for description of the flavor of wheat sourdough bread has been developed [107].

C. Longer Shelf Life

During storage of bread, several different physical and microbiological changes occur, lowering the quality of bread. The bread crumb becomes hard, the bread crust changes from crispy to leathery, and the characteristic and favorable bread flavor disappears. All these changes are characterized for the staling process. Within few days the bread might be spoiled due to contamination and growth of molds on the surface or development of rope in the bread crumb caused by *Bacillus* spp. Addition of sourdough in the bread recipe can be used to retard the staling process of the bread, prevent the bread against ropiness and prolong the mold free period. Sourdough addition is the most promising procedure to preserve bread from spoilage, since it is in agreement with the consumer demand for natural and additive free food products.

1. Anti-Mold Activity of Sourdough Bread

Mold is the most frequent cause of bread spoilage. Addition of sourdough in the bread recipe increases the mould-free period both for rye bread [21,32] and wheat bread [78,108]. The length of mold-free period was prolonged from 4 days in wheat bread to 6 to 8 days in sourdough bread [78], or from 9 days in wheat bread supplemented with a prefermented dough to 20 days in bread supplemented with 20% sourdough [108]. No correlation was found between pH and bread shelf life.

The mold-free period was prolonged 1 to 3 days in slices of sourdough rye bread inoculated with *Aspergillus glaucus* when the sourdough was fermented with heterofermentative LAB compared to homofermentative LAB, or bread without addition of sourdough [32]. The antimicrobial effect of the heterofermentative LAB was supposed to be their production of acetic acid.

Two hundred and thirty two strains of sourdough LAB belonging to nine different species were screened for production of anti-mold substances against *Aspergillus niger*, *Fusarium graminearum*, *Penicillium expansum* and *Monilia sitophila* using agar-well-diffusion assay [109]. The anti-mold activity varied very much among the strains and was mainly detected within obligately heterofermentative LAB. *L. sanfrancisensis* had the largest spectrum of anti-mold activity. Not only the acetic acid had inhibitory effect, but the LAB produced also formic, propionic, butyric, n-valeric and caproic acid, and a mixture hereof was responsible for the anti-mold effect.

2. Prevention of Rope Spoilage

Ropiness is spoilage of wheat bread noticed as an unpleasant odor similar to that of over-ripe melons, followed by the occurrence of a discolored sticky bread crumb and sticky threads, that can be pulled from the crumb. This bread spoilage is caused by heat-resistant strains of *Bacillus* and occurs particularly in summer when the climate favors growth of the bacteria. It is mainly caused by *Bacillus subtilis,* formerly referred to as *B. mesentericus*, because the heat resistant spores can survive the baking process, sporulate and multiply in the baked bread. The rope symptoms can be recognized when the level of *Bacillus* in bread crumb is 10^8 bacillus/g [110]. Its incidence has increased during the last decade, presumably because most bread is now produced without preservatives and often with the addition of raw materials such as oat products, wheat bran and sunflower seed with a high contamination level of *Bacillus*

spores [110]. Even a low level of the heat-resistant spores (10^1–10^2 bacillus/g) in raw materials resulted in a level of 10^7 bacillus/g bread in two days.

One potential way to prevent development of rope is to include sourdough in the bread recipe. Addition of 10% sourdough inhibited the natural *Bacillus* contaminants in wheat dough, but it was insufficient to inhibit the *Bacillus* strains inoculated at a level of 10^6 spores/g [40]. Addition of 15% sourdough was more efficient as the strains of rope producing *Bacillus* were effectively inhibited by sourdough fermented by strains of *L. sanfranciscensis*, *L. brevis, L. maltaromicus* or by three different strains of *L. plantarum*. In this investigation *B. subtilis* tended to be inhibited, if the TTA value in the sourdough was more than 10 and when the pH of the bread crumb was below 4.8. Röcken [29] demonstrated that sourdough effectively decreased the heat resistance (D_{97}-value) of a rope-producing strain of *Bacillus*. He found that the heat resistance was reduced from 143 min without the addition of sourdough to 5.9 min and 6.9 min with the addition of 10% and 20% sourdough, respectively.

3. Bread Firmness and Staling Rate

Bread becomes firmer during storage, and retrogradation of starch towards a more crystalline form is considered to be the primary cause of this bread staling. Several sourdoughs have been investigated for their potential effect on delaying the development of bread firmness and staling rate of wheat bread, but most investigations did not find any influence on staling rate by the sourdough compared to yeast- and sponge-leavened bread [108,111]. However, delayed staling rate has been observed in sourdough bread [112]. The rate of starch retrogradation was not influenced if the acidification was rather low, whereas a standard sourdough (*L. sanfranciscensis* 57, *L. plantarum* 13, *S. cerevisiae* 141) was able to retard the staling rate. The staling rate was mostly influenced if the starter culture had amylolytic activity (*L. amylovorus* or a genetic modified strain *L. sanfranciscensis CB1 Amy*).

In some investigations the addition of sourdough resulted in lower bread firming. However, sourdough wheat bread has higher bread volume [31,86,88] and the measured resistance will thus be lower.

VI. NUTRITIONAL VALUE

The addition of sourdough to the bread recipe has a positive influence on the nutritive value of the bread, as the minerals become bioavailable [113], and the blood glucose and insulin responses are lowered after eating sourdough bread compared to wheat bread [114].

A. Reduced Phytate Content by Sourdough

Whole meal cereals are good sources of minerals such as K, P, Mg, Fe and Zn, but without treatment the bioavailability is poor for those minerals which are stored as phytate, an insoluble complex with phytic acid (myoinositol hexa-phosphoric acid, IP6). The content of phytate is 6 mg/g rye grain [115], 3–4 mg/g in flour of soft wheat and 9 mg/g in hard wheat flour [116]. Phytate accounts for more than 70% of the total phosphorus in cereals, and it can be degraded during the bread making process due to the activity of endogenous phytase and thus liberate the bound minerals when the ester-bound phosphoric acids are hydrolyzed. The pH-optimum of rye phytase is found to be at pH 6.0 [115].

Sourdough fermentation has been shown to be more efficient than yeast fermentation in reducing the phytate content in whole bread (−62% and −38% respectively) [113]. The prolonged fermentation with sourdough enhanced the acidification and led to increased solubility of Mg and P. Five different strains of LAB isolated from sourdoughs have been tested for their ability to degrade phytic acid, but no difference was observed among the strains in the levels of phytic acid hydrolyses [117].

B. Reduced Glycemic Response with Sourdough Bread

Conventional wheat bread products are rapidly digested and absorbed, thus giving rise to high blood glucose and insulin responses. Eating wholemeal sourdough bread resulted in both lowered blood glucose and insulin response compared to wholemeal bread made without sourdough [118]. This nutritional positive effect was possibly due to a reduced gastric emptying rate caused by the lactic acid produced during the sourdough fermentation [114].

ACKNOWLEDGMENT

The information in this chapter has been modified from "Sourdough bread," by A. S. Hansen, in *Handbook of Food and Beverage Fermentation Technology*, Editors: Y. H. Hui et al., Marcel Dekker, NY 2004.

CONTENTS

I. INTRODUCTION

The objective of food processing and preparation is to provide safe, wholesome, and nutritious food to the consumer. The responsibilities for accomplishing this objective lie with every step in the food chain; beginning with food production on the farms, and continuing through processing, storage, distribution, retail sale, and consumption. Producing safe food is a continuum, where each party has certain obligations to meet and certain reasonable expectations of the other parties involved in the process. No single group is solely responsible for producing safe food, and no single group is without obligations in assuring the safety of food.

Food producers have a reasonable expectation that the food he or she produces will be processed in such a manner that further contamination is minimized. Food producers are an integral part of the food production system, but are not solely responsible for food safety. It is not practical to deliver fresh unprocessed food that is completely free of microorganisms, whether the food in question is of animal or plant origin. The environment in which the food is produced precludes the possibility that uncontaminated food can be grown or produced. However, appropriate methods can be utilized to reduce, to the extent possible, this level of background contamination. These methods are referred to as "Good Agricultural Practices" (GAPs) (1). Alternately, producers have an obligation to use these same reasonable practices to prevent hazards from entering the food chain. As an example, when dairy cattle are treated with antibiotics for mastitis, producers have an obligation to withhold milk from those animals from the normal production lot.

Milk from these animals must be withheld for the specified withdrawal time, so that antibiotic residues will not occur in milk delivered to dairies. In contrast, production of salmonellae-free poultry in the United States has been an elusive goal for poultry producers. While it is not a reasonable expectation for producers to deliver salmonellae-free birds to poultry processors, it is reasonable to expect producers to use good livestock management practices to minimize the incidence of *Salmonella* within a flock.

Food processors have reasonable expectations that raw materials delivered to the processing facility are of reasonable quality and not contaminated with violative levels of any drugs or pesticides. In addition, processors have a reasonable expectation that processed food will be properly handled through the distribution and retail chain, and that it will be properly prepared by the consumer. The latter is particularly important, as processors have responsibility for products because they are labeled with the processor's name, even though the food is no longer under processor control once it leaves the processing facility. Processor obligations are to process raw foods in a manner that minimizes growth of existing microorganisms as well as minimizes additional contamination during processing. These obligations extend from general facility maintenance to the use of the best available methods and technologies to process a given food.

Clearly, consumers have an important role in the microbiological safety of foods. However, it is not reasonable to expect every consumer to have a college degree in food science or microbiology. Consumers have an expectation that foods they purchase have been produced and processed under hygienic conditions. They also have a reasonable expectation that foods have not been held under unsanitary conditions, or that foods have not been adulterated by the addition of any biological, chemical, or physical hazards. In addition, consumers have an expectation that foods will be appropriately labeled, so that the consumer has information available on both composition and nutritional aspects of products. These expectations are enforced by regulations that govern production, processing, distribution, and retailing of foods in the U.S. The vast majority of foods meets or exceeds these expectations, and the average consumer has relatively little to be concerned with regarding the food they consume.

Some consumers have advocated additional expectations, which may or may not be reasonable. For example, some would argue that raw foods should be free of infectious microorganisms. Initially, this would appear to be reasonable; however, in many cases technologies or processes do not exist in a legal or practical form to assure that raw foods are not contaminated with infectious agents. Two recent examples are the outbreaks of *Cyclospora* epidemiologically linked to imported raspberries and *Escherichia coli* O157:H7 in raw ground beef. With the exception of irradiation, technologies do not exist to assure that either of these foods would be absolutely free of infectious agents while still retaining desirable characteristics associated with raw food. Therefore, in some cases, the expectation that raw foods should be free of infectious agents may not be reasonable.

Consumers have several obligations regarding food safety. As part of the food production to consumption chain, consumers have similar obligations to food processors. Namely, not holding foods under unsanitary conditions prior to consumption and not adulterating foods with the addition of biological, chemical, or physical agents. Improper food handling can increase foodborne illness risks by allowing infectious bacteria to increase in numbers or by allowing for cross contamination between raw and cooked foods. In addition, consumers have an obligation to use reasonable care preparing foods for consumption, as do personnel in food service operations. As an example, consumers should cook poultry until it is "done" (internal temperature at or above 68°C) to eliminate any concerns with salmonellae.

Consumer education on the basics of food safety in the home should be a priority. Every consumer should understand that food is not sterile, and the way food is handled in the kitchen may affect the health of individuals consuming it. Although our long-term goal is to reduce or eliminate foodborne disease hazards, in the near term we need to remind consumers of what some of the potential risks are and how consumers can avoid them. In the end, it is the consumer who decides what they will or will not consume.

II. ADMINISTRATIVE REGULATION

Several regulatory groups are involved in the regulation of food safety and quality standards, from local and state agencies to international agencies. Since there is tremendous variation within and between local and state agencies, this discussion will be confined to the national and international agencies that regulate food. At the national level, two federal agencies regulate the vast majority of food produced and consumed in the United States; namely, the U.S. Department of Agriculture (USDA) (2) and the Food and Drug Administration (FDA) (3).

A. U.S. Department of Agriculture

USDA has responsibility for certification, grading, and inspection of all agricultural products. All federally inspected meat and meat products, including animals, facilities, and procedures, are covered under a series of meat inspection laws that began in 1906 and have been modified on several different occasions, culminating in the latest revisions in 1996 (4). These laws cover only meat that is in interstate commerce, leaving the legal jurisdiction of intrastate meats to individual states. In the states

that do have state inspected meats, in addition to federally inspected meats, the regulations require that the state inspection program be "equivalent" to the federal program. Key elements in meat inspection are examination of live animals for obvious signs of clinical illness and examination of gross pathology of carcasses and viscera for evidence of transmissible diseases. The newest regulations also require the implementation of a HACCP system and microbiological testing of carcasses after chilling. Eggs and egg products are also covered by USDA inspection under the Egg Products Inspection Act of 1970 (5). This act mandates inspection of egg products at all phases of production and processing. USDA inspection of meat processing is continuous; that is, products cannot be processed without an inspector or inspectors present to verify the operation.

B. U.S. Food and Drug Administration

FDA has responsibility for ensuring that foods are wholesome, safe, and have been stored under sanitary conditions, as outlined by the Food Drug and Cosmetic Act of 1938. This act has been amended to include food additives, packaging, and labeling. The last two issues relate not only to product safety and wholesomeness, but also to nutritional labeling and economic fraud. FDA is also empowered to act if pesticide residues exceed tolerances set by the U.S. Environmental Protection Agency. Unlike USDA inspection, FDA inspection is discontinuous, with food processing plants being required to maintain their own quality control records while inspectors themselves make random visits to facilities.

C. Milk Sanitation

Perhaps one of the greatest public health success stories of the 20th century has been the pasteurization of milk. The U.S. Public Health Service drafted a model milk ordinance in 1924, which has been adopted by most local and state regulatory authorities and has become known as the Grade A PMO (Pasteurized Grade A Milk Ordinance) (6). This ordinance covers all phases of milk production, including but not limited to animal health, design and construction of milk processing facilities, equipment, and most importantly, the pasteurization process itself. The PMO sets quality standards for both raw and processed milk, in the form of cooling requirements and bacteriological populations. The PMO also standardizes the pasteurization requirements for fluid milk, which ensures that bacteria of public health significance will not survive in the finished product. From a historical perspective, it is interesting to note that neither the public nor the industry initially embraced pasteurization, but that constant pressure from public health officials finally succeeded in making this important advance in public health almost universal.

D. International Administration

The Codex Alimentarius Commission, created by the Food and Agriculture Organization and the World Health Organization, has the daunting task of implementing food standards on an international scale (7). These standards apply to both general and specific food categories and also set limits for pesticide residues in foods. Acceptance of these standards is voluntary and at the discretion of individual governments, but acceptance of the standards requires that the country apply them equally to both domestically produced and imported products. The importance of international standards is growing daily as international trade in food expands. Many countries find that they are both importing and exporting foods, and a common set of standards is critical in establishing trade without the presence of non-tariff trade barriers.

III. PRE-REQUISITE PROGRAMS

In order to achieve the goal of producing a safe food product, food processors should have in place a variety of fundamental programs covering the general operation of the process and the processing facility. These programs are considered "pre-requisites," as without these basic programs in place, it is impossible to produce safe and wholesome foods, irrespective of the available technology, inspection process or microbiological testing. These pre-requisite programs fall generally under the term "good manufacturing practices" (GMPs), but also include sanitation, equipment and facility design, personal hygiene issues, and pest control.

A. Good Manufacturing Practices (GMPs)

GMPs cover a broad range of activities with the food-processing establishment. Although there is general guidance in the Code of Federal Regulations (8), GMPs are established by the food processor, and are specific to their own operation. There is also general guidance on GMPs available from a variety of organizations representing specific commodities or trades. Specific applications of GMPs are discussed in the following sections, but GMPs also apply activities that affect not only the safety of the product, but also the quality. As an example, a refrigerated holding or storage temperature may be set by a GMP at a point below that which is actually required for product safety, but is set at that point for product quality reasons. Conversely, if a raw material or partially manufactured product, which under normal circumstances would be kept refrigerated, were subsequently found to be at a higher temperature, it would be deemed to be out of compliance with the GMP.

GMPs may also focus on the actual production processes and controls within those processes. GMPs may be viewed as rules that assure fitness of raw materials and

ingredients, rules that maintain the integrity of processed foods, and rules to protect the finished product (foods) from deterioration during storage and distribution. Other GMPs may address the presence of foreign materials in the processing area, such as tramp metal from equipment maintenance or broken glass from a shattered light bulb. These GMPs are established to provide employees with specific guidance as to the company's procedures for addressing certain uncommon but unavoidable issues.

While GMPs by their nature cover broad areas of operation, the individual GMP is usually quite specific, presenting complete information in a logical, step-wise fashion. An employee should be able to retrieve a written GMP from a file, and should be able to perform the required GMP function with little or no interpretation of the written material.

B. Training and Personal Hygiene

Personnel who are actually involved in food processing operations should also understand the necessity for proper cleaning and sanitation, and not simply rely on the sanitation crew to take care of all issues. In addition, all employees must be aware of basic issues of personal hygiene, especially when they are in direct contact with food or food processing equipment. Some key elements, such as hand washing and clean clothing and gloves, should be reemphasized on a periodic basis. An important aspect of this is an emphasis on no "bare handed" contact with the edible product, using utensils or gloves to prevent this from occurring. This information has been outlined by the U.S. Food and Drug Administration in the Good Manufacturing Practices section of the Code of Federal Regulations (8).

C. Pest Control

Pests, such as insects and rodents, present both physical as well as biological hazards (10). While the consumer would undoubtedly object to the proverbial "fly in the soup," the concerns with the introduction of biological hazards into the foods by pests are even greater. Integrated Pest Management (IPM) includes the physical and mechanical methods of controlling pests within the food processing environment and the surrounding premises. At a minimum, the processing environment and the area surrounding the processing plant should be evaluated by a competent inspector for both the types of pests likely to be present, and the potential harborages for such pests. A comprehensive program should be established that addresses flying insects, crawling insects, and rodents, the objective of which being to prevent access to the processing environment. Given that it is impossible to completely deny pest access to the processing environment, internal measures should be taken to reduce the numbers of any pests that enter the processing area. Since it is undesirable to have poisonous chemicals in areas surrounding actual food production, active pest reduction methods should be mechanical in nature (traps, insect electrocuters, etc.).

Record keeping is an important aspect of pest management. Documentation of pest management activities should include maps and maintenance schedules for rodent stations, bait stations, insect electrocutors, an inventory of pesticides on the premises, and reports of inspections and corrective actions. There should be standard operating procedures for applying pesticides, and they should only be applied by properly trained individuals. Many food-processing establishments contract with external pest control operators to address their pest control needs.

IV. SANITATION

Sanitation is the fundamental program for all food processing operations, irrespective of whether they are converting raw products into processed food or preparing food for final consumption. Sanitation impacts all attributes of processed foods, from organoleptic properties of the food to the safety and quality of the food itself. From a food processors perspective, an effective sanitation program is essential to producing quality foods with reasonable shelf lives. Without an effective program, even the best operational management and technology will ultimately fail to deliver the quality product that consumers demand.

Sanitation programs are all encompassing, focusing not only on the details of soil types and chemicals, but the broader environmental issues of equipment and processing plant design. Many foodborne microorganisms, both spoilage organisms and bacteria of public health significance, can be transferred from the plant environment to the food itself (11). Perhaps one of the most serious of these microorganisms came to national and international attention in the mid-1980s, when *Listeria monocytogenes* was found in processed dairy products. *Listeria* was considered to be a relatively minor veterinary pathogen until that time, and not even considered a potential foodborne agent. However, subsequent research demonstrated that *Listeria monocytogenes* was a serious human health concern, and more importantly was found to be widely distributed in nature. In many food processing plants, *Listeria* were found to be in the general plant environment, and subsequently efforts have been made to improve plant sanitation, through facility and equipment design as well as focusing more attention on basic cleaning and sanitation.

A. Sanitary Facility Design

Some of the basic considerations of food processing facility design include the physical separation of raw and processed products, adequate storage areas for nonfood items (such as packaging materials), and a physical layout that minimizes employee traffic between raw and

processed areas. While these considerations are easily addressed in newly constructed facilities, they may present challenges in older facilities that have been renovated or added on to. Exposed surfaces, such as floors, walls, and ceilings, in the processing area should be constructed of material that allows for thorough cleaning. Although these surfaces are not direct food contact surfaces, they contribute to overall environmental contamination in the processing area. These surfaces are particularly important in areas where food is open to the environment, and the potential for contamination is greater when temperature differences in the environment result in condensation (12). As an example, a large open cooking kettle will generate some steam that may condense on surfaces above the kettle. This condensate may, without proper design and sanitation, drip back down into the product carrying any dirt and dust from overhead surfaces back into the food. Other obvious considerations are basic facility maintenance as well as insect and rodent control programs, as all of these factors may contribute to contamination of food.

B. Sanitary Equipment Design

Many of the same considerations for sanitary plant design also apply to the design of food processing equipment. Irrespective of its function, processing equipment must protect food from external contamination and from undue conditions that will allow existing bacteria to grow. The issue of condensate as a form of external contamination has already been raised. Opportunities for existing bacteria to reproduce may be found in the so-called "dead spaces" within some equipment. These areas can allow food to accumulate over time under conditions that allow bacteria to grow. These areas then become a constant inoculation source for additional product as it moves through the equipment, increasing the bacteriological population within the food. Other considerations of food equipment design include avoiding construction techniques that may allow product to become trapped within small areas of the equipment, creating the same situation that occurs in the larger dead spaces within the equipment. As an example, lap seams that are tack welded provide ample space for product to become trapped. Not only does this create a location for bacteria to grow and contaminate the food product, it also creates a point on the equipment that is difficult if not impossible to clean.

C. Cleaning and Sanitizing Procedures

Cleaning and sanitizing processes can be generically divided into five separate steps that apply to any sanitation task (13). The first step is removal of residual food, waste materials, and debris. This is frequently referred to as a "dry" clean up. The dry clean up is followed by a rinse with warm (48° to 55°C) water, to remove material that is only loosely attached to surfaces and to hydrate material that is more firmly attached to surfaces. Actual cleaning follows the warm water rinse, which usually involves the application of cleaning chemicals and some form of scrubbing force, either with mechanical brushes or with high-pressure hoses. The nature of the residual food material will determine the type of cleaning compound applied. After this, surfaces are rinsed and inspected for visual cleanliness. At this point, the cleaning process is repeated on any areas that require further attention. Carbohydrates and lipids can generally be removed with warm to hot water and sufficient mechanical scrubbing. Proteins require the use of alkaline cleaners, while mineral deposits can be removed with acid cleaners. Commercially available cleaning compounds generally contain materials to clean the specific type of food residue of concern, as well as surfactants and, as necessary, sequesterants that allow cleaners to function more effectively in hard water (14).

When surfaces are visually clean, a sanitizer is applied to reduce or eliminate remaining bacteriological contamination. Inadequately cleaned equipment cannot be sanitized, as the residual food material will protect bacteria from the sanitizer. One of the most common sanitizing agents widely used in small and medium sized processing facilities, is hot water. Most regulatory agencies require that when hot water is used as the sole method of sanitization, the temperature must be at or above 85°C. While heat sanitization in effective, it is not as economical as chemical sanitizers because of the energy costs required to maintain the appropriate temperature. Chlorine containing sanitizers are economical and effective against a wide range of bacterial species, and are widely used in the food industry (15). Typically, the concentrations of chlorine applied to equipment and surfaces are in the 150 to 200 parts per million range. Chlorine sanitizers are corrosive and can, if improperly handled, release chlorine gas into the environment.

Iodine containing sanitizers are less corrosive than chlorine sanitizers, but are also somewhat less effective. These sanitizers must be used at slightly acidic pH values to allow for the release of free iodine. The amber color of iodine sanitizers can give an approximate indication of concentration, but can also leave residual stains on treated surfaces. Quaternary ammonium compounds (QACs) are noncorrosive and demonstrate effective bactericidal action against a wide range of microorganisms. These sanitizers are generally more costly and not as effective as chlorine compounds, but they are stable and provide residual antimicrobial activity on sanitized surfaces. Food processing plants will frequently alternate between chlorine and QAC sanitizers to prevent development of resistant bacterial populations or will use chlorine sanitizers on regular production days and then apply QACs during periods when the facility is not operating (for example, over a weekend).

Another element in food plant sanitation programs is the personnel who perform the sanitation operations as well as the employees who work in the processing area.

Sanitation personnel should be adequately trained to understand the importance of their function in the overall processing operation in addition to the training necessary to properly use the chemicals and equipment necessary for them to perform their duties.

V. HAZARD ANALYSIS CRITICAL CONTROL POINT SYSTEM (HACCP)

The basic concept of HACCP was developed in the late 1950s and early 1960s as a joint effort to produce food for the manned space program. The U.S. Air Force Space Laboratory Project Group, the U.S. Army Natick Laboratories, and the National Aeronautics and Space Administration contributed to the development of the process, as did the Pillsbury Company, which had a major role in developing and producing the actual food products. Since that time, the HACCP system has evolved and been refined, but still focuses on the original goal of producing food that is safe for consumption (16).

Since development, HACCP principles have been used in many different ways. However, recent interest in the system has been driven by changes in the regulatory agencies, specifically the U.S. Department of Agriculture–Food Safety and Inspection Service, and the U.S. Food and Drug Administration. USDA-FSIS recently revised the regulations that govern meat inspection to move all federally inspected meat plants to a HACCP-based system of production and inspection (4). FDA has also changed the regulations for fish and seafood, again moving this to a HACCP-based system for production (17). It is likely, given current trends by federal agencies, that most commercially produced foods will be produced under HACCP systems within the next ten years.

The goal of a HACCP system is to produce foods that are free of biological, chemical, and physical hazards (18). HACCP is a preventative system, designed to prevent problems before they occur, rather than trying to fix problems after they occur. Biological hazards fall into two distinct categories, those that can potentially cause infection and those that can potentially cause intoxications. Infectious agents require the presence of viable organisms in the food and may not, depending on the organisms and the circumstances, require that the organism actually reproduce in the food. As an example, *Escherichia coli* O157:H7 has an extremely low infectious dose for humans (possibly less than 100 viable cells), and as such the mere presence of the bacterium in foods is a cause for concern. In contrast, organisms involved in intoxications usually require higher numbers of the organism in the food to produce sufficient amounts of toxin to cause clinical illness in humans. However, some of the toxins involved in foodborne diseases are heat stable, so that absence of viable organisms in the food is not necessarily an indication of the relative safety of the food. *Staphylococcus aureus* is a good example, where it typically requires greater than 1,000,000 to 10,000,000 cells per gram of food to produce sufficient toxin to cause illness in humans (19). However, because the toxin itself is extremely heat stable, cooking the food will eliminate the bacterium but not the toxin, and the food can still potentially cause an outbreak of foodborne illness.

Chemical hazards include chemicals that are specifically prohibited in foods, such as cleaning agents, as well as food additives that are allowed in foods but only at regulated concentrations. Foods containing prohibited chemicals or food additives in levels higher than allowed are considered adulterated. Adulterated foods are not allowed for human consumption and are subject to regulatory action by the appropriate agency (USDA or FDA). Chemical hazards can be minimized by assuring that raw materials (foods and packaging materials) are acquired from reliable sources that provide written assurances that the products do not contain illegal chemical contaminants or additives. During processing, adequate process controls should be in place to minimize the possibility that an approved additive will be used at levels not exceeding maximum legal limits for both the additive and the food product. Other process controls and GMPs should also insure that industrial chemicals, such as cleaners or lubricants, will not contaminate food during production or storage (8).

Physical hazards are extraneous material or foreign objects that are not normally found in foods. For example, wood, glass or metal fragments are extraneous materials that are not normally found in foods. Physical hazards typically affect only a single individual or a very small group of individuals, but because they are easily recognized by the consumer, are sources of many complaints. Physical hazards can originate from food processing equipment, packaging materials, the environment, and from employees. Physical contaminants can be minimized by complying with good manufacturing practices and by employee training. While some physical hazards can be detected during food processing (e.g., metal by the use of metal detectors), many non-ferrous materials are virtually impossible to detect by any means and so control often resides with employees.

VI. HACCP PLAN DEVELOPMENT

Prior to the implementation of HACCP, a review should be conducted of all existing pre-requisite programs. Deficiencies ion these programs should be addressed prior to the implementation of HACCP, because a HACCP plan presumes that these basic programs are fully functional and effective. Development of a HACCP plan begins with the formation of a HACCP team (20). Individuals on this team should represent diverse sections within a given operation, from purchasing to sanitation. The team is then responsible for development of the plan. Initial tasks that the team must accomplish are to identify the food and

method of distribution, and to identify the consumer and intended use of the food. Having done this, the HACCP team should construct a flow diagram of the process and verify that this diagram is accurate.

The development of a HACCP plan is based on seven principles or steps in logical order (21). With the flow diagram as a reference point, the first principle or step is to conduct a hazard analysis of the process. The HACCP team identifies all biological, chemical, and physical hazards that may occur at each step during the process. Once the list is completed, it is reviewed to determine the relative risk of each potential hazard, which helps identify significant hazards. Risk is the interaction of "likelihood of occurrence" with "severity of occurrence." As an extreme example, a sudden structural failure in the building could potentially contaminate any exposed food with foreign material. However, likelihood of the occurrence of such an event is small. In contrast, if exposed food is held directly below surfaces that are frequently covered with condensate, then the likelihood of condensate dripping on exposed food is considerably higher. An important point in the determination of significant hazards is a written explanation by the HACCP team regarding how the determination of "significant" was made. This documentation can provide a valuable reference in the future, when processing methods change or when new equipment is added to the production line.

The second principle in the development of a HACCP plan is the identification of critical control points (CCPs) within the system. A CCP is a point, step, or procedure where control can be applied and a food safety hazard can be prevented, eliminated, or reduced to acceptable levels (18). An example of a CCP is the terminal heat process applied to canned foods after cans have been filled and sealed. This process, when properly conducted according to FDA guidelines, effectively eliminates a potential food safety hazard, *Clostridium botulinum*. Once CCPs have been identified, the third principle in the development of a HACCP plan is to establish critical limits for each CCP. These limits are not necessarily the ideal processing parameters, but the minimum acceptable levels required to maintain the safety of the product. Again, in the example of a canned food, the critical limit is the minimum time and temperature relationship to insure that each can has met the appropriate standards required by FDA.

The fourth principle, following in logical order, is to establish appropriate monitoring requirements for each critical control point. The intent of monitoring is to ensure that critical limits are being met at each critical control point. Monitoring may be on a continuous or discontinuous basis. Presence of a physical hazard, such as metal, can be monitored continuously by passing all of the food produced through a metal detector. Alternately, presence of foreign material can be monitored on a continuous basis by visual inspection. Discontinuous inspection may involve taking analytical measurements, such as temperature or pH, at designated intervals during the production day. Some analytical measurements can be made on a continuous basis by the use of data recording equipment, but it is essential that continuous measures be checked periodically by production personnel.

The fifth principle in the development of a HACCP plan is to establish appropriate corrective actions for occasions when critical limits are not met. Corrective actions must address the necessary steps to correct the process that is out of control (such as increasing the temperature on an oven) as well as addressing disposition of the product that was made while the process was out of control. A literal interpretation of the HACCP system and a CCP is that when a CCP fails to meet the critical limits, then the food product is potentially unsafe for human consumption. As a result, food produced while the CCP was not under control cannot be put into the normal distribution chain without corrective actions being taken to that product. Typically this means that the product must be either re-worked or destroyed, depending on the nature of the process and the volume of product that was produced while the CCP was out of control. This argues for frequent monitoring, so that the actual volume of product produced during each monitoring interval is relatively small.

The sixth principle in the development of a HACCP plan is verification. Verification can take many forms. Microbiological tests of finished products can be performed to evaluate the effectiveness of a HACCP plan. Alternately, external auditors can be used to evaluate all parts of the HACCP plan, to ensure that the stated goals and objectives are being met. A HACCP plan must also be periodically reviewed and updated, to reflect changes in production methods and use of different equipment. Another critical aspect of verification is education of new employees on the HACCP plan itself. As HACCP is phased in to many food-processing environments, many employees who are unfamiliar with the concepts and goals of HACCP will have to be educated on the necessity of following the plan. In one sense, USDA-FSIS regulations have guaranteed that meat processors will follow HACCP plans, as the penalty for not following the HACCP plan can be as severe as the loss of inspection at an establishment. However, HACCP is an excellent system for monitoring and improving production of food products, and many food processors will discover that HACCP plans offer many benefits, well above and beyond the legal requirements of the regulatory agencies.

The seventh principle in the development of a HACCP plan is the establishment of effective record keeping procedures. In many respects, a HACCP plan is an elaborate record-keeping program. Records should document what was monitored, when it was monitored and by whom, and what was done in the event of a deviation. Reliable records are essential from both a business

and regulatory perspective. From the business perspective, HACCP records allow a processor to develop an accurate longitudinal record of production practices and deviations. Reviewing HACCP records may provide insight on a variety of issues, from an individual raw material supplier whose product frequently results in production deviations, to an indication of an equipment or environmental problem within a processing plant. From a regulatory perspective, records allow inspectors to determine if a food processor has been fulfilling commitments made in the HACCP plan. If a processor has designated a particular step in the process as a CCP, then they should have records to indicate that the CCP has been monitored on a frequent basis and should also indicate corrective actions taken in the event of a deviation.

VII. SUMMARY

The intent of food processing is to deliver safe and wholesome products to the consumer. Basic food safety programs, including GMPs and sanitation, are the minimum requirements to achieve this goal. HACCP is a logical extension of these programs, and focuses on the prevention of hazards before they occur, rather than waiting for a failure to occur, and then addressing the problem. HACCP provides the most comprehensive approach to food safety in the processing environment, but is not foolproof. Perhaps the most challenging aspect is that, even with the best designed and implemented HACCP plan, it may not always be possible to "prevent, eliminate or reduce to acceptable levels" the pathogen of concern. This is particularly true with foods that are purchased by the consumer in their raw state, and then cooked. A specific example is *Escherichia coli* O157:H7 in ground beef. Irrespective of the preventative efforts of the processor, it is not possible to assure that the product is free of the bacterium, and there is no "acceptable level" of this organism in ground beef.

CONTENTS

I. INTRODUCTION

Microbial testing has been a concern since it was determined that microbes play an integral role in food quality and safety. One of the earliest volumes that discussed standardized testing methods was Food Adulteration and its Detection (1), which was followed by numerous other texts. Today many similar volumes are in use by a variety of regulatory agencies, industries and scientific groups. These include, but are not limited to the Food and Drug Administration's (FDA) Bacterial Analytical Manual (BAM), U.S. Department of Agriculture's (USDA) Microbiological Laboratory Guidebook (MLG), AOAC's Official Methods of Analysis and the American Public Health Association's (APHA) Compendium of Methods for the Microbiological Examination of Foods.

This chapter will briefly review some of the basic concepts surrounding food microbiology, microscopy, and testing. It will touch upon a variety of microscopy- and media-based methodologies, but will exclude antibody or enzyme linked immunosorbent assays (ELISA) and genetic-based testing.

II. MICROORGANISMS

Microorganisms are single to multi-celled microscopic living units that are generally categorized as bacteria, viruses, yeasts, molds, algae, and protozoa. Microorganisms are ubiquitous, including but not limited to humans, animals, plants, soil and water. They first appeared on earth over 3 billion years ago and have coexisted with humans providing both beneficial and detrimental consequences on our food supply (2). Of most concern for food quality and safety have been bacteria, yeasts, and molds. While other microorganisms are still significant, this chapter will focus on the aforementioned three.

A. Bacteria

Although bacteria are extremely diverse with great differences in their structural and biochemical components, they share a basic cellular organization. Bacteria are the smallest and fastest growing of all living cells. They have physical shapes that are generally classified as cocci (round) or rods. Rods can be straight, spiral, or curved in

appearance. Often, the types of morphological forms observed depend upon environmental conditions in which the bacterial cells are cultured. Depending on the conditions present, cells may differentiate into spores, a dormant state, or form actively growing cells referred to as vegetative (3). Spores, commonly referred to as endospores, are produced as a bacterial survival strategy. Some vegetative cells form spores during periods of environmental stress such as depletion of nutrients or moisture needed for growth. Spores exhibit no metabolism and are capable of withstanding adverse conditions such as heat, radiation, disinfectants, desiccation, and ultraviolet light. When optimum environmental conditions are introduced, spores germinate and form a single vegetative bacterial cell. Common spore-formers that are important to the food industry are Gram-positive members of the *Bacillus* and *Clostridium* genera (4).

B. Yeasts

Yeasts are members of a higher group of microorganisms called fungi. They are single-celled organisms of spherical, elliptical, or cylindrical shape. Their size varies greatly but is generally larger than bacterial cells. Yeasts may be divided generally into two groups according to their method of reproduction; those that reproduce by budding only (asporogenous), and those that reproduce by both budding and spore formation. Unlike bacterial spores, yeasts form spores as a method of reproduction (3).

C. Molds

Molds are filamentous, multi–celled fungi with an average size larger than both bacteria and yeasts (10×40 μm). Each filament is referred to as a hypha. Mats of hyphae that spread over a food substrate are called mycelia. Molds may reproduce either asexually or sexually, sometimes both within the same species (3).

Some mold species produce only one type of asexual spore, while others are capable of producing several types. Most mold species produce asexual spores called conidia. Some molds reproduce asexually through a process of fragmentation, in which the hyphae separate into individual cells called arthrospores. Other mold asexual spore states include zoospores or chlamydospores among others. Asexual spores may be produced in the tip of fruiting hyphae, along the length of the hyphae, or in swollen structures called sporangia. When reproducing sexually, sexual spores are produced by nuclear fission in times of unfavorable conditions to ensure survival.

III. MICROBIAL GROWTH FACTORS

There are a number of factors that affect the survival and growth of microorganisms in food and in culture media. Intrinsic factors inherent to the food include but are not limited to the following: nutrient content; water activity; pH; reduction-oxidation (redox) potential; temperature; humidity; available oxygen; biological structures; and antimicrobial constituents. These factors all play a role in the survival, growth and subsequent recovery of microorganisms (3).

A. Nutrient Requirements

Microbial growth is achieved through the synthesis of cellular components and energy from the catabolism of nutrients. All of the nutrients necessary for growth are obtained through the immediate environment of the microbial cell. Essential nutrients required for microbial growth include a carbon source such as sugar, or compounds with sugar moieties, a nitrogen source such as ammonia, nitrates or other compounds, and growth factors such as vitamins, minerals, and water. From these building blocks, microorganisms can synthesize carbohydrates, proteins, and lipids needed to produce complex cellular structures like the cell wall, membranes and organelles (4).

B. Moisture Content

Water is one of the most important factors involved in the degradation of food. Water activity (a_w) is a measure of free unbound water and is defined as the ratio of the vapor pressure of water in a food, P, to the vapor pressure of pure water, P_0, at the same temperature. Most fresh, raw food products have a_w levels of 0.98 or higher, which will support growth of most microorganisms. Generally, Gram-negative bacteria have the highest a_w requirement ranging from 0.99–0.88, while some yeasts and molds are capable of growing at much lower a_w than bacteria (4). There is a correlation between a_w, temperature, and nutrition. At any given temperature, microorganisms have a reduced ability to grow when the a_w is lowered. Also, when nutrients are present, there is an increase in the range of a_w in which microorganisms are able to survive (3).

C. pH

The term pH is defined as the logarithm of the reciprocal hydrogen ion concentration in solution. The measure of the hydrogen ion concentration, or pH, generally corresponds to the degree of acidity in a sample (5). The majority of microorganisms thrive in a neutral pH (6.6–7.5), although some microorganisms are capable of growing below a pH of 4.0 (3). Other bacteria, such as *Alicyclobacillus* spp., are known as acidophiles and grow only at lower pH levels found in acidic foods such as fruit juices.

D. Redox Potential (Eh)

The reduction–oxidation or redox potential (Eh) measures the potential difference generated by a coupled reaction in

which one substance is oxidized and the second substance is reduced simultaneously. The reduced substance gains electrons while the oxidized substance loses electrons. When electrons are transferred, there is a potential difference created which can be measured electrometrically with most pH meters (measured in millivolts or mV). Microorganisms can be grouped according to the Eh range capable of supporting growth. Aerobes grow between the range of +500 and +300 mV, facultative anaerobes grow best between +300 and −100 mV, and anaerobes are most capable of growing between +100 and −250 mV and less (2). Redox potentials are dependant on pH and are useful in determining the degree of anaerobiosis. Eh can also be estimated by using common redox dyes such as methylene blue and resazurin (5). The redox potential of a specific food can be influenced by several factors: the characteristic redox potential of the original food, the poising capacity, the oxygen tension of the atmosphere around the food and the access of the atmosphere to the food (3).

E. Temperature

Microorganisms are capable of growing over a wide range of temperatures. The simplest way of organizing these organisms is placing them in three categories: psychrophiles, mesophiles and thermophiles. Psychrophiles have an optimum growth temperature ranging from 10°C to 15°C, but can also grow well at or below 7°C and may grow at sub 0°C temperatures. These bacteria may produce spoilage or safety issues in refrigerated foods. Mesophiles grow well between 20°C and 45°C with an optimum between 30°C and 40°C. Although mesophiles are often found on foods held under refrigeration temperatures, they are usually not capable of proliferation at those temperatures. Those mesophiles that can grow under refrigeration are called psychrotrophs. Their growth is best at mesophilic temperature and very slow under refrigeration. Thermophiles require high temperatures for growth with an optimum range between 55°C and 65°C. The bacteria included in this category are of special interest in the canning industry (3). It should be noted that some microorganisms of importance to food spoilage are true psychrophiles ("cold loving") and will only grow under refrigeration conditions. An example, *Mrakia frigida*, is a fermentative yeast isolated from some spoiled, chilled fruit juices.

F. Relative Humidity

Relative humidity is important with respect to the a_w within foods and the growth of microorganisms at the surface of foods. Relative humidity and temperature have a relationship that should be carefully considered when storing foods. Generally, an inverse relationship exists in that the higher the temperature, the lower the relative humidity, and vice versa. It is important that foods under storage conditions are exposed to an appropriate relative humidity that inhibits microbial growth. The best way to prevent surface spoilage of foods such as chicken and beef is to store them at a low relative humidity (3).

G. Atmosphere

It is possible to classify microorganisms by oxygen requirements that facilitate their growth and survival. Obligate aerobes require oxygen, while facultative organisms are capable of growing in the presence or absence of oxygen. Microaerophilic organisms grow best at very low levels of oxygen. Aerotolerant anaerobes do not require oxygen for growth but are not harmed if oxygen is present. Obligate anaerobes can only grow in complete absence of oxygen and if present oxygen can be lethal (6).

There are two important atmospheric gases that exhibit antimicrobial properties. The most important is carbon dioxide (CO_2), which is commonly used as a food preservative. It has been known since 1882 that raising the CO_2 concentration in the immediate environment of fresh meat will increase the shelf life of the product (3). In a study utilizing modified atmosphere packaging with chilled storage temperatures, growth of *Aeromonas hydrophila* on fresh turkey and pork slices was strongly inhibited at 1°C, especially in those meats packaged with CO_2. No growth of *A. hydrophila* was observed on the pork or turkey at 40/60 CO_2/O_2 concentrations (7).

Ozone (O_3) is another important atmospheric gas that displays antimicrobial properties. This gas has been shown to be effective against many microorganisms. Since ozone is a strong oxidizing agent, it should not be used on foods that have high lipid contents due to the likelihood of rancidity development from the oxidized fats. In 1997, ozone was granted GRAS (generally recognized as safe) status in the United States for food use (3). While *Escherichia coli* O157:H7 can be destroyed within 20 to 50 minutes upon exposure to ozone at 3 to 18 ppm in culture media (8), its usefulness in foods is not fully realized. One reason for this may be that ozone concentration in the processing plant environment and subsequent employee exposure to the compound must be carefully monitored and controlled to ensure employee safety.

H. Biological Structures

There are many foods that have natural exterior barriers that provide protection from spoilage microorganisms. Some examples are the shells of nuts and eggs, the hides of animals, and the outer coverings of fruits and vegetables. Once these protective barriers have been compromised, the interior substances are generally susceptible to the invasion of microorganisms (3).

I. Antimicrobial Constituents

As part of the natural protection against microorganisms, many foods contain constituents such as essential oils that may have antimicrobial properties. Some examples of these

oils are eugenol in cloves and allicin in garlic. Cow's milk contains antimicrobial substances such as lactoferrin, conglutinin, and the lactoperoxidase system (3). Lactoperoxidase is an enzyme that is naturally present in raw milk, saliva, colostrums, and other natural secretions. An antimicrobial compound is formed when this enzyme reacts with thiocyanate in the presence of hydrogen peroxide. This reaction is commonly referred to as the lactoperoxidase system (4). Ground beef studies have demonstrated that the lactoperoxidase system is effective against food-borne pathogens. A broad range of food products may be treated with the lactoperoxidase system in order to prevent the growth of pathogenic microorganisms (9).

IV. SAMPLING PLANS

Since it is not practical to examine an entire lot of food for the presence or absence of microorganisms, an appropriate sampling plan must be employed. Statistical methods of population probability must be utilized to determine the number and size of sample units needed to produce statistically valid analytical results (4).

A. Attribute Plans

When shipments of food are received, very limited information may accompany the shipment about the processing methods. Attribute plans are most appropriate for this type of situation. One of the simplest ways to choose whether to accept or reject a food lot can be based upon the results from a microbiological test performed on several sample units (n). Attribute plans test for the presence or absence of a microorganism. Concentrations of microorganisms can be allocated to a specific attribute class by observing whether they are above or below a preset concentration (10).

B. Variable Plans

Unlike attribute plans, variable plans are utilized when the distribution of microorganisms is known or can be estimated. Variable plans can be considered more useful than attribute plans because they determine microbial counts instead of assigning counts to categories or ranges. The greatest advantage of variable plans is that fewer samples are required, which in turn results in a lower cost to obtain the same protection as a single attribute plan. The most significant disadvantage includes the numerous calculations involved in evaluating a lot, the multiple calculations needed for each variable, and the requirement that a probability distribution must be known or assumed for each measurement (10).

V. MICROSCOPY

One of the first steps in the identification of microorganisms is the direct examination of the isolated organism using microscopy. The organisms can be viewed live or as prepared stained isolates. The following summarizes the common types of microscopy used by researchers and the food industry.

A. Light Microscopy

The invention of the light microscope is first accredited to Antony van Leeuwenhoek in 1668. It consisted of a single lens that was moved by a screw mechanism. Today there are an enormous variety of microscopes that utilize numerous light microscopy techniques to study microbes and their environment. The light microscope has many limitations, but this form of microscopy is usually the first employed for microbiological evaluation of food and water. A light microscope consists of three essential components, the eyepiece, the objective, and an illumination source, with the last two components having the greatest influence on image quality (11). A major disadvantage of the microscopic examination of foods is that particulate matter often interferes with the observation.

B. Phase Contrast Microscopy

Presently, there are small and easily useable phase contrast microscopes that are capable of quickly identifying microbial characteristics such as morphology, motility, and spores. A limiting factor for this type of microscopy is that there must be a fairly high bacterial count, greater than 10^5 CFU/mL, before the cells would be visible. Utilizing a Petroff-Hauser cell counter or other suitable counting device, it is possible to conduct a direct microscopic count to estimate the cell density viewed with a phase contrast microscope (2).

C. Epifluorescence Microscopy

Epifluorescence microscopy or EFM is a visual set-up for a fluorescence microscope where the objective lens is used to focus ultraviolet light on the specimen and collect fluorescent light. This form of microscopy has a greater efficiency than transmitted fluorescence, in which a separate lens or condenser is utilized to focus ultraviolet light on the sample. Epifluorescence allows for fluorescence microscopy to be merged with another type of microscopy in the same device (12). A recent study comparing the effectiveness of virus enumeration using an epifluorescence microscope, transmission electron microscope, and flow cytometry demonstrated that the epifluorescence microscope displayed the greatest accuracy and precision. The epifluorescence microscope deviated less than 5% from the true and relative errors. It was also shown that an EFM is considerably more time and cost efficient than a transmission electron microscope (13).

D. Transmission Electron Microscopy

A transmission electron microscope (TEM) consists of an electron gun, which generates electrons, a series of

condenser lenses that focuses the electron beam onto the specimen, a goniometer stage that manipulates the specimen under the electron beam, another series of lenses that produces a magnified image, and a phosphor screen on which the image of the specimen being observed is projected. There are several disadvantages to TEM that restrict its usefulness. These include specimen stability in vacuum, the need for very thin samples to produce an image, and damaging effects on the specimen produced by the high current density of the electron beam (14).

E. Scanning Electron Microscopy

The scanning electron microscope (SEM) uses a thinly focused electron beam to scan the surface of a sample and produce high quality images with magnification up to 100,000X. SEM also has a large depth of field that enables the entire surface of the specimen to be focused (14). With the use of TEM and SEM, it is possible to observe the effects of various technologies to inactivate microorganisms present in foods. With these advanced microscopes, changes in the cell cytoplasm and cell membrane can be clearly observed (15).

F. Low-Voltage Field-Emission Scanning Electron Microscopy

Field-emission scanning electron microscopes (FESEM) are capable of producing clear sharp images of superior resolution to conventional SEM. One distinct advantage to FESEM is that low kinetic energy electrons are able to probe close to the specimen surface to produce high quality, low voltage images with minor electrical charging of samples. With FESEM, there is no need to introduce conducting coatings on insulating materials (16). Testing procedures for bacterial microfiltration membranes often utilize FESEM to observe entrapment of bacteria in the membrane matrix (17).

G. Variable-Pressure Scanning Electron Microscopy

A scanning electron microscope functions in high vacuum mode by scanning a focused beam of high-energy electrons over the surface of a sample. The advantage of variable pressure modes is that they allow for the microscopy of wet, oily and nonconductive specimens in their natural state without the addition of conventional sample preparation and coating (18).

H. Cryo-Scanning Electron Microscopy

The most direct approach for electron microscopy of organic material is through the imaging of fast-frozen samples. This method does not require chemical fixation and drying of artifacts that might influence results. One advantage to this method is that charged artifacts and the effects of beam damage are greatly decreased. This method is particularly suitable for high-pressure frozen samples (19).

I. Environmental Scanning Electron Microscopy

A major advantage of ESEM is that it is capable of being operated with a low vacuum in the specimen chamber. Conventional scanning electron microscopy requires a moderately high vacuum in the specimen chamber in order to avoid atmospheric interference with primary or secondary electrons. This method is termed "wet mode" imaging. This method allows the specimen chamber to be isolated from the rest of the vacuum system by valves, pressure-limiting apertures, and a large-diameter bypass tube. The most commonly used imaging gas is water vapor and is controlled by a separate vacuum pump in the specimen chamber. The electron beam of ESEM consists of primary electrons and ejects secondary electrons from the surface of the sample. As a result, the secondary electrons collide with water molecules, functioning as a cascade amplifier to deliver the secondary electron signal to the positively biased gaseous secondary electron detector (GSED). Due to the loss of electrons in this exchange, the water molecules become positively ionized and are attracted to the specimen which may be nonconductive and uncoated and acts to neutralize the negative charge produced by the primary electron beam (20).

J. Confocal Laser Scanning Microscopy

Confocal laser scanning microscopy (CLSM) has many advantages over light microscopy in that there is improved contrast at high resolution, improved resolution in fluorescent specimens, and improved depth resolution which allows for optical sectioning of the specimen being observed. Compared to transmission electron microscopy, CLSM has poorer resolution but requires less specimen preparation and is capable of relaying three-dimensional information about internal structures with greater convenience. Regarding biological applications, CLSM was mainly developed with fluorescent staining and especially for localization with fluorescent markers used to derive three-dimensional images (21). In a recent CSLM study, viable and nonviable cells of *E. coli* O157:H7 that were labeled with a fluorescent antibody were observed on fresh fruits and vegetables (22).

VI. DETECTION AND IDENTIFICATION

There are numerous methods that can be utilized for the evaluation or detection of microorganisms. They are broadly grouped as quantitative or qualitative methods. The quantitative methods are used to enumerate or to

directly or indirectly estimate the microbial load in a test sample. Some examples of quantitative methods used are aerobic plate counts, coliform counts, yeast and mold counts, direct microscopic counts, and most probable number protocols. Qualitative methods are intended to determine if a sample contains a specific microbial species amidst the total microbial population based upon a presence/absence determination. These methods are commonly used to detect the presence of certain foodborne pathogens including *Salmonella*, *E. coli* O157:H7, and *Clostridium botulinum* (2).

A. Indicator Organisms

Groups of microorganisms, such as Enterobacteriaceae, total coliforms, thermotolerant coliforms, and *E. coli*, are sometimes utilized to indicate potential contamination of food and water by enteric pathogens. Testing for thermotolerant coliforms is often used as a presumptive test for *E. coli*, which often indicates fecal contamination. Although testing for total coliforms is sometimes used as an indicator for the possible presence of *E. coli*, the usefulness of this test method is questionable since there are many coliforms that are not of fecal origin. Standard methods for the enumeration of indicator organisms rely on the use of specific microbiological media and protocols that isolate and enumerate viable cells in the sample (23).

B. Culture Media

Bacteria are differentiated using several major characteristics, including cultural requirements of each microorganism. The nutrients that each organism requires for optimal growth can be used to identify it from closely related organisms.

1. Selective Media

Many media contain selective components that prevent the growth of non-target microorganisms. Selective media are useful in the isolation of specific microorganisms from mixed populations. In many media, compounds are included as sole sources of carbon or nitrogen so that only a few types of microorganisms can proliferate. Selective toxic compounds are also frequently added to select for the cultivation of particular microorganisms. These toxic compounds are incorporated into media to suppress the growth of the background microbiota while allowing for the cultivation of the target microbe. Examples of toxic chemicals are bile salts, azide, sodium lauryl sulfate, and various dyes such as crystal violet and methylene blue (24).

2. Differential Media

The use of certain chemicals, food sources, and reagents can result in a pattern of growth or change in expression that can be used to differentiate between different types of microorganisms (23). An example of this type of media is blood agar plates. Some bacteria can hemolyze the red blood cell, resulting in a clear zone on the agar. These bacteria can easily be distinguished from microorganisms that do not produce hemolysins. In this example, the blood-agar plates serve both as a differential medium and as a source for enrichment.

3. Synthetic Media

A synthetic medium is one that is composed completely of chemically defined nutrients. Most synthetic media contain a mineral base, which provides the inorganic nutrients necessary for microbial growth. This base can then be supplemented, as required, with a carbon source, a nitrogen source, and any required growth factors. These supplements will vary with the nutritional properties of the particular organism being cultured (25).

4. Complex Media

Complex media is one that contains ingredients of unknown chemical composition. An example would be potato dextrose agar, which contains a potato extract of unknown composition. Complex media are useful for the cultivation of a wide range of microorganisms, including those whose precise growth-factor requirements are unknown. Even when the growth-factor requirements of a microorganism have been precisely determined, it is often more convenient to grow that organism in a complex medium, especially if the growth-factor requirements are numerous (25).

5. Liquid Media

Many larger-celled bacteria, protozoa, and algae are not capable of growth on solid media. Often, these microorganisms are easily isolated by the use of liquid media. The simplest procedure of isolation in liquid media is the dilution method. The sample is serially diluted into a sterile medium, with the goal being to inoculate a series of tubes with a microbial suspension so dilute that the probability of introducing even one individual into a given tube is very small. From this, if a tube shows any growth, there is a high probability that the growth resulted from the introduction of a single organism (25).

6. Enrichments

When a mixed microbial population is introduced into a liquid selective medium, competition for nutrients among that population will arise. Liquid enrichment media will select the microorganism of highest growth rate among all the members of microbial population. The resulting growth from enrichment can be greatly modified by variation of

other factors such as temperature, pH, aeration or source of inoculum (25).

7. Commercially Available Agars

Several companies market selective and differential agars targeting common pathogens. These have been used for the rapid screening of pathogens found on food. ALOA™ is a prepared selective and differential medium for the isolation of *Listeria* spp. from foodstuffs and other samples and for the presumptive identification of *Listeria monocytogenes* (26). The selectivity of the medium is due to lithium chloride and the addition of an antimicrobial mixture. The differential activity is due to the presence in the medium of the chromogenic compound X-glucoside as a substrate for the detection of beta-glucosidase enzyme, common to all *Listeria* species. The specificity is obtained by detecting the metabolism of a substrate by an enzyme (phospholipase), which is only present in the *L. monocytogenes* species. The combination of both substrates allows the differentiation of non-*monocytogenes Listeria* spp., which develop blue colonies, from *Listeria monocytogenes*, which develops blue colonies surrounded by an opaque halo.

ASAP™ is a selective medium for the isolation of *Salmonella* from foodstuffs, clinical, and environment samples. The activity of the C8-esterase, which is found in all *Salmonella* species, is detected using a chromogenic substrate. The enzymatic activity of *Salmonella* is visualized by the pink to purple coloration of their colonies.

Biolog, Inc. manufactures several types of differential media such as Rainbow® Agar O157 and Rainbow® Agar *Salmonella*. The selective and chromogenic properties of Rainbow® Agar O157 make it particularly useful for isolating pathogenic *E. coli* strains. The medium contains chromogenic substrates that are specific for two *E. coli*-associated enzymes: β-galactosidase and β-glucuronidase. Rainbow® Agar *Salmonella* utilizes a formulation designed to take advantage of H_2S production common among *Salmonella* spp. Black colonies are formed by even weak H_2S-producing strains. In addition, other compounds increase the recovery rate of *Salmonella* while inhibiting the growth of other microorganisms and inhibiting H_2S production by *Citrobacter* and other H_2S positive species (27).

Chromagenic *Shigella* spp. Plating Medium (CSPM) (28) is a selective medium (bile salts, antibiotic supplementation) that offers an alternative to differentiation methods that are based on lactose fermentation. Instead, differentiation on CSPM is based on proprietary agents consisting of select carbohydrates, pH indicators, and chromagens. *Shigella* spp., which are negative for the select carbohydrates and the chromagens, produce white to clear colonies on CSPM. Colonies of *Enterobacter* spp., *Klebsiella* spp., and *Acenitobacter* spp. are blue on CSPM, while colonies of *Citrobacter* spp. are green.

C. Culturing Methods

Almost all measurements in microbiology are method dependent. When selecting the methods to be used in the laboratory, it is vital to utilize published standard methods. Sources of standard culture methods that are commonly used by food microbiologists include the Official Methods of Analysis of AOAC International, Compendium of Methods for the Microbiological Examination of Foods published by APHA, FDA's Bacteriological Analytical Manual, and USDA FSIS's Microbiological Laboratory Guidebook.

1. AOAC

The Association of Analytical Communities (AOAC) International is a worldwide provider and facilitator in the development and use of validated analytical methods and laboratory quality assurance programs and services. Primarily, the AOAC focuses on the validation of chemical and microbiological analytical methods. AOAC International also acts as the primary source for knowledge exchange, networking, and high-quality laboratory information for its members. In order to establish these goals, AOAC International has three method validation programs: AOAC® Official Methods℠ Program®, Peer-Verified Methods℠ Program, and AOAC® Performance Tested Methods℠ Program. Methods validated by AOAC International are utilized worldwide by various governments and industries for the analysis for a variety of products, especially those related to food, agriculture, public health and safety, and the environment (29).

2. American Public Health Association Standard Methods

The Compendium of Methods for the Microbiological Examination of Foods is widely utilized by food microbiologists as a collection of standard methods for microbiological detection and enumeration techniques. It is published by the American Public Health Association and is a comprehensive and all-inclusive reference for protocols related to specific food products. The Compendium presents information on standard enumeration/detection procedures, sampling plans and analysis preparations, indicator organisms, microbiological aspects of specific food products, and methods related to specific spoilage and safety-related microorganisms.

3. Food and Drug Administration's Bacteriological Analytical Manual

FDA's Bacteriological Analytical Manual or BAM is a compilation of methods and techniques preferred by analysts in the U.S. Food and Drug Administration laboratories for the detection of pathogens in food and cosmetic

products. Methods included in the BAM have been analyzed and peer reviewed by FDA scientists and other researchers (30). BAM methods have been organized into an accessible spreadsheet format and are complimentary in the hopes of increasing awareness of microbial safety of food and water (31). These methods are available on line at http://www.cfsan.fda.gov/~ebam/bam-mm.html.

4. United States Department of Agriculture, Food Safety Inspection Service's Microbiology Laboratory Guidebook

The Microbiology Laboratory Guidebook (MLG) is a manual created by the USDA agency FSIS to aid in the microbiological analysis of meat, poultry, and egg products. The MLG contains techniques that FSIS prefers to employ for the analysis of these foods. Because USDA does not endorse or approve these techniques for use in the food industry, inclusion of a specific method in the MLG should not be interpreted in this manner (32). These methods are available on line at http://www.fsis.usda.gov/ophs/microlab/mlgbook.htm.

VII. ENUMERATION OF VIABLE CELLS

Standard plate counts, Most Probable Number (MPN), membrane filtration, plate loop methods, and spiral plating are techniques that allow for the estimation of viable cells. These methods can be successfully utilized in the food industry to enumerate fermentation, spoilage, pathogenic, and indicator organisms (6).

Several pathogens of interest such as *Salmonella*, *Campylobacter* spp., pathogenic *E. coli* and *Vibrio* spp. are not capable of sporulation; however, they may exist in a viable but non-culturable (VNC) state in which they cannot be cultured using normal microbiological techniques (4). VNC cells are typically severely injured and incapable of reproduction under standard protocols. Pathogenic *Vibrio parahaemolyticus* is known to demonstrate a VNC state when subjected to low incubation temperatures and starvation. Previously, it was unknown whether this microorganism was capable of resuscitation or if regrowth of a few remaining culturable cells occurred. Recent studies have shown that the VNC cells are capable of being resuscitated after plating onto agar containing H_2O_2-degrading compounds such as catalase or sodium pyruvate (33). It is unknown whether VNC pathogens are capable of causing illness, but there is concern that this physiological state could result in disease outbreaks from foods that have yielded false negative detection results for specific pathogens.

A. Direct Enumeration

The direct microscopic count or DMC is utilized to obtain a gross estimation of cell density that includes both viable and nonviable cells. DMC is most efficient when there are a large number of microorganisms in the sample (greater than 10^5 CFU/mL). Due to the fact that DMC cannot differentiate between live and dead cells and requires a large number of cells in the test sample, its use for food analyses is limited for quality issues in which a gross, highly variable enumeration is adequate (4).

B. Indirect Enumeration

Unlike direct enumeration of microbes by microscopy, indirect enumeration can be accomplished by plate counts or statistical estimation. The plate count technique involves spreading a sample on a nutrient agar surface or incorporation of the sample within the agar. If organisms are present and if they are plated on a suitable medium, each will grow a viable unit called a colony. Each colony-forming unit (CFU) can be counted and thus theoretically relates to the viable number of microorganisms in the sample. Statistical estimations, such as the Most Probable Number assay, are useful when the microorganisms in question need an enriched environment to grow or are in very low numbers.

1. Plate Counts

Aerobic plate counts (APC) indicate the level of microorganisms in a product. Aerobic plate counts generally do not relate to food safety hazards, but sometimes can be useful to indicate quality, shelflife and post-heat-processing contamination. The plating medium used in an APC can affect the number and types of bacteria isolated because of the variation in nutrient and salt requirements of various microorganisms (34).

The commercially available 3M Petrifilm™ plate decreases labor by eliminating the need for media preparation. Another benefit of this product is it delivers consistent easy-to-read results, creating a lesser chance for error than with conventional agar methods. There are numerous formulations that allow for several common types of microbial testing, including coliform, aerobic, *E. coli*, *Staphylococcus aureus,* and yeast and mold counts. 3M Petrifilm™ plates enable food processors to test products and equipment easily, which can assist in rapid detection and resolution of problem areas. These sample-ready microbial testing products reduce the possibility of human error in test preparation to produce consistent results (35). They have been particularly useful in field application due to the reduced need for incubator space. One disadvantage of Petrifilm™ is that samples with numerous particles may be difficult to read.

2. Most Probable Number (MPN)

The Most Probable Number or MPN is a broth dilution technique that is especially useful when establishing low

concentrations of microrganisms, specifically less than 100 per gram. The method as described in the classic paper by Oblinger and Koburger (36) has several advantages over other enumeration procedures. One advantage is that the sample is prepared to ensure that bacteria are distributed randomly and do not clump together thereby giving an equal opportunity for any one sample to contain viable cells if they are present in the food. Also, culture medium and incubation conditions are carefully chosen to encourage even one viable organism to generate detectable growth. The amount of food sample that produces growth at each dilution will suggest an estimate of the original, undiluted concentration of bacteria in the sample (30).

Isogrid is a hydrophobic grid membrane filter method utilized for the detection and quantification of target microorganisms such as *Salmonella* spp., *Listeria* spp., total *E. coli* and *E. coli* O157:H7, coliforms, *S. aureus*, yeast and mold, and total bacteria count. A sample's total bacterial count is enumerated through a membrane filter containing a grid of 1,600 squares. Diluted samples are filtered through a 5 μm stainless steel prefilter to eliminate any food particles. Samples are then filtered through a hydrophobic membrane, and the membrane is placed on Tryptic Soy Fast Green Agar (TSFGA). TSFGA is specially formulated to provide a total bacterial count. After incubation the membrane filter is examined, and all squares containing one or more green or blue colonies are counted. The total number of positive squares is converted to the corresponding Most Probable Number (MPN) determined by the Isogrid manual (37). As with Petrifilm™, samples that contain large numbers of particles may obscure the results. This system has been used for milk, meat, black pepper, flour, mushrooms, seafood, and oysters (38–41).

The SimPlate™ system includes specific formulations of media and a patented plating device. The SimPlate™ device has a broad counting range to minimize the number of dilutions needed for accurate counts. This unique combination of media and plating device offers advantages over some other techniques, including greater accuracy, ease of use, and faster time to obtain results. SimPlate™ tests are available for the quantification of total plate counts (TPC), total coliforms and *E. coli*, yeast and mold, and *Campylobacter*. Another benefit of the SimPlate™ is that positive and negative results can be easily distinguished by simply counting the number of positive wells and referring to the SimPlate™ Conversion table provided with the kit. SimPlate™ results are usually available in 24 hours, with the exception of *Campylobacter* and yeast and mold, which takes 48–72 hours, still days faster than other methods. SimPlate™ media comes pre-measured and ready to hydrate for single or multiple tests. While agar plate and film counting ranges may be limited to 300 CFU or less, SimPlate™ devices are available in two sizes with maximum counting ranges of 738 or 1659 CFU per plate. The number of dilutions and reruns are minimized, saving labor, time, and material costs (42).

VIII. METABOLIC ACTIVITY MEASUREMENT

Dye reduction tests, acid production, electrical impedance, and batteries of other metabolic assays are all used to determine cell population sizes and to identify specific isolates. The level of bacterial activity can be used to assess the quality and freshness of food products. Toxin levels can also be measured to indicate the presence of toxin producing pathogens (6). Measurable undesirable metabolites produced from the action of specific microorganisms on certain food products include histamine in canned tuna, lactic acid in canned vegetables, cadaverine and putrescine in vacuum-packaged beef, and mycotoxins in various cereal and fruit based products (4). Specific substrate utilization can be used to determine the type of microorganism in question. The following sections will discuss common tests used for this purpose.

The AOAC has developed a comprehensive list of test kits that are available to measure or detect specific chemicals or microorganisms commonly referred to as analytes. The performance tested certified kits have been extensively reviewed by the AOAC Research Institute, a subsidiary of the AOAC International. All performance tested certified kits have been evaluated for accuracy, precision, detection limits, false positive/negative rates, stability and compared to an already existing method. There are several test kit analyte categories consisting of potential biological and chemical agents, microbiological, antibiotic, toxin, hormones, chemical, biochemical, and genetically modified organisms. The biochemical test kits include analytes such as ATP, sugars, enzymes, DNA, and many others (43).

A. VITEK

VITEK by bioMérieux is an automated instrument that offers rapid results within 2 to 6 hours, random or batch processing, and a quality control module. This instrument is used for bacterial and yeast identification, antimicrobial susceptibility testing, and urine screening. Since the VITEK is an automated system, this allows for greater safety and eliminates repetitive manual operations to quicken response time and provide faster results (44).

B. API Strips

Another reliable product used for the rapid identification of microbes is API Strips, which generally contain 20 miniature biochemical tests and databases. To date, there are 16 identification products covering most bacterial groups and more than 550 different species. There are test

kits to identify Gram-positive and negative bacteria and also yeasts. API Strips are economical when compared to the cost of preparing numerous biochemical media, are generally user-friendly, and have a long shelf-life (45).

C. BBL Crystal

There are many different BBL Crystal miniature identification kits available. Those utilized most for the identification of microorganisms are the Gram-Positive ID Kit, Rapid Gram-Positive ID Kit, and the Anaerobe ID Kit. The Gram-Positive ID kit is the most comprehensive Gram-Positive ID System available. Both the Gram-Positive ID System and the Rapid Gram-Positive ID System utilize modified conventional, fluorogenic, and chromogenic substrates. These kits are capable of identifying 121 Gram-positive bacteria including cocci and bacilli. The Gram-Positive ID System can be completed in 18 hours while the Rapid Gram-Positive ID System can be completed in 4 hours. The Anaerobe ID kit is a miniaturized 4 hour identification method for clinically significant anaerobes (46).

D. Impedance

Impedance is described as the resistance to the flow of a sinusoidal alternating current through a conducting material. Detection of cells by electrical impedance is determined from changes in the growth medium associated with the increase in biomass of metabolically active microorganisms. The components of growth media such as proteins, carbohydrates, and lipids are uncharged or weakly charged substrates. As microorganisms metabolize these compounds, they are converted into more highly charged molecules such as amino acids, lactate, and acetate. Consequently, these metabolic products increase the conductivity of the growth medium. Because this increase is small, a microbial level of at least 10^6 CFU/mL must be attained before significant changes can be observed. There are also disadvantages to electrical impedance method. The most critical disadvantage is that this method cannot function under high salt concentrations that are often found in particular growth media (5). In a recent study to determine the efficiency of a modified impedance method, numerous samples of ground beef were inoculated with 12 different serotypes of *Salmonella*. The method proved to be a reliable way for rapid detection of different *Salmonella* serotypes in fresh meat (47).

There are several commercial systems available that utilize a color system to monitor levels of contamination. Red generally depicts samples that are "highly contaminated"; yellow signifies "caution zones" and green signifies "acceptable" levels. Common impedance-monitoring devices are the Bactometer, the RABIT, the Malthus and the BacTrac (5).

The Bactometer by bioMérieux can be utilized to test raw materials and finished products. It is used to make important quality control decisions quickly, prevents unnecessary delays in production, reduces testing costs, and helps protect companies' reputations. The Bactometer consists of a processing unit (BPU), computer, and printer. The Bactometer analyzes samples that are simultaneously incubated and read by the BPU every six minutes. The computer continuously monitors operations and interprets the results. The terminal allows all results to be displayed quickly at any time. The Bactometer can be used to assay for total microbial counts, coliforms, yeast and mold, lactic acid bacteria, shelf-life testing, and environmental monitoring. Typical testing times can be reduced to less than 48 hours while conventional methods can take up to 5 days. Additional benefits associated with the Bactometer are a 512 sample capacity, performing different tests simultaneously, and working with a wide temperature range, all of which increase laboratory efficiency (50).

E. BioSys

The BioSys system is a computerized instrument designed to rapidly detect microbial contamination in industrial samples. It can be applied to foods, beverages, dairy, wine, cosmetics, toiletries, and nutraceuticals (48,49). The system has applications for the detection of the presence of various groups of microorganisms in food samples or swabs (e.g., Total Viable Count, Enterobacteriaceae, Coliforms, Yeast, Lactic Acid Bacteria, *E. coli*, etc.). Other tests performed by the system are the detection of spoilage microorganisms, shelflife assessment, microbial limits and preservative challenge test, and environmental sponges and swabs for the presence of certain organisms such as *Listeria* spp.

BioSys system uses vials consisting of a nutrient broth with an agar plug at the bottom. The system measures microbial growth by monitoring changes in pH or other biochemical reactions, thereby resulting in a color change as microorganisms grow and metabolize. Color changes in the agar mirror the color change in the broth, without letting the sample particles or turbidity influence the measurements.

Light from light emitting diodes passes though the agar and a photo diode on the other side of the vial reads the color change as microbial growth occurs. A measurement is taken every six minutes. As soon as a color change is detected, the time of such detection is recorded. Detection times (DT) are inversely related to the number of organisms in the sample.

F. Bioluminescence

Bioluminescence is defined as the production of light by living organisms. Common bioluminescent organisms

include certain fungi and bacteria that continuously emit light. The production of bioluminescent light is formed as a result of the conversion of chemical energy to light energy (51). Adenosine triphosphate (ATP) is the main source of energy in all living organisms. Two hours after cell death ATP completely disappears. One of the simplest techniques that measures ATP is the firefly luciferin-luciferase test. When ATP is present, luciferase produces light that is measured with a liquid scintillation spectrometer or a luminometer. The amount of light that is produced by the luciferase is directly proportional to the amount of ATP. The luciferase method is an example of a rapid and sensitive test that indicates the presence of bacterial cells (3).

A rapid system has been developed using bioluminescence to detect bacteria with minimal cultivation. Food samples are cultivated to produce a sufficient amount of ATP and are sprayed with luminescent reagents. Bioluminescent cells appear as spots to indicate the presence of bacteria in the sample. This method of detection is fast and is useful in hygiene testing for food, beverages, and water (52). In a recent study, ground beef containing *E. coli* O157:H7 was analyzed using a luciferin-luciferase assay. It was determined that in the presence of glucose, the cellular ATP of the *E. coli* increased causing significant luciferin-luciferase bioluminescence in beef hamburger. This method, coupled with an immunomagnetic capture technique allowed for rapid detection of viable *E. coli* O157:H7 cells in certain food samples (53).

G. ATP Test Kits

There are many different ATP test kits available that are used as a measure of total hygiene after sanitation or are used to detect presence/absence of microorganisms in samples. Bev-Trace™ is an example of an ATP test specially designed for the rapid detection of microbial contamination in beverages, such as beer, wine, and soft drinks (54). Results from ATP tests can be obtained faster than traditional techniques, saving time and money. The luminometers that are commonly used with this type of test are usually lightweight, easy to operate, and might be able to provide printed results. Some key features of these tests are earlier detection of contamination, decreased chance of recall, brand protection, and reduced stock holding requirements.

Another type of ATP test kit is used as a sanitation check on equipment surfaces. An example is the PocketSwab (55). These types of test kits are generally self contained, single service hygiene tests that use the firefly luciferin-luciferase enzyme system to emit light when unclean surfaces are detected. Tests are capable of verifying within intervals as short as 30 seconds if a surface is clean enough for production. ATP from food residues, microorganisms, biofilms, and human contact are detected to provide a quick check for cleaning effectiveness that enhances overall food safety.

IX. OTHER DEVELOPMENTS IN MICROBIAL TESTING

Rapid methods for microbiological analysis of foods also include improvements in sample preparation. One of the more useful instruments developed for sample preparation is the Seward/Tekmar Stomacher™ (Norfolk, UK) and similar devices (56). After transferring a food sample to a sterile plastic bag that contains appropriate diluents, the sample is placed within the stomacher where two paddles massage the bag for 1 to 5 minutes or longer using alternate strokes. The massage action simulates activity of the human stomach to mix the sample and dislodge microorganisms for further microbiological analysis, such as plate counting of viable cells.

Conventional viable cell count, or standard plate count, is tedious and time consuming. As a result, alternative methods to enumerate colony forming units within a food sample have been developed. One particular instrument, the spiral plater has gained wide acceptance and has become an essential element in many food microbiology laboratories (56). This instrument spreads a liquid sample onto an agar surface in an Archimedes spiral pattern. The sample is applied such that there is a concentration gradient starting from the center and decreasing as the spiral progresses outward on the plate. After the liquid containing the microorganism is spread, the plate is incubated to allow colonies to develop. The colonies are then counted either manually or electronically. The sample gradient is spread across the agar surface in such a manner that the equivalent of three standard dilutions can be read from one plate. This substantially decreases sample preparation and plating time and reduces supplies needed to enumerate microorganisms in a sample.

Major advancements in spiral platers include automation and plate readers. Automated spiral platers require little more than the presentation of a liquid sample followed by the press of a button. This activates the plater to apply an appropriate size sample to an agar surface after which the instrument goes through a clean and sanitation cycle. Despite the benefit of automation, there have been complications involving clogging of the dispensing stylus by large food particles. This problem was largely eliminated with the use of sterile sample preparation bags with filters that separate large food particles from the liquid sample (56).

Automated plate readers are designed to allow real-time enumeration of colonies on a plate. Scanners originally used with the early spiral platers were based on laser technology. Automatic readers today often utilize camera imaging coupled with sophisticated software to detect and count colonies. These readers can be utilized with any type of plating method; pour, spread, or spiral.

X. SUMMARY

No review can completely cover all the methods currently available, especially when considering that products continuously enter and leave the marketplace. It is critically important for safety and quality reasons to conduct microbiological analyses of food samples. Some microorganisms that are occasionally found in food products can cause illness or death, while other microorganisms produce spoilage and economic losses. Numerous variables are considered during the selection of a method to detect or enumerate microorganisms. The analyst must decide if a qualitative or quantitative test is required, and which microorganisms are of importance for the sample. If regulatory issues are involved, an analyst might want to consider the type of sampling plan used, and other factors such as speed, specificity, cost, and ease of use. Relatively rapid methods include direct microscopic observations, ATP assays, and test kits to detect or enumerate specific microorganisms or groups of microorganisms. Conventional methods of enumeration (plate counts or MPNs) generally consume more time and supplies than rapid methods, but are often less expensive and can yield more accurate data.

186 Immuno-Based Methods for the Detection of Bacterial Pathogens

Keith R. Schneider and Minh Lam
Food Science and Human Nutrition Department, University of Florida

Mickey E. Parish
Lake Alfred, CREC, University of Florida

CONTENTS

I. INTRODUCTION

According to the Centers for Disease Control and Prevention (CDC), there are over 250 known different foodborne diseases (1). These diseases are caused by bacteria, viruses, chemicals, toxins, and fungi. In the United States, where the food supply is one of the safest in the world, the number of food related illnesses is estimated to result in 76 million sick individuals, and nearly 5,000 deaths yearly. Many of these pathogens, such as *Campylobacter jejuni*, *Escherichia coli* O157:H7, and *Listeria monocytogenes*, were not recognized as major causes of foodborne illness until recently (2).

One of the main reasons for the emergence of foodborne pathogens is the increased complexity of food products and processes. Each year, hundreds of thousands of new food products are introduced into the market place, and as a result different and more complex food matrices are produced. Other reasons that foodborne disease outbreaks appear to be increasing are: increasing consumer demand for fresh, unprocessed, and minimally processed foods that are inherently less safe than pasteurized or processed counterparts; public health officials have established national surveillance programs that are more sensitive at outbreak detection; there are increasing imports of foods from countries that may not have programs that would decrease contamination levels; and, innovative packaging and processing techniques may allow for much longer shelflife of sensitive foods, thereby allowing a very small pathogen population to proliferate to infective levels. Despite efforts by the government and the food industry to curtail illnesses, such as through the

use of programs like Hazard Analysis and Critical Control Point (HACCP) and Good Manufacturing Practices (GMPs) there is still a need for rapid and efficient microbiological testing.

There have been many improvements in the last few decades in both the conventional and newer microbiological techniques. Driven by food safety issues and economics, advanced pathogen detection and identification protocols make use of rapid and automated microbiological analyses. This includes the use of microbiological, biochemical, immunological, and serological methods for improving the isolation, early detection, characterization, and enumeration of microorganisms and their products. Whether these methods were originally developed for a clinical, industrial, or environmental setting, such innovative technology has been adopted by the food industry over the past decade.

II. IMMUNOLOGICAL METHODS

Immunological methods rely on the specific binding of an antibody to an antigen. An antigen is a substance that is capable of eliciting the production of antibodies in a living organism (the host). Figure 186.1 illustrates the Y-shaped structure of an antibody, with the antigen binding sites on the arms of the Y structure. It is these binding sites that account for the specificity of the antibody, particularly the regions termed the light and heavy chains. The suitability of the antibodies for food application toward a particular microbiological target depends on their specificity, including whether they are monoclonal or polyclonal. Polyclonal antibodies contain an assortment of antibodies, each with different specificities for specific antigens. Monoclonal antibodies react with only one antigen. Improvements in monoclonal antibody production have led to better supplies of these potentially powerful diagnostic tools (3). Typically, monoclonal kits are portrayed as having less variability than polyclonal-based kits.

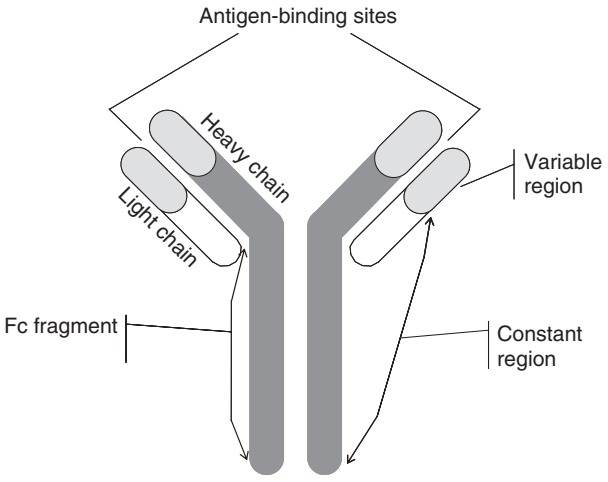

FIGURE 186.1 Antibody Structure. The immunoglobulin molecule consists of two identical light and heavy chains. Binding occurs at the variable regions.

Commonly used immunological techniques include enzyme-linked immunosorbent assay (ELISA) (sometimes referred to commercially as an enzyme immunoassay, or EIA), immunomagnetic separation (IMS), latex agglutination, precipitation assays, immunostaining, biosensors and automated systems. Numerous commercial products to simplify immunodiagnostics are based on these detection systems.

III. ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA) METHODS

In an enzyme-linked immunosorbent assay (ELISA), an enzyme is used as a label on an antigen or antibody, which will then bind to the antigen (or antibody) of interest (the analyte). After binding, the enzyme portion can be assayed, which allows for the detection of an immune reaction and the estimation of the analyte (4).

Occasionally, the term enzyme immunoassay (EIA) will be encountered, rather than the term ELISA. EIA is a nonspecific term used to refer to all ELISA-like assays, including those designed to detect nucleic acids as well as antigens or antibodies. Thus, the terms EIA and ELISA are oftentimes used interchangeably.

There are two general forms of enzyme immunoassays, the heterogeneous and the homogeneous, typically differentiated by the use of an incubation period and a wash step. The most commonly used form, and the one most often associated with the term ELISA, is the heterogeneous enzyme immunoassay method. In heterogeneous ELISA, the antibody or antigen is bound either covalently or noncovalently to the solid matrix. The unreacted antigen or antibody in the heterogeneous method is removed by washing or centrifugation. Unlike the heterogeneous assay, the homogeneous ELISA has no separation of the immune complex and the free reactants via a wash step.

Heterogeneous ELISA can be simple or complex. In simple ELISA, there is just binding of the labeled antibody to the antigen, followed by a detection step. The more complex sandwich ELISA, in which a primary antibody is "sandwiched" between a bound antigen and a second labeled antibody, is commonly used to detect bacterial antigens in foods. Figure 186.2 is a schematic diagram of the sandwich ELISA and the components involved in the assay. A list of ELISA test kit manufacturers can be seen in Table 186.1.

A. Microtiter Plate Format

These assays are usually performed on plastic microtiter plates. These are trays containing a fixed number of wells,

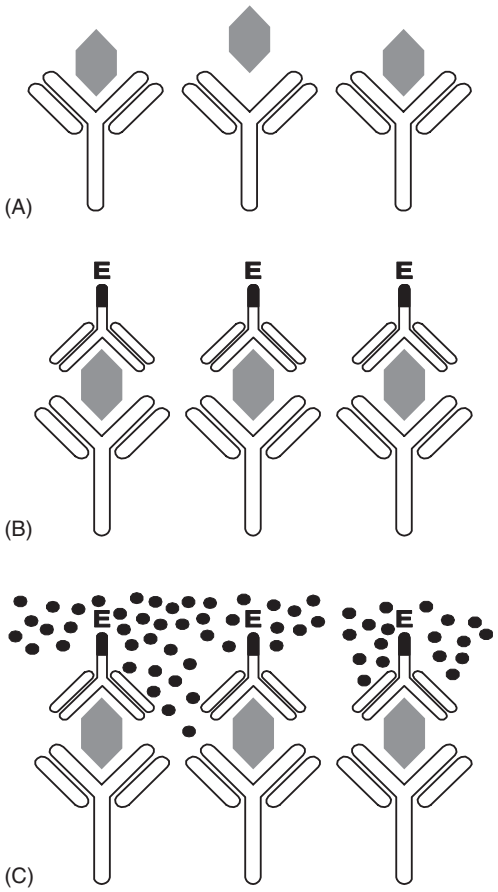

FIGURE 186.2 The double antibody sandwich methods for the detection of specific antibodies. A) Antibody specific for target antigen(s) is bonded to surface (e.g., plate, bead, paper, etc.). Sample is added and antigen binds with antibody. B) Enzyme-linked antibody specific for the target antigen(s) is added and binds to antigen. C) Enzyme substrate is added and reaction produces a visible color change. (Reprinted by permission from Tecra Diagnostic, Ltd.)

typically 24, 48, or 96. When the antibody (or antigen) is added to the well, it then binds to the inside surface of the well. This binding is due to the hydrophobic interaction between the hydrophobic residues on the protein and the nonpolar plastic surface. Once it is bound, the protein cannot be easily washed from the surface of the well. After application of the sample and subsequent binding of labeled antigen or antibody, the response, either enzymatic or isotopic, is then read via the plate reader.

One commercially available ELISA, manufactured by BioControl Systems, Inc. (Bellevue, WA) uses a mixture of monoclonal antibodies specific for *Salmonella* detection (BioControl). Another manufacturer, TECRA Diagnostic Ltd. (NSW, Australia) uses polyclonal antibodies rather than monoclonal antibodies for the detection of pathogens (5,6). Figure 186.3 shows an example of a standard ELISA test kit and Table 186.1 gives a list of the various manufacturers and/or distributors of ELISA based detection systems.

IV. IMMUNOPRECIPITATION

Immunoprecipitation, also called immunochromatography, is another method that is antibody-based. These assays use the technology originally developed for home pregnancy tests. It utilizes the same "sandwich" technology described in the section on ELISA assays. The main

FIGURE 186.3 Typical ELISA kits for the detection of a bacterial pathogen. In addition to detecting pathogens such as *E. coli* O157:H7, *Salmonella* and *Listeria monocytogenes*, some test kits will test for the presences of bacterial toxins (e.g., *Staphylococcus aureus*). (Reprinted by permission from Tecra Diagnostic, Ltd.)

difference between the two systems is that instead of enzyme conjugates, the detection antibody is bound to latex beads or to colloidal gold, which produces a color change. The sample is placed on the device and is wicked across media. The antibodies for the specific components in a sample are then bound to an antibody. It is this binding of the antibody/antigen complex which results in a visibly detectable line known as a precipitation band (7).

A. Lateral Flow Devices

These assays combine the recognition ability of an immunoassay with the separation power of chromatography. In the lateral flow device (LFD) an extracted sample is introduced onto one end of a membrane strip, usually encased in a plastic holder. The sample is drawn through to a reagent zone containing labeled antibodies specific for the target analyte. A positive reaction occurs when the analyte in the sample extract combines with the labeled antibody where it stops at a line of anchored antibodies. This zone also has antibodies specific for the target analyte. Here they form an antibody-antigen-antibody "sandwich" that is visualized as a line. A second "control" zone also wicks from the reagent zone and forms a second line further along the device (Figure 186.4). One benefit of this class of tests is that they can be read visually. Strategic Diagnostics, Inc. (Newark, DE) has developed rapid screening tests for *E. coli* O157 (including O157:H7) and for *Salmonella* via their RapidChek™ kits. The RapidChek™ *E. coli* O157 system has been approved by the AOAC for use in ground beef, boneless beef, and apple cider (7). Neogen Corporation (Lansing, MI) has also developed commercially available lateral flow devices for the detection of *Salmonella*, *Salmonella enteritidis, E. coli*

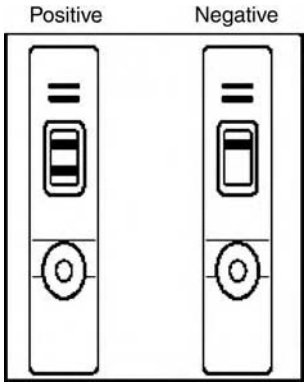

FIGURE 186.4 The RapidChek™ Lateral Flow Assay is an immunoassay which employs a combination of anti-pathogen antibodies and colloidal gold conjugate coated on the surface of a membrane encased within a plastic cassette. (Reprinted by permission from Strategic Diagnostics, Inc.)

O157:H7, as well as *Listeria* in their line of Reveal® kits (8,9). BioControl Systems, Inc. (Bellevue, WA) produces the VIP® test kit for *Salmonella*, *Listeria*, and *E. coli* O157:H7 (10). These as well as other commercially available lateral flow kits are listed in Table 186.2.

B. Dip Stick Assays

Dip stick assays, such as Tecra Diagnostics Ltd.'s *E. coli* 0157 Immunocapture and UNIQUE™ test kits, offer yet another iteration of the ELISA methodology. These assays use an antibody-coated dipstick to capture target antigens from an enriched sample. All steps take place within a self-contained module that contains all necessary reagents and eliminates media preparation (11). These and other commercially available dip stick assays are listed in Table 186.2.

C. Immunodiffusion

BioControl Systems, in addition to its VIP™ line of immunoprecipitation tests also produces the 1–2 test used for detection of motile *Salmonella* in food. The method, sometimes referred to as an immunoimmobilization assay (12), utilizes a unique two-chamber unit. One unit contains the enrichment media while the other is used for the immunoimmobilization process. Anti-*Salmonella* antibodies are added to one chamber as the motile *Salmonella* migrate in the other. At the point where the diffusing antibodies contact the advancing microorganisms, a visual "immunoband" is formed when a positive result is present.

V. IMMUNOMAGNETIC SEPARATION

Immunomagnetic separation is the selective concentration of a target organism using antibody-coated magnetic beads or other devices to selectively trap the target

microorganism (13). The beads are typically uniform polymeric particles coated with a polystyrene shell, providing a smooth hydrophobic surface (15). This allows for the facilitated absorption of the immunoglobulin molecules. It can be effectively used to reduce background flora and eliminate interfering food particles, but is sometimes labor intensive and therefore not well suited for high-volume users. Both VICAM (Watertown, MA)

and Dynal Biotech (Oslo, Norway) have successfully developed magnetic beads coated with various antibodies for the detection of specific pathogens, such as *Salmonella* (*Salmonella* Screen/*Salmonella* Verify™) (15) and enteropathogenic *E. coli* (Dynabeads®) (16). VICAM also produces beads for *Listeria* detection under the name of ListerTest®. Immunomagnetic bead separation technology can rule out the possible presence of pathogens in less than 24 hours, with similar or better sensitivities as conventional methods. Upon use of this method, further microbiological procedures, such as direct plating or ELISA tests, can be performed on the charged beads. This is quite useful for foods with very low numbers of target pathogens such as *Listeria* and *Salmonella* (5). Magnetic bead separation has been used for detection of pathogens in many food and environmental matrices, such as *Cryptosporidium* species in water samples, *Bacillus* spores in food and environmental samples, and *Staphylococcus* species in milk (17–20). Commercially available immunomagnetic kits are listed in Table 186.2.

VI. LATEX AGGLUTINATION

Another relatively fast and simple immunological method for food pathogen detection involves latex agglutination. This method, sometimes referred to as the slide test, involves the reaction of latex particles coated with a specific antibody to the corresponding pathogenic antigen (21). A positive test yields agglutination, or visible clumping of the test reagents, while a negative control is indicated by the absence of clumped particles. Latex agglutination has been developed for many foodborne pathogens as well as their toxins; commercial products are available for *Salmonella*, pathogenic *E. coli*, *Staphylococcus aureus*, and *Clostridium.* These test kits have similar or better sensitivities than conventional or ELISA methods (21–25). Oxoid Ltd. (Scotland) produces various commercial latex agglutination kits for microorganisms such as *Bacillus cereus* (BCET-RPLA), *E. coli* and *Vibrio cholerae* (VET-RPLA). Other latex agglutination products that are readily available can be found in Table 186.2.

VII. IMMUNOSTAINING

Immunostaining, also known as immunoblotting, is the transfer of antigenic material from one surface onto a nitrocellulose membrane, and is often used in conjunction with ELISA. Once antigens are transferred to the membrane, antibodies specific to the antigen are added. The resulting membrane containing the antigens and antibodies is then assayed as with the ELISA method (12).

Few commercial immunostaining kits are currently in use for food pathogen detection. 3M Corporation had developed a system for the detection of *E. coli* O157:H7, which involved the inoculation of a Petrifilm™ Test Kit-HEC plate. If the target bacteria were present, colonies would form on the plate. Colony antigens were then transferred from the plate to a reactive disc. If the *E. coli* O157:H7 antigens were present, they would be transferred to the disc and would capture the enzyme-labeled antibody, which was added later. The antibody-antigen complex was then visually detected via the presence of a black spot on the plate. This system is no longer available and is only mentioned to provide historical background, although this technique is still used as a research tool for the detection of bacteria in food matrices (12).

VIII. BIOSENSORS

A biosensor is a compact analytical device incorporating a biological or biologically derived sensing element. These can include enzymes, antibodies, or DNA, either integrated within or associated with a physiochemical transducer (27). The biological compounds can be used to detect changes in the environment, such as the presence of microorganisms, and can vary from simple temperature sensitive paint, to very complex DNA-RNA probes (28). Biosensors provide a means for production of very sensitive, miniaturized systems that can be used to detect microbial activity or the presence of biological compounds.

There are two commonly used definitions for the term biosensors. The first definition refers to any device or instrument consisting of a biological sensing element combined or attached to a transducer (29,30). Thus enzymes, antibodies, cells, DNA, and tissues are considered the sensing element while typical transducers for these molecules can consist of electrochemical, calorimetric, optical, acoustical, or even mechanical means. The second definition for biosensors refers to a self-contained analytical system that is capable of responding both directly and selectively to biological species (29,30).

Enzymes are the most commonly used biological elements. Biosensors using microorganisms are called microbial biosensors and they exploit the metabolic functions of living microorganisms to effect detection and measurements of analytes (31). Immunosensors are biosensors that use antigens or antibodies as sensing elements, and are analytical devices based on the affinity and specificity of the antigen-antibody reaction.

At Georgia Institute of Technology, a biosensor has been developed that operates with three primary components – integrated optics, immunoassay techniques, and surface chemistry tests (32). It indirectly detects pathogens by combining immunoassays with a chemical sensing scheme. In the immunoassay, a series of antibodies selectively recognizes the target bacteria. An antibody, termed the "capture antibody" is bound to the biosensor and captures the target bacterium as it passes nearby. Then a set of "reporter" antibodies, which bind with the same target pathogen, contain the enzyme (urease), which breaks down

urea that is then added and produces ammonia. The chemical sensor detects the ammonia, affecting the optical properties of the sensor and signaling changes in transmitted laser light.

Biosensor development has been accelerated by improvements in materials research and miniaturized technologies. Biosensors' specificity for the biological binding reaction is derived from numerous types of interactions and affinities (33,34). Some common interactions that have been studied for biosensor applications include antigen/antibody, enzyme/substrate/cofactor, receptor/ligand, energy transducer systems, synthetic chemical interactions, and nucleic acid hybridization.

Funded by the United States Department of Agriculture, a group at the University of Rhode Island's Fiber Optic and Biosensor Research lab has developed sensors that use vibrating quartz crystal or fiber optic probes in conjunction with antibodies for the detection of *Salmonella* (35). Another group at Cornell University has used nucleic acid sequences to detect pathogens (36). In this system, the biosensor consists of disposable microchannels with areas for capture and detection. DNA probes complimentary to the target pathogen RNA serves as the biorecognition element. To obtain a signal, two other probes are used, one coupled to dye encapsulated liposomes, and the other coupled to superparamagnetic beads for target capture. The probe then hybridizes to the target RNA and the liposome-target bead complex is captured on a magnet.

Biosensor techniques are still commercially limited, but hold promise with applications in the poultry, beef, and seafood industries (32).

IX. AUTOMATED SYSTEMS

The latest immunological detection methods involve the development of automated systems. These allow for the rapid testing of multiple samples concurrently. Typically, these automated systems are comprised of an analytical module, a computer, and a recording device such as a printer. The analytical module is capable of automatically performing all stages of the analysis, such that all that is required for analysis is the addition of the sample to the analyzer.

VIDAS® (bioMérieux) and mini VIDAS® are two currently available autoimmuno-analyzers that use enzyme linked fluorescent assays (37). VIDAS® is capable of analyzing four different modules concurrently, thus allowing it to run 240 tests per hour. The mini VIDAS® is a smaller version of the VIDAS® and contains a built in computer, keyboard, and printer. It has two independent sections capable of analyzing a total of 12 samples simultaneously. This system has been used for the detection of *E. coli* O157 in cheese, and *Listeria* in milk (38,39). The Tecra Diagnostics, Ltd. UNIQUE PLUS™ system automates the steps required for the UNIQUE™ dip stick test kit. The system currently supports assays for *Salmonella* and *Listeria* (11). Figure 186.5 shows the UNIQUE PLUS™ automated system by Tecra Diagnostics, Ltd.

X. SUMMARY

Immunological assay methods, particularly ELISA and latex agglutination, are routinely used for the detection and analysis of pathogens in food products. The use of automated systems and biosensors is not as common, but should increase in popularity as sensitivity increases and costs decline with these systems. Most developments in immunological assays have come about within the last few decades and future improvements are likely to continue at the same pace, as immuno-techniques have potential for superior accuracy and can provide rapid analytical results.

CONTENTS

I. INTRODUCTION

The food industry is witnessing a tug-of-war as processors make a slow transition from the use of traditional microbiological methods for quality control/quality assurance of foods, which are essentially designed around the recovery and enumeration of viable bacteria in the food matrix, to miniaturized rapid methods and molecular tools that achieve the same purpose with greater sensitivity, specificity, and in less time. In order to successfully counter increasing consumer demand for high quality food, to remain abreast of emerging food-associated pathogenic bacteria, and in keeping with Hazard Analysis and Critical Control Point (HACCP) implementation, significant resources are being invested in monitoring food during and immediately following processing to preclude spoilage and/or pathogenic bacteria from contaminating food, or detect them prior to shipment for retail sale (1).

Novel means of detecting and enumerating bacteria of interest are continually being reported. Some of these strategies still rely heavily on traditional, relatively inexpensive microbiological methods, but the majority of new assays in the literature entail a molecular component that affords rapid (8–48 hour), sensitive, and specific results for detection of particular target microbes (or their products). Such techniques may offer the food processor higher sample throughput, greater assay versatility, and speed compared to traditional (albeit more widely accepted) manual methods (2,3). This chapter will present a comparative overview of many of the commonly used

approaches in food microbiology for enumeration and/or detection of bacteria in foods, including many of the emerging molecular-based technologies currently flooding the literature.

II. BACKGROUND ON TRADITIONAL MICROBIOLOGICAL METHODS IN FOOD

Of the more than 200 known diseases transmitted through food in the United States yearly, at least 5,000 deaths are recorded on average from over 75 million reported cases. Surveillance and detection of food-associated pathogenic bacteria is complicated by emerging strains not routinely encountered, and the unclear route of transmission of many bacteria, which may be problematic in being spread by water or direct contact, in addition to contaminating specific foods (4). Routine screening of an increasingly diverse array of fresh and processed foods obligates pre- and post-harvest food safety measures be dynamic, sensitive, specific, as well as versatile and cost-effective for large sample numbers. In order to assess the microbiological quality of foods, detection of viable bacteria is traditionally performed by implementing a means of culturing/measuring growth of individual microorganisms. Hundreds of commonly used bacteriological media used in the food industry are met with unique ways of applying them to best monitor for spoilage and/or pathogenic bacteria in food (5). The use of routine nonselective media such as trypticase soy agar or standard methods agar, known as the aerobic plate count (APC) or standard plate count (SPC), offer low cost and ease of use. However, these approaches are not sensitive below levels of approximately 10^2 viable cfu/ml or gram of suspect food, require extended incubation times, and do not adequately address the presence of key virulence determinants in specific food-associated pathogens that may or may not be present in target bacteria. The widespread use of these traditional approaches is being superseded by molecular tools that are protein- and nucleic acid-based. The latter, in particular, lend themselves well to not only sensitive and specific detection of spoilage or pathogenic bacteria, but DNA typing/fingerprinting, quantitation, and differentiation of viable from dead microorganisms, frequently in real-time depending on the format of the assay. Following are descriptions of some of the most common nucleic acid-based methods used in quality control/quality assurance within the food industry, as well as some specialized DNA and RNA technologies that have demonstrated potential for application in food safety.

III. PULSED FIELD GEL ELECTROPHORESIS

Nucleic acid-based analysis of food-associated spoilage and pathogenic bacteria encompasses a diverse array of methods, many of which have had their origins in the clinical arena. One such method dates back to the early 1980s and is now the basis for the PulseNet molecular subtyping network of bacterial foodborne disease surveillance. Pulsed field gel electrophoresis (PFGE) is a fundamental method in molecular biology for separation of high molecular weight DNA for typing bacterial strains and tracing foodborne disease outbreaks through standardized protocols and data sharing.

In 1984, Schwartz and Cantor (6) described PFGE and demonstrated the ability of this technique to resolve yeast chromosomal DNA fragments and in doing so, raised the upper limit on the size of nucleic acids able to be separated electrophoretically. Following this initial high-profile study, a battery of subsequent papers reported on the utility of PFGE in genetic analyses of other organisms, as well as improvements on the protocol itself (7,8,9,10). In principle, PFGE is based on the physics of high molecular weight DNA fragments (i.e., chromosomal DNA or bacterial genomic DNA) not being resolved when exposed to constant voltage, but if the DNA is forced to change through periodic polarity inversion during electrophoresis, the mobility of large molecular weight DNA is altered and separation as distinct bands may be obtained (11). Various instruments and protocols are commercially available that reorient the DNA at unique angles depending on the specific experimental objectives, in an effort to obtain optimal separation within particular size ranges, but the separation principle is essentially the same (12,13,14).

In an effort to standardize protocols for molecular subtyping of bacterial food pathogens, PFGE has been developed as the tool of choice for characterizing and epidemiologically tracing isolates associated with foodborne illness outbreaks. In 1996, the Centers for Disease Control and Prevention in Atlanta, GA, and several state health departments established PulseNet with just 10 laboratories focusing on a single pathogen – *Escherichia coli* O157:H7 – following an outbreak of hemorrhagic colitis from contaminated ground beef consumed in a fast food restaurant (15). PulseNet now encompasses nearly every state in the US, and several provincial Canadian laboratories in an effort to meet the growing frequency of documented foodborne illness outbreaks with information on strain designations, tracing outbreak clusters, and sharing improvements on DNA extraction and end point analysis methods (16,17,18,19). PulseNet is also established overseas, and implements the same PFGE technology in the molecular subtyping of bacteria associated with foodborne illness outbreaks in Japan (20). In terms of applicability to food safety, PFGE has been useful for typing *Listeria monocytogenes* (21,22), *Staphylococcus aureus* (23,24), *Shigella flexneri* (25), *Campylobacter jejuni* (26), *Salmonella* spp. (27), *Clostridium perfringens* (28), and pathogenic *E. coli* (29,30).

IV. POLYMERASE CHAIN REACTION (PCR)

A. General Principles of PCR-Based Detection

Ideally, the development of a commercially viable detection assay for spoilage or pathogenic bacteria would be supplemented by a molecular approach with the potential for extreme sensitivity and specificity, while still maintaining low cost per assay. The polymerase chain reaction (PCR) has been in use in the food microbiology arena for over 10 years, with many variations of the common theme of this technique (Figure 187.1), some of these manifesting themselves as commercial assays (31,32) (Table 187.1). PCR has the potential to significantly reduce the necessary time for detection and screening of foods for pathogenic or spoilage bacteria, with a myriad of offshoot technologies that afford real-time, fingerprinting, quantitative, and/or RNA-based virulence gene expression assessment in a variety of data generation and collection formats (33,34).

The specificity of PCR usually relies on DNA sequence-specific oligonucleotide primers that initiate repetitive rounds of *in vitro* replication of a target gene fragment through denaturation, primer annealing, and new strand synthesis (35) (Figure 187.1). The end product, or amplicon, is traditionally analyzed by agarose gel electrophoresis, and visual confirmation establishes that the expected size fragment has been amplified from DNA extracted from contaminated food. The general PCR technique has been used in many applications for pathogen detection in food, enough to be previously well reviewed in a variety of sources (36–46).

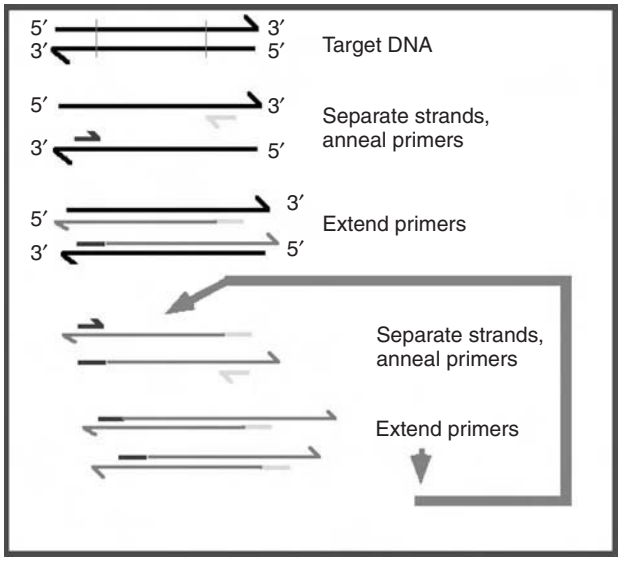

FIGURE 187.1 Process of polymerase chain reaction (PCR), showing template strands, sequence-specific primers (usually) employed that anneal to complementary base sequences, and extension (new strand synthesis) using *Taq* DNA polymerase. Each cycle of PCR theoretically doubles the amount of DNA in the reaction tube, but only within the region spanned by the forward and reverse primers.

The composition of the food medium directly impacts PCR assay sensitivity, however, and thus no universal DNA extraction procedure exists; rather, each food matrix presents its own set of challenges according to composition and must be addressed on a case-by-case basis (47,48). In fact, many factors affect efficiency of DNA template purification from food matrices, subsequent PCR amplification robustness, or both. For example, in dairy products and meats lipids, proteases, divalent cations, carbohydrates, or a host of undefined organic material may drastically interfere with PCR assay detection sensitivity (49–53). Rarely is one able to apply a PCR-based detection assay that lacks sample processing and template cleanup prior to setting up reactions (54). In virtually all foods under scrutiny by PCR-based analyses, debris and other inhibitory components may be at least partially sequestered or minimized using specialty buffer or detergent cocktails, solvent extractions, PCR additives, or a combination of these (55–61).

Several means have been described for removing the target spoilage or pathogenic bacterium from the food medium prior to DNA extraction as an additional efficient way to obtain PCR template of higher quality than solvent-extracted DNA. Immunomagnetic separation (IMS)

is perhaps the best described method, and has been used to concentrate *E. coli*, *Salmonella*, *Campylobacter* spp., *Bacillus* spp., and other food-associated pathogenic bacteria from a variety of foods, including fruit juices, dairy products eggs, seafood, ethnic foods, chicken, and meat homogenates (62–85). Additionally, insoluble metal hydroxides have been employed with great success for bacteria and spore immobilization in food suspensions for subsequent removal, resuspension, and DNA purification in a cleaner environment more conducive to high template yields (68,86–88). Metal hydroxides, essentially a supersaturated suspension of zirconium, titanous, or hafnium chloride in pH-adjusted ammonium hydroxide and sterile saline bind to the negatively-charged bacterial surface and sequester the cells from polluted suspensions such as food slurries or other contaminated liquid matrix. Once the cell-free supernatant is decanted following a low speed centrifugation, the cells may be rinsed, plated, or subjected to DNA extraction (89). The various factors that may antagonize DNA extraction and yield, template purity, or PCR amplification efficiency have been comprehensively reported (90) for clinical, food, and environmental DNA template purification applications.

B. Multiplex and Nested PCR

In order to balance PCR assay versatility with optimal levels of detection sensitivity and specificity under varied contaminated food matrices, multiple primer sets may be employed to simultaneously detect two or more target bacterial DNA sequences followed by agarose gel electrophoresis (91). This approach, called multiplex PCR, reduces the incidence of false-negative results. If one or more of the DNA fragments are visible, the sample is presumably positive. In most cases, multiplex PCR targets two gene sequences at once, although several target sequences may be possible (92–94). The notion of multiplex PCR may lend itself well to high throughput sample processing because once experimental conditions are optimized for a specific food/bacteria system, reactions may be in large part prepared ahead of time and stored in bulk, frozen until needed (95).

When designing primers for multiplex PCR reactions, one needs to ensure that the primers will have minimal tendency to form primer dimers or secondary structure elements when placed together in the same tube. Primary sequence homology and GC content of each primer should be analyzed individually and in concert with the other primers to be used in the assay to confirm that the T_m of each is within a few degrees for optimal annealing efficiency. Additionally, the multiplex amplicons should be different enough in size to resolve using agarose gel electrophoresis (91). Multiplex PCR affords increased assay versatility, but sacrifices assay sensitivity. Multiplex detection of *Salmonella* and *Vibrio* spp. in shellfish and mussels (93,96), and enterotoxigenic *Staphylococcus aureus* in skim milk and cheddar cheese (97) have been documented.

The use of multiplex PCR for detection of food-associated bacteria is quite prevalent in the literature, and in many cases this tool as a rapid method is partially negated by the need for a selective or nonselective enrichment from the food matrix that may add up to 20 hours to the assay (53,98–102) while other multiplex regimes follow confirmation plating steps on selective media (103), or are not demonstrated in a food system, limiting their potential applicability in a food processing environment and with a diverse array of foods (101).

While multiplex PCR techniques decrease the likelihood of obtaining false negative results, assay sensitivity may be improved with a nested PCR approach. This method utilizes sequence-specific primers for an initial round of amplification that when analyzed using agarose gel electrophoresis, may not yield visible amplicon bands. By using some of the PCR product in a second round of reactions with primers internal in annealing position with respect to the first set, a reamplification is done, with the goal of obtaining a visible amplicon (albeit one smaller than the original) on the gel (33).

Although nested PCR has largely been supplanted by faster and more sophisticated real-time methods, the basic technique has merit in terms of sensitivity, being used for detecting *Listeria monocytogenes* and *Yersinia enterocolitica* in raw milk (105–107), *Campylobacter* spp. (108), verotoxigenic *E. coli* in ground beef (109), and *Vibrio vulnificus* in fish (110), to cite but a few representative studies. As in standard PCR detection assays applied in food systems, nested PCR protocols generally implement an enrichment step and typically yield sensitivity on the order of 10^1–10^2 cfu per m contaminated food following such steps.

C. RAPD-PCR and Rep-PCR for DNA Fingerprinting

The application of random amplified polymorphic DNA (RAPD) analysis for typing of food-associated spoilage and pathogenic bacteria is widely reported in the literature. This technique employs relatively short (~10 bases) arbitrarily designed primers (one or two) in PCR reactions having a much lower annealing temperature than standard sequence-specific amplifications. Such conditions allow for the generation of PCR amplicons that represent more or less a DNA fingerprint of particular bacterial strains under that set of defined conditions (111). Although potentially useful as a rapid screening tool for tracking contaminants by the RAPD banding pattern on gel electrophoresis, this technique has limitations, including difficulty in obtaining reproducible amplicon banding profiles within replicates. The issue of variable results due to

random primer design and low annealing temperatures used, negate the utility of the technique as a feasible quality assurance tool in the food industry. Nevertheless, RAPD-based PCR detection assays have been reported in the detection of food-associated bacteria ranging from arcobacters in poultry (112) to assessment of *Bacillus cereus* ecology and contamination in processing facilities and commercial dairy powders, (113–115). RAPD analysis has also been reported for the typing pathogens such as *E. coli* O157:H7 (116), *Salmonella* (117–119), *Vibrio* spp. (120,121), *Campylobacter* spp. (122–125), and *L. monocytogenes* (126–129) in food matrices as diverse as cheese, seafood, pork, and beef.

A unique PCR-based approach to characterizing pathogens, repetitive element palindromic-based PCR (rep-PCR), has been applied in clinical settings to differentiate the genetic diversity of bacterial pathogens from hospitals (130). Rep-PCR is used to amplify repetitive, noncoding DNA sequences interspersed within bacterial genomes using primers specific to the repeated elements (Figure 187.2). Differences in the resulting banding profile are used to categorize new isolates, or identify strains based on known DNA banding patterns, or fingerprints (131–135) (Figure 187.2). Rep-PCR has been recently employed in typing *Bacillus sporothermodurans* and other *Bacillus* spp. isolated from milk (136,137), and to differentiate *Bacillus anthracis* strains (138,139) and enterotoxigenic *Bacillus* spp. from nonenterotoxigenic strains in contaminated milk (140). Rep-PCR shows broader species applicability and better discriminatory power than biochemical profiling and RAPD analysis and allows consistent pattern formation and storage of strain typing information in a database as a digitized image. Because this technique is sequence-specific, rep-PCR fingerprints are highly reproducible, unlike RAPD analyses. Unknown strains characterized by rep-PCR can be compared against the stored databases across laboratories for identification purposes and to monitor changes in microbial populations (141), similar to the PulseNet infrastructure using pulsed-field gel electrophoresis (PFGE) as the means of generating strain typing data.

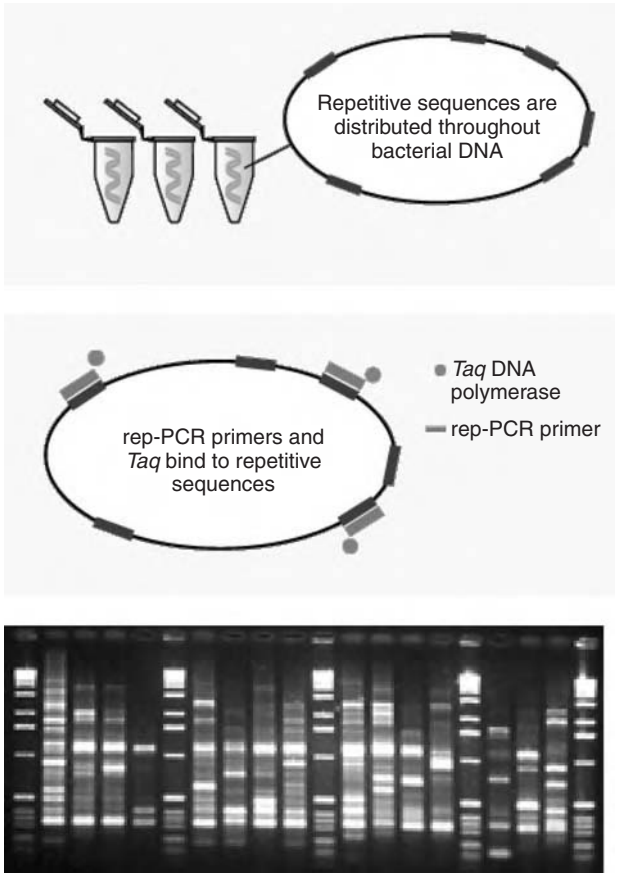

FIGURE 187.2 Repetitive element palindromic polymerase chain reaction (rep-PCR). Primers in rep-PCR are specific for conserved noncoding DNA elements found throughout the genome of bacteria, and as such generate muliple, but reproducible amplicon banding patterns useful for molecular subtyping following electrophoretic separation.

D. Quantitative-Competitive (QC-) PCR

For detection and enumeration of target genome equivalents or bacterial numbers in foods, including viable-but-nonculturable (VBNC) state cells, QC-PCR may be used (142). Enumeration of cells is possible through the coamplification of the target sequence with a shorter fragment (the competicon) containing the same primer annealing regions, allowing amplification of both target and competicon to occur with equal efficiency (143). By assembling QC-PCR reactions using titrations of competicon DNA concentrations but constant levels of target DNA, a series of doublet bands result following electrophoresis, with band intensity of competicon fragments decreasing with inversely increasing band intensities of the slightly larger target DNA sequence. The concentration of competicon that is equal in band intensity to that of the target fragment is calculated by scanning densitometry of the gel image and/or generation of a regression plot. Genome equivalents are determined and converted to a value for cell number in the suspect food sample. QC-PCR has been applied to a few food-based systems, such as quantitation of *E. coli* O157:H7 (142), and for GMO screening in grains (144). Because of the logistical difficulty in optimizing QC-PCR assays, the approach has limited potential for large-scale applications in the food industry as a rapid method, particularly in light of the many real-time chemistries in use.

E. Real-Time PCR

Despite the specific advantages as a sensitive tool for detection and/or screening suspect foods for the presence

of spoilage or pathogenic bacteria, PCR and the variations discussed above all have one caveat in common — the need to analyze the data using traditional end point analysis (i.e., agarose gel electrophoresis). While this technique is well-understood by many and does not require expensive equipment, analysis of amplicon band intensity in a gel following a cycle run adds 1–2 hours to the assay, may not be quantitative, and possesses a narrow dynamic range when attempting to detect differences in amplification efficiency among multiple samples. Moreover, post-PCR processing is necessary if one wishes to confirm amplicon identity by restriction enzyme digest analysis or a hybridization assay, either of which would completely negate the effect of using PCR as a rapid method for pathogen detection by stretching the protocol from hours to days.

The nature of PCR chemistry dictates that the exponential phase of amplification is the most accurate stage for quantification of products, rather than the plateau phase when reaction conditions are suboptimal and the relative amplicon band intensities of a set of templates that were at varying concentrations prior to PCR are now essentially equivalent (33). PCR assays that measure the reaction progress during each amplification, rather than after reaching a plateau, represent an attractive means of obtaining real-time quantitative data for rapid and sensitive detection using uniplex, multiplex, nested, or fingerprinting-based variations on the common theme of PCR to detect DNA (or RNA) (145,146). Currently, a number of real-time chemistries are commercially available for use in PCR. These can be divided into those that are not sequence specific—such as DNA minor groove binding dyes, and those approaches that are sequence-specific and may even afford simultaneous detection and confirmation of target amplicon during the PCR reaction.

1. Nonspecific Real-Time Chemistries

The standard method for nonspecific real-time detection of PCR amplicons is use of fluorescent double-stranded (ds) DNA intercalating dyes such as SYBR Green™ I or SYBR Gold™. Both of these commercial dyes are DNA minor groove binding dyes that fluoresce after interacting with dsDNA (Figure 187.3). Most real-time PCR instruments are programmed to read near the emission and excitation wavelength spectrum of SYBR Green™ (495 and 537 nm, respectively). This dye is very light sensitive, degrading quickly following dilution to working concentrations, but when fully active, affords the user the ability to obtain real-time fluorescence emission data (relative fluorescence units on the y-axis of a plot) as a function of cycle number on the x-axis. Since relative fluorescence units for each sample are plotted during the exponential phase of amplification, results are quantitative and thus useful for determining copy number and genome equivalents from

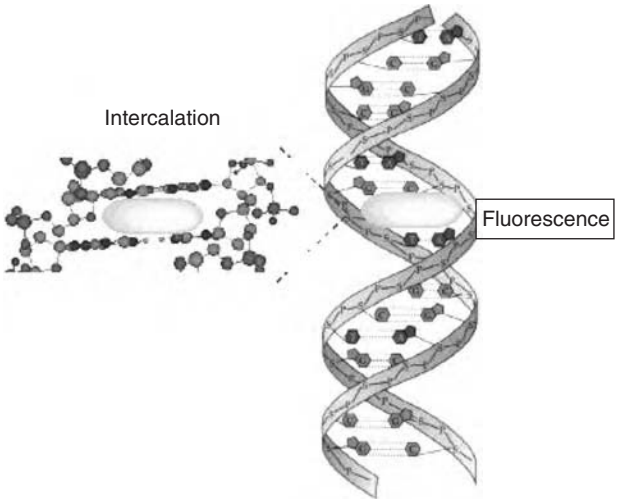

FIGURE 187.3 Interaction of SYBR Green™ I intercalating dye with double-stranded DNA and subsequent fluorescence under appropriate wavelength. The interaction is not sequence-specific.

template DNA purified from food. SYBR Green™ I has been used as an alternative to ethidium bromide for staining DNA in agarose gels, but is also useful for real-time PCR detection assays in food systems, such as quantification of enterotoxigenic *S. aureus* in cheese (147), *E. coli* O157:H7 in a multiplex design (148), and for GMO screening in grains (144). Due to the logistical difficulty in optimizing QC-PCR assays, the approach has limited potential for large-scale applications, particularly in light of many of the real-time chemistries.

In addition to simply quantitative detection of target pathogenic or spoilage bacteria in foods, intercalating dyes such as SYBR Green™ I allow one to discriminate among amplicons in a multiplex PCR reaction by using melt curve analysis. This approach subjects the PCR reactions to slow and continual heating to 95°C while monitoring fluorescence over time. Since each amplicon of a varying length and/or GC content will melt at a slightly different temperature, fluorescence will decrease incrementally according to the population of products in the reaction tube. Once conditions are optimized, the negative derivative of the fluorescence vs. temperature line will allow for small sequence differences, and certainly differences in length of products to become apparent (33) (Figure 187.4). Melt curve analysis has been applied primarily for mutation screening in specific clinical pathogens, but also may be useful for food pathogen detection.

2. Specific Real-Time Detection Chemistries

A diverse array of fluorescently labeled probes are in use clinically and industrially for sequence-specific detection of target DNA or RNA, and many of these have been applied in food analysis. The primary category of these

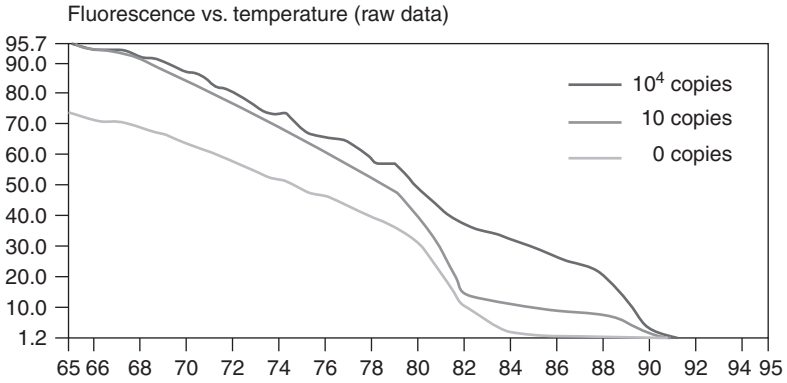

FIGURE 187.4 Melt curves of typical multiplex PCR amplicons showing the typical patterns that may be generated as fluorescence decreases with increasing temperature of samples. Melt curve profiles are useful in distinguishing amplicons in multiplex PCR reactions, or for mutation screening.

involves fluorescence resonance energy transfer (FRET) between a specific fluorophore and a quencher group. Perhaps the most widely used FRET conjugate pair for real-time PCR assays includes the fluorophore FAM (fluorescein) and the quencher TAMRA. The resonance energy from the fluorophore is passed to the appropriate quenching moiety, and if in close proximity (as described below for specific primer and probe regimes), generates low levels, if any, detectable fluorescence as measured by a PCR cycler with fluorimeter capabilities. If separated or alone in solution, the fluorophore will not be quenched and the resonance energy will be emitted as a detectable fluorescent signal at the appropriate wavelength. Depending on the format of the PCR assay, the signal generated will be directly correlated with the amount of target DNA present or amplicon concentration (Figure 187.5). Regardless of the specific means in which the fluorophore/quenching pair is applied, the basis remains the same, and includes the added advantage of sequence specificity that dsDNA intercalating dyes do not offer.

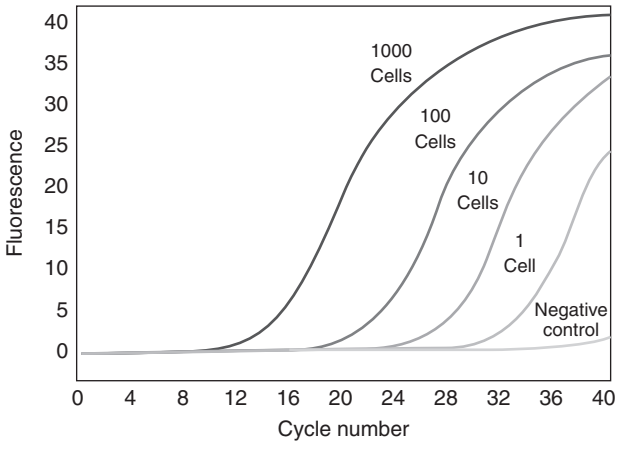

FIGURE 187.5 Real-time fluorescence plot of multiple samples at varying target cell densities analyzed using FRET-labeled probes. Relative fluorescence units are plotted as a function of time or cycle number on the x-axis.

One of the earliest uses for the FRET-based probe approach was the 5′-nuclease (TaqMan) assay, first described as a radioisotopic system, but soon modified to be based on fluorogenics (149). The 5′-nuclease activity incorporates a target gene-specific primer set and a dual-labeled probe that will hybridize to a region on one of the template strands within the primer annealing sites (Figure 187.6). During the extension phase of a PCR cycle, the 5′-3′ exonuclease activity of *Taq* polymerase will cleave the 5′ fluorophore from the terminal end of the hybridized probe, separating it from the quenching moiety, eliciting fluorescence at a specific wavelength (150) (Figure 187.5). Depending on the instrument being used for real-time detection, the investigator may choose to use multiple TaqMan primer and probe combinations in the same reaction tube for multiplexing, with each being detected in a unique optical channel at the respective wavelength. Regardless, TaqMan is a specific and sensitive assay for detection of pathogenic and/or spoilage bacteria in food. In recent years, the TaqMan approach has been reported for *E. coli* O157:H7 in raw milk and other foods (151,152), *Salmonella* spp. in meat and seafood (153,154), *Campylobacter jejuni* from poultry, shellfish, and other commodities (155,156), *Vibrio cholerae* in raw oysters (157), *Yersinia enterocolitica* in raw meats and tofu (158), *Clostridium botulinum* in MAP-packaged Japanese mackerel (159), enterotoxigenic *Bacillus cereus* from nonfat dry milk (160), and *L. monocytogenes* in dairy foods (161,162). These representative studies illustrate the versatility of the TaqMan assay for a very diverse array of foods to detect pathogens to levels as low as 10^1 cfu per ml, although frequently following several hours of preenrichment.

Though not as prevalent in the literature for applications in foods, another interesting variation on the use of double dye FRET-based probes for real-time PCR is the use of molecular beacons. Molecular beacons, first described

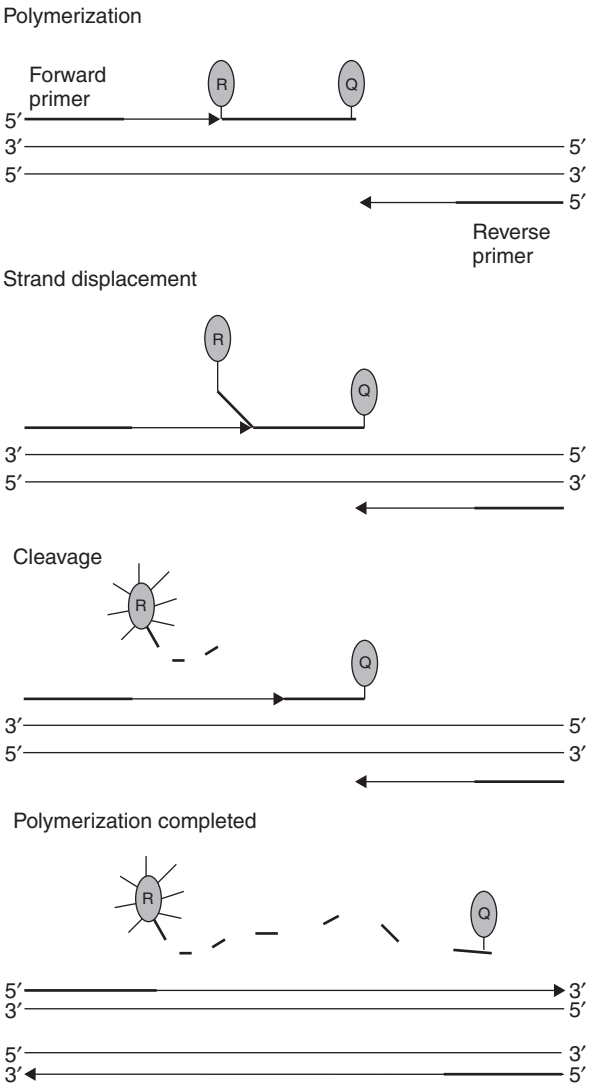

FIGURE 187.6 Mechanism of TaqMan 5′ nuclease assay for real-time detection of PCR products using FRET-labeled probe internal to the sequence-specific primers. R denotes the reporter dye while Q represents the quenching moiety.

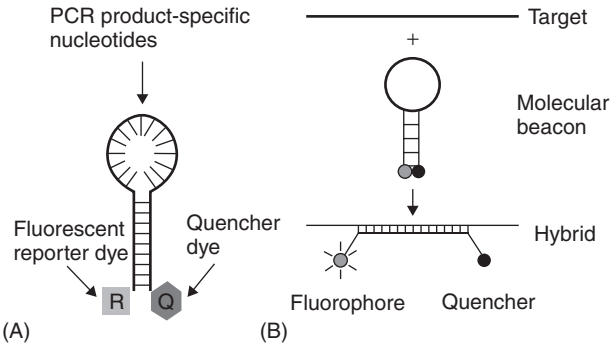

FIGURE 187.7 (A) Molecular beacon stem-loop conformation that forms by intramolecular base pairing when in solution without the presence of complementary target nucleic acid. (B) When in the presence of target DNA or RNA, the molecular beacon unfolds because the bases comprising the loop (probe) region form more numerous and more stable base pairs than those allowing the stem-loop secondary structure to form. A single base mismatch between the target nucleic acid and the probe portion drastically decreases stability of molecular beacon interaction and may preclude it altogether.

by Tyagi and Kramer (163), are short ssDNA probe molecules that are complimentary to target DNA sequences within the gene (or transcript) under study (Figure 187.7). Beacons are comprised of a loop region (the probe sequence) flanked by stem sequences 4–6 bases in length. The loop is comprised of bases with complete complementarity to the target DNA or RNA, and must match with perfect identity to the nucleic acid sequence being detected. The stem portions are designed to be complementary to each other and frequently are comprised of a majority guanine and cytosine bases. A fluorophore reporter dye is conjugated to one end of the molecular beacon and a quencher is attached to the other end (164). When the labeled probe is in solution alone, the beacon assumes the secondary structure conformation by forming intramolecular base pairs involving the stem portion. In this state, the beacon does not fluoresce, or fluoresces at baseline levels. When in the presence of the target nucleic acid, the loop attraction to the target sequence is stronger than the C/G bonds holding the beacon as a stem-loop, resulting in an unfolding of the probe, separating the quencher and reporter dye and emitting detectable fluorescence (163,165).

Although not widely employed in foods to date, molecular beacon technology offers many advantages, including simultaneous detection and confirmation of target nucleic acid when incorporated in PCR reactions flanked with sequence-specific primers. The stability of the stem structure helps to ensure that unfolding and hybridization will only occur in the presence of perfectly complementary base pairs, making the use of molecular beacons essentially a solution-based fluorimetric Southern blot. FRET-labeled beacon probes have been used as a clever means of assessment for ribonuclease H activity *in vitro* (166), but have recently been demonstrated on pathogens relevant to the food industry, including *Salmonella* and *E. coli* O157:H7 (167–169). Although extremely specific and capable of multiplexing, molecular beacons are still fairly cost-prohibitive, a feature likely to delay extended use as a means of rapid pathogen detection in foods. Specific variations of the FRET chemistries exist commercially, such as the Scorpion® primer (Eurogentec, Belgium) approach that relies on a quenched hairpin loop-based PCR primer that unfolds following the extension step and elicits fluorescence (170). Although not widely used yet in the food industry, such proprietary spin-off technologies offer great utility beyond the clinical arena. Regardless of the real-time chemistry selected, a number of commercial real-time instruments are

available such as the ABI Prism® 7000 (Applied Biosystems), RotorGene (Corbett Research), Cepheid's Smart Cycler® II System, and the BioRad iCycler iQ Real-Time Detection System. Most of these offer 2–4 optical channels to allow for multiplex capabilities, as well as interactive software for user-friendly data analyses.

V. RNA ASSAYS—MONITORING VIRULENCE GENE EXPRESSION IN FOOD PATHOGENS

A. The VBNC Dilemma

Although DNA (i.e., virulence determinant gene sequence) is the most frequent choice of target molecule when designing a PCR-based detection assay for foodborne pathogens, differentiation of living from dead bacteria is not possible, as DNA may be quite persistent in dead cells (171–175). Moreover, traditional culture-based approaches for enumeration of sublethally injured and/or viable-but-nonculturable (VBNC) bacteria are not accurate, as the selective media employed prevents many such bacteria from growing to visible, countable colonies. Specialized approaches utilizing viability dyes that interact specifically with DNA from dead cells and prevent it from being amplified by PCR may be augmented using additional fluorescent tags that allow for quantitation with confocal laser scanning microscopy are not practical for high-throughput sample analyses (176). Therefore, in order to accurately detect and monitor pathogenic foodborne bacteria (particularly VBNC cells) as well as virulence gene expression, RNA-based methods must generally be used.

When selecting RNA as a determinant of cell physiological state (177), one must bear in mind that ribosomal RNA (rRNA) is not an appropriate target, as bacterial ribosomes are stable for at least 48 hours after cell death (174). Ultimately, only mRNA is ideal to use as an indicator of either the metabolic status of bacteria or assessment of VBNC pathogens that must be assumed to still pose a threat if ingested by the consumer in contaminated food (178,179). Initial studies reporting the detection and measurement of gene expression in foodborne pathogenic bacteria implemented reverse transcriptase PCR (RT-PCR) as the means to the qualitative end of mRNA analysis. This labor-intensive protocol involves total RNA extraction from enrichment cultures, DNase-I treatment to eliminate genomic DNA (to preclude the incidence of false positive results), reprecipitation of RNA, and a reverse transcriptase step to enzymatically convert target transcripts to cDNA using a sequence–specific primer. The product is eventually converted to dsDNA in traditional PCR cycling using a second (forward) primer flanking the region of interest. In addition to samples, one needs to prepare a no reverse transcriptase control reaction to confirm the absence of gDNA carryover, as well as a no template control as a contamination screen (both of which should never yield an amplicon on the gel).

In practice, mRNA amplification using RT-PCR has been used to monitor cell viability in bacteria of relevance to the food industry (172,173,179–181). However, because of the inherent sensitivity issue (owing to the laborious process of RNA recovery), as well as moderate sample-to-sample variations in yield, RT-PCR is not a feasible means of high throughput gene expression analysis for the food industry, even with the onset of new commercial products such as single step RT protocols designed to streamline the process.

B. Nucleic Acid Sequence-Based Amplification (NASBA)

A more rapid means of RNA analysis has been applied in studies of virulence gene expression in bacteria and viruses for clinical microbiology, and also lends itself particularly well for viable cell determination (182,183). First described by Compton (184) and Fahy et al. (185), nucleic acid sequence-based amplification (NASBA) is an isothermic cyclical series of reactions utilizing RNA as template (either purified using acidic/phenol or 'whole cell' NASBA starting template) combined with an enzyme cocktail (Figure 187.8). NASBA begins with first-strand cDNA synthesis catalyzed by AMV reverse transcriptase using a transcript-specific forward primer. RNase H activity digests only the RNA half in the RNA-DNA heteroduplex, leaving ssDNA. Second-strand DNA synthesis then occurs by way of a second sequence-specific (reverse) primer containing a T7 RNA polymerase promoter sequence engineered on the 5′ end, extended with the DNA polymerase activity of the AMV reverse transcriptase. Double-stranded

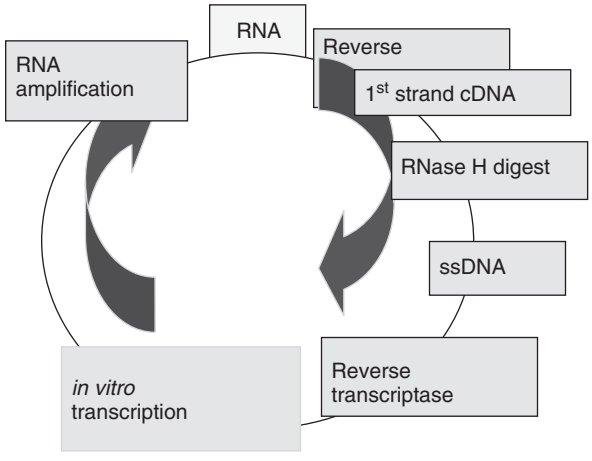

FIGURE 187.8 Nucleic acid sequence-based amplification (NASBA) for RNA amplification (i.e., virulence gene expression studies). Details of this isothermic process are explained in the text.

DNA results, allowing *in vitro* transcription to occur using T7 RNA polymerase (interacting at the promotor site on the second primer, incorporated into the dsDNA extension products), generating many mRNA copies of the original transcript template. A typical 90 minute NASBA reaction series is performed at 42°C and may amplify mRNA some 10^{15}-fold as *in vitro* transcription products serve as template for subsequent rounds of NASBA. The amplified RNA may be visualized via subsequent RT-PCR, or any of a number of real-time chemistries with appropriate fluorophores.

Because of the promotor-containing reverse primer utilized in NASBA assays, this procedure may be performed in a DNA background, unlike RT-PCR. Therefore, NASBA is more rapid than traditional methods for RNA detection, and if linked with real-time detection chemistry such as FRET probes (i.e., molecular beacons), has the ability to detect virulence gene expression in any pathogen relevant to the food industry. NASBA has recently been applied in the study of *Campylobacter jejuni* in foods (186,187) and to monitor enterotoxin gene (*hblC*) expression in three strains of toxigenic *Bacillus* spp. in contaminated milk (188). Although seemingly a very specialized technology at first glance, the speed and versatility of NASBA to be modified with a variety of uniplex or multiplex real-time chemistries make this method an attractive option when one wishes to assess virulence gene expression in target foodborne pathogens. To date, only one commercial supplier (Organon Teknika, Durham, NC, USA & Markham, Ontario, Canada) manufactures a NASBA assay in kit form (Nuclisens®), although the individual enzymes are available from virtually any supplier of molecular biology reagents for individual optimization sample-to-sample.

C. Microarrays

It is widely believed that thousands of genes and their products (i.e., RNA and proteins) in a given living organism function in a complicated and orchestrated way that creates the mystery of life. However, traditional methods in molecular biology generally work on a one gene in one experiment basis, which means that the throughput is very limited and the whole picture of gene function is hard to obtain. In the past several years, a new technology, called DNA microarray, has attracted tremendous interests among biologists and offers much in the way of high throughput analysis of virulence gene expression in food-associated pathogenic bacteria (189). This technology promises to monitor the whole genome on a single chip so that researchers can have a better picture of the interactions among thousands of genes simultaneously. An array is an orderly arrangement of samples. It provides a medium for matching known and unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. An array experiment can make use of common assay systems such as microplates or standard blotting membranes, and can be created by hand or make use of robotics to deposit the sample (189,190). In general, arrays are described as *macroarrays* or *microarrays*, the difference being the size of the sample spots. Macroarrays contain sample spot sizes of about 300 microns or larger and can be easily imaged by existing gel and blot scanners. The sample spot sizes in microarrays are typically less than 200 microns in diameter and these arrays usually contains thousands of spots. Microarrays require specialized robotics and imaging equipment that generally are not commercially available as a complete system (Figure 187.9).

There are two major application forms for DNA microarray technology: 1) Identification of sequence (gene/gene mutation); and 2) Determination of expression level (abundance) of genes. In the former, a cDNA probe (500–5,000 bases long) is immobilized to a solid surface such as glass using robot spotting/lithography and exposed to a set of targets either separately or in a mixture. This method, traditionally called DNA microarray, is widely considered as developed at Stanford University (191,192). The second method is likely to prove more directly useful in the food industry over the next several years as a means of global gene expression analysis. In this variation, an array of oligonucleotides (20–80-mer oligos) are synthesized either *in situ* (on-chip) or by conventional synthesis followed by on-chip immobilization. The array is exposed to labeled sample DNA, hybridized, and the identity/abundance of complementary sequences are determined using quantitative instrumentation (Figure 187.9). DNA microarray technology has been a most powerful technique in areas of clinical and environmental microbiology since its inception, and will likely demonstrate great potential in the food industry as a sensitive means of detecting gene expression in a battery of target pathogens.

VI. SUMMARY

In an effort to stay abreast of heightened public awareness of food safety, and in light of contemporary concerns of food bioterrorism, research and development of nucleic acid-based molecular tools for pathogen detection, enumeration, and subtyping must expand. Such DNA- and RNA-based assays offer versatility in reducing the incidences of false negative quality assurance screening measures, sensitivity in processing heterogenous food matrices, specificity in differentiating among closely related target bacterial strains, and speed, as in the case of many of the real-time fluorescent chemistries flooding the market (3). Although some of these nucleic acid-based technologies are unlikely to supersede conventional culture, biochemical, or antibody based testing regimes completely, most offer significant

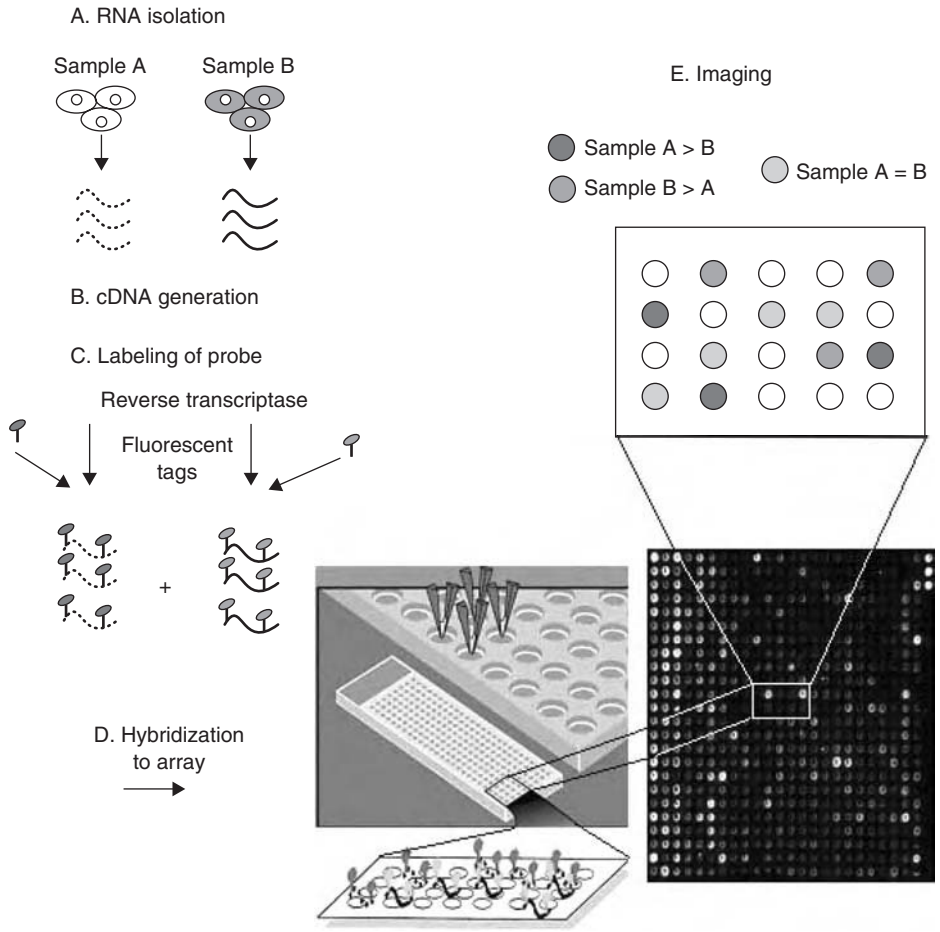

FIGURE 187.9 DNA microarray showing the steps in preparing oligonucleotide fragments that are subsequently probed using complementary sequences for quantitative large-scale, high throughput screening of gene expression using fluorescence. Details are explained in the text.

potential for high throughput and reliability, advantages that offset the cost of initial equipment needs and ongoing maintenance.

The notion of quality control by performing a PCR assay and sample analysis by agarose gel electrophoresis is obsolescent. The need to perform an enrichment step in order to increase cell numbers prior to the appropriate assay will likely be replaced with molecular approaches that are powerful enough to elicit reliable data in the midst of carbohydrates, lipids, and cellular debris from varied food matrices. Whether this will involve a spin-off of one of the existing approaches discussed on the previous pages remains to be seen (193), but in a time when the public demands both fresh ready-to-eat foods and a wide safety margin, detection of existing and emerging bacterial foodborne pathogens, and quantitation of spoilage microbes for accurate shelf life prediction is vital to meet an ever-increasing demand for a growing spectrum of convenience as well as fresh, ready-to-eat foods. The food industry's proverbial tug-of-war between conventional microbiological techniques for ensuring food safety and the implementation of molecular approaches must be carefully staged and stringently refereed.

188 Methods for the Detection of Viral and Parasitic Protozoan Pathogens in Foods

Doris H. D'Souza, Julie Jean, and Lee-Ann Jaykus
Department of Food Science, College of Agriculture and Life Sciences,
North Carolina State University

CONTENTS

I. INTRODUCTION

Both the human enteric viruses and the parasitic protozoa are now recognized as significant causes of human disease, perhaps being responsible for as much as 68% and 3% of all foodborne illness in the U.S., respectively (1). Although they have been recognized for years, the human enteric viruses and parasitic protozoa could be considered "emerging" agents of foodborne disease, largely because scientists have only recently been able to detect these pathogens. In fact, prior to the advent of molecular biological techniques, epidemiological criteria were the primary means by which cases of enteric viral and parasitic illness were recognized. Unfortunately, epidemiology had several limitations including the fact that the diseases caused by most gastrointestinal viruses and parasites were (and are) not reportable in the U.S.; only the largest, most severe, and/or most widespread outbreaks were (and are) investigated, leaving smaller outbreaks and sporadic disease underestimated; and early detection capabilities, even for clinical (fecal and blood) specimens, were severely limited. These early detection methods, which sought to

directly detect either the virus particle or parasite cyst or oocyst, were based mostly on some form of microscopy. Later methods relied on detection of antigen (enzyme immunoassay) in the stool, or alternatively, on seroconversion, i.e., a rise in specific antibody titer against the pathogen. The microscopic methods had poor sensitivity, and the reagents necessary for the serological methods were not always available to clinical laboratories. Among other factors, the absence of dependable detection methods contributed to an underestimate of the true scope and significance of foodborne viral and parasitic protozoan infections.

The human enteric viruses replicate in the intestines of infected human hosts, are excreted in the feces, and are therefore transmitted by the fecal-oral route through contact with human fecal pollution. In some instances, the parasitic protozoa are less species specific and can therefore be transmitted by the fecal oral-route through contact with either human and animal feces. Both viruses and parasites can also be spread by person-to-person contact, a phenomenon which is frequently responsible for the propagation of primary foodborne outbreaks. Contamination may occur directly, through poor personal hygiene practices of infected food handlers, or indirectly, via contact with fecally contaminated waters or soils. Since both types of agents must survive the pH variations and enzymes present in the human gastrointestinal tract, they are regarded as highly environmentally stable, allowing virtually any food to serve as a vehicle for their transmission and enabling them to withstand a wide variety of food processing and storage conditions. Neither viruses nor parasitic protozoa are able to replicate in contaminated foods. Furthermore, when found in foods, they are likely to be present in low numbers, but since their infectious doses are presumed to be low, any level of contamination may pose a public health threat.

The human enteric viruses of primary epidemiological significance include the hepatitis A virus (HAV) and the Noroviruses, formerly known as the Norwalk-like viruses (NLVs) and before that, as the small round structured viruses (SRSVs) (reviewed in ref. 2). The Sapoviruses (previously called Sapporo-like viruses) which are genetically related to the Noroviruses, have also caused cases of viral gastroenteritis in humans. Both the Noroviruses and the Sapoviruses are members of the *Caliciviridae* family, an antigenically and genetically diverse group of gastrointestinal viruses. The other viruses that can cause food and waterborne disease include the astroviruses, the human enteroviruses (polioviruses, echoviruses, groups A and B coxsackieviruses), hepatitis E virus, parvoviruses, and other relatively uncharacterized small round viruses. The rotaviruses, which are the leading cause of infantile diarrhea worldwide, are transmitted primarily by contaminated water but can on occasion be foodborne.

The parasitic protozoa of primary foodborne significance include *Cyptosporidium parvum, Giardia lamblia, Cyclospora cayetanensis*, and *Toxoplasma gondii* (reviewed in refs. 3–6). The former three organisms cause predominantly gastrointestinal manifestations, while the latter organism is associated with severe birth defects in infants whose mothers become infected during pregnancy. All of the parasitic agents can cause serious disease in immunocompromised hosts. Like the viruses, parasitic protozoa are obligate intracellular parasites that produce environmentally stable forms that serve as the vehicle for infection. Both *Cryptosporidium* and *Giardia* are primarily transmitted by waterborne routes, but foodborne infections have been reported. Toxoplasmosis has long been recognized as an uncommon but nonetheless severe foodborne infection that can be transmitted by the consumption of contaminated meats, offal, or unpasteurized milk, as well as by waterborne routes and contact with cat feces (5). *Cyclospora cayetanensis*, which to date has been almost exclusively foodborne, has been associated with the consumption of contaminated imported produce items (7).

Historically, the detection of human enteric viruses from food concentrates has been based on virus infectivity assays using susceptible, live laboratory hosts. Host systems employed were mainly mammalian cell cultures of primate origin, particularly primary and secondary human embryonic kidney and monkey kidney cell cultures. However, it is critical to note that to a large degree, the epidemiologically important human enteric viruses, including the Noroviruses and wild-type hepatitis A virus, cannot be propagated in mammalian cell culture systems and so these are not viable detection options. For the parasitic protozoa, many of the same considerations exist. For instance, cell culture and animal models for the propagation of *C. cayatanensis* are in developmental phases only (3). Although *C. parvum* can be assayed for infectivity using either cell culture or the mouse bioassay, neither method is very practical for the routine detection of this pathogen.

Likewise, immunological and DNA hybridization-based assays are not practical approaches for the detection of viruses and parasitic protozoa in foods. For viruses, this is due in part to the unavailability of immunological reagents, particularly for the antigenically diverse Noroviruses. While acid fast and immunologically based fluorescent staining techniques (or autofluorescence for *Cyclospora*) may be considered the "gold standard" for the detection of parasitic protozoa in environmental samples, and many effective kits exist for their detection in clinical specimens (8), these methods are laborious, require highly trained personnel, and are subject to interpretive problems when sample matrix components interfere with the assay. Furthermore, immunological methods tend to have relatively poor assay detection limits ($>10^3$–10^5 detection units/sample) which restricts their applicability to food samples, which are likely to be contaminated with small numbers of pathogens. Much the same can be said for DNA hybridization methods.

Without question, nucleic acid amplification methods have emerged as a promising approach when it comes to methods to detect enteric viruses and parasitic protozoa in foods. Methods such as the polymerase chain reaction (PCR) have the theoretical ability to replace standard cultural enrichment methods with faster nucleic acid enrichment. For the detection of viruses and parasitic protozoa, where cultural enrichment methods are virtually not feasible, this is a tremendous improvement. The purpose of this chapter is to discuss recent developments in molecular detection methodology that are enabling scientists to begin detecting viruses and parasitic protozoa in foods, and to identify research needs that must be effectively addressed before this effort can become a routine reality.

II. GENERAL DETECTION CONSIDERATIONS

There are significant impediments to the development of effective virus and parasitic protozoan detection methods as applied to food commodities. Similar to bacterial pathogens, these agents are likely to be present at low levels in contaminated foods. However, unlike bacterial pathogens, both viruses and protozoa require live mammalian cells in order to replicate, so the traditional food microbiological techniques of cultural enrichment and selective plating cannot be used. The general concept, then, is to separate and concentrate the agents from the food matrix prior to detection. In summary, in order to effectively detect viruses and parasitic protozoa from foods, one must consider the following restrictions: (i) the agents are inert in the food; (ii) they are likely to be present in very low numbers or intermittently in the product; (iii) because of (ii) above, it is necessary to process relatively large sample volumes to assure representation and promote detection; and (iv) the food matrix possesses inhibitory substances or interferences that can later compromise detection. In general, molecular detection schemes for viruses and parasitic protozoa in foods rely on five sequential steps, which can be designated (i) sampling; (ii) pathogen concentration and purification; (iii) nucleic acid extraction; (iv) detection; and (v) confirmation. These will be discussed in detail below.

III. SAMPLING

For effective sampling, a large and representative sample size is needed. A sample size of 25−100 g is usually recommended, which is large enough to provide adequate representation yet small enough to work with in the laboratory. To further increase the chances for detection, the analyst may choose to obtain multiple samples of the suspected or implicated product. For complex food products such as sandwiches, it may be easier to divide the product into its component parts, processing each part separately for pathogen concentration and detection. For instance, some investigators have processed dissected digestive tracts in an effort to improve virus recovery efficiency from contaminated raw molluscan shellfish. Although the viruses and parasites may be relatively stable in the food matrix, food samples should nonetheless be refrigerated upon collection and processed immediately for virus recovery upon receipt by the testing facility. Freezing may inactivate parasitic protozoa and should hence be avoided if attempting detection of these pathogens (9).

IV. PATHOGEN CONCENTRATION

The most common molecular amplification method applied for the detection of pathogens, including the parasitic protozoa, is the polymerase chain reaction (PCR). Since the nucleic acid for the enteric viruses is RNA, the PCR must be preceded by a reverse transcription step, producing cDNA which can then be readily amplified in a subsequent PCR, hence the designation RT-PCR. When using PCR or RT-PCR for the detection of viruses or parasitic protozoa in foods, one must consider pathogen concentration as a prerequisite to detection. In actuality, appropriate sample preparation prior to detection is even more important when applying molecular methods because of the small sample volumes ($<$10 µl) used in nucleic acid amplification reactions, as compared to 0.5–1.0 ml volumes used for cell culture infectivity assays or ELISA methods. Therefore, the pathogens and/or their nucleic acids must be concentrated and purified from food matrices before applying detection methods such as PCR or RT-PCR. The challenges of high sample volumes, low levels of contamination, and the presence of residual food components that can act as enzymatic inhibitors (10–14) must all be considered in designing these assays.

A. Principles of Virus Concentration in Foods

The purpose of virus concentration methods is to reduce sample volume and remove matrix-associated interfering substances, all the while recovering most of the viruses that are present in the food sample. Sample manipulations undertaken during concentration utilize the property of the viruses to behave as proteins in solutions, and their ability to remain infectious at extremes of pH or in the presence of organic solvents such as chloroform, trichloro-trifluoro ethane (Freon), and the more environmentally friendly solvent Vertrel® (DuPont Chemical Company). Almost all of the early work in virus concentration and purification from foods was limited to bivalve molluscan shellfish, largely because of their frequent association with viral foodborne disease outbreaks. More recent efforts have targeted a wider variety of at-risk foods.

As applied to shellfish, two general schemes for virus concentration have been reported, designated

extraction-concentration and adsorption-elution-concentration (15). These methods were developed in the decades between 1970 and 1980 and produced concentrates that could be assayed for virus infectivity using mammalian cell culture techniques. Both schemes employ conditions that favor the separation of viruses from shellfish tissues, primarily through the use of filtration, centrifugation, adsorption, elution, solvent extraction, precipitation, and organic flocculation. All protocols begin with sample blending in some type of buffer, usually containing amino acids and an elevated pH. Further processing may sometimes be preceded by a crude filtration step, through a mesh material such as cheesecloth, to remove particularly large sample particulates. A general theme in all of these scenarios is that viruses, since they are so small, do not sediment unaided, even at high centrifugation speeds (10,000 × g). This means that that routine centrifugation can be used without substantial virus loss as long as the virus-containing supernatant is recovered in the process. By pH manipulation or the addition of precipitation agents, conditions can be created such that viruses adsorb to the shellfish tissues, and when followed by centrifugation, the adsorbed viruses will sediment with the tissues and residual fluids are discarded with the supernatant. This is usually followed by an elution step, whereby virus desorption from the tissues is facilitated by further pH and/or ionic manipulations and subsequent centrifugation, discarding the precipitated tissue in the process. In this case, a large proportion of the food matrix can be disposed of while retaining a relatively clear solution that contains most of the recovered viruses and smaller amounts of matrix-associated organic material.

Other sample manipulations are designed to further remove matrix-associated organic materials and reduce sample volume, all the while optimizing recovery of viruses. For instance, a variety of organic solvents can be used to remove lipid materials, capitalizing on the fact that virus infectivity remains intact even after exposure to organic solvents. Virus precipitation can be accomplished using pH reduction, called acid precipitation, or else through the use of polyethylene glycol (PEG). Both methods are based on the fact that viruses behave as proteins in solution; by reducing the pH to that approximating the virus isoelectric point, the virus will precipitate, along with other matrix-associated proteins. Polyethylene glycol essentially removes water, allowing proteins to fall out of solution. A related precipitation method is organic flocculation. Used extensively in water treatment, flocculating agents interact with organic material in the matrix, causing the formation of a gelatinous "floc" to which the viruses adsorb. In the case of acid and PEG precipitation, and in organic flocculation, the virus-containing solid materials can be readily harvested by centrifugation. Finally, methods such as ultrafiltration can further reduce same volumes. The same general principles of filtration, centrifugation, adsorption, elution, solvent extraction, precipitation, and organic flocculation are used when extracting and concentrating viruses from food commodities other than shellfish. For purposes of illustration, a candidate virus concentration and detection protocol is illustrated in Figure 188.1. Note that this is only one of literally hundreds of iterations of the basic techniques used for the concentration of viruses from foods.

With the advent of molecular biology methods and their use in detection, additional virus concentration methods have been reported. For instance, alternative

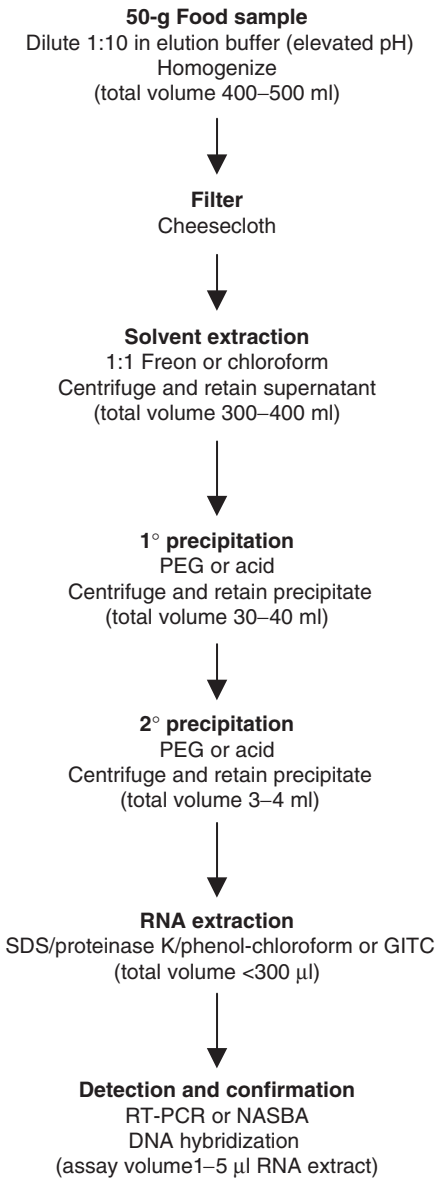

FIGURE 188.1 Representation of virus concentration and detection scheme for foods, consisting of sequential steps of filtration, solvent extraction, primary and secondary precipitation, RNA extraction, detection and confirmation.

commercial virus purification agents such as ProCipitate™ and Viraffinity™ (LigoChem, Inc., Fairfield, NJ 07004) (11,16,17) have been found to eliminate polysaccharides, an important matrix-associated inhibitor in shellfish and produce. Likewise, the cationic detergent cetyltrimethylammonium bromide (CTAB) (16,18–20) also promotes the removal of polysaccharides. Several other protocols utilizing Sephadex (21), cellulose (22), or Chelex (23) effectively eliminate salts and small proteins. D'Souza and Jaykus (24) used zirconium hydroxide to concentrate enteric viruses in a method resembling organic flocculation. Another active area of research has been immunomagnetic separation (25–28).

1. Virus Concentration Methods for Shellfish

Historically, two different approaches have been applied to prepare food samples for nucleic acid-based methods to detect enteric viral contamination. The first and most common approach relies on some form of virion concentration prior to release or extraction of nucleic acid and subsequent amplification. The second circumvents the need for virus concentration methods altogether by resorting to direct nucleic acid extraction of the food matrix. As with the early virus concentration work that was done to facilitate detection in cell culture, most methods to concentrate viruses in preparation for molecular detection were initially developed and evaluated for shellfish commodities.

In the case of virion concentration, the investigator aims at concentration of viruses and removal of inhibitors prior to the application of nucleic acid amplification, with or without prior nucleic acid extraction. In early work, Atmar et al. (19,20) processed artificially contaminated shellfish samples using an initial concentration and purification scheme consisting of solvent extraction and PEG precipitation, followed by nucleic acid extraction and subsequent amplification. Cetyltrimethylammonium bromide (CTAB) was added to remove residual inhibitors from crude nucleic acid extracts, and the resulting solution was amplifiable using RT-PCR. These investigators were able to further improve detection limits by dissecting the oysters, discarding the muscle tissue and processing only the digestive diverticula. This has remained the sampling method of choice for a number of other investigators (29–35). Other investigators have used also used glycine buffer elution, single or sequential PEG precipitation, and/or Freon extraction to initially purify the viruses from large sample sizes of shellfish, followed by extraction of total nucleic acids and subsequent RT-PCR amplification (33,36–42).

Some investigators have focused on optimization of virus extraction methods from shellfish. For instance, Croci et al. (43) evaluated four different elution buffers (PBS, pH 9.5; glycine, pH 9.5; and 0.3 or 3% beef extract, pH 9.5) and four different concentration techniques (acid precipitation, PEG precipitation, ultracentrifugation, and ultrafiltration) in an effort to optimize RT-PCR detection of viruses from mussels. Muniain-Mujika et al. (44) looked at the effect of alternative elution buffers (borate buffer, pH 9.5; glycine buffer with conductivity changes, pH 7.5; nutrient broth with Tween 80; and glycine buffer, pH 10) on the recovery of viruses from shellfish, finding the latter to be the most efficient. Likewise, Traore et al. (45) investigated four methods of elution (borate buffer, gycine buffer, saline beef extract, and beef extract-Freon) and three methods of concentration (PEG 6000, PEG 8000, and organic flocculation) to prepare mussel samples for the detection of three enteric viruses using RT-PCR. These investigators found that borate or glycine buffers performed best, as did both PEG 6000 and organic flocculation as concentration methods.

Other investigators have started with an adsorption-elution-precipitation method for the concentration of viruses from 50-g samples of shellfish, resulting in an aqueous solution of 10–20 ml in volume (46,47). This has been followed by additional virus concentration steps which included two consecutive extractions using Freon followed by virus precipitation with polyethylene glycol and further removal of matrix-associated inhibitors, particularly polysaccharides, using proprietary agents such as ProCipitate™ or Viraffinity™ (11,16,48). In a recent study, Mullendore et al. (49) reported a modified virus concentration method that consisted of acid adsorption at pH 4.8, two sequential elutions using glycine and threonine-based buffers, respectively, two PEG precipitations, and two chloroform extractions. After nucleic acid extraction and RT-PCR, detection limits were 1 PFU HAV/g oyster meat.

Others have used an antibody capture step to further concentrate and purify viruses from shellfish extracts prior to detection using RT-PCR. In its first application, Desenclos et al. (50) implicated hepatitis A virus in oyster outbreak specimens by immunocapture of the virus, heat release of viral nucleic acids, and subsequent RT-PCR detection. Building upon the clinical work of Jansen et al. (51), other investigators coated paramagnetic beads with anti-HAV IgG, mixed these with one ml volumes of oyster extract initially processed for virus concentration using a combination of elution, polyelectrolyte flocculation, filtration and/or ultrafiltration, and then captured the HAV to provide further virus concentration (25,27). Antibody capture steps have been used as a final virus concentration step by others as well (28).

Some investigators have used a direct nucleic acid extraction RT-PCR method that involves extraction of total sample RNA, including viral RNA, without any prior sample manipulations. Although perhaps best suited for simple sample matrices such as the surfaces of fresh fruits and vegetables, Legeay et al. (29) reported a method that involved enzymatic liquefaction of shellfish digestive tissues, followed by clarification using dichloromethane

extraction. This method produced a concentrate that could be extracted directly for nucleic acid isolation and subsequent virus detection using RT-PCR.

2. Virus Concentration Methods for Other Foods

Gouvea et al. (52) were the first to systematically develop a method to detect Norwalk virus and rotavirus from representative food commodities other than shellfish, including orange juice, milk, lettuce, and melon. By blending or washing, clarification by centrifugation, and RNA extraction with further removal of inhibitors using a Freon extraction, these investigators were able to detect both viruses in various foods. Schwab et al. (53) reported the use of TRIzol, a proprietary RNA extraction method, to wash deli meats, including samples artificially contaminated with Norwalk virus and ones linked to an outbreak of Norwalk-like viral gastroenteritis, for subsequent detection by RT-PCR. While the TRIzol surface wash method was reportedly simple, nucleic acid amplification inhibition persisted unless sample concentrates were diluted 10- to 100-fold.

Leggitt and Jaykus (17) developed a prototype method employing homogenization, filtration through cheesecloth, Freon extraction (hamburger only) and two sequential PEG precipitations to concentrate poliovirus, hepatitis A virus, and Norwalk virus from 50 g samples of artificially contaminated hamburger sandwiches and lettuce. The sequential precipitations were done at increasing PEG concentration and resulted in a 10- to 20-fold sample volume reduction from 50 g to approximately 2.5 ml. When appropriate, the resuspended PEG precipitate could be assayed for virus recovery by mammalian cell culture infectivity assay, with virus recoveries approximating 50% for poliovirus but only 4% for hepatitis A virus. Subsequent nucleic acid extraction resulted in an additional 100-fold sample volume reduction and detection could be achieved at initial inoculum levels of $\geq 10^2$ infectious units/50-g food sample. Similar to the TRIzol wash method of Schwab et al. (53), the final RNA concentrates obtained in this study were compatible with nucleic acid amplification after a one- to two-$\log_{10}$ dilution (17).

Most recently, Bidawid et al. (54) reported a method for the concentration of hepatitis A virus from lettuce and strawberries. After washing to remove the viruses, the wash solution was passed through a positively charged filter, eluted, and further concentrated by immunocapture. The investigators reported that as few as 10 PFU of cell culture-adapted hepatitis A virus per piece of lettuce or strawberry could be detected by RT-PCR, but residual amplification inhibition remained problematic.

It should be clear from the above discussion that by preceding nucleic acid amplification with virus concentration and sample purification steps, the investigator can achieve significant sample volume reductions with recovery of infectious viruses. The antibody capture methods may require even fewer sample manipulations, making these methods perhaps simpler than others. This strategy also has advantages in that a positive reaction demonstrates the presence of antigen-associated viral nucleic acid, which may be more highly associated with infectious virus than detection of free viral nucleic acid (25). However, concentration methods are not without their disadvantages, including the need for multiple sample manipulations which may result in substantial virus loss during the extraction steps, impacting assay detection limits. While the specificity of antibody capture methods may be appealing, limited reagent availability and the fact that only a single virus type can be targeted in a specific antibody capture reaction are considered limitations by some. Schwab et al. (26) used human hyperimmune serum in immunocapture methods to target a wider variety of enteric viruses, but these reagents can be costly and are not available to all laboratories. The direct nucleic acid extraction methods, while simpler, almost always result in residual RT-PCR inhibition and may not provide adequate sample volume reduction.

When taken together, virus concentration methods result in sample volume reductions ranging from 10- to 1000-fold, which means that a 25-g sample theoretically can be reduced to 25 µl–2.5 ml volumes with recovery of infectious virus. In the food matrix, the yields after virus concentration have ranged from as low as 1–2% to as high as 90%. Yield is almost always virus-specific, and a general rule of thumb is that recovery efficiency for hepatitis A virus is usually quite low, that for the human enteroviruses (poliovirus as a model) are quite high, and that for the *Caliciviridae* is in an intermediate range. Further volume reductions can be achieved through effective nucleic acid extraction, and this is discussed below. It is important to remember that there are many methods for the extraction and concentration of viruses from foods, all of which use the same general sample manipulations in varying combinations. Interested readers are advised to consult Jaykus et al. (55) for a more detailed review of methods to detect enteric viruses in shellfish or Jaykus et al. (13) for a more detailed discussion of specific virus detection methods in foods. There are, however, limitations to all of these virus extraction and concentration approaches that ultimately impact the ability to detect the relatively low levels of virus that might be anticipated in naturally contaminated foods. Tables 188.1 and 188.2 highlight the detection limits reported by a number of investigators in their efforts to develop methods to detect viruses from artificially contaminated shellfish and other food commodities, respectively.

B. Principles of Parasitic Protozoa Concentration in Foods

Like viruses, parasitic protozoa must also be concentrated and purified from the food matrix prior to detection. Almost exclusively, the early parasite concentration

methods were developed for environmental water samples and focused on the two important waterborne parasitic protozoa, i.e., *C. parvum* and *G. lamblia*. As applied to environmental waters, detection has included three basic steps, e.g., pathogen concentration, purification, and detection (3). Both filtration and centrifugation approaches are effective for the concentration and purification of protozoa, largely because the cysts or oocysts are much larger than viruses or bacteria, so they can be readily captured on filters and will sediment at relatively low centrifugal forces. Filtration is a common first step, and both cartridge and membrane filters have been used, the former being an excellent choice when processing large sample sizes of environmental waters. After elution of the pathogens from filters, centrifugation approaches have been used for further pathogen concentration and purification. These include differential centrifugation, density gradient centrifugation, and/or immunomagnetic separation. The latter are available commercially for the further concentration of *Cryptosporidium* oocysts (8).

1. Parasitic Protozoa Concentration Methods for Foods

Relatively less work has been done in developing methods to concentrate and purify parasitic protozoa from a

potentially contaminated food matrix. In part, this is because of a general lack of epidemiological data linking foods as a critical vehicle of transmission for the common enteric protozoa. However, food matrices may at times be more complex than environmental waters, further complicating the development of concentration and purification methods. Most of the developmental work in this area has been done on shellfish matrices, with only a few studies attempting pathogen concentration from other potentially contaminated foods. In the few instances when these techniques have been applied to shellfish matrices, investigators have recovered hemolymph and used it directly for immunofluorescent staining or PCR for detection. Alternatively, oocysts have been recovered by PBS washing of dissected gill tissue (56–60) or else by using an alkaline digestion method (61). In recent work, Graczyk et al. (60) processed whole mussels by grinding in PBS, sieving the homogenate with recovery of the finest particle fraction (<100 μm), followed by overnight sedimentation at 4°C and cesium chloride density gradient centrifugation to achieve further concentration and purification of oocytes. Deng et al. (62) used an immunomagnetic separation method to concentrate *C. parvum* from apple juice and milk. These investigators carried out a primary concentration step using sucrose flotation, and then treated the concentrate with rabbit anti-*C. parvum* antibodies, which were subsequently captured using magnetic beads coated with anti-rabbit IgG. After subsequent elution, the oocysts were visualized by fluorescent microscopy.

With the emergence of *C. cayetanensis* in the 1990s, several investigators developed prototype methods to concentrate and purify the oocyctes of this organism from contaminated produce items in preparation for detection by molecular amplification methods. In the first study of its kind, Ortega et al. (7) eluted the oocytes by washing large sample sizes of raspberries using distilled water, then centrifuged at approximately 2000 × g to sediment the oocytes, and used the wash sediment (designated RWS) for further testing or processing. A similar sample concentration method was used by Steele et al. (63), but in this case, applied to artificially inoculated basil and mesclun lettuce as well as to berries. The RWS could be further processed for *Cyclospora* concentration using sucrose flotation (63) or glass wool column chromatography (64). Robertson and Gjerde (65) processed fresh fruits and vegetables for detection of a variety of parasitic protozoa using surface elution aided by sonication, followed by further sample concentration using centrifugation and, when appropriate, immunomagnetic separation.

Like the virus concentration methods, the methods for parasitic protozoa concentration suffer from many of the same limitations. These include the potential for poor recovery of parasites after completion of the concentration steps, the inability to recover very low levels of contamination, and a general lack of available immunocapture reagents for pathogens such as *C. cayetanensis*. Because so much less work has been done to develop effective concentration and purification

methods for parasitic agents in foods, at least when compared to virus methods, there is much that remains to be done in this field.

V. NUCLEIC ACID EXTRACTION

The reliability of nucleic acid amplification methods, as applied to the detection of pathogens in all types of samples (clinical, environmental, and foods), depends in large part on the purity of the target template and the number of target molecules. Extraction of nucleic acids from food samples is therefore one of the most important steps preceding the detection of pathogens using molecular amplification methods. It should be noted that since the viral genomes are almost always composed of RNA, the nucleic acid extraction methods preceding virus detection are RNA extraction methods. For the parasitic protozoa, either DNA or RNA can be used as the target nucleic acid. The purpose of these sample processing steps are (i) to make the nucleic acids available for amplification and detection; (ii) to provide for further sample concentration; and (iii) to remove any residual matrix-associated inhibitory substances that might remain even after the initial pathogen concentration steps are completed. Molecular methods can be inhibited by a wide variety of compounds, including divalent cations, matrix-associated components which degrade the target and/or primer nucleic acids, and by matrix-associated compounds which inactivate or inhibit enzymes (10,66,67). For instance, several reports have demonstrated that proteoglycans (68), polysaccharides (18,19,69), glycogen (16,19) and lipids (53,70,71) all can inhibit molecular amplification methods. Unfortunately, many of the methods to extract and concentrate pathogens from foods result in the simultaneous co-extraction of these inhibitory substances. Nucleic acid extraction methods, like virus concentration methods, must therefore be designed to further concentrate the nucleic acids while removing these inhibitory substances, without degrading the nucleic acid target or contributing additional inhibitory substances in the process.

A. Nucleic Acid Extraction of Food Concentrates — Viruses

In early work, nucleic acids from shellfish concentrates were often released by heat, making them available for nucleic acid amplification while circumventing the need for RNA extraction (11,16,72). At the same time, other early studies used SDS-proteinase K digestion to release nucleic acids from shellfish concentrates, followed by phenol chloroform extraction with or without the addition of cetyltrimethylammonium bromide (CTAB) for further removal of inhibitors (20,35,38,73). With the introduction of guanidinium thiocyanate (GuSCN)-based methods, this became for many investigators the RNA extraction method of choice, largely because the method is effective at deproteinization of nucleic acids while providing ample protection of RNA against the effects of native RNases. In fact, many guanidinium-based protocols have been commercialized over the last decade and a variety of these commercial kits have been used in more recent studies (33,39,53,70,74).

In many instances, multiple extraction methods have been used in combination to purify nucleic acids. Boom et al. (75) developed a simple and rapid protocol for the purification of nucleic acid that uses a combination of the chaotropic agent GuSCN and silica particles. The Boom method has been modified and commercialized by bioMerieux (Durham, NC) for use in RNA extraction prior to nucleic acid amplification using the NucliSens® Basic Kit Nucleic Acid Sequence-Based Amplification (NASBA) assay. Others have used a GuSCN method followed by RNA binding to glass powder in order to provide further purification (37,76). Over the last several years, a number of investigators have compared alternative RNA extraction methods for fecal or food matrices. For instance, Hale et al. (77) compared four different RNA extraction methods to precede RT-PCR detection of Noroviruses in fecal specimens, finding that the GuSCN/silica (Boom) method was best at removal of inhibitors, while RNA extraction methods using the metal chelating agent Chelex-100, or alternatively, Sephadex G200 column chromatography, provided the best detection limits. Svensson (78) reported similar results in that guanidinium thiocyanate is the most efficient at removal of inhibitory substances.

In another study, seven RNA extraction methods were compared to prepare hepatitis A virus RNA from stool and shellfish concentrates for RT-PCR detection (74). In this case, GuSCN-silica methods were found to be the most suitable for their rapidity and low cost. In very recent studies, total sample RNA has been extracted using phenol-chloroform-based methods followed by further selection for viral RNA using magnetic poly(dT) beads (33,36,42,79).

A small number of studies have described RNA extraction and purification for virus concentrates originating from other type of foods. Gouvea et al. (52) used deproteinization with GuSCN, adsorption of RNA to hydroxyapatite and sequential precipitation with CTAB and ethanol to purify RNA from shellfish and other selected foods. Phenol-chloroform based methods have also been used for more complex commodities such as hamburger, deli sandwich and deli meats (53,80). More recently, commercial RNA extraction kits have been used on concentrates from fruits and vegetables (54,81) and those from oysters (49). Sair et al. (70) compared multiple RNA extraction methods with respect to their efficacy in removing RT-PCR inhibitors from model food commodities (hamburger sandwiches and lettuce) in preparation for RT-PCR detection of enteric viruses. The methods compared included GuSCN, commercial microspin columns, the QIAshredder™ Homogenizer and TRIzol™, and various combinations thereof. These

investigators found that the use of TRIzol™ followed by further sample preparation using the QIAshredder™ Homogenizer yielded the best detection limits (<1 RT-PCR amplifiable units/reaction) for Norwalk virus in food samples.

When considered as a whole, the RNA obtained after extraction steps may be of relatively high purity, yet food-related amplification inhibitors frequently remain. Also, multiple sample manipulation steps can result in incomplete recovery and/or potential degradation of RNA during the extraction procedure (55,82). Another problem with RNA extraction is that, in destroying the integrity of the virion, one loses the ability to directly correlate infectivity to RT-PCR detection limits, at least when effective cell culture-based methods are available. Researchers continue to work on refining extraction procedures to provide higher nucleic acid yields and improved purity in an effort to further improve molecular amplification assay detection limits.

B. Nucleic Acid Extraction of Food Concentrates — Parasitic Protozoa

Template preparation for the detection of parasitic protozoa is perhaps more complicated than that for viruses due to the nature of the organisms, which are largely resistant to disruption and lysis. Three methods used frequently to disrupt cysts or oocysts for detection from fecal specimens, and these include sonication, freeze-thaw, and glass bead disruption; these can be followed by DNA binding in the presence of chaotropic agents for further template purification (83). Jinneman et al. (84) investigated various methods to prepare DNA template from *Cyclospora* oocysts, including multiple freeze-thaws in liquid nitrogen to release the nucleic acid, followed by direct DNA extraction with or without the addition of various proprietary enhancement agents. Basicially, PCR detection from raspberries artificially seeded with *C. cayetanensis* could be achieved, but no one template preparation method outperformed another. Orlandi and Lampel (64) reported a method to prepare template from the pathogenic parasitic protozoa using FTA filters. These filters are impregnated with denaturants, chelating agents, and free radical traps, causing most cells to lyse on contact and in turn, binding the DNA to the filter matrix. Other matrix associated inhibitory substances are removed by washing the filter, and the filters can be used directly in nucleic acid amplification reactions. These investigators showed that the FTA filters effectively lysed the cysts or oocysts of various parasitic protozoa and when applied to artificially contaminated raspberry extracts, the DNA template could be detected by PCR at initial seeding levels of 30 *C. cayetanensis* oocysts per 100 g of berries. Higgins et al. (85,86) reported on the efficacy of various commercial DNA extraction kits for the preparation of *C. parvum* DNA for PCR after its initial release by multiple cycles of freeze-thaw, finding that some commercial methods outperformed others. Most recently, Steele et al. (63) reported *C. cayetanensis* template preparation from produce washes using a combination of glass bead disruption followed by three freeze-thaw cycles and final template preparation using a commercial DNA extraction method originally designed for stool samples. In the only study of its kind, Warnekulasuriya et al. (87) were able to detect *T. gondii* in artificially contaminated ready-to-eat cured meats at levels of 10^3 trophozoites/g by applying a simple SDS-proteinase K DNA extraction method directly to emulsified meat specimens. Similarly, Deng et al. (62) used three sequential proteinase K/phenol extractions to isolate PCR-amplifiable genomic DNA from *C. parvum*.

VI. DETECTION

Virtually all of the molecular approaches for the detection of viruses in foods originated from the clinical literature. For both clinical and environmental samples, the sensitivity and the specificity of molecular amplification methods is largely dependent on the choice of primers. Due to the tremendous genetic diversity in the *Caliciviridae* family, primer design for the detection of the Noroviruses is quite complicated. The first Norovirus primers, NV 5'/3' and NV 36/35, were based on sequences in the prototype Norwalk virus genome and were extremely specific (21,88). As more sequence information on related viruses was collected, more broadly reactive primers were designed (31,89–92). Typically, the highly conserved RNA-dependent RNA polymerase region is the amplification target for the detection of the Noroviruses, although on occasion the capsid region has been chosen for primer design (93–96).

For a long time, the genogroup I (GI) and genogroup II (GII) primer sets developed by Ando et al. (89) were the "gold-standard" with respect to Norovirus detection and strain discrimination in clinical (fecal) and food samples (95,97,98). Degenerate primers, a mixture of oligonucleotides varying in nucleotide sequence but having the same number of nucleotides, have also been developed and used for the detection of the Noroviruses (30,31,90,99). The advantage of using degenerate primers lies in the fact that every possible combination of nucleic acid sequence that could code for a given amino acid sequence can be generated and used for PCR amplification. Currently, combinations of the Ando et al. (89) GI and GII primers, as well as one or more degenerate sets, are routinely used in Norovirus epidemiological investigations (70,100,101).

By and large, there is no consensus for the choice of the primer pair(s) to detect the Noroviruses and optimal detection protocols may actually change by year or with locale (97). In a review of nine sets of PCR primers used for the detection of the Noroviruses, no single primer pair

could be used to detect all strains, but the NV110/NV36 primer set was the most efficient of the nine sets tested in the study (101). More recently, in an effort to address international harmonization of Norovirus detection methods, five laboratories in five countries evaluated the performance of different RT-PCR protocols on a coded panel of 91 fecal samples (102). Although no single assay was superior by all criteria of sensitivity, detection limit, assay format, and successful implementation, the authors recommended the assay based on the Boom extraction method and using the JV12/JV13 primer set for laboratories seeking to newly initiate Norovirus diagnostics. It should be clear from the above discussion that Norovirus primer design is a work in progress and is likely to change as more sequence information becomes available. Unlike the great diversity of primers for the detection of the Noroviruses, primers used for the molecular epidemiological studies of hepatitis A virus target the VP1/2A junction sequence (51).

Because it is so highly conserved and is frequently used in phylogenetic analysis, the target gene for most PCR-based methods to detect the parasitic protozoa is that corresponding to the small subunit (SSU) 18S ribosomal RNA gene. For instance, Relman et al. (103) developed 18S rDNA-based primers for the detection of *C. cayetanensis*, and these have been used subsequently by others (63,64,84,104). Likewise, a similar gene target has been used for the PCR-based detection of *Cryptosporidium* (57,64,85,86). On a few occasions, alternative targets have been used, including genes corresponding to *Cryptosporidium* oocyst wall protein (62,85,86) and the *Toxoplasma* p30 gene (87).

A. RT-PCR Detection of Viruses in Foods

In complex matrices such as food systems, the choice of primer is even more critical since the matrix can be responsible for non-specific amplification and the potential for false positive results. Alternatively, matrix inhibition can cause false negative assays result. Those consequences are especially important in food samples in which the level of contamination is comparatively lower than in clinical samples. The criteria for primer selection when attempting to detect viruses in food should include (i) a reasonably high annealing temperature; (ii) a relative lack of primer sequence degeneracy; and (iii) broad reactivity. These criteria are essential since high stringency and primer specificity are necessary to prevent the non-specific amplification that readily occurs with food and environmental sample matrices. An additional consideration for the genetically diverse Norovirus group is the use of primers that are broadly reactive and hence will be able to detect as many genetically distinct strains as possible in a single assay.

Table 188.3 summarizes various *Caliciviridae* primers that have been used in studies to develop RT-PCR methods to detect the Noroviruses in different food matrices. As for clinical samples, all of the primers reported in Table 188.3 target either the viral RNA-dependent RNA polymerase or the capsid protein genome regions. Several investigators have used the NV 36/35 primer set for Norovirus detection in shellfish and deli meat samples (19,20,35,53,76,105). Previously, our group has used the NV-3/5 primer set to detect the Norwalk agent in shellfish and ready-to eat foods such as hamburger and lettuce (11,16,17,72). The NI/E3 primer set has been used for the detection of the GII Noroviruses in shellfish (12,76,106). Shieh et al. (107) used primer sets targeting both the RNA polymerase and capsid genes, Mon381/383 and SR33/46, respectively, to identify a GII Norovirus in oyster samples implicated in a California outbreak. Recently, Dubois et al. (81) used a newer primer pair that detects both Noroviruses and Sapoviruses, as applied to the detection of viruses in artificially contaminated produce. Sair et al. (70) systematically compared four Norovirus primer pairs, reporting the best detection limits for the NVp110/NVp36 primer combination as applied to virus detection in various food matrices (hamburger sandwiches and lettuce). Furthermore, Honma et al. (101) found that this same primer pair was broadly reactive with a range of Noroviruses, without requiring separate amplifications for the two Norovirus genogroups. Other researchers have also used those primers together or in association with NI or NVp69 for the detection of Noroviruses in shellfish (30,31,33). As for the Noroviruses, most of the methodological approaches described for the detection of hepatitis A virus in foods have been applied to artificially contaminated shellfish species (Table 188.4).

To improve assay sensitivity, "nested" RT-PCR has been used for the detection of Noroviruses (26,52,76,108) and hepatitis A virus (36,40,76,109–111) in foods. While nested reactions can improve assay sensitivity, they have rightfully earned a reputation of being risky from the standpoint of contamination. To bypass those issues, novel single-tube nested RT-PCR methods have been described. For instance, Ratcliff et al. (112) separated the reagents required for the nested amplification in a "hanging drop" that was intended to be introduced by centrifugation after the first RT-PCR amplification. Burkhardt et al. (113) compartmentalized the nested RT-PCR cocktail in a "tube-within-a-tube" (TWT) device using inexpensive and simple materials such as a pipette tip and a microcentrifuge tube.

In all, methods such as these have been used by many investigators for the detection of viruses in environmental and food samples, with detection limits ranging from approximately 1–100 infectious units/g food. Some assays have used internal amplification standards to simultaneously evaluate RT-PCR inhibition and/or to provide a semiquantitative assay (20,31,34,73,99,105, 114,115).

B. PCR Detection of Parasitic Protozoa in Foods

In general, considerably less effort has been put into using molecular amplification methods for the detection of parasitic protozoa in foods. In the first study of its kind, Fayer et al. (57) screened commercial oyster harvesting sites from the Cheasepeake Bay region by PCR for the presence of *C. parvum*-specific DNA. Using an 18S rRNA gene-based nested assay, these investigators identified *Cryptosporidium* from all sites surveyed but only two genotypes (human and bovine) were found. The IMS-PCR method of Deng et al. (62) was able to achieve detection limits of 10 oocysts of *C. parvum* per 100 ml of apple juice or milk. A series of studies to develop methods to detect various parasitic protozoa in produce have resulted in PCR detection limits ranging from 10–40 *C. cayetanensis* oocyts/100 g raspberries (63,64) and 1000 *C. cayetanensis* oocyts/100 g mesclun lettuce (63). Finally, Warnekulasuriya et al. (87) developed a PCR-based assay to detect *T. gondii* in ready-to-eat cured meat products with a detection limit of 5×10^3 trophozoites/g. It is important to note that almost all of these studies have required nested amplification reactions in order to achieve adequate detection limits for artificially contaminated foods.

C. Alternative Nucleic Acid Amplification Methods

Nucleic Acid Sequence-Based Amplification (NASBA) is a nucleic acid amplification method specifically designed to detect RNA. The system utilizes three enzymes, (i) a reverse transcriptase (AMV-RT); (ii) an RNase H; and (iii) a T7 RNA polymerase, all of which act in concert with two oligonucleotide primers specific to the target (116). One of the primers (P1) contains the T7 RNA polymerase promoter sequence at 5' terminal. The transcription-driven NASBA reaction is carried out at a single temperature (41°C) and theoretically amplifies the RNA target more than 10^{12}-fold within 90 min. The final product of the amplification is mostly single-stranded RNA, which can be readily detected by probe hybridization without the need for a denaturation step.

From a clinical standpoint, NASBA commercial kits (NucliSens®, bioMerieux, Inc. Durham, NC) are available for the detection of human pathogens such as HIV and cytomegalovirus in blood or plasma. NASBA assays have also been developed for the detection of foodborne enteric viruses (Table 188.5). For instance, Jean et al. (117) developed a NASBA-based method to detect hepatitis A virus which performed adequately when tested on artificially contaminated lettuce and blueberry samples. The same group (118) also developed a NASBA assay to detect human rotavirus. Most recently, Greene et al. (119) applied the NucliSens® Basic Kit NASBA protocol for the detection of Norwalk virus RNA in stool using primers targeting the RNA polymerase region of the Norwalk virus genome. This NASBA assay could consistently detect 10^4 RT-PCR detectable units of NV RNA. When applied to stool specimens from human challenge studies and outbreaks of foodborne disease, the NASBA assay yielded 100% sensitivity, 50% specificity and 67% concordance using RT-PCR as the "gold standard."

In general, the NASBA method is more rapid (6–8 hr) and may demonstrate 10- to 100-fold improvements in detection limits when compared to RT-PCR. Although the NASBA is likely to be impacted by many of the same restrictions as RT-PCR (e.g., contamination control, sample volume considerations, matrix-associated reaction inhibitors), it is likely to remain an important alternative detection method for foodborne pathogens.

VII. CONFIRMATION

After any nucleic acid amplification reaction, the amplicons generated should be detected and confirmed to assure the sensitivity and the specificity of the assay. The most common confirmatory testing tool is agarose gel electrophoresis followed by Southern blot hybridization. In the case of RNA products (for NASBA), Northern blot analysis using labeled internal oligonucleotide probes has been used (101,120). Interestingly, an oligonucleotide array dot-blot format for the simultaneous confirmation of Norovirus amplicons and strain genotyping has recently been reported, offering the promise of providing both detection and strain typing in a single test (121). It is, however, important to note that Southern and Northern hybridization are largely being replaced by more rapid and user-friendly hybridization methods based on enzymatic, chemiluminescent, or fluorescent endpoints.

DNA enzyme immunoassay (DEIA) methods are an appealing confirmation approach because they can be readily automated and are familiar to many individuals working in testing laboratories. For most of these methods, a capture probe is immobilized to a microtiter plate well. A labeled amplicon can then by detected directly, or alternatively, an unlabeled amplicon can be hybridized to a second labeled detector probe followed by detection after the addition of an enzyme-conjugate and appropriate chromogen substrate. After each step, unbound compound is removed by washing; for colorimeteric, luminescent, or fluorescent endpoints, absorbance is read using a conventional microtiter plate spectrophotometer or fluorescent plate reader, and the intensity of the signal may be approximately proportional to the concentration of amplicon. Microtiter plate assay sensitivity is usually equal to or better than Southern hybridization and has the advantages of ease of interpretation and more rapid (4 hr) amplicon confirmation (35,118).

Electrochemiluminescence (ECL) detection technology has been developed by bioMerieux for the detection

of NASBA amplicons generated using the NucliSens® Basic Kit. The technology involves a liquid sandwich hybridization employing two specific oligoprobes; a capture probe immobilized to streptavidin-labeled magnetic beads and a generic detection probe complexed to a ruthenium chelate. The hybrid is drawn into the ECL flow cell, magnetic particles are trapped on an electrode, and unbound reagents are washed away. Application of a voltage trigger to the electrode induces the ECL reaction, and the emitted light is detected and the signals interpreted by the NucliSens® Reader and associated software. ECL technology has been used by Fox et al. (122) as applied to the detection and confirmation of enterovirus NASBA amplicons obtained from clinical samples and by Greene et al. (119) for the detection Norwalk virus in stool samples. The NASBA-ECL system usually allows for confirmed detection results in a single working day.

Other amplicon confirmation methods have included specific "nesting" reactions (52,76,108,109) and restriction endonuclease digestion of RT-PCR products (52,109). As nucleic acid sequencing equipment became more widespread, direct amplicon sequencing for the confirmation of RT-PCR products has become the method of choice (31,53,76). However, all of these confirmation methods require significant amounts of sample manipulation and remain time-consuming.

In the case of parasitic protozoa, confirmation of PCR amplicons has been achieved by classic DNA hybridization (for *C. parvum*) (123), nested reactions (for *C. parvum*) (57,64,85,86), restriction enzyme digestion of amplicons (for *C. cayetanensis*) (63,84), or by oligonucleotide ligation assay (for *Cyclospora*) (84). For the most part, species and strain specific typing methods for *Cryptosporidium* and *Cyclospora* are based on polymorphisms in either the 18S rRNA gene or intervening transcribed spacer regions between rRNA genes (124–126). Accordingly, a second group of investigators have used PCR-Restriction Fragment Length Polymorphism (RFLP) assays for both confirmation and genotyping of *C. parvum* (57) and *C. cayetanensis* (104).

A. Real-Time Detection

Several achievements have been made during the last decade enabling nucleic acid amplification and hybridization technologies to be linked so that detection and confirmation occur simultaneously, resulting in so-called "real time" detection. There are currently five main chemistries used for real-time amplification and detection technologies, including DNA binding fluorophores, the 5' endonuclease assay, adjacent linear and hairpin oligoprobes and self-fluorescing amplicons (127). Recently, investigators have developed real-time PCR systems for the detection of pathogens in foods (128–134). Prototype real-time PCR and RT-PCR amplification technologies have been developed for the detection of hepatitis A virus (135), the Noroviruses (136), *C. cayetanensis* (137), and *C. parvum* (138), although none of these methods has yet been applied to the detection of these pathogens in food matrices.

VIII. DETECTION OF VIRUSES AND PARASITIC PROTOZOA IN FIELD AND FOODBORNE DISEASE OUTBREAK SPECIMENS USING MOLECULAR METHODS

It should be clear from the above discussion that much of the developmental work in the detection of viruses and parasites in foods has focused on applications to

TABLE 188.6
Recent Investigations in Which Viruses Have Been Detected in Foods Epidemiologically Linked to Foodborne Disease Outbreaks

artificially contaminated shellfish species. Only a few of the early methods were applied to naturally contaminated shellfish (12,14,20,48,50,76,109,139). Successful detection of viruses in food samples epidemiologically linked to disease has been reported only rarely and as applied to shellfish (14,31,33,50,76,108), deli meats (53), and raspberries (140) (Table 188.6). Many investigators have found it necessary to use nested amplifications to achieve the sensitivity needed to detect viruses in naturally contaminated products (12,31,39,42,53,76,106,108,109,141). Interestingly, recent survey work originating from Europe, including France (30), Italy (42,142), Spain (106,141,143), Brazil (38), and Greece, Sweden, and the United Kingdom (106) has reported consistent detection of hepatitis A virus, the Noroviruses, human enteroviruses, adenoviruses, and rotaviruses from field shellfish harvesting sites, sometimes at prevalence rates exceeding 40% (30,141,143). A field study of market lettuce from Costa Rica demonstrated sample pools that were positive for both hepatitis A virus and rotavirus during a period of high diarrhea prevalence in that country (144).

Protozoan parasites such as *Giardia* and *Cryptosporidium* species may be present in shellfish-growing waters and the ability of shellfish to concentrate *Giardia* and *Cryptosporidium* was first demonstrated by Toro et al. (145). The first isolation of *Giardia* from market bivalves was also reported by this same group (61). Later studies postulated the potential role of oysters in the epidemiology of *Cryptosporidium* infection (146) and were followed by studies that reported oocyst stability for 4–12 weeks in artificial seawater (56) with detection of *Cryptosporidium* ocysts in Eastern oysters harvested from commercial sites in the Chesapeake Bay (56). *Cryptosporidium* oocystes have also been recovered from Bent mussels (*Ischadium recurvum*) (58) and from various clams, mussels, and oysters harvested in Europe (147).

With respect to non-shellfish food commodities, Warnekulasuriya et al. (87) reported finding viable *T. gondii* in one of 67 ready-to-eat cured eat samples screened in their study. Ortega et al. (7) found a prevalence of 14.5% and 1.8% of *C. parvum* and *Cyclospora* oocysts, respectively, in their market survey of vegetables collected from a Peruvian periurban slum. Robertson and Gjerde (65) reported that 6% of the fresh fruit and vegetables sampled in their survey were contaminated with either *Cryptosporidium* or *Giardia*, although the pathogen concentrations were generally low.

IX. DISCUSSION AND CONCLUSIONS

Although the advent of molecular methods has revolutionized our ability to detect viral and parasitic contamination in foods, these methods are far from perfect. The reality remains that detection of these agents in foods is done infrequently, usually only in response to known or suspected foodborne disease outbreaks, and rarely are these methods applied routinely. Although there are many reasons for the hesitance to routinely use these assays, the most important among these are: (i) the association (or lack thereof) between detection and viability; (ii) the lack of widely accepted, collaboratively tested methods; and (iii) the expense and need for highly trained personnel.

One of the more serious limitations of molecular methods is their failure to discriminate between viable and inactivated viruses or parasitic protozoan cysts or oocysts. This is of critical importance because the inactivated forms of these pathogens pose no real public health threat, and yet the pathogens might be expected to be at least partially inactivated during routine processing and storage of foods. For instance, some investigators have reported that free viral RNA is stable for days to weeks and that its detection by RT-PCR is not necessarily an indication of infectious

virions (71,148). To avoid positive RT-PCR results that might occur with inactivated viruses, Nuanualsuwan and Cliver (149) pre-treated virus-containing samples with proteinase K and ribonuclease before RT-PCR amplification, finding that amplification was inhibited when inactivated viruses were pre-treated with these enzymes. Others have developed combined mammalian cell culture-RT-PCR methods for virological analysis, attempting to confirm infectivity with the cell culture step (48,150). Unfortunately, this approach will not work for the epidemiologically important non-culturable enteric viruses.

For the parasitic protozoa, the issue of viability is no less important. In general, a dependable indicator of cyst or oocyst infectivity is needed. Although the use of vital dyes and *in vitro* excystation assays have been used to establish the viability for *C. parvum*, recent evidence indicates that these are not always reliable (4). Although not always practical, this organism may also be tested for infectivity using the mouse model (9,56). Molecular tests for *Cryptosporidium* viability have been attempted, including fluorescent *in situ* hybridization (151) and cell culture followed by RT-PCR (152,153). Recently, Jenkins et al. (154) estimated the viability of *C. parvum* oocysts by RT-PCR using a mRNA amyloglucosidase target. The issue is even more complicated for *C. cayetanensis*, for which cell culture and animal models are only in developmental phases (3). It should also be noted that an additional hurdle is the necessity to differentiate between *Cryptosporidium* genotypes that are pathogenic to humans as compared to those that are not. In the past, this has been approached by PCR-RFLP or sequencing analysis of antigen, structural and/or housekeeping genes (4), although recently this has been facilitated by real-time PCR (138).

There is a need to develop more universal sample extraction methods. Although virus and parasitic protozoa concentration from foods is likely to remain at least in part product dependent, research is needed to develop and refine the prototype methods into collaboratively-tested protocols. This has only been done on a limited basis for viruses in shellfish (73) and not at all for the parasitic protozoan methods as applied to foods. In general, as investigators attempt to refine methods, they must continue to seek effective methods to concentrate the pathogens from the food matrix, all the while removing matrix-associated inhibitors. Furthermore, additional experimentation is needed to establish the relationship between detection using molecular amplification techniques and the presence of infectious virus particles or parasitic protozoan cysts and oocysts, in shellfish, other foods, and environmental samples. Since the concepts of viral and protozoan pathogen detection differ so dramatically from those used for the detection of bacteria in foods, scientists need to continue to educate food safety professionals about the principles of pathogen concentration, and provide technology transfer to bring these methods into the commercial realm. However, even with the best developmental efforts, the methods will probably never be perfect and will always require a high degree of sample manipulation on the part of the laboratory personnel. We are hopeful, though, that with sufficient improvement, effective methods for the rapid detection of human enteric viruses and parasitic protozoa in foods can become more widely available to the food safety community.

ACKNOWLEDGMENTS

This effort was supported in part by a grant from the USDA National Research Initiative, Competitive Grants Program, Ensuring Food Safety Division, contact #2002-35201-11610. The use of trade names in this paper does not imply endorsement by the North Carolina Agricultural Research Service nor criticism of similar ones not mentioned.

189 Methods for Detection of Molds and Mycotoxins

Hassan Gourama
Pennsylvania State University

I. INTRODUCTION

Fungi are a large and diverse group and include the yeasts and molds. They are widely distributed in nature. Due to their versatile nutritional and environmental requirements, fungi are common contaminants of agricultural commodities, foods, beverages, and feeds. The overall economic losses of foods and crops due to mold growth are high (1,2). In addition to economic losses, mold growth on foods and crops presents a health hazard to humans and animals by producing mycotoxins. Before the discovery of aflatoxins, scientists and consumers considered fungal spoilage undesirable only because of economic losses and the unaesthetic and organoleptic changes that result from fungal spoilage. However, after the Turkey X outbreak disease of 1960 that killed 100,000 turkey poults in England, scientists and regulatory officials became aware of the health hazards of mycotoxins (1,3,4,5).

Mycotoxins are naturally occurring compounds produced by some mold species. Mycotoxins can be toxic to humans and animals. The origin of the word mycotoxin is from "mykes," a Greek term for fungus, and "toxicum," a Latin word for poison or toxin. The exposure of humans and animals to mycotoxins has been documented since ancient times. In the Middle Ages ergotism, also known as "St. Anthony's Fire," killed thousands of people in some European countries. The cause of their death was attributed to ergot alkaloids produced by *Claviceps purpurea* that infested rye and other grasses. In the late 1800s and early 1900s a combination of *Penicillium* toxins caused what was called "Yellow rice" outbreak, characterized by severe liver damage in farm animals (3,6,7).

During World War II a human outbreak known as Alimentary Toxic Aleukia (ATA) occurred in Russia due the consumption of moldy grains. The disease was characterized by severe dermal necrosis, hemorrhaging, decrease in leukocytes, and bone marrow degeneration. In 1960 the investigation of the "Turkey X-disease" outbreak led to the discovery of mycotoxins produced by *Aspergillus flavus* subsp. *parasiticus*, known as aflatoxins (for *Aspergillus flavus* toxins) (3,4). The production of mycotoxins occurs in the field, and during distribution, processing, and storage. The production of mycotoxins presents a unique challenge to food safety experts due to the fact that mycotoxins are natural toxins and their production is sometimes unavoidable, and depends on various environmental factors in the field and during storage conditions. The main mold producers of mycotoxins include *Aspergillus*, *Penicillium*, *Fusarium*, and *Alternaria* (4,8,9,10). Various environmental factors affect the growth of molds and the production of mycotoxins, including temperature, pH, moisture content, oxygen levels, carbohydrates, trace elements, the mold strains, and microbial competition.

There is no direct relationship between the presence of molds in foods and crops and the production of mycotoxins. On the other hand, the absence of mold fragments and/or mold spores in foods and crops does not guarantee that they are free from mycotoxins, because these toxins are heat resistant and can survive long after the molds have been destroyed or inactivated. A number of mycotoxins produced by different mold species have been reported in the literature. The majority of these toxins have been investigated

under laboratory conditions, and only limited numbers of them have been encountered in nature.

The major mycotoxins that are of concern to human and animal health include aflatoxins, ochratoxins, patulin, zearalenone, fumonisins, moniliformin, and trichothecenes (Table 189.1).

Aflatoxins are secondary metabolic products produced by *Aspergillus flavus*, *A. parasiticus*, and *A. nomius* (11) in a number of commodities, especially corn and peanuts. Other nuts and grains are susceptible to aflatoxins as well. The main aflatoxins of concern are B_1, B_2, G_1, and G_2. Generally these toxins are found together at various levels. Aflatoxin B_1 is considered the most potent hepatocarcinogen to animals and presumably to humans. Generally young animals are more susceptible to aflatoxins than older animals (12).

Ochratoxin A is a naturally occurring mycotoxin produced by certain species of the genera of *Aspergillus* and *Penicillium*, such as *Penicillium verrucosum* and *Asepergillus ochraceus*. Ochratoxin A is linked to kidney damage (nephrotoxic) in animals and humans. A number of investigations have reported the presence of ochratoxin A in animal tissues, human blood serum, and milk. Ochratoxin A also has been reported to affect the immune system. Ochratoxin is commonly found in corn, barley, wheat, oats, and coffee beans (6,13). Another mycotoxin that usually coexists with ochratoxin is citrinin, which is produced by some *Aspergillus* and *Penicillium* species and causes kidney damage and mild liver damage.

Patulin is a low molecular weight mycotoxin that is produced by a number of *Penicillium* species (especially *P. expansum*), *Aspergillus*, and *Byssochlamys* species. *P. expansum* is the usual mold causing apple rot (6). These molds are the most important producers of patulin in apples, apple juice, and other apple derived products. Patulin has been reported to have immunological, neurological, and gastrointestinal effects on animals. The potential presence of patulin in products that are consumed by children and adults, such as apple juice and apple cider, constitutes a significant a health risk.

Fumonisins, especially Fumonisin B_1 and Fumonisin B_2, are produced in corn by *Fusarium moniliforme*, *F. proliferatum* and other *Fusarium* species. Fumonisins were found to be extremely toxic to horses, causing what is known as equine leucoencephalomalacia (ELEM), which is characterized by loss of appetite, brain liquefaction, liver damage, and respiratory complications (6,8,14). A number of studies have also linked fumonisins and the occurrence of esophageal cancer in humans in northern Italy, South Africa, and China.

Trichothecenes are a group of 148 related compounds produced by the following *Fusarium* species: *F. tricinctum*, *F. sporotrichioides*, *F. poe*, and *F. equiseti*. The most common trichthecenes isolated from agricultural commodities include T-2 toxin, HT-2 toxin, neosolaniol, deoxynivalenol (DON), 3-acetyldeoxynivalenol, and nivalenol. Trichothecenes have been isolated from corn, oats, peanuts, rice, sorghum, wheat, barley, rye, corn meal,

TABLE 189.1
Important Mycotoxigenic Molds and Their Mycotoxins Found in Foods

Mycotoxin	Primary Mold Species	Food Commodity
Afaltoxins B_1,B_2, G_1, G_2	*Aspergillus flavus* *Aspergillus nomius*	Peanuts, corn, dried fruits, spices
Afaltoxins B_1, B_2	*Aspergillus parasiticus*	Peanuts, corn, dried fruits, spices
Aflatoxins M_1, M_2	*Aspergillus flavus*	Milk and dairy products
Ochratoxins	*Penicillium verrucosum* *Aspergillus ochraceus*	Cereals, coffee beans, beer, nuts
Patulin	*Penicillium expansum*	Apples, apple juice…
Citrinin	*Penicillium verrucosum*	Cereals
Deoxynivalenol	*Fusarium graminarium*	Cereals
Nivalenol	*Fusarium culmorum*	
Trichothecens		
Fumonisins	*Fusarium moniliforme* *Fusarium proliferatum*	Corn, corn products
Zearalenone	*Fusarium graminearum* *Fusarium culmorum*	Cereals
Moniliformin	*Fusarium proliferatum* *Fusarium subglutinans*	Cereals
Alternariol	*Alternaria alternata* *Alternaria tenuis*	Tomatoes, fruits, oil seeds, cereals

breakfast cereals, bread, and snack foods. Trichothecenes are toxic to animals at the cellular and organic system level. They inhibit the synthesis of proteins. Some of the common symptoms include refusal to eat, weight loss, digestive disorders, dermal irritation, vomiting, diarrhea, hemorrhage of the large intestine, and weakening of the immune system (6,8).

Moniloformin is another common mycotoxin that is produced by *Fusarium* species. It has been detected in cereals such as wheat and rice. Moniloformin produces intestinal hemorrhage and heart problems in laboratory mice. It has been linked to Keshan disease in humans in certain areas of China.

Alternaria toxins are a group of compounds produced by *Alternaria* species including *A. citri*, *A. alternata*, and *A. tenuissima*. These are common contaminants of crops, especially fruits, vegetables, and oilseeds at the preharvest stage. The most commonly detected *Alternaria* toxins are tenuazonic acid, alternariol, and alternariol monomethyl ether. These toxins have been linked to a number of disorders in humans and animals (3,6).

Other mycotoxins have been reported in the literature. These include citreoviridin, gliotoxin, ergot alkaloids, mycophenolic acid, penicillic acid, PR toxin, roquefortine C, Rubratoxin A, vioxanthin, and xanthomegnin.

II. MOLD DETECTION AND ENUMERATION: GENERAL CONSIDERATIONS

Accurate enumeration and identification of spoilage and mycotoxigenic molds is essential to the control of these fungi in the food supply (11,15–17). The current food mycology techniques that are used to enumerate mold spores and propagules consist of microscopic examination and plate count techniques, which are inherited from food bacteriology. Measurement of mold growth is more complicated than bacterial counts. The significance of mold count has to be carefully interpreted, since the mold colony counts can result from mold fragments and/or individual mold spores. A heavy mold sporulation that can result in a significant increase of viable counts does not automatically reflect an increase in the fungal biomass. In addition the blending of samples can easily increase the counts by breaking mycelial fragments into smaller filaments. The results of mold counts should take into consideration a number of points including the history of the food product, its chemical composition, and the sampling technique. Recently, progress has been made in the development of potential rapid methods for the detection of molds in foods and feed. These potential rapid techniques can be grouped in the following categories: chemical methods, direct methods, immunological methods, and genetic methods (18).

Any mycological methods should use a proper sampling method. The sampling plans developed by the International Commission on Microbiological Specifications of Foods (ICMSF) are suitable for food mycology (2,19).

Direct plating and dilution plating are the two main methods used to detect and enumerate molds in foods. Direct plating is generally more accurate than other plating techniques. In direct plating, solid food particles are deposited on solid media. Sometimes the food particles such as grain kernels are disinfected in chlorine solution to eliminate surface contamination. The results of direct plating are expressed as percentage of infected particles. Dilution plating is recommended for powdered and liquid foods. Generally the sample is blended for two minutes using a stomacher. To dilute powdered foods and grains intended for flour manufacturing, peptone diluent (0.1%) is recommended. After serial dilutions, 0.1 ml aliquots are surface plated on an agar surface, with plates incubated at 25°C for five days. It is recommended that plates should not be stacked more than three high and they should not be inverted. The plates should not be disturbed during the incubation period. After incubation, plates containing between 10–150 mold colonies are counted.

III. SELECTION OF MEDIA

The selection of agar media is critical in the success of mold detection and enumeration in foods and feeds. A general purpose mycological medium should satisfy a number of considerations: inhibition of bacterial growth without affecting fungal growth, suppression of rapidly spreading fungi such as *Rhizopus* species, and support the growth of the target fungi. Generally these media contain both differential and selective ingredients. To inhibit bacterial growth, antibiotics such as chloramphenicol and chlorotetracycline are used. To slow colony spread, rose Bengal and 2,6-dichloro-4-nitoalinin (dichloran) are used. Another important consideration is the water activity of the agar medium and the food to be analyzed. For help in proper selection of mycological media the reader is referred to Table 189.2. To simplify preparation, 3M Microbiology Products (Minneapolis, MN) developed Petri film yeast- and mold-count plates (Petrifilm YM). Comparison studies have shown that Petrifilm YM plates to be comparable to traditional methods, with the advantage of time savings, because there is no need for media preparation and addition of antibiotics (19–24).

IV. ENUMERATION AND DETECTION OF MYCOTOXIGENIC MOLDS

The versatile nature of molds in their environment and their unique nutritional requirements allow them to grow in many agricultural commodities and food products. Molds are generally aerobic microorganisms; however, a number of mold species can grow at very low oxygen level. Their pH requirements are broad, ranging from pH

TABLE 189.2
Recommended Agar Media for the General Detection, Enumeration, and Isolation of Molds

Food Products	Type of Molds	Medium*
High water activity fresh foods (milk, fruits, cheese)	Molds in general	DRBC, MA PDA, PCA + antibiotics
Cereal grains and nuts freshly harvested	Molds in general	DRBC
Dried foods including stored cereals	Molds in general	DG18
Flour	Molds in general	DG18
Confectionary	Xerophiles	MY50G
	Extreme xerophiles	MY70GF
Salty foods	Molds in general	DG18
	Halophilic fungi	MY5-12 My10-12
Any food	Afaltoxigenic molds	AFPA
Any food	Ochratoxigenic molds	DRYS
Any food	*Fusarium* species	CZID

*AFPA- *Aspergillus flavus* and *parasiticus* agar; CZID – Czapek iprodione dichloran agar; DRBC – Dichloran rose Bengal chloramphenicol; DG18 – Dichloran 18% glycerol agar; DRYS – Dichloran rose Bengal yeast extract sucrose agar; MEA – Malt Extract Agar; MY50G – Malt extract yeast extract 50% glucose agar; MY70GF – Malt extract yeast extract 70% glucose fructose agar; MY5-12 and MY10-12 – Malt extract yeast extract 5% (or 10%) salt 12% glucose agar; PCA – Plate count agar; PDA – Potato dextrose agar.
Source: Pitt and Hocking (2), Tournas et al. (19).

2 to 9.5. The majority of molds can grow at water activity (a_w) of 0.85 or less. The majority of molds will grow at temperature range of 10–35°C. There are a number of *Penicillium* and *Cladosporium* species that can grow at refrigeration temperatures. Other factors that affect mold growth and mycotoxin production include the nutritional status of the substrate, its physical state, presence of preservatives, and competitive microorganisms.

The three major mycotoxin mold producers are *Aspergillus*, *Penicillium*, and *Fusarium* species. *Aspergillus* and *Penicillium* species mainly attack commodities during storage, while *Fusarium* species are generally considered field fungi. Mycotoxin production is more prevalent in commodities such as corn, peanuts, nuts, wheat, and barley. Due to the fact that mycotoxins are natural fungal toxins, the total prevention and control of their production in the field and storage is almost impossible. However, an accurate detection and identification of mycotoxigenic molds, in combination with other measures, is essential in minimizing the problem of mycotoxins (2,25).

During the last 20 years, food mycologists are increasingly developing various selective and differential media to enumerate and detect specific mold species.

Selective mycological media will help the isolation and the identification of mycotoxigenic molds such as *A. flavus* strains, producers of aflatoxins. Although good progress has been made in the development of selective media, a significant level of research is still needed to improve the existing media and to develop new ones. One of the first selective media for *A. flavus* was called *Aspergillus* differential medium (ADM). The main ingredients include 1% yeast extract, 1.5% tryptone, and 0.05% ferric acid. In this medium *A. flavus* and *A. parasiticus* are identified by their characteristic production of reverse orange-yellow color (9,25,26). Only a few other molds such as *A. niger* produce the same reverse coloration. It was demonstrated that the production of the orange-yellow color is due to the reaction of aspergillic acid that is produced by the mold and the ferric ammonium citrate (27). ADM was reformulated to develop *Aspergillus flavus-parasiticus* agar (AFPA). When AFPA is incubated at 30°C for 42–48 hours, aflatoxigenic molds (*A. flavus*, *A. parasiticus*, and *A. nomius*) are diagnosed by their production of bright orange-yellow reverse color prior to their production of olive green conidia. *A. niger* and *A. ochraceus* have been found to produce false positive results. However, after 48 hours incubation, these mold species start to produce their characteristic colors that are different from the color of the aflatoxigenic molds. AFPA is generally used to detect aflatoxigenic molds in nuts, corn, peanuts, various seeds, animal feed, and other commodities.

Frisvad (28,29) developed a selective medium (DRYES) for molds producing ochratoxin A, by adding 50 mg/L chloramphenicol, 50 mg/L chlorotetracycline, 2 mg/L dichloran, and 25 mg/L rose bengal to yeast-extract

sucrose agar. The main producer of ochratoxin, *P. verrucosum* produces yellow pigment on the colony reverse. DRYES was reported to distinguish between producers of ochratoxin A and citrinin (*P. verrucosum*) and producers of xanthomegnin and viomellein (*P. viridicatum* and *P. aurantiogriseum*). It is recommended to incubate DRYES at 20°C for 7–8 days.

To isolate *Fusarium* species, the following selective media have been reported (2,25,30,31): Nash-Snyder medium, modified Czapek-Dox agar, Czapek iprodione-dichloran (CZID) agar, potato-dextrose-iprodione-dichloran (PDID), and dichloran-chloramphenicol-peptone agar (DCPA). In Nash-Snyder medium, pentacholoronitrobenzene (PCNB) is the selective ingredient. However, the potential carcinogenic properties of PCNB limited its use in food mycology laboratories. DCPA is recommended when *Fusarium* species are dominant due to their high production of macroconidia. When these selective media for *Fusarium* species were compared, PDID and CZID were found more effective. Identification of *Fusarium* isolates in CZID is more difficult; therefore, their culture on Carnation Leaf Agar (CLA) is recommended.

V. DETECTION OF XEROPHILIC MOLDS

Xerophilic fungi are characterized by their ability to grow under low to very low water activity (a_w). Moderately xerophilic molds can grow on normal media with high a_w, while extreme xerophiles need a medium with low a_w. Media for xerophilic fungi should be able to inhibit the growth of non-xerophilc microorganisms due to addition of various humectants such as glucose, sucrose, sorbitol, and glycerol. These media are useful for the analysis of high-sugar food products. Addition of sodium chloride to media is recommended for the analysis of high-salt foods. Dichloran –18% glycerol agar (DG18) is recommended as a general medium for the isolation of the moderately xerophilic molds in dry products. Fastidious xerophiles, such as *Xeromyces bisporus, Chrysosporium* spp., and *Eremascus*, grow poorly on DG18 and require other media such as malt extract-yeast extract –50% glucose (MY50G) agar. Pitt and Hocking recommend the use of malt extract-yeast extract –70% glucose-fructose (MY70GF) agar to isolate fastidious xerophiles (2,32–34).

VI. DETECTION OF HEAT RESISTANT MOLDS

Heat resistant molds such as *Byssochlamys, Talaromyces*, *Neosartorya,* and *Eupenicillium* species, are a unique group of fungi in that they can cause the spoilage of shelf stable foods and can survive standard heat processing operations. The isolation of heat resistant molds from heat processed food products such as fruit juices and concentrates is accomplished by using a plating method or direct incubation method after heating the samples at 75–80°C for 30 minutes. It is recommended to heat a 100 g sample that then should be dispersed in an equal volume of double strength agar medium of a defined composition. Generally, Malt Extract Agar (MEA), Potato Dextrose Agar (PDA) and Oxytetracycline Glucose Yeast Extract (OGY) supplemented with antibiotics are used. The plates are incubated at 25–30°C for two to four weeks (2,35,36).

VII. RAPID DETECTION METHODS

Current methods, such as direct plating and dilution plating, that are used to detect and enumerate molds in food and feed are time consuming and do not offer rapid assessment of the quality of foods and ingredients. In the last 10 to 15 years, a number of potential rapid techniques have been investigated. These techniques include chemical and biochemical techniques, electrical impedence, and immunological methods (18,37–39). The chemical and biochemical techniques are based on the detection and quantification of specific components of the molds, such as chitin, ergosterol, and adenosine triphosphate (ATP).

Chitin, a polymer of N-acetyl-D-glucosamine, is one of the most frequently occurring polysaccharides in mold spores and mycelia. One of the major non-fungal sources of chitin are insects. However, chitin does not exist in bacteria and in the absence of insect infestation is not found in food and feed products. Therefore, the detection of chitin in foods and feeds can indicate fungal activity, even if the mold contaminants have been destroyed. There is a good correlation between chitin or its breakdown compounds (glucosamine, N-acetylglucosamine) and mycelial growth in cereal grains. Methods such as colorimetry, chromatography (HPLC, GC), microscopy with fluorescent and non-fluorescent dyes, and infrared spectroscopy have been used to detect chitin. The disadvantages of these assays are that sophisticated instruments are used, and the methods have low sensitivity and reproducibility problems (40–43).

Ergosterol is another fungal chemical that has been suggested for use to measure fungal growth in cereal grains. Ergosterol is the principal sterol in fungal membranes. Ergosterol does not occur in high quantities in plants. There is some correlation between ergosterol level and mold growth and associated mycotoxin production. The methods of analysis for ergosterol are based on direct saponification, extraction with hexane, and quantification using high-pressure liquid chromatography (HPLC), thin liquid chromatography (TLC), liquid chromatography (LC), or spectrophotometric techniques (UV, infrared) (41,44–50).

Research on the use of immunological techniques to detect food-borne fungi has also been active for the last 10 to 15 years (51). These techniques are based on the binding of fungal antigens and their corresponding antibodies.

Fungal antigens have been found to be heat resistant, and they can last after the destruction of the mold species. The fungal antigens used were mainly mold spores, fungal proteins, extracellular polysaccharides, and ergosterol. One of the major issues related to the detection of molds using immunological techniques is the lack of specificity and cross reactivity with food components (38,52–57).

Other potential rapid detection techniques include genetic methods (i.e., DNA fingerprinting, polymerase chain reaction, and DNA-DNA hybridization), electrical impedence methods, automated hydrophobic grid membrane filter techniques, and detection of fungal volatile compounds (58–64). More research is needed in order for all these promising methods to be applicable for routine and online analysis.

VIII. DETECTION OF MYCOTOXINS

There is no single method that is appropriate for the detection of all mycotoxins. These methods depend on many factors including the chemical nature of the mycotoxin and the substrate. Appropriate sampling methods are critical for the accurate detection and quantification of mycotoxins in foods and feeds. The routine analytical steps for the analysis of mycotoxins include sample preparation, extraction, clean up, qualitative detection, confirmation, and quantification.

Mycotoxin extraction is generally done using polar solvents such as methanol, acetone, and chloroform. For some mycotoxins a combination of organic solvents and water or water alone are used. Usually these extracts are cleaned to remove impurities by using liquid-liquid partitioning or column clean up, such as immuno-affinity cartridges. These cartridges contain monoclonal antibodies that are specific to the target mycotoxin(s). Different mycotoxins or other chemical components in the sample are separated by thin-layer chromatography (TLC), gas liquid chromatography (GLC), or high performance liquid chromatography (HPLC). Quantification is done using fluorodensitometry or fluorescence detection with HPLC. Other detection methods use U.V. absorbance, electrochemical, or flame ionization. Naturally occurring mycotoxins should be determined using the methods outlined in the Official Methods of Analysis (25,65,66). Recently a number of immunoassay methods, such as enzyme-linked immunosorbent assays (ELISA) have been developed and are commercially available (Table 189.3). The big advantage of these immunoassay techniques is that they are simple and practical to use for qualitative screening of a large number of samples.

IX. SUMMARY

Despite recent advances in the detection of foodborne molds, many practitioners still use very traditional methods (67). Much of these methods are based on macroscopic and microscopic techniques. As such, there is potential risk that this knowledge will not be adequately passed on to the next generation of mycologists. Perhaps more modern methods will replace the traditional techniques before food microbiologists are pondering the need for a fungal analysis.

TABLE 189.3
Commercially Available Immunoassay Test Kits

Company	Test Kit	Mycotoxin
Neogen Corporation (www.neogen.com)	Microwell ELISA	Aflatoxin, Vomitoxin, Fumonisin, Ochratoxin, Zearalenone, T-2 toxin
Vicam LP (www.vicam.com)	Immunoaffinity Column	Aflatoxin, Vomitoxin, Fumonisin, Zearalenone, Ochratoxin
R-Biopharm (www.rbiopharm.com)	Microwell ELISA	Afaltoxin, Vomitoxin, Fumonisin, Zearalenone, T-2 toxin
Editek (Medtox Laboratories) (www.medtox.com)	Card ELISA	Aflatoxin, Zearalenone, T-2 toxin, Ochratoxin
International Diagnostic Systems (www.ids-kits.com)	Cup ELISA	Aflatoxins, Fumonisin B_1
Romer Laboratories (www.romerlabs.com)	Clean-up	Aflatoxin, Ochratoxin, Patulin, DON, T-2 toxin, Zearalenone, Fumonisins, Sterigmatocystin

CONTENTS

I. INTRODUCTION

Source water quality is not the same all over the world. Arguably, it has the most variability of any raw material associated with the food industry. Deep wells, shallow wells, reservoirs, lakes, streams, rivers, even the oceans themselves are potential sources of useable water. The control and management of these water sources can vary along a spectrum from completely private control (for example, a plant well) to completely public control (for example, a municipal water source). Irrespective of whether a food plant has its own well, or it draws its water from a modern municipal treatment plant, each individual water supply presents its own particular problems. This chapter discusses the importance of water sources to the food industry and provides information on minimizing risk through the use of source selection and protection strategies.

II. WHY SOURCE WATERS ARE CRITICAL TO THE FOOD INDUSTRY

A. Contaminants in Water Supplies

Contaminants in water supplies present a danger to the taste, odor and appearance of food products. In extreme cases there are potential risks regarding public health.

Physical discrepancies in water, such as high turbidity, off-colors, off-odors or off-tastes, can have an almost immediate effect on the flavor, appearance or shelf-life of the food products it is used to manufacture. Chemicals and minerals present in the water supply can also have adverse effects. For example, high salts content can change the taste of the food products, thereby making them unpalatable and unacceptable to the consumer. Another example is high alkalinity which can quickly neutralize the delicate acidity of carbonated beverages, lessening their "tang" and making them more susceptible to spoilage. Microorganisms, algae, or even small amounts of organic matter in the water can cause unsightly sediment to develop in food products and lead to premature spoilage. A particular danger when using a surface water supply (for example, reservoir, lake, stream or river) is where seasonal changes result in "blooms" of algae or "inversion," where organic debris rises from the basin. In addition to the debris that is produced, microbial metabolites from several types of algae can produce highly sensory-active organic compounds. Two of the more common compounds are *geosmin* and methylisoborneol which are sensory active at nanogram per liter (ng/l) concentrations and have been a major cause of sensory complaints at municipal water works and some food plants. These concerns, in addition to a growing number of organic compounds being detected in water supplies historically considered safe and of high quality, make the quality of source water and its appropriate treatment extremely important to the food industry.

B. Regulations

On a world-wide basis, our knowledge regarding the effects of contaminants in water is increasing. Much of this advancement is due to the huge progress in the area of analytical chemistry. Water testing instruments are becoming more and more sensitive and sophisticated. Coupled with this is the fact that water has such a simple sample matrix. The result is the measurement of trace materials in water at levels previously impossible. Test results reported in parts per billion and parts per trillion are now commonplace. Regulatory agencies, understanding the importance of water quality to the health of the population, and now having analytical tools to support them, are striving to make water supplies as safe as possible. As a result, drinking water regulations around the globe are in a period of change and refinement. Source waters for products such as natural mineral waters, or other bottled water categories, often must meet extremely stringent requirements and the allowable treatments are often limited.

It is important that food plants be in compliance with all regulations regarding their water source, as well as those relating to water treatment and treated water quality. As analytical capabilities increase and the limits that instruments can detect decrease, regulators, suppliers and end users of water will be forced to continually learn and refresh their understanding of the nature and adverse effects of all potential contaminants.

C. Consumer Awareness and Sensitivities

Water is like no other food industry raw material in terms of consumer knowledge and sensitivity. Water quality-related issues are increasingly apparent in the public domain. Almost any day newspapers will contain some water-related issue. *Cryptosporidium parvum* or *Giardia lamblia* outbreaks, *E. coli* contamination, algae blooms, high arsenic levels, methyl-tertiary-butyl-ether in groundwater, disinfection by-products such as trihalomethanes or bromate and depletion of water resources are some of the more common examples of this. This media coverage has helped increase the global awareness of the quality of water, something that for centuries has been taken for granted. This heightened consciousness underscores the need for water and its environmental and ecological considerations to be valued and adequately addressed by food companies.

D. Treatment Selection

The list of possible contaminants in a given source water supply could literally take all day to review. We should recognize this variability and know as much as possible about the water source that is used at each food processing location. Chemical, physical, microbiological and radiological analytical data can provide valuable information with respect to the characteristics of a given source water supply. Historical data, seasonal variation and plans for development of the source and surrounding areas can help determine its consistency. Water treatment system design at each food plant should be based on this complete understanding and is source specific.

E. If Something Goes Wrong, Alternative Water Sources Are Usually Limited

Water is not like other raw materials that can usually be procured from an alternative supplier if there is a problem. Droughts can result in reduced availability of water at certain times of the year. In some coastal areas, it is not uncommon that intensive pumping of fresh groundwater will cause salt water to intrude into fresh water aquifers. Contamination from accidental spills, waste disposal, industrial effluent, run-off and numerous other events can potentially compromise the quality of a plant's source water supply. Intentional contamination, such as terrorist activity, could easily result in widespread contamination, as relatively small amounts of a contaminant can have substantial effects. For example, the U.S. Environmental Protection

Agency estimates that less than one gallon of gasoline can contaminate one million gallons of groundwater to the point where it is unusable for drinking purposes (1).

III. WATER SOURCE PROPERTIES

Clearly, both the quality and quantity of water available to food plants need to be preserved. The selection, protection and subsequent treatment design are paramount to helping assure that only a safe, consistent, high quality treated water is used. This requires a thorough understanding of the characteristics of the source water supply. The following paragraphs will provide an overview of different types of source water supplies and their attributes.

A. Comparison of Surface and Groundwater Sources

Water sources may be classified into two major categories, namely groundwater and surface water. Examples of surface waters include reservoirs, lakes, streams, rivers and oceans. Examples of groundwater include confined and unconfined aquifers, artesian supplies and springs. The two categories differ greatly in the characteristics of the water they supply, as does water from groups even within the same category. Due to this wide variability, it is not possible to describe with certainty what a "typical" surface or ground water looks like in terms of its chemistry. The best we can do is provide generalities, see Table 190.1, with the condition that there are truly exceptions to every rule.

TABLE 190.1
Relative Comparison of Ground and Surface Water Supplies

Parameter	Ground Water	Surface Water
Total Dissolved Solids (TDS)	Higher	Lower
Suspended solids	Lower	Higher
Turbidity and color	Lower	Higher
Alkalinity	Higher	Lower
Total Organic Carbon (TOC)	Lower	Higher
Microbiology		
• Protection from bacteria and viruses	Highly protected	Highly susceptible
• Protection from protozoa	Highly protected	Highly susceptible
• Presence of iron and/or manganese bacteria	Common	Rare
Hydrogen sulfide gas	Common	Uncommon
Aeration/dissolved oxygen	Lower	Higher
Temperature	More consistent	More variable
Flow rate	Very slow	Very fast
Flow pattern	Laminar	Turbulent
Susceptibility to pollution via surface run-off	Low	High
Time for a contaminant plume to resolve	Very Long	Usually short

Source: Adapted from Bena (2001).

B. Surface Water Sources

In general, surface supplies can be highly variable in every respect—chemically (total dissolved solids, alkalinity, etc.), microbiologically (bacteria, viruses, protozoan "cysts," etc.) and physically (turbidity, color, etc.). Many surface waters are subjected to contamination which may present in many forms, including:

1. Bacteria and other organisms from animal wastes via direct introduction (animals) or indirect introduction (poorly or untreated wastewater)
2. Algae blooms, which are typically acute, seasonal events
3. "Natural" chemical contamination as evidenced by high levels of natural organic matter (primarily the humic substances from decaying vegetation and animal waste)
4. "Synthetic" chemical contamination from surface run-off (outflow) of agricultural chemicals (pesticides, herbicides, insecticides, etc.)
5. Intentional human contamination (sabotage, terrorism, war, etc.).

Again, it must be underscored that the characteristics above, and those that follow, are intended to provide general trends in terms of water composition and characteristics. Exceptions to virtually every characteristic described have been observed.

1. Lakes

Due to their relatively stagnant flow patterns and long water residence time, natural lakes are usually of consistent composition relative to other types of surface supplies. One major climatic event which may have drastic changes in lake water quality is seasonal "inversion." This refers to the phenomenon whereby water at the surface of the lake reaches a temperature at which it is most dense (3.98°C, or 39.2°F). The water below it has not yet reached this state, and density and temperature gradients are therefore formed. This "heavy" water then begins to descend, and displaces the water below it. The displaced water then inverts (hence the term "inversion") and moves from the bottom of the lake toward the upper portion. The resulting agitation brings with it much of the sediment, and associated unwanted components, which make municipal and industrial monitoring even more critical during this time. As you might imagine, both the phenomenon of inversion and its related thermal stratification, are actually much more complex. Their effects on aquatic life and the eutrophication process (basically, the

nutrient enrichment of a body of water, usually lakes or ponds, which results in algae growth or "blooms") have been studied under many other scientific disciplines. Unfortunately, industrial waste effluent and sewage treatment plant discharge are often re-introduced into the same body of water that originally supplied the influent water (this is also often the case for many large streams). These practices are coming under more scrutiny and there is ever increasing political pressure for regulatory reform.

2. Reservoirs

Reservoirs, or "man-made" lakes, are similar in overall characteristics to those described above for natural lakes. They are often regarded as huge storage reservoirs for municipal water supplies prior to treatment. As surface supplies go, reservoirs are of fairly consistent quality, reasonable turbidity (due in large part to natural oxidation and settling mechanisms) and often afford lower bacteria counts than other surface supplies (2). However, as a consequence of their relatively low flow patterns and lack of agitation, algae blooms are often a problem.

3. Streams

In general, streams are often of reasonable chemical/physical composition. Due to their locations and physical dimensions they offer easy access for a multitude of animal life. With this comes the frequent introduction of microorganisms of fecal origin, in addition to appreciable amounts of organic matter. This organic material is typically considered to be the precursor material of trihalomethanes and a host of other chemical by-products which can be formed once this water supply is disinfected. Smaller streams are often influenced by rain events, whereby their flows are increased, with subsequent increase in suspended solids and turbidity. Larger streams are generally at higher risk of having industrial waste (often poorly or inadequately treated) discharged into them. They are often more of a concern, due in part to their larger surface area, in terms of accepting surface run-off and sub-surface drainage.

4. Rivers

Rivers represent perhaps the most difficult of the surface water supplies to address. In general, they are of highly inconsistent quality, very high turbidity and suspended solids, prone to considerable temperature fluctuations and vary widely with respect to their flow patterns (that is, areas of excessive turbulence and areas of minimal movement may exist within close proximity to each other). Rivers, as a result of their great length and flows, are recipients of surface run-off from many types of areas. For example, a river might flow across areas of agrarian activity, with the potential to incorporate pesticides, herbicides, nitrate, and other contaminants along its route. This same river might later flow through an industrial zone, pick up run-off from poorly contained chemical storage tanks, drains, sewers, etc. and possibly even meet the discharge of one or more waste treatment plants! Imagine the contaminant "soup" that would result. For this reason, any methods of treatment for river water must be preceded by thorough characterization of the supply. The treatment itself must be capable of addressing a wide range of quickly changing water qualities.

C. Groundwater Supplies

In comparison to surface supplies, groundwater supplies are generally more consistent in every respect—thermally, microbially, chemically and physically. They have historically been considered a much safer supply, or one which produces "purer" water. Two hundred years ago, this blanket statement might have been more universally true. However, along with the development of the chemical and related industries came the increased potential for groundwater contamination. With increasing industry, came increasing underground chemical storage, increasing contaminant spills, increasing numbers of poorly located and/or poorly constructed septic systems, along with a host of other problems for the groundwater environment that needed to be addressed (in fact, many still do).

As with surface water supplies, there are different classifications of groundwater, with some being more preferred than others in terms of providing consistently good quality water. A brief discussion of each, in terms understood by the novice hydrogeologist (which is a discipline becoming increasingly important for anyone involved with water operations to know), follows below.

1. Aquifers and the Underground Environment

An aquifer may be defined as "a geologic formation with sufficient interconnected porosity and permeability to store and transmit significant quantities of water under natural hydraulic gradients"(3). Critical terms in this description are "store," "transmit," and "significant quantities." All three should be satisfied to consider a supply an aquifer. The first two are straightforward. For example, huge amounts may be stored but unable to be transmitted, in which case this supply, however large, should not be considered an aquifer. The third term, "significant quantities" is more nebulous and linked to the intended use of the supply, such as a residential well, a large municipality, or multiple industrial users tapped into a community well. Clearly, "significant quantities" would be defined differently for these three applications.

Figure 190.1 describes the different layers or zones encountered as we move downward from the surface of the ground to the water bearing strata below it. As we move from the surface, the first zone encountered is the

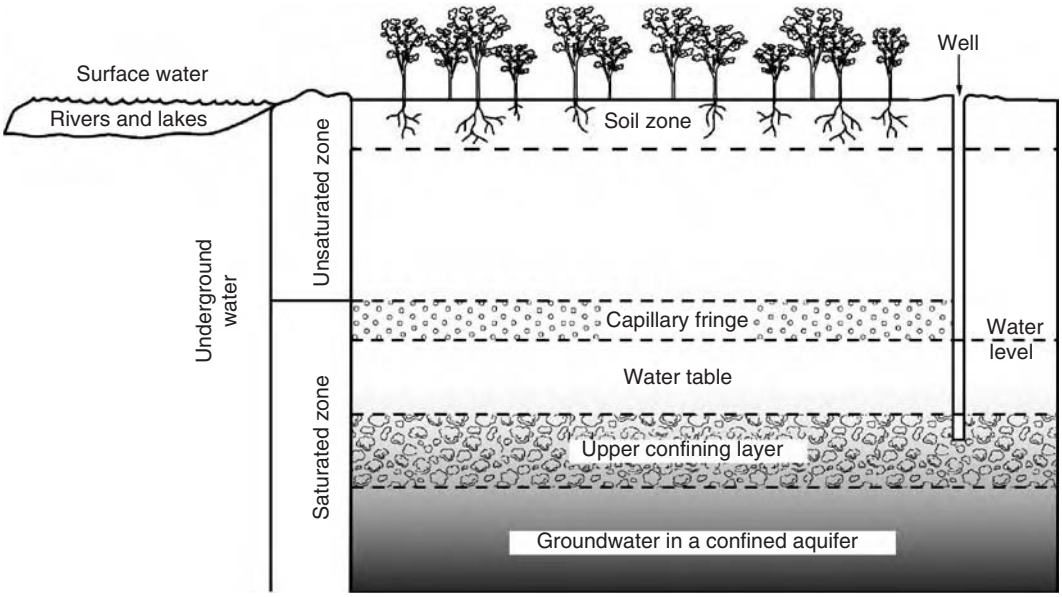

FIGURE 190.1 The underground environment.

"unsaturated zone" (also referred to as the "vadose zone"). In this area, the geologic media (dirt, clay, sand, etc.) contains a mixture of water and void spaces with air—hence, the terms "unsaturated" or "variably saturated." Continuing downward, we reach the "capillary fringe," which is generally considered the beginning of the "saturated zone," but is sometimes considered a distinct entity. This interface between unsaturated and saturated zones is not completely understood and is the subject of much study with regard to movement of certain contaminants within it. The "saturated zone" is the area where air is at a minimum and water is at a maximum. The geologic media here are saturated with water. Dissolved oxygen in the saturated zone is extremely rare. Many deep groundwater formations exist under anaerobic or hypoxic conditions. It is within the saturated zone where we find our aquifers and where most production wells are placed. Throughout the saturated zone, many strata of varying permeability will be found. Most importantly, this is where groundwater supplies are found.

2. Unconfined and Confined Aquifers

Aquifers may be grouped into the two broad categories of "unconfined" and "confined." Unconfined aquifers (sometimes referred to as "water table aquifers") are those water bearing, geologic formations which are under atmospheric pressure at their upper boundary. The "water table" (sometimes referred to as the "phreatic surface") is the upper boundary of the saturated zone. Water levels in wells which tap unconfined aquifers should be the same as the level of the water table. The plane which connects the upper levels of water in all wells which penetrate unconfined aquifers is known as the "potentiometric surface." Confined aquifers (sometimes called "artesian aquifers") are those water bearing geologic formations whose upper and lower boundaries are comprised of geologic material of low permeability, and which are under pressure greater than atmospheric.

In the case of confined aquifers, due to the internal pressures, the water levels in wells which tap them may often exceed the level of the water table (which may result in a "flowing artesian well" or "spring"). In the food industry, conversational knowledge of confined and unconfined aquifers will account for nearly all of the hydrogeologic discussions into which a food technologist might become engaged.

In addition to aquifers being classified as confined or unconfined, the geologic material of the aquifer may be described as consolidated or unconsolidated. "Unconsolidated" deposits are formed from loose geologic material, such as sand, clay, silt, gravel, and even sea-shell remains. "Consolidated" deposits are formed by mineral particles combining from heat and pressure, or via chemical mechanisms. They include sedimentary rocks, such as limestone, dolomite, shale, and sandstone; igneous (formed from molten) rocks, such as granite and basalt; and metamorphic rocks, such as limestone and gneiss (4). Fractured rock formations almost always refer to fractures or fissures in consolidated deposits. Ground water and contaminant flows through this type of formation are highly unpredictable, since it is difficult to determine

which route the water will take through this hard rock maze. Carbonate aquifers (also known as "karstic formations") are formations of limestone and other water-soluble rocks whose fractures have been widened by erosion to form sinkholes, caves, or tunnels (5). As you might expect, with such little resistance, the flows through fractured and carbonate formations can be rapid enough to rival surface water sources. Flows, though rare, have been reported up to 450 meters (approximately 1500 feet) per day (5).

D. Municipal Supplies

Municipal supplies of water may come from either surface or groundwater supplies, or a mixture of the two. In many cases, the regulatory oversight of municipal water treatment plants and distribution systems affords water of normally very high quality. However, this should not be depended upon as a guarantee. Even if a food plant is lucky enough to have a normally high quality municipal supply, it is still necessary for them to monitor their source water and have appropriate water treatment systems. This is largely due to the fact that problems can occur with municipal treatment and distribution, as will be discussed below. It is also partly because municipalities have different treatment objectives and requirements to food industry plants. For example, high total dissolved solids, high alkalinity levels and disinfectant residuals (e.g. chlorine) might be acceptable in municipally treated water but can adversely impact the quality of many food products.

Some of the chemicals used by municipalities can lead to problems with food plant water treatment systems. For example, chloramines which are often used for disinfection purposes by municipalities (or may form unintentionally through municipal chlorination if ammonia is present in the source water supply) can negatively affect food plant water treatment operations, especially those which operate conventional coagulation water treatment systems. Conventional coagulation systems are also especially prone to gross upset to the floc formation if polyphosphate use is instituted by a municipality for corrosion control within their distribution system. Even the simple act of flushing out distribution lines and fire hydrants, which can occur on a periodic basis, can stir up loose particles of iron, debris and/or organic material leading to short periods of highly undesirable water quality entering the food plant water supply. Flushing of municipal distribution systems can also introduce contaminants from the scouring agents which are regularly used. Other problems for which the municipal treatment sometimes does not adequately address include sensory issues, such as those related to algae blooms (see above discussion on "inversion"), high levels of disinfection byproduct formation (for example, trihalomethanes, bromate, etc.) and accidents (such as cross-connections or damaged valves/pipes that can potentially introduce contamination such as that from septic sewage). At the time of writing there are still cities in the U.S. (most notably New York) and in Europe (for example, Belfast and Manchester) that receive surface water from protected catchments that have essentially had no treatment other than addition of a disinfectant, fluoridation and corrosion control. The view that catchment control alone provides water that is safe after disinfection is becoming less and less acceptable as there have been too many outbreaks of waterborne diseases (especially those associated with protozoan parasites such as *Giardia lamblia* and *Cryptosporidium parvum*). In addition, there is increasing pressure for recreational access to protected catchments.

Many municipal treatment problems occur in the developing world where there are important differences in water priorities compared to developed countries. Waterborne diseases are one of the greatest health hazards across much of the world and the high incidence of such diseases is one of the key factors that cause high infant mortality rates. The priorities in the developing world is thus to provide water from reliable supplies of microbially safe water at an affordable cost. That is not to say that physiochemical quality criteria are ignored, but they are considered with due regard to the supply of a microbially safe water at an affordable cost. Unfortunately, water treatment processes in the developing world all to often fail, even with their primary objectives.

It is highly advantageous for food plant personnel to understand the challenges faced by their municipal water supply authority. This allows them to be prepared with the appropriate in-plant monitoring and water treatment. Maintaining a good relationship can also be very useful so as to be informed if and when changes to the municipal water treatment process are being planned or if flushing of municipal water distribution systems is to occur near the food plant. Municipalities can also provide valuable analytical data which helps a food plant determine the characteristics and consistency of its source water supply.

IV. WATER SOURCE SELECTION CONSIDERATIONS

The categories above briefly discussed the major sources of water supplies to food plants. Obviously, there are others (oceans, lagoons, glaciers, etc.) and many possible combinations of supplies. The keys to any consideration of a water source are:

1. First and foremost—what is its microbial quality? As discussed above, in some areas of the world, the potability of a supply, even a municipal supply, may not be guaranteed.
2. Chemical/physical quality—is it safe? Is it too high a risk to even consider? Can it be treated economically and within regulatory guidelines?

These questions must be answered on a case-by-case basis, and will depend on the degree of due diligence desired by a parent company, presiding regulations, corporate policies and a risk assessment of the impurities themselves.

3. Consistency of composition—is it consistent? Will water quality vary beyond the capability of the proposed treatment? Gathering any and all available data will aid in answering this question. Make use of municipal monitoring data, plant testing data, third party testing laboratory data, rainfall data and hydrogeologic or surface water surveys.
4. Its recharge—is run-off a concern? The volume of recharge, or replenishment, of the aquifer is important, as is the quality and origin of the water being used for that recharge.
5. Volumes/supply—can it currently meet the plant's needs? Will it in the future? In addition to the quality and safety components, supply is a key parameter to help ensure that the volume of water will be available for the long-term needs of the business. In many areas, the volume of withdrawal of water from an aquifer falls under government control or guidance, and this must be considered.
6. Future plans for the source or surrounding areas—is a municipality planning to develop the source and treat it? For example, is there planned construction or industrial entry to the area?

These questions highlight the value of considering water a dynamic ingredient throughout its supply chain. Irrespective of surface vs. ground, or private vs. municipal, absolute diligence in the selection, qualification and on-going monitoring of water sources and treatment systems, in addition to vigilant physical control of these areas (fenced, locked access, etc.), are paramount in helping to minimize the risk to the food industry and its brands.

V. WATER SOURCE PROTECTION PROGRAMS

From the standpoint of water source protection, the ideal situation is a completely fenced in watershed owned by the food plant or by the municipal water authority. Unfortunately, this is not usually possible. When examining alternative source protection activities there are two categories to consider, namely groundwater and surface water.

A. Groundwater Source Protection

Private wells are most common wherever water distribution systems are not reliable or simply do not reach industrial users. The use of private groundwater sources also represent important cost savings opportunities where the full cost of high quality water and wastewater services apply. As a result, private wells are the most common water source for food plants in many international markets. It is widely considered good practice for food plants using private wells to develop a well protection program to reduce the vulnerability of water supplies from a quality, availability and economic standpoint. The well protection program steps indicated below were adapted from those suggested for municipal drinking water companies by governmental agencies such as the U.S. Environmental Protection Agency (7,8). They have been amended to apply to the needs of food plants.

1. Form a team or at least identify the person(s) responsible for coordinating the plant's well protection program. This team will gather map information, contacts with local authorities and consultants, if necessary.
2. Delineate the area to be protected. The water may travel through hundreds of meters of surface and sub-surface land before becoming available at the well. Ideally, the protection perimeters would be defined with the help of local regulatory officials, hydrogeologists, and others. Realistically, checking the land immediately surrounding the well-head is often the most practical method to define the capture zone for small systems (arbitrary or calculated fixed radius).
3. Identify and locate potential sources of contamination. This is critical. Often, potential contaminant sources, which may be quickly and economically addressed, go unnoticed until it is too late.
4. Manage the plants well protection area. This may range from removing or stabilizing leaking underground storage tanks, to educating the farmers adjacent to the plant on the use of alternative fertilizers or pesticides. This step must be approached from both a strategic point-of-view and an economic one. Strategically, build the relationships that would help this program over time (local regulators, government officials, testing labs, etc.). Economically, include the appropriate expenses in the business plan [for example the costs for re-grouting or re-digging a well or constructing security measures around the well-head (shed, lockable cover, sampling ports, fences, etc.)].
5. Develop contingency plans with responses for the most likely scenarios identified. At this point, it may be important to list all water supply alternatives for the case of major disruptions.

Contingency plans must also secure funding sources and trained responders.

6. Monitor results and evaluate the well protection plan. It is critical in any planning process to compare results with the goals and assess the success or failure of the effort. Monitoring water quality and quantity is the key factor and may require maintaining a network of monitoring wells in addition to pumping tests and water analysis. Evaluation of the management activity outlined in step 4, both from an individual point-of-view and from the plan itself, must be conducted every year to ensure that the objectives are being achieved and the plan is adjusted to new realities. The team should take the time to reflect on its contribution to the protection of our main ingredient. Recognition from management and/or from the community for its achievements help sustain the effort over time.

These six steps should be considered as general information. Some parts can be immediately implemented, while others will be longer term. The key is keeping everyone informed and involved throughout the process, since the success of the plan relies heavily on the awareness and support from the public.

B. Surface Water Source Protection

A watershed management program can be a useful tool to help reduce risks associated with surficial supplies. Managing the watershed is typically the responsibility of the local water authority. The best way for the authorities to enforce protective measures is to have the backing of its citizens. Public education and news media play a critical role and public relations opportunities allow businesses to exercise good citizenship. Users of large quantities of water, like many food manufacturing plants, are especially encouraged to support the community where they operate and eventually lead the process, if necessary, in order to ensure the continuity and quality of the water supply.

Whenever a surface water source is used, the boundary of the entire "hydrographic" basin delineates its ideal protection zone. Topographic maps indicating features such as vegetation, roads, open land, sewers and industrial activities are particularly useful for outlining the area. A knowledge of potential sources of contamination within the area is critical. Community engagement has proven very effective in obtaining this type of information (resident associations, senior citizens, environment protection groups, etc.). Overlaying maps containing information about the points of water withdrawal, animal populations, potential erosion, sewered areas, zoning, land use and development plans provide a good understanding of the overall vulnerability of the watershed. The risk assessment step is more complex for surface water supplies than for groundwaters as it must take into account all current and potential values of the surface water resources to a given community (cultural, environmental, recreational, spiritual, aesthetic, as well as economic values).

191 Water: Purification and Distribution

Manus Mitchell
Quality Technology, Pepsi Cola International

CONTENTS

I. INTRODUCTION

Abundant, clean and safe water is essential for good public health. Of all the advancements made possible through science and technology, the purification and distribution of water for safe use is truly one of the most significant. For example, before cities began routinely treating drinking water, cholera, typhoid fever and hepatitis A had reached epidemic proportions. The implementation of effective water purification technologies has virtually eliminated these diseases in developed countries.

An overview of some key dates in water treatment is provided in Table 191.1. Archeological evidence suggests that as early as 2000 BC, people living across the Tigris, Euphrates and Nile rivers possessed the desire to improve their water quality (1,2). It is thus clear that water purification is not a modern concept. Four thousand years later we still strive for the same goal.

TABLE 191.1
Some Key Dates in Water Purification

Approximate Date	Drinking Water Treatment Development
Circa 2000 B.C.	Use of alum for water clarification in ancient Egypt (1)
1804	First municipal water filtration plant constructed in Paisley, Scotland (1,2).
1855	Dr. John Snow proves that cholera was transmit ted via contaminated drinking water (2). Slow sand filters coming into widespread use (3).
1880s	Louis Pasteur develops theory of germs (3)
1890s	First application of chlorine disinfectants to treatment of drinking water begins in England (4)
1906	Ozone used as a water disinfectant in Nice, France (1).
1908	US cities began routinely treating drinking water with chlorine (starting with Chicago and Jersey City) (4)
1915	First U.S. drinking water bacterial standard (4)
1952	The first recorded law was passed, in London, requiring filtration for all drinking waters (2).
1959	Reverse Osmosis membrane treatment invented (5)
1990s	Widespread use of granular activated carbon and ozone in Europe, primarily to remove pesticide residues (2, 6).

Developed by the author.

Effective treatment ensures that the water used in producing food products meets all standards and requirements. Many parameters need to be managed by water treatment, some for regulatory compliance, some for product safety, some for process control and others for product sensory performance and stability. Stringent water treatment processes are necessary to consistently meet these water quality needs.

II. REASONS FOR WATER PURIFICATION

If water appeared clean two centuries ago then it was considered suitable for drinking. In addition, there were very few environmental concerns relating to its use for waste disposal. By the early 19th century, urbanization and industrialization led to the gross pollution of rivers serving the larger cities and waterborne diseases became commonplace. Intensive agriculture ensued, and with it the widespread use of agricultural chemicals. More recently, with increasing scientific research, terms such as genotoxin and carcinogen have been used to classify a seemingly endless number of compounds in relation to their health effects. Water quality standards and regulations were developed to combat these threats to public health. The water industry has responded in admirable fashion developing many water treatment technologies. A testimony to this advancement is that the technology is now available to treat almost any water supply to potable drinking water standards. However, a continuing hurdle to the provision of safe drinking water to the entire global population is the affordability of these technologies.

As scientific knowledge in relation to the different aspects of water quality increases, our expectations as to what constitutes safe and consistent water quality is changing. For example, a food plant might have a treatment process that produces water hitherto considered potable. But now the treated water at this plant might be unacceptable because of, for example, a failure to comply with new turbidity, trihalomethane or bromate standards. The importance of effective and reliable treatment has been reinforced by the threat from *Cryptosporidium parvum* for which the U.S. Environmental Protection Agency has set a treatment standard (7). This is a prime example of public confidence relying on effective water treatment.

Demanding numerical drinking water quality standards throughout the world provide the framework for what is considered safe water. Regulatory compliance, including the expectations for water treatment and quality, is required by whatever regulatory agency has jurisdiction. Historically, water for food applications needs to meet, as a minimum, the water standards that apply to potable drinking water. For example, in the United States, this means adherence to U.S. Environmental Protection Agency primary drinking water standards (8), in addition to all applicable local standards and company/product specific water standards. Around the globe, the foundation of many drinking water quality standards is the World Health Organization Guidelines for Drinking Water Quality (9). National drinking water standards are usually enforced by means of close scrutiny from various governmental agencies.

In addition to meeting regulatory standards, a specific water quality is often required to make individual food products in the way they were designed. As food products require ingredient water of varying composition, the food plant water treatment process needs to be designed to consistently deliver the desired water quality. First and foremost, treated water must be absolutely safe to drink, from a physiochemical, microbiological and radiological perspective. Second, the receptors in our bodies are sensitive to certain chemical substances contained in the food we eat and air we breathe. Because food products contain large amounts of water, adherence to key water treatment principles ensures a consistent taste, odor and appearance in food products, no matter where in the world they are manufactured. Food plants are also required to deliver water of a quality that is suitable and operationally efficient for use as a process aid. This includes use in applications such as rinsing, cleaning, sanitation, lubrication, warming, cooling and boiler operations.

III. PRIMARY WATER TREATMENT TECHNOLOGIES

Many water treatment technologies can be used to purify water. There may not necessarily be a single correct process chain to treat a particular raw water supply, but a number of possible options. The on-site water treatment technologies most widely used in the food industry are conventional coagulation, membranes and ion exchange, each configured with the appropriate pre- and post-treatment unit operations. In some cases the food plant source water source might already meet the necessary water quality requirements and none of the primary water treatment technologies will be needed. Table 191.2 provides an overview of the effectiveness of the primary treatment technologies, along with some of the pre-and post-treatment unit operations, with respect to chemicals that are of health significance in drinking water (10).

The actual on-site water treatment process that is selected at a given food plant facility will depend on several factors, including:

1. The nature of the source water, especially its physiochemical, microbiological and radiological characteristics and consistency. A suitable water treatment system assures consistency by easily addressing source water or distribution system problems, often without the plant staff even knowing that these problems had occurred.
2. The desired treated water quality. The treatment selection to achieve the desired quality is highly dependent on source water attributes, the nature of the food product being produced and company treated water requirements. This protects the designed sensory aspects of the food product and helps ensure it has an

adequate shelf-life in the market. In this respect, the plant water treatment process protects the trademark and helps build consumer confidence on a continuous basis.

3. A consideration of capital and operating costs. This includes the initial capital investment, replaceable costs based on anticipated life (e.g. carbon, membranes, etc.), service agreement costs, operating supplies and their availability, chemicals, labor and energy.
4. Projected water volume demand. Often the flexibility to upgrade the process for future

plant expansions is a key consideration at the outset of a plant design.
5. The space available to construct the water treatment plant.
6. Restraints due to the need to upgrade an existing plant can result in limitations on the processes that can be used.
7. Source water costs. The cost of source water can be an important factor to take into consideration. For example, a reverse osmosis water treatment system is typically 75% efficient in terms of the amount of treated water that is produced from its feed-water, the other 25% ending up in the concentrated waste or "brine" stream. In fact, the % efficiency of reverse osmosis may sometimes be lower than 75% depending on source water quality and pretreatment. By contrast, a conventional coagulation system is often greater than 99% efficient in terms of water usage.
8. The costs associated with disposing of sludge or liquid waste discharge to the drain (for example, sewer surcharges) also need to be considered. In particular, total water volume to drain, total dissolved solids, chemical residuals (e.g. chlorine), effluent license restrictions, etc., can influence selection of treatment. Effluent costs can be very significant, and have often been the key factor for food plants deciding on one treatment technology over another.
9. Often, company or personal preferences are a major influence.

A. Conventional Coagulation

Conventional coagulation treatment is also commonly referred to by other descriptions such as conventional lime treatment systems (CLTS), the cold lime process and batch coagulation/flocculation. Note that the two terms coagulation and flocculation are often used interchangeably by water technologists, which is incorrect. For clarity, coagulation is the destabilization and coalescing of colloidal particles which occurs extremely quickly. Flocculation, on the other hand, is a longer term process whereby larger particles are formed by aggregation of smaller particles that are formed by the coagulation process. In the past, conventional coagulation was at the core of many food plant water treatment systems, and was applied to treat source water of virtually any quality. Indeed, this system does address a broad range of water contaminants including particulates, alkalinity, hardness, metals, natural organic matter, bacteria, viruses and protozoan populations as well as off-colors, off-tastes and off-odors. Conventional coagulation is often adequate as a primary treatment for many food plant water purification applications, but may also be used as a superb pre-treatment for membrane processes, ion-exchange, or electrodialysis.

A major disadvantage of conventional coagulation is that it does not effectively reduce chloride, sulfate or nitrate concentrations which means that it cannot be used alone if reduction of these parameters is part of the water treatment objectives. Additional difficulties that may be encountered include the requirement for sludge disposal, a high potential for formation of trihalomethane compounds (which are strictly regulated in most jurisdictions) under certain conditions and difficulties operating with some water supplies that have low levels of dissolved solids. Membrane-based processes have decreased the dependence on this technology. Despite the limitations and the availability of cost competitive membranes, conventional coagulation arguably remains the most important primary water treatment process for the food industry around the globe.

Simply put, conventional coagulation involves mixing three primary chemicals in a reaction tank and allowing a contact time of at least two hours for the ensuing reactions to proceed. The three primary chemicals typically used are 1) a coagulant; 2) hydrated lime; and 3) a chlorine source. Less commonly applied chemical treatments are 4) the application of calcium chloride or sulfate, 5) the addition of soda ash, 6) the use of coagulant aids and 7) the use of chemicals (other than hydrated lime) for pH adjustment. Coagulation jar testing can prove helpful to determine the optimal type and dosage of treatment chemicals. The coagulant, with the assistance of the chlorine, hydrated lime, and/or any other chemical used, forms a heavy floc which entraps particles of debris, dirt, organic matter and other undesirable material in the water, and settles slowly toward the bottom of the tank. While the floc is forming, the precipitated alkalinity also settles slowly toward the bottom of the tank. The water in the tank flows toward the draw-off pipe located at the top of the reaction tank and the floc, because of its own weight, is left behind, continually trapping particles of debris as it settles. The treated water flows upward toward the treated water draw-off pipe and out of the tank toward the post-treatment system.

1. The Coagulant

The primary purpose for coagulant addition is to cause particles to coagulate. The coagulant also assists in the precipitation of the insoluble alkaline salts created by the lime-based reactions. The coagulant, aided by steady non-turbulent agitation, overcomes the repulsive negative charges present on colloidal matter in the water supply. This charge neutralization and subsequent destabilization allows the coagulant to form a floc of ever-increasing size and density. As it forms, it incorporates the precipitating calcium carbonate, along with a host of other contaminants present

in the incoming water. Two commonly used coagulants are ferrous sulfate and ferric sulfate. They both provide good coagulation over a wide range of water conditions, especially at the high pH typically encountered where hydrated lime addition occurs (pH 9.6 to 10.5). Anecdotal data suggest that, when ferrous sulfate is used, oxidation of ferrous to ferric in the reaction tank results in appreciable silica removal. Aluminum sulfate, or "alum," can be used but its effectiveness is optimum in the 5.5 to 8.0 pH range which is typically cited as too low for alkalinity reduction. Despite this, there is an appreciable amount of plant operating data where alum is used effectively with hydrated lime at pH values near 10. Research into inorganic coagulants in the 1960s led to polymeric aluminium salts such as polyaluminium chloride and polyaluminium silicate sulfate.

2. Hydrated Lime

It might seem ironic that in order to reduce the water's hardness and alkalinity levels, hydrated lime is added which contains both hardness and alkalinity. Note that the word lime is often loosely used to cover both calcium hydroxide ($Ca(OH)_2$, slaked lime or hydrated lime) and calcium oxide (CaO, quicklime or lime). Calcium oxide is rarely used due to difficulties with its handling and control. Hydrated lime increases the pH of the water in the reaction tank to above 9.6, and at this pH soluble hardness and alkaline salts are converted into insoluble ones which precipitate out of solution. That is, it forces the conversion of bicarbonates to carbonates. The chemical reactions that occur to precipitate calcium carbonate are:

$$Ca(OH)_2 + Ca(HCO_3)_2 \rightarrow 2CaCO_3 + 2H_2O$$

$$Ca(OH)_2 + Mg(HCO_3)_2 \rightarrow MgCO_3 + CaCO_3 + 2H_2O$$

and also

$$Ca(OH)_2 + MgCO_3 \rightarrow Mg(OH)_2 + CaCO_3$$

At this high pH, naturally occurring alkalinity, usually present in the form of bicarbonate alkalinity, converts to carbonate alkalinity. The calcium carbonate is virtually insoluble in water at this pH, and precipitates from solution.

3. Chlorine

The third primary chemical applied in conventional coagulation is chlorine, which can be supplied from liquid sodium hypochlorite, solid calcium hypochlorite or chlorine gas. Residual chlorine levels are typically maintained in a range of 6 to 8 ppm free chlorine in order to ensure an effective kill of microorganisms, including bacteria, yeast and algae, at the high pH ranges typically encountered in the lime treatment system. Protozoans, like *Cryptosporidium parvum* and *Giardia lamblia*, are more resilient to chlorine and will be less affected by the chlorine at the high pH employed in conventional coagulation treatment systems. However, the chlorine, aided by the physical entrapment and removal of these organisms during the coagulation process, will still typically result in a substantial reduction in their numbers. Indeed, conventional coagulation is widely regarded as being one of the effective barriers in a multiple barrier approach against protozoans. In addition to the microbial disinfection effects of chlorination, the following benefits also result from its use:

- Improved coagulation by oxidizing organic matter, thereby assisting in its removal. This is preferred as organic matter may hinder the coagulation process and impart objectionable odor and taste to the water.
- Removal of components which contribute to off-taste, off-color, and off-odor.
- Facilitate the removal of soluble metals like iron, manganese, arsenic and others through oxidation.
- Reduction of chloramines through breakpoint chlorination.
- Oxidation of ferrous hydroxide to ferric hydroxide when ferrous sulfate is used as a coagulant.

4. Calcium Chloride or Calcium Sulfate

In some cases, water contains sodium alkalinity. This essentially means that the sodium salts of bicarbonate ($NaHCO_3$) or carbonate (Na_2CO_3) are present, instead of the calcium and magnesium salts of bicarbonate (e.g. $Ca(HCO_3)_2$) or carbonate (e.g. $CaCO_3$). The presence of sodium alkalinity is indicated by the water hardness being less than the alkalinity, both expressed as $CaCO_3$ equivalents. Where this happens, the lime-based reactions may need the assistance of some form of calcium or magnesium (usually calcium chloride or magnesium chloride) in order to effectively reduce the total alkalinity. The calcium provided to the reaction tank allows the calcium carbonate to precipitate out of the water. The following reaction is involved where calcium chloride is added to effect alkalinity reduction:

$$Na_2CO_3 + CaCl_2 \rightarrow CaCO_3 + 2\ NaCl$$

Notice that, even though the alkalinity will now decrease (through precipitation of calcium carbonate), the chloride level (or sulfate level if calcium sulfate is used) will increase. This must be accounted for in the dosing so that treated water chloride levels remain within acceptable thresholds.

5. Soda Ash

Non-carbonate or permanent hardness will not be reduced with lime addition alone. The addition of soda ash (sodium

carbonate; Na_2CO_3) is often required to reduce non-carbonate calcium hardness. Reduction of non-carbonate magnesium hardness may also require additional hydrated lime. Addition of soda ash should be done with care as it will also result in an increase in treated water sodium levels.

6. Coagulant Aids

When a chemical is used to strengthen or enlarge flocs formed by coagulation, it is normally referred to as a coagulant aid. Coagulant aids are not normally needed for food plant conventional coagulation operations. Sodium aluminate is sometimes used only in systems that use aluminum sulfate as the coagulant. When needed, calcium carbonate may be used at 50% of the lime dosage to aid floc settling. The term polyelectrolyte is used as a generic term to describe high molecular weight organic polymers that may be used as coagulant aids. For example, bentonite and Fuller's sand can be used as so-called "weighters" to assist removal of colloidal matter. For a properly sized and designed system, coagulant aids should not be necessary on a long-term basis.

7. pH Adjustment

Optimum coagulation is generally, but not always, obtained between pH 9.5 to 11 when using ferrous or ferric sulfate and between pH 6.5 to 7.5 when using aluminum sulfate (alum). For systems that use aluminum sulfate as the coagulant (i.e. where hydrated lime addition does not take place), soda ash or caustic is sometimes used for pH adjustment in place of hydrated lime. Acid-enhanced coagulation refers to the practice of lowering pH during coagulation to enhance the removal of natural organic matter. A food grade mineral acid such sulfuric acid or hydrochloric acid is most often used for this application. While acid-enhance coagulation is widespread in relation to municipal water treatment, it is rare in the food industry as it would work against the precipitation of calcium carbonate.

The design of the coagulation reaction tank can be important in relation to the effective operation of a conventional coagulation system. A depiction of a conventional coagulation reaction tank is provided in Figure 191.1. The basic design includes a minimum two hours retention and appropriate agitation using mixing paddles. Sludge recirculation can sometimes be important in the treatment of waters with low bicarbonate concentrations. This results in enhanced flocculation through "seeding" which involves the production of larger particles that will precipitate more easily. Some settling basins are equipped with settling tubes (angled at 60°) or a Lamella-type inclined plate design, which promote the settling of suspended floc. Temperature can also play a role in terms of coagulant effectiveness. For example, a Canadian study on cold weather treatment revealed that ferric and ferrous salts might be more effective than alum for some Canadian waters during winter. Alum, on the other hand, seemed more effective in summer according to the same study (11).

Conventional coagulation and "in-line" coagulation (also commonly referred to as direct filtration) are two very different types of treatment, and should never be confused or regarded as equivalent. In-line coagulation is typically viewed as a sort of "enhanced filtration." It uses a

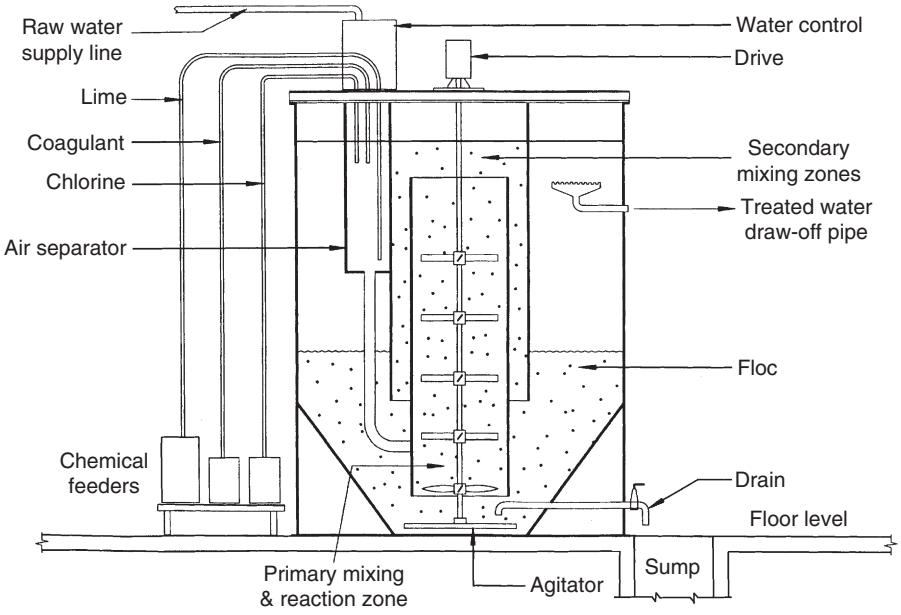

FIGURE 191.1 Conventional coagulation reaction tank.

coagulant, which is already oxidized (like ferric sulfate), which is injected in-line ahead of a static mixer. This forms a floc, which is captured atop a media filter. Typically, in-line coagulation affords little to no alkalinity reduction and should only be considered when the incoming water is already of consistent, high quality. However, it can be a useful pre-treatment to water treatment systems such as reverse osmosis where colloidal fouling of the membranes might be a potential issue. The flocculation and subsequent capture of in-line coagulation systems takes place over the course of approximately 6 to 8 minutes, and is not nearly as effective at removing contaminants as is conventional coagulation which typically has a reaction time of 2 hours or greater.

B. Membrane Processes

The term "membrane process" applies to technologies that use membranes to remove particulates, colloids, microorganisms, molecules and ions from water. The types of membrane water treatment process encountered in food plant operations are, in order of decreasing pore size, microfiltration, ultrafiltration, nanofiltration and reverse osmosis. Thus, the use of membranes may range from the use of a simple five-micron microfilter to help remove granular activated carbon fines, to reverse osmosis which has pores so small that molecular ions are removed. Figure 191.2 provides a visual representation of the relative particle size removal of the each membrane process. The driving force behind each membrane process is pressure. When pressure is applied across the membrane, purified water is forced through the membrane, leaving unwanted impurities behind. Table 191.3 compares the typical removal percentages of reverse osmosis, nanofiltration and ultrafiltration for a variety of water impurities (12).

Ultrafiltration, nanofiltration and reverse osmosis can all afford removal of many microbial impurities. Absolute rated microfilters of 0.45 microns (1 micron is 1×10^{-6} meters) or less are also effective at removing many microorganisms. However, a critical point which must be understood is that none of these processes, not even reverse osmosis, produces a commercially sterile water. Believe it or not, this is still a common misconception among many in the food industry. Owing to the nature of cross-flow technology, the high pressures used, the integrity of the seals and the variability in the pore structure of the membrane materials, these membrane treatment operations will remove a large percentage of the microorganisms to which they are introduced, though not all. As a consequence, additional disinfection of the water supply is usually undertaken (for example, chlorination, ozone, ultraviolet irradiation, etc.).

1. Microfiltration

Microfiltration is a direct extension of conventional particulate filtration into the sub-micron range. Microfiltration membranes have a filtration range that is typically from 12 to 0.01 microns. It rejects suspended and some colloidal material at operating pressures of approximately 15 to 30 pounds per square inch (psi). Due to their controlled pore size distribution (when absolute rated) microfilters are often used for mechanical removal of bacteria from water streams. For this application, a stepped removal approach is often employed which will include filters of decreasing pore size oriented in series, so as to minimize the plugging potential of the smallest pores (for example, a 5 micron particulate filter, followed by a 1 micron microfilter and finally a 0.2 micron microfilter which helps assure adequate bacterial reduction).

2. Ultrafiltration

Ultrafiltration is excellent for removing particulate matter, large organic matter (which includes humic acids, fulvic acids and related materials that comprise the natural organic matter in many water supplies) and microorganisms such as bacteria, yeast, mold, viruses and protozoa. The usual ultrafiltration range is from greater than 0.01 to 0.1 microns. The pore sizes of these membranes are not small enough to remove dissolved inorganic salts. Typical operating pressures range from 80 to 150 psi.

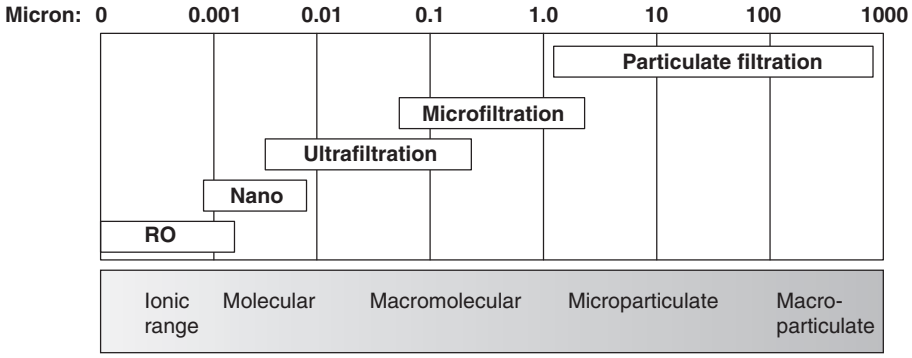

FIGURE 191.2 Range of particle sizes associated with membranes.

TABLE 191.3
Comparison of Approximate Removal Percentages of Ultrafiltration, Nanofiltration and Reverse Osmosis Membrane Processes

Component	Ultrafiltration	Nanofiltration	Reverse Osmosis
Alkalinity	None	50 to 70%	95 to 98%
TDS	None	50 to 70%	95 to 98%
Particulates	nearly 100%	nearly 100%	nearly 100%
Organic matter	some >2000 MW	most >200 MW	most >100 MW
THM precursors	30 to 60%	90+%	90+%
Sodium	None	35 to 75%	90 to 99%
Chloride	None	35 to 60%	90 to 99%
Hardness	None	50 to 95+%	90 to 99%
Sulfate	None	70 to 95+%	90 to 99%
Nitrate	None	20 to 35%	90 to 95%
Protozoa	near 100%	near 100%	near 100%
Bacteria	near 100%	near 100%	near 100%
Viruses	near 100%	near 100%	near 100%
Operating pressure	80 to 150 psi	100 to 200 psi	200 to 450 psi

Actual performance is system-specific.

3. Nanofiltration

For removal at the level of dissolved inorganic salts, nanofiltration and reverse osmosis are the only two feasible options. Both are very similar technologies, so similar, in fact, that nanofiltration used to sometimes be referred to as "reduced pressure reverse osmosis." Two major differences are that the percent rejection of nanofiltration membranes (30 to 70%, in general) is much lower than that of reverse osmosis membranes, and the operating pressures for nanofiltration systems, which typically range from 100 to 200 psi, are generally lower than for reverse osmosis systems. Nanofiltration is an excellent technology where inorganics (salts) removal needs are less important (approx. 50% removal) than removing organics and microorganisms. There is less concentration of salts into the concentrated waste-water effluent which, in some cases, can be critical (e.g. for regulatory compliance). As there are so many similarities between nanofiltration and reverse osmosis, the discussion below in relation to mechanisms of how reverse osmosis works and membrane fouling is also applicable to nanofiltration systems.

4. Reverse Osmosis

Reverse osmosis, or in some countries termed inverse osmosis, can afford removal of from 95 to greater than 99% of many dissolved salts, resulting in a treated water exiting the system with a total dissolved solids concentration often below 10 mg/L. Significantly, it reduces inorganics not reduced by coagulation, such as sodium, chloride, sulfate and nitrate. It reduces large organic molecules and microorganisms (bacteria, mold, viruses and water-borne parasites) at efficiency of greater than 99%. Typical operating pressures range from 200 to 450 psi. The major disadvantage of reverse osmosis is the volume of concentrated waste-water that is produced (typically 20–25%). This can be costly on both ends i.e. where cost of source water is high and where sewer surcharges are high for concentrate disposal. Membrane materials of construction include cellulose acetate, polyamide and thin film composite, the latter having become predominant in the food industry in recent years. A comparison of the attributes of each type of membrane is provided in Table 191.4.

The mechanism of operation of reverse osmosis systems can become complicated, but the principle is fairly straightforward. In normal osmosis, water flows from a less concentrated salt solution through a semi-permeable membrane into a more concentrated salt solution. By applying pressure in excess of the osmotic pressure, this process is reversed, and water will flow through the membrane, leaving most of the salts, organics and microbial life to remain in the high salts solution (or concentrate). The purified water (or permeate) then goes on to be used for production. Several mathematic models exist which describe the movement of water and its components across the reverse osmosis membrane, but the key point is to design the system in such a way so as to maximize the water flux (flow through the membrane per unit of surface area in a given time). Water flux will naturally decrease as the membrane ages, but the key to any pre-treatment operations is to minimize membrane fouling, thereby minimizing the flux reduction and maximizing the useful life of the membrane. The pre-treatment processes will normally include the in-line dosing of acid, antiscalant, or both. These steps help prevent a loss of membrane

TABLE 191.4
Comparison of Cellulose Acetate, Polyamide and Thin Film Composite Membranes

Parameter	Cellulose Acetate	Polyamide	Thin Film Composite
Operating pH range	4–8	1–11	1–12
Langelier index, preferred	Slight negative	Slight negative	Slight negative
Chlorine tolerance, free, mg/l	0.2–1.0	0.0	0.0, or slightly higher
Bacterial resistance	Very low	Very high	Very high
Required silt density index, %	< 5	< 5	< 5
Overall rejection, %	90–99	95–99+	95–99+
Turbidity, NTU	< 1	< 1	< 1
Temperature (operating), °C	4–30	4–30	4–30
Life expectancy, years	3	5	5
Membrane cost	Medium	High	High

performance due to metal oxide fouling, scaling or related processes which might occlude the membrane pores.

"Membrane Fouling" is generally defined as any process that results in a decline of permeate flux. Some processes are chemically or hydrodynamically reversible, others are not. Any fouling processes must be avoided to protect the reverse osmosis membrane. This damage to the membrane can proceed via several mechanisms, but is most often related to membrane degradation [bacterial, hydrolytic (pH), or oxidative (disinfectants)] or membrane blockage [suspended solids, silicates, metal oxides/hydroxides or scaling]. Proper pre-treatment design, which will vary depending on system specifics, can avoid any of the fouling mechanisms described above.

5. Electrodialysis

Electrodialysis is not a true filtration or osmotic process. It makes use of different types of membranes than those used for reverse osmosis and nanofiltration. Electricity is used to divert cations and anions through a semi-permeable membrane to the waste stream. Electrodialysis systems are designed such that treated water total dissolved solids, alkalinity and ion concentrations are reduced by greater than 80%. Similar to reverse osmosis and nanofiltration, electrodialysis removes inorganic ions not removed by coagulation technology. Organics and organisms are not effectively removed by electrodialysis.

C. Ion Exchange

Ion exchange has long been used in the food industry for treating water. Its early use was not usually for treating water that was in direct contact with food products, but instead for treating water that was used in plant utilities (boilers, heat exchangers, etc.) in order to minimize scaling which would impact their operational efficiency. However, the development of many new ion exchange resin technologies has led to its widespread use in processing water for many food applications.

As its name implies, ion-exchange uses natural or synthetic resin material to exchange less desirable ions with more desirable ions of like charge. The reactions are reversible, which means that the resin can be regenerated to be used repeatedly for many years. Many naturally occurring materials have been found to exhibit ion-exchange properties to some degree. Soil, for example, can be an effective ion-exchange material. Although many natural resin materials are still used today, many synthetic resin materials are also available. Ion-exchange resins for most food plant water treatment operations may be divided into two major categories, namely cation resins, which remove positively charged ions (cations) like calcium, magnesium and sodium; and anion resins, which remove negatively charged ions (anions) like nitrate, sulfate and chloride. Each of these categories can then be further subdivided into "weak" or "strong" depending on their affinity of the chemical functional group attached to the resin material for cations or anions. Therefore, there are four major classifications of resins:

1. Strong acid cation (SAC) exchange
2. Weak acid cation (WAC) exchange
3. Strong base anion (SBA) exchange
4. Weak base anion (WBA) exchange

The resin manufacturers prepare the resin in a particular form, depending on its intended use. For example, cation resins can be purchased in either the hydrogen form (H^+) or the sodium form (Na^+). Anion resins can be purchased in either the hydroxyl form (OH^-) or the chloride form (Cl^-). The ions that are attached to the resin (in this example, either the hydrogen, sodium, hydroxyl or chloride) are attached in a very weak fashion. Because of this, other ions in the water, with a stronger attraction to the resin, will compete with the ions that were originally attached, and displace them. In this way, the ions originally on the resin are exchanged for the ions in the water. Hence, the ions on the resin to begin with are the ions that will end up in the treated water.

Ion exchange systems are often referred to as co-current and counter-current. These terms refer to the direction of flow during normal operation and regeneration. Where water flows downwards during normal operation, it is a counter-current system if regeneration is carried out with an upward flow of regenerant solution. Conversely, if regeneration involved downward flow the system would be co-current. The significance of this is that regeneration will be most effective in those parts of the resin bed which are treated with the freshest regenerant solution. The bottom of the resin bed for a co-current system would be the area least effectively regenerated, so there will tend to be some leakage of ions from this area of the bed during normal operations. In practice, counter-current regeneration is preferable for demineralization applications, but there is generally little difference for other types of ion exchange applications (13).

Applications of ion exchange include: 1) demineralization (near complete or partial removal of total dissolved solids to required level); 2) zeolite softening of water (the removal of calcium and magnesium to an acceptable level); 3) dealkalization (reduction of alkalinity); and, 4) specialty applications such as removal of nitrate, arsenic, iron silica or other targeted impurities.

1. Near-Complete and Partial Demineralization

It is possible to use combinations of resins to remove almost all of the inorganic components in a water supply resulting in a TDS of less than 1 mg/l. This is often referred to as either complete demineralization or near-complete demineralization. In some cases too much of the inorganic component is removed, in which case a flow bypass may be operated whereby the resins are by-passed with partially treated water, and then both streams are combined later in the water treatment chain (partial demineralization). Demineralization includes reduction of sodium levels to meet any necessary labeling requirements for specific products (such as "sodium free" or "very low sodium"). In a demineralization process, a strong acid cation (SAC) resin in the hydrogen removes cations, and a strong base anion (SBA) resin in the hydroxide form removes anions. Separate columns are normally installed for each type of resin (i.e. "two bed" systems). However, there are many commercially available "mixed-bed" deionization systems, so called because the two resin types are intimately mixed together in one column. Regeneration requires the use of an acid for the SAC resin, usually sulfuric or hydrochloric acid, and caustic (sodium hydroxide) for the SBA resin. Regeneration is initiated after a preset number of gallons have been de-ionized, or when a signal from the conductivity (or resistivity) monitor indicates regeneration is required. The effluent from these regenerations usually requires neutralization prior to discharge from the plant.

2. Zeolite Softening

Zeolite softening is the simplest and most common form of ion exchange used in the food industry. It is now mostly used for the treatment of water for auxiliary plant uses (boiler, heat exchangers, etc.) to prevent mineral scale buildup. Softening is also sometimes required so as to not hinder the effectiveness of food preservatives, to prevent precipitation in sensitive beverages (for example, oxalic acid containing teas which are prone to calcium oxalate precipitation) or as a pre-treatment to unit operations such as reverse osmosis (to inhibit membrane fouling).

This process typically uses zeolite SAC resins to remove the calcium and magnesium hardness ions, replacing them with sodium ions. Resins are regenerated with brine (sodium chloride) prior to reaching their capacity limits. Typically, the regeneration mode is initiated after a pre-determined volume of water has passed through the resins. Keep in mind that zeolite softeners increase the sodium concentration in treated water by 46 mg/l for every 100 mg/l of $CaCO_3$ removed. Therefore, if used for food applications then compliance to all sodium related product requirements and regulations must be ensured (e.g. labeling requirements, product standards, local regulations, etc.).

3. Dealkalization

Dealkalization involves the use of a WAC exchange resin in the hydrogen ion (H^+) form. This resin will exchange the hydrogen ion for weakly bonded cations in the water. The predominant cations removed are those that comprise hardness (primarily calcium and magnesium). In addition, some sodium may be removed in the process, but only after the hardness is removed. As the hardness is removed, and exchanged for hydrogen ions, these hydrogen ions combine with the naturally occurring bicarbonate alkalinity in the water to form carbonic acid (H_2CO_3). This newly formed carbonic acid quickly dissociates into water and carbon dioxide, and the carbon dioxide is usually removed with a downstream degasifier. By forming the carbonic acid and removing the carbon dioxide, the alkalinity of the water is reduced proportionally. Hence, dealkalization using weak acid cation exchange resin removes both hardness and alkalinity in one treatment unit. Typically, regeneration takes place after a pre-determined volume of water has passed through the resins. If sulfuric acid regenerant is used, the concentration is normally kept below 0.5–0.7% to prevent calcium sulfate precipitation in the resin.

4. Specialty Applications

Many specialty ion exchange applications are being offered by suppliers, including the removal of nitrate, arsenic, iron, silica, or other targeted impurities. The

difference between many of these specialty applications and those outlined above is that it is likely that only a small percentage of the total ions present will be ions that are targeted for removal. The challenge, therefore, is to develop resins that will preferentially remove some ions as opposed to others. In weak solutions, the main factor is valency, with ions of higher valence being preferred. However, the size of the ion is especially noteworthy as ion exchange is not simply a surface phenomenon with up to 99% of the ion exchange reactions occur inside the resin bead (14). Thus, it is possible to optimize the resin for the removal of specific ions.

The ionic composition of the water being treated is critical as there will be competition between it and other ions in water. For example, in the case of many traditional strong base anion exchange resins, the order of selectivity is sulfate, nitrate, chloride and bicarbonate – sulfate will be exchanged first, and bicarbonate will be exchanged last. If the sulfate content in the water being treated is low, the next anion of preference is nitrate, so nitrate will be effectively removed. If sulfate levels are high, then the SBA's capacity for nitrate will be low, and other options should be explored (for example, a more nitrate-selective ion exchange resin).

IV. PRE- AND POST-TREATMENT TECHNOLOGIES

Many unit operations are intended not as primary treatment but rather to augment the treatment to result in a robust, complete treatment chain designed to deliver a high quality treated water that is required for food and beverage plant applications. A wide variety of pre- and post-treatment unit operations may be grouped into this category, including those depicted in Figure 191.3. This chapter will not address all of the possible pre-and post-treatment unit operations, but will address some of the more common ones that are used in the food industry. The choice of proper pre- and post-treatment operations is a key considerations when selecting and designing a food plant water treatment system.

The primary goal of pre-treatment processes is to protect the integrity of primary treatment operations, such as reverse osmosis membranes or ion exchange resins, which often represent a substantial portion of the capital cost. The membranes and resins are susceptible to a variety of processes and impurities which may foul or degrade them, thereby rendering them inefficient, ineffective, or, in the worst case, totally destroyed. Post-treatments include additional steps of disinfection, organics removal and polishing which are needed to provide a consistently high quality treated water. The unit operations discussed herein are granular activated carbon filtration, chlorination, ozonation, ultraviolet irradiation, media filtration and particulate filtration. They may be used for both pre- and post-treatment applications.

A. Granular Activated Carbon Filtration

Granular activated carbon (GAC) filtration is a common unit operation in food plant water treatment processes.

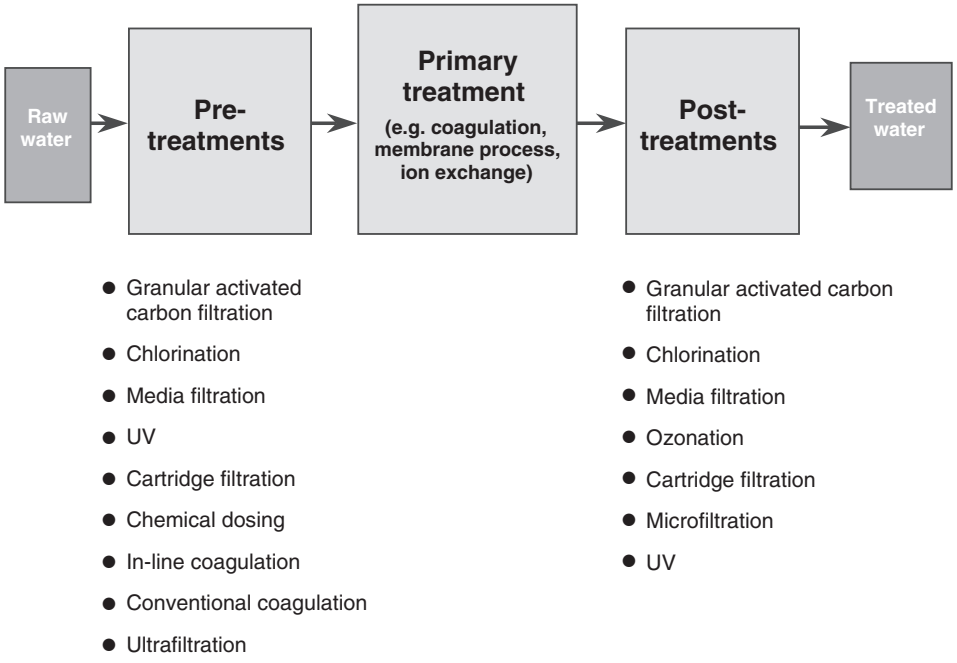

FIGURE 191.3 Pre- and post-treatment unit operations. (*Source*: Developed by the author.)

The primary water application of activated carbon has been to effect the removal of the chlorine species used to disinfect the treated water. The other major application of organic impurity removal, which is relatively new to the food industry, is the provision of broad protection against a wide range of possible contaminants through the removal of pesticides and other trace organic chemicals (for example, see Table 191.2), taste and odor compounds, algal toxins and natural organic matter. In fact, granular activated carbon is recognized as the "best available technology" (B.A.T.) by many regulatory agencies, including the United States Environmental Protection Agency, for removing a variety of natural and synthetic organic contaminants.

A critical distinction must be drawn between the catalytic mechanisms carbon employs to dechlorinate and its adsorptive mechanisms of organic contaminant removal. The catalytic mechanism refers to the formation of a surface oxide on the activated carbon medium as a result of the reaction of the carbon with hypochlorous acid, according to the following reaction:

$$HOCl + C^* \rightarrow HCl + C^*O$$

Hypochlorous acid + carbon → hydrochloric acid + carbon surface oxide

The catalytic reaction is not reversible, and, in fact, carbon bulk is destroyed in the process.

Adsorption refers to the adhesion, bonding and other chemical attractive forces that retain impurities on the surface of the carbon and within its pores. Unlike the catalytic mechanisms, adsorption is usually a reversible process, to varying degrees.

Carbon may be obtained from a variety of different starting materials, including coal, lignite, peat, coconut shells and wood. The carbon is activated either thermally (steam) or chemically. Steam activation, the more common, involves two steps: 1) carbonization, and 2) activation. Carbonization involves the conversion of the raw material into a disordered carbon structure with a very low volatile content. Carbonization is done at elevated temperatures in an oxygen-lean environment which keeps it from burning. In activation, some carbon atoms are vaporized, leaving behind the highly porous structure. Steam activation is carried out in temperatures of approximately 1,800°F (982°C). At these conditions, carbon reacts with steam to form carbon monoxide and hydrogen, which exit as gases. The result: a highly porous carbon material. Chemical activation is used to produce very high pore volume in wood-based carbons, particularly in the medium-size pore range. The most common process consists of mixing wood dust or some other cellulose-based material with a strong dehydrating agent and then heating to a designated temperature. The activating agent not only extracts moisture but also helps prevent collapse of the pore structure during activation (15).

Activated carbon is generally available in the powdered or granular form, but granular activated carbon (GAC) is used for the vast majority of water treatment applications in the food industry. In addition to the pesticide and volatile organic impurities mentioned above, and the removal of chlorine and chloramine, GAC also affords treated water protection against adversely sensory-active compounds, like the microbial metabolites geosmin and 2-methyl isoborneol. These compounds may be odor active in nanogram per liter concentrations and represent a substantial proportion of off-odor complaints to municipal water treatment works (16).

The activated carbon unit operation must be diligently maintained and sanitized as part of normal food plant operations. Many microbial complaints and sensory excursions in the food industry have been linked, at least in part, to inadequate carbon bed management practices. One of the reasons for this required diligence is that the core of the GAC bed has the potential to provide optimal conditions for the growth of troublesome microorganisms—specifically, the chlorine is absent, the environment can vary in its level of air or dissolved oxygen, and, in most cases, the organic microbial nutrients abound (since GAC is so proficient at removing organic compounds, including natural organic matter, from water supplies). These conditions combine to make carbon an excellent medium for the support of microbial growth. Once established, the extremely large surface area within the carbon pores can make control of an unwanted microbial population a daunting task. Routine and diligent backwashing and sanitization of the carbon bed should be viewed as an absolute requirement for any food plant water treatment system. Hot water, steam, or a combination are generally employed to sanitize the carbon filters, provided their material of construction can withstand the temperature needed. When performed regularly, this helps prevent a biofilm from becoming firmly established in the bed and avoids problems often associated with poor carbon maintenance, including high bacteria counts, off-odor production within the bed, poor dechlorination or chlorine breakthrough and loss of adsorptive capacity.

B. Chlorination

The commercially available forms of chlorine for the food industry are chlorine gas, solid calcium hypochlorite pellets and sodium hypochlorite solutions. The traditional and most common form that is used for disinfection of treated water by the food industry is the last, sodium hypochlorite solutions, although the others are also employed at some locations. Chlorine gas is usually reserved for large-volume food plants, and considerable drawbacks to its use are the strict transport, handling,

storage, metering, permitting, and use requirements being enforced by many regulatory agencies. Calcium hypochlorite is utilized, but in many international markets it is more costly than sodium hypochlorite. Irrespective of which form is chosen, once in aqueous solution, the chlorine chemistry becomes essentially the same.

The chlorine species, when dissolved in water, will eventually dissociate into primarily two active forms: 1) hypochlorous acid (HOCl); and, 2) the hypochlorite anion (OCl^-). The ratio of these two chlorine species varies as a function of pH, with hypochlorous acid predominating at acidic pH, and the hypochlorite anion predominating at alkaline pH. One critical concept to link with these chlorine equilibria is that hypochlorous acid (predominant at lower pH) has been described as 80 to 100 times more potent a germicide than the hypochlorite anion (predominant at higher pH). As a result of this, the World Health Organization suggests a pH of less than 8.0 to help assure effective disinfection of water with chlorine (9,10). In conventional coagulation water treatment systems, where the operating pH in the reaction tank is often above 10.0, the chlorine equilibrium favors the existence of hypochlorite anion, which is why, in addition to allowing adequate floc settling time, a minimum two hours of retention must be designed in these systems.

In summary: 1) chlorine is an effective disinfectant against bacteria and viruses, although it is less effective against protozoan organisms like *Giardia* and *Cryptosporidium*; 2) the effectiveness of chlorine varies markedly with pH, owing to the distribution between the more effective hypochlorous acid, and the less effective hypochlorite anion; and, 3) the preferred operating range for chlorine disinfection is roughly pH 6.0 to 7.5; below this, corrosion may occur, above this, its effectiveness declines. Although the actual disinfection criteria for individual applications must be decided within each plant or corporation, a long-standing industry practice for water disinfection using chlorine in conventional treatment systems is to maintain a free chlorine residual of 6 to 8 mg/L over the course of a two-hour contact time. For other treatments, where the pH is lower, the free chlorine residual concentration and/or contact time is often decreased.

C. Ozonation

Ozone (O_3) is an unstable, colorless gas that is an allotrope of oxygen (O_2). It has a distinctive pungent odor, from which its name is derived (from Greek *ozein*, "to smell"). Ozone has been used for municipal scale treatment of drinking water since 1906 (Nice, France) (1). It is formed naturally in air by the ionizing effects of environmental lightning, and in the earth's stratosphere by ultraviolet irradiation. It is also formed during combustion in automobile engines, thereby contributing to the troublesome phenomenon of "photochemical smog." Ozone safeguards us from the damaging effects of the sun by inhibiting the penetration of much of the sun's UV waves, preventing them from reaching the earth's surface. The major use of ozone in the food industry currently is the treatment of bottled water. Its use in the treatment of water for wider food industry is still uncommon.

TABLE 191.5
Relative Effectiveness of a Variety of Disinfectants against *Cryptosporidium*

Disinfectant	Effectiveness	Estimated CT-99
Free Chlorine	Poor	7200 mg-min/L
Chloramine	Poor	7200 mg-min/L
Mixed Oxidants	Fair	1000 mg-min/L
Ozone	Good	5–15 mg-min/L
Chlorine Dioxide	Good	80 mg-min/L
UV Irradiation	Excellent	2–5 mJ/cm^2

Note: CT-99 is the Concentration × Contact time required for 99% *Cryptosporidium* Inactivation.

Source: Aquionics UV Systems, Inc. (2001).

Most ozone for commercial applications is produced on-site via the Corona Silent Arc Discharge process (17). With the Corona Discharge, a gas feed of dry oxygen or dry air passes through an electrode pair (high and low voltage) where free electrons are of sufficient energy to split the diatomic (i.e. two atoms) oxygen molecules apart. The "single" atomic oxygen species then recombine with other diatomic oxygen to form a molecule with three atoms of oxygen, ozone (O_3). The net result is that three oxygen (O_2) molecules become two ozone molecules (O_3).

In ozone generation by Corona discharge, it is essential that the feed air or oxygen be dry. Moist air fed into ozone generators may result in formation of nitric acid inside the generator (through the reaction of nitrous oxides with water). In addition to reduced ozone output, nitric acid can corrode ozone generator internals and cause generator failure. Feed gas must also be free of particulates, coalescible oil (hydrocarbon) mists and gas impurities (methane, ammonia, etc.) all of which reduce ozone yield. When compressed purified oxygen gas is used as the feed, in place of treated air, roughly twice the amount of ozone is produced for the same energy input. For most bottled water applications (where ozone is frequently used), even despite the increased output, the cost of the compressed oxygen usually makes its use uneconomical. There are many designs of ozone generators, including tubular, plate, water-cooled, refrigerated and air-cooled.

As with any chemical disinfectant, when ozone is used for disinfecting water supplies, the ozone demand must first be met, and then a residual ozone concentration established, and maintained for the desired contact time. An industry practice, which dates back to data nearly four decades old, is to utilize an ozone CT value of 1.6 mg-min/L (CT refers

to the ozone concentration multiplied by its contact time). This is generally done by maintaining a residual of 0.4 mg/L ozone for 4 minutes. A CT of 1.6 mg-min/L is adequate to provide at least a two-log reduction in bacteria, virus, and *Giardia lamblia* populations. However, as with chlorine, *Cryptosporidium parvum* remains resilient to inactivation, so higher CT values will be necessary to address this organism (18).

Operationally, the three major drawbacks to the more widespread application of ozone to the food industry include the fact that: 1) it must be generated and used immediately on-site and cannot be stored; 2) due to its short half-life, it does not provide adequate residual disinfectant activity; and 3) there is a high potential to form bromate, a strictly regulated disinfection by-product of ozonation, which can result if bromide is present in the water. As with other disinfectants, the dose and half-life of ozone will vary as a function of pH, temperature, organic matter and other variables, but somewhat unique to ozone is its behavior at varying levels of total dissolved solids (TDS). The lower the level of total dissolved solids, the longer the ozone residual will last (19). Finally, ozone is a very powerful chemical oxidant and can be extremely aggressive toward equipment, both in air and in aqueous phase. Care must be taken to ensure that all materials used are suitable for ozone contact and that all employee safety precautions are observed.

D. Ultraviolet Irradiation

UV radiation energy waves are 100 to 400 nm long, lying between X-ray and visible light spectrums in the electromagnetic spectrum. The division of UV radiation may be classified as Vacuum UV (100–200 nm), UV-C (200–280 nm), UV-B (280–315 nm) and UV-A (315–400 nm). In terms of germicidal effects, the optimum UV range is between 245 and 285 nm. UV disinfection typically utilizes a mercury source, although Xenon sources are also commercially available. UV systems for food plant applications are usually in the form of either: 1) low-pressure lamps that emit maximum energy output at a wavelength of 253.7 nm; 2) medium-pressure lamps that emit energy at wavelengths from 180 to 1370 nm; or, 3) lamps that emit at other wavelengths in a high intensity "pulsed" manner. Pulsed UV is a relatively new technology to the food industry and is not widely employed at present. While both low and medium pressure designs have their own advantages and disadvantages, they have both proven to be adequate for water disinfection applications.

The degree to which the destruction or inactivation of microorganisms occurs by UV radiation is directly related to the UV dose. The UV dosage, D, is calculated as the arithmetic product of intensity, I, in milli- or micro-watt seconds per square centimeter, and time, t, in seconds. Internationally, the dose is often expressed in millijoules per square centimeter, which is exactly equivalent to milliwatt-seconds per square centimeter (1 mJ/cm^2 = 1 mW-s/cm^2 = 1000 microW-s/cm^2). Research indicates that when microorganisms are exposed to UV radiation, a constant fraction of the living population is inactivated during each progressive increment in time. This dose-response relationship for germicidal effect indicates that high intensity UV energy over a short period of time would provide the same kill as a lower intensity UV energy at a proportionally longer period of time. The UV dose required for effective inactivation is determined by site-specific data relating to the water quality and log removal required (20).

The mechanism of inactivation of microorganisms by UV is complicated, but has been reported many times in the literature. Fundamentally, the organism's genetic material (for example, bacterial deoxyribonucleic acid, or DNA) absorbs the UV radiation, which results in a chemical disruption of the DNA's chemical bases. Though many various photoproducts form as a result of this, the major rearrangement is the dimerization of the thymine base. This change renders the organism unable to replicate their DNA, and, therefore, cannot reproduce. As you might expect, ultraviolet disinfection does not provide any residual disinfectant activity.

Just as with ozone and chlorine, ultraviolet energy also has an accepted industrial "rule of thumb" which has been established for decades. A typical UV system used for the disinfection of food plant water treatment is sized to deliver a dose of at least 30 mJ/cm^2 at the end of its service life (typically 8,000 hours). To achieve this, since UV intensity naturally decreases over time as the lamp ages, the initial dose design is usually on the order of 60 mJ/cm^2. This design has traditionally been credited with providing at least a three-log (99.9%) inactivation of bacteria, yeast, and virus populations. Data published in late 1999 (21) and confirmed since then in several industry journals, suggest that the same 30 mJ/cm^2 dose also provides at least a three-log inactivation of *Cryptosporidium parvum*, a protozoan organism highly resistant to disinfection by chlorine and, to a lesser extent, ozone. This is promising news for the water treatment and food industries, since it confirms the effectiveness of UV as part of a multiple barrier water treatment process to help ensure the microbial safety of our treated water.

E. Media Filtration

The passage of water through any of a variety of coarse filtration materials can be referred to as media filtration. Applications of media filtration for the food industry includes the removal of particulates (for example from source water or the overflow of conventional coagulation reaction tanks), prevention of occlusion of carbon pores, avoiding the fouling of ion-exchange resins and providing

the required contact time for chlorine and coagulant (for in-line coagulation systems). Traditionally, the most common medium for food plant water treatment was simple filtering sand, supported by a bed of gravel. The major intent of these sand filters is to provide a coarse straining of the water stream. Sand filters may be located at different points in the treatment chain, but for conventional lime treatment systems, the industry practice is to locate the sand filter downstream of the reaction tank. Logically, this was done to capture any loose floc carryover, precipitated calcium carbonate, or other particulates that might not have settled adequately in the reaction tank. In some applications, like in-line coagulation, the sand filter which is used serves not only to filter the floc which is intentionally formed in-line, but to provide part of the contact time of the water with the chlorine disinfectant.

In addition to sand, garnet, anthracite and diatomaceous earth are common media used as part of a dual or mixed media filter bed. Other media are commercially available to suit a variety of applications. For example, some reverse osmosis and nanofiltration membrane systems might incorporate "greensand" as one of the pre-treatment operations. Greensand is a naturally occurring mineral that consists largely of dark greenish grains of glauconite, possesses ion-exchange properties (22) and is used for the removal of soluble iron and manganese from water streams to prevent fouling of downstream membrane systems.

Media filtration, like granular activated carbon filtration and virtually all water treatment processes, requires diligent maintenance in order to help assure its on-going performance. Since media filters remove particulate matter from the water, these impurities must then somehow be removed from the filter itself. This is accomplished by frequent backwashing of the filter medium, often with treated water, to suspend and expand the filter bed into the freeboard of the filter vessel, thereby allowing collected impurities to be washed to the drain. Some media filters, more commonly in municipal applications, augment the water backwash by the injection of air. This air scouring also helps suspend the bed and conserves the overall volume of water necessary for the backwash cycle. The frequency and conditions of backwash depend on the quality of water/ amount of debris going into the filter, the type of filter media, the vessel design, supplier recommendations and corporate policies. The range of operating conditions usually include a frequency of anywhere from daily to monthly, and a backwash rate of from two to five times the normal flow. Intimately linked with the maintenance described above is the routine sanitation of the media filters. Several methods may be used, including heat and chemical sanitizers, but this critical operation must not be overlooked. It is possible for bacterial populations to become established in media filter beds and for biofilms to form, which may be extremely resistant to remove.

F. Cartridge Filtration

Cartridge filters were once considered only as a point-of-use water treatment method for removing larger particulate matter. However, breakthroughs in filter design, such as the controlled use of blown microfiber filters (as opposed to wrapped fabric or yarn-wound filters), have tremendously broadened cartridge filter utilization (5). Cartridge filters are usually disposable, cost-effective, have a high flow capability and are commercially available in the particle removing range of 100 to 0.1 microns. Particulates, and other matter that are removed from the water, are held within the media matrix and are not generally subject to release, even where system fluctuations occur. There are two broad categories of cartridge filters, namely "depth" and "pleated."

Depth style cartridge filters have become a standard tool of the food industry to remove particulate matter and reduce turbidity to low levels. In a depth style cartridge filter, water flows through the thick walls of the filter where the particles are trapped throughout the complex openings in the filter media. The filters are often constructed of blown microfibres of polymers, such as polypropylene, or from cotton, cellulose or synthetic yarns. Filter media is usually provided with continuously graded fiber density. This yields progressively finer particulate retention through the depth of the media. Generally, they are not an absolute method of filtration since a small amount of particles within the micron range may pass into the filtrate. Depth style filters are used as both pre-treatment and post-treatment unit operations. Their main pre-treatment function in food industry water treatment applications (typically sized at 5 micron nominal rating) is to condition water prior to reverse osmosis membranes or ion exchange resins to prevent particulate fouling. They are also widely used as a pre-treatment to ultraviolet irradiation systems to ensure minimal turbidity is present which diffract incident ultraviolet light thereby reducing the dose and resulting disinfection performance. The main post-treatment application (typically sized at a 5 or 10 micron nominal rating) is to "polish" treated water. For example, they remove small floc particles, oxidized iron, granular activated carbon "fines," or precipitated calcium carbonate that might have carried over from the primary treatment process.

Absolute rated pleated cartridge filters can perform in the microfiltration range (see previous discussion on membrane processes) providing protection against bacteria and many water parasites. They use flat sheet media, either membranes or non-woven fabric materials. They typically act as surface filters with the media being pleated to increase the usable surface area. Pleated cartridge filters are not usually cost effective for particulate filtration applications as particles greater than 1 micron quickly plug them. However, they serve well for water that has already passed through depth cartridge filters, or other treatment steps, in applications such as sub-micron

particulate, bacteria and protozoan removal filtration. The National Sanitation Foundation (NSF International) has published a standard for cartridge filters, Standard 53, which assures removal of a large percentage of protozoan oocysts ("cyst reduction filters").

V. DISTRIBUTION

A variety of factors can affect water quality in municipal and plant distribution systems. This includes the quality of water entering the distribution system, contaminants formed or added by the system, cross connections, maintenance, construction and restoration. There are many ways in which municipal water quality deteriorates on the way from the municipal water works to the food plant or domestic consumer (23). A discussion on this topic is beyond the scope of this chapter. However, keep in mind that even the simple act of a municipality flushing out distribution lines, which can occur on a periodic basis, can stir up loose particles of metals, debris and/or organic material leading to short periods of highly undesirable water quality entering the food plant water supply. At the food plant, close monitoring of incoming municipal source water quality helps identify many of these issues (24). In addition, having the necessary in-plant treatment that can address upsets in municipal water quality is paramount.

The water distribution system within the food plant can also lead to a deterioration in water quality. Monitoring the microbial quality of water throughout a food plant water distribution system can indicate a variety of conditions that need correction. For example, water entering the system may have poor microbial quality resulting in inferior water quality in the plant system (this underscores to need for adequate monitoring of the incoming water supply), the filtration process may not be functioning correctly (filtration performance can be usefully monitored using turbidity, differential pressure and microbial monitoring measurements), there may be microbial biofilms in the distribution system (especially where dead-legs, unprotected storage and/ or rough internal surfaces are present), microbial contamination of one or more of the water treatment unit operations (highlighting the need for diligent maintenance and sanitation practices for water treatment system unit operations, especially granular activated carbon filters), the disinfection step(s) in the process might not be adequately functioning or is under-designed (insufficient concentrations and/or contact times of chemical disinfectants, improper UV operation, etc.), or there is a cross-connection within the plant distribution system (operator error, poor system design and malfunctioning valves may be possible causes). Closely monitoring the plant distribution system for microbial indicator organisms and identifying and monitoring potential corrosion products helps a plant to recognize emerging problems.

A prevalent problem at food industry plants is where inferior or unsuitable materials of construction are used, either in food plant or in the municipal water distribution systems that are largely outside of plant control, resulting in extensive corrosion and/or leaching of metals from internal into the plant water. It is important for food plants to use materials that have smooth surfaces and high resistance to oxidation and corrosion and to have adequate treatment processes to effectively deal with potential issues from the municipal distribution system. 316 stainless steel is recommended by many suppliers and food industry corporations for plant treated water distribution applications (22). If adequate materials are not used, corrosion of internal surfaces of the distribution system can introduce contaminants to the water, reduce flow capacity and provide environments for biofilm growth. For example, iron pipe corrosion has led to complaints of red water, caused fouling of membranes and ion exchange resin, caused taste complaints in water and food products, and the increasingly rough surfaces provide harborage sites for microorganisms. Corrosion from brass pipes, valves and fittings can result in leaching of lead, copper and zinc. Where galvanized iron pipes and plumbing might be used, leaching of iron, zinc and cadmium can often be problematic. Corrosion can result from a variety of causes. The water supply may be aggressive to pipes and plumbing because of its particular chemical makeup. In particular, water with very low pH and TDS (such as RO permeate or ion exchange effluent) and/or high levels of chlorine, ozone, chloride, sulfate, carbon dioxide, or other constituents, can result in increased corrosion. Though corrosion is generally difficult to predict and quantify, its results are easily observed through regular inspections of equipment as part of the plant preventative maintenance schedule.

192 Water: Chemistry and Analysis

Manus Mitchell
Quality Technology, Pepsi Cola International

CONTENTS

I. INTRODUCTION

Pure water has virtually no color, taste or smell. On the face of it, what could be more boring? But the hidden qualities of this substance make it a most interesting subject. In fact, absolutely pure water is never found in nature. Instead, water is often described as the "universal solvent" largely because of the seemingly infinite number of substances that dissolves in it. Some of these substances are considered contaminants, others are considered therapeutic, and still others are considered essential for life. The chemistry and microbiology of key water quality parameters will be discussed, in broad terms, in this chapter including the general approach adopted for their analysis by the food industry. This work is not intended to provide detailed chemistry, microbiology and instruction for how to test each parameter as this would entail a large book unto itself.

II. SUSPENDED MATTER

Water contains complex and shifting combinations of suspended substances. They may be derived from mineral, geologic, biologic and organic materials and particle sizes can vary widely in size, as is outlined in Table 192.1 (1).

TABLE 192.1
General Classification of Suspended Particle Sizes

Description	Approximate Particle Size (micron)
Gravel	64,000 to 2,000
Sand	2,000 to 62
Silt	62 to 4
Clay	4 to 0.24

Source: Adapted from United States Geological Survey at http://ga.water.usgs.gov/edi/dictionary.html

The amount of particles being carried by a given body of water is highly dependent on the speed of water flow. Fast-flowing water is capable of picking up and suspending more material than calm water. As surface water supplies have higher flow rates (in particular, rivers often have flow rates as high as one meter per second or more), they are generally considered to be more prone to high levels of suspended matter. However, keep in mind that even with a groundwater that has a typical flow of one meter per day, suspended matter might be present. An example of this is a groundwater for which there has been improper selection of the well screen sizing (length, diameter and size of openings of the screen) (2). Total suspended solids (TSS) is a parameter that provides a gross measurement of the amount of particulate matter present in a water sample. To test for TSS, a well mixed sample is filtered through a weighed standard glass fiber filter and the residue retained on the filter is dried in an oven. The increased weight of the filter represents the TSS (3).

A. Turbidity

Turbidity is an expression of the amount of solid particles that are suspended in water that cause light rays shining through the water to be scattered and absorbed, rather than transmitted. Thus, turbidity makes the water cloudy or even opaque in extreme cases. According to the Standard Methods for the Examination of Water and Wastewater (4), turbidity in raw water "...is caused by suspended and colloidal matter such as clay, silt, finely divided organic and inorganic matter, and plankton and other microscopic organisms." Turbidity measurement can detect potential problems in a food plant treated water, including microbiologic contamination, floc carryover, filter channeling, carbon fines leakage and increase in iron/manganese levels. In general, any disinfection process will be more effective on waters of low turbidity than on waters of high turbidity. In the case of ultraviolet disinfection, the particles that cause turbidity in effect "shield" the microorganisms from the ultraviolet bombardment and cause the beam to scatter. For chemical disinfectants such as chlorine and ozone, the turbidity particles provide harborage sites for the microorganisms thereby decreasing the surface contact and germicidal effectiveness.

Water turbidity is typically measured utilizing the principle of nephelometry and is reported in nephelometric turbidity units, or NTU. This technique provides high accuracy, precision, and stability over a wide range of turbidity levels. It is based on the measurement of the amount of light scattered at a 90 degree angle to the incoming (or incident) light beam. This right angle-scattered light is then correlated to the actual level of turbidity in the sample (4). Many companies offer devices that can measure turbidity in-line in the plant water treatment process.

B. Colloids

Colloids are characterized as small particles, including silica, clays, algae, bacteria, viruses and natural organic matter, that do not settle in water. The majority of colloidal particles in water have a slight negative charge that are stabilized by a cloud of positive counter-ions. This means that they repel each other, preventing them from coalescing together to form larger settable particles. Although colloids are too small to see with the naked eye, they are increasingly important from an operational perspective for the food industry due to the sensitivity of reverse osmosis membranes, and related water treatment unit operations, to colloidal fouling. When water that has high levels of colloidal material is fed to a membrane treatment unit, particulate matter tends to collect on the membranes and in the inter-membrane passages, causing reduced performance.

The Silt Density Index test, or SDI, is a widely used test to measures the quantity of colloidal contamination in waters above 0.45 micron (5). It measures how fast a sample of water pumped at a pressure of 30 psi will plug a 0.45 micron filter disc. The time it takes to collect a fixed volume (usually 500 ml) of filtrate through a clean disc is compared with the time it takes to collect the same volume after 15 minutes of filtration through the same disc. Obviously, the dirtier the water, the longer it will take to collect the final volume. In general, the higher the SDI, the more frequently chemical or physical cleaning will be required to restore reverse osmosis membrane performance.

SDI is not the perfect indicator of membrane fouling potential. The zeta potential, a measure of the electrical charge on the particles, and hence their fouling potential, will be altered by pH, ionic strength of the water and by inhibiting agents added. As result of these variables, there are cases where high SDI waters do *not* foul membranes and cases where low SDI waters *do* cause fouling. Despite these limitations and exceptions, however, SDI measurements are an important tool for tracking the consistency of incoming water with respect to colloids, and for tracking the performance of membrane pre-treatment equipment.

III. DISSOLVED SOLIDS

Concentrations of dissolved solids in water vary considerably in different regions due to differences in the local geology and environment. The bulk of the dissolved residue is typically inorganic minerals. In addition, water typically contains small amounts of dissolved organic matter. An aggregate measurement of the dissolved solids in water is provided by total dissolved solids, or TDS, testing. This test does not measure a single, specific component, but provides instead a single measurement for a variety of components. TDS is useful to gauge the overall consistency of the mineral content in the water. For operations using reverse osmosis (or similar membrane processes), TDS measurement provides a critical indication of the overall rejection characteristics of the membrane. For food plants using ion-exchange, TDS is important to determine both overall effectiveness of the resin and adequate blend ratios if a flow by-pass is operated.

Most official methods for measuring TDS, as recognized by regulatory agencies and certified laboratories, involve a "gravimetric" approach. In these methods, a water sample is coarsely filtered to remove suspended solids, then evaporated to complete dryness in an oven and the remaining residue is accurately weighed (6). This residue is expressed as the mg/l of total dissolved solids in the original water sample. These methods, however, routinely require anywhere from two to four hours before a result can be obtained. An alternative "conductometric" procedure was developed primarily for its speed and simplicity as compared to the "official" methods (7). The method has gained wide acceptance as the standard in the food industry. It is based on the fact that most of the components of TDS, when present in a water sample, will conduct an electric current. Remember that pure water, with almost no TDS, is a very poor conductor of electricity. Conversely, salt water, with a high TDS content, conducts electricity very well. Correlations have been found between the measure of the conductivity of a solution, and the actual level of TDS determined by drying. It is best to develop a local factor through empirical testing specific to the local water supply at each plant location, and these factors typically range from 0.5 to 0.9. Many automatic TDS meters, however, come already calibrated with an internal factor. It is important to know what the factor is so that results among laboratories may be compared.

A. Derived from Minerals

Minerals account for the vast majority of dissolved solids in water. They may be categorized into cations and anions.

1. Common Cations

Common cations, or positively charged ions, in water include the ions of calcium, magnesium, sodium, iron and manganese.

Dissolved calcium and, to a lesser extent, magnesium cause hardness in water. Water hardness is discussed in more detail later in the chapter. Sodium, along with the associated anions, may be a major contributing factor where high levels of total dissolved solids are determined. It should be noted that some water softeners can add significantly to the sodium content of treated water. This is because softeners remove the cations that cause hardness, calcium and magnesium, by replacing them with sodium cations (which do not cause water hardness). Sodium usually only becomes a concern for the food industry with regard to label claims (for example, "very low sodium," "sodium free," etc.). However, concentrations of sodium in excess of 200 mg/l may give rise to unacceptable taste in water (8), and this can also impact the taste of any food product it is used to manufacture.

Iron and manganese concentrations can often reach several mg/l in water, high levels being more prevalent in groundwater than surface water supplies (8). Iron may also be present in drinking water as a result of the use of iron-containing coagulants or the corrosion of steel or cast iron pipes during water distribution. If adequate treatment is not in place, the presence of high levels of iron and/or manganese may be problematic for the food industry for many reasons. These include taste impacts in the water and products it is used to manufacture, water and product discoloration, potential catalytic activity with chemicals in food product matrices and undesirable deposits that create havoc with valves and piping in the plant water distribution systems. In addition, without adequate pre-treatment, iron and manganese can result in fouling of plant water treatment membranes and ion exchange resins. Certain bacteria can further complicate iron problems. Organisms such as *Crenothrix*, *Sphaerotilus* and *Gallionella* use iron as an energy source. These iron reducing bacteria eventually form a rusty gelatinous sludge that can plug a water pipe (9). Concentrations of iron below 0.1 mg/l and manganese below 0.05 mg/l are typically acceptable for food industry applications.

Concentrations of individual cations may be measured using sophisticated analytical instrumentation such as flame atomic absorption (AA) spectrometry and ion coupled plasma (ICP) emission spectrometry (10–13). With AA, a sample is aspirated through a flame and atomized. A source lamp composed of that element's characteristic absorption wavelength is used. The amount of energy absorbed at the characteristic wavelength is proportional to its concentration in the sample. ICP uses a flowing stream of argon gas that is ionized by an applied radio frequency field. A sample

aerosol is generated in the nebulizer and spray chamber which is carried into the plasma. This subjects the constituent atoms to temperatures of approximately 6000 to 8000°C which results in the atoms producing ionic emission spectra. The efficient ionic excitations of ICP, coupled with use of precise monochromators and polychromators, allow effective multi-element detections that can provide greater sample throughput.

Hardness (calcium and magnesium) can be measured using the traditional hardness test which involves a titration with a standard solution of ethylenediaminetetraacetic acid (usually abbreviated as EDTA) (14). Hardness may also be calculated directly from the concentration of calcium and magnesium ions which might be determined using AA or ICP instruments. The formula ($[Ca^{2+}]*2.50$) + ($[Mg^{2+}]*4.12$) is used, the result being expressed as the equivalent quantity of calcium carbonate (15). Convenient iron and manganese on-site test kits are widely used throughout the food industry. The iron test kits typically use the phenanthroline method (16), while the preferred field method for manganese detection is often the persulfate method as it controls interferences from limited chloride ion concentrations (17).

2. Common Anions

Common anions, or negatively charged ions, in water include the ions of chloride, sulfate, nitrate and bromide.

Chlorides are present in water from natural sources, but sewage and industrial effluents, urban run-off containing de-icing salt, and saline intrusion can lead to increased levels. Excessive chloride concentrations increase rates of corrosion leading to elevated concentrations of leached metals in the water (e.g. iron or lead). Chloride concentrations in excess of about 250 mg/l can give rise to detectable taste in water (8). Sulfate is widely distributed in nature. As with chloride, high sulfate can contribute to the corrosion of distribution systems. Taste thresholds for sulfate in water have been found to vary with the nature of the associated cation, ranging from 250 mg/l for sodium sulfate to 1000 mg/l for calcium sulfate (8). The nitrate concentration in water is normally low but can reach high levels as a result of run-off from erosion of natural deposits, agricultural fertilizer use, refuse dump run-off, or contamination with human or animal wastes (8,18,19). High nitrate levels (typically well above 50 mg/l, expressed as nitrate ion) are implicated with methaemoglobinaemia, more commonly referred to as "blue-baby syndrome". Nitrate is reduced to nitrite in the stomach of infants, and nitrite is able to oxidize hemoglobin to methaemoglobin, which is unable to transport oxygen around the body. This is thought to be partly due to the larger proportion of fetal hemoglobin present in infants which is more easily oxidized (20). Bromides have only recently become widely recognized as a potential raw water quality problem. When water containing bromide is ozonated, there is a risk of bromates forming for which the allowable concentrations are typically very low.

Chloride, sulfate, nitrate and bromide can be measured in water by ion chromatographic (21,22) and capillary ion electrophoresis (23) methods for concentrations above 0.1 mg/l. A commonly employed wet chemistry analytical technique for chloride in water is a titration with silver nitrate solution (24). It is not uncommon to determine sulfate in aqueous solutions by means of a gravimetric method in which sulfate is precipitated as barium sulfate by the addition of barium chloride (25). For nitrate determinations, a common method uses ultraviolet to measure the absorbance of the nitrate ion at 220 nm (26). A widely used colorimetric method for determination of bromide uses phenol red indicator solution (27).

B. Natural Organic Matter

Natural organic matter refers to the gross content of organic matter in the water. This includes humic acids, fulvic acids and related materials that can originate from plant or animal residues, or substances made by living organisms. All are based upon carbon compounds. It is often difficult to treat waters that contain high natural organic matter content. For example, chlorination can lead to the production of high levels of disinfection by-products such as the trihalomethanes (THMs). This topic is further discussed below under the "Impurities Added to or Formed by Water Treatment" heading.

Total organic carbon, or TOC, is a widely used measure of natural organic matter in water. To determine the quantity of TOC, the organic molecules must be broken down and converted to a single molecular form that can be measured quantitatively. Two techniques that are used to achieve this for TOC analysis are high temperature combustion (28) and persulfate oxidation (29). The measurement of chemical oxygen demand, or COD, can provide relative indications of organic matter (30). Likewise, a UV spectrophotometer may be used to track the relative organic loading of waters by monitoring the absorbency at 253.7 nm (31). While not directly correlated to total organic carbon or natural organic matter, COD or UV monitoring do provide useful screening techniques for food plants, especially to track seasonal variations for surface water supplies. Assimilable organic carbon (AOC) is yet another surrogate measure of organic levels. AOC is used to measure the potential of a particular water for biological regrowth in the distribution system. The AOC determination is made by measuring the maximum growth level of a particular microorganism in a sample of water from which the original bacteria have been eliminated (32).

C. Organic Pollutants

In Figure 192.1, the message is clear…"nothing disappears from the earth." This applies to all industrial processes,

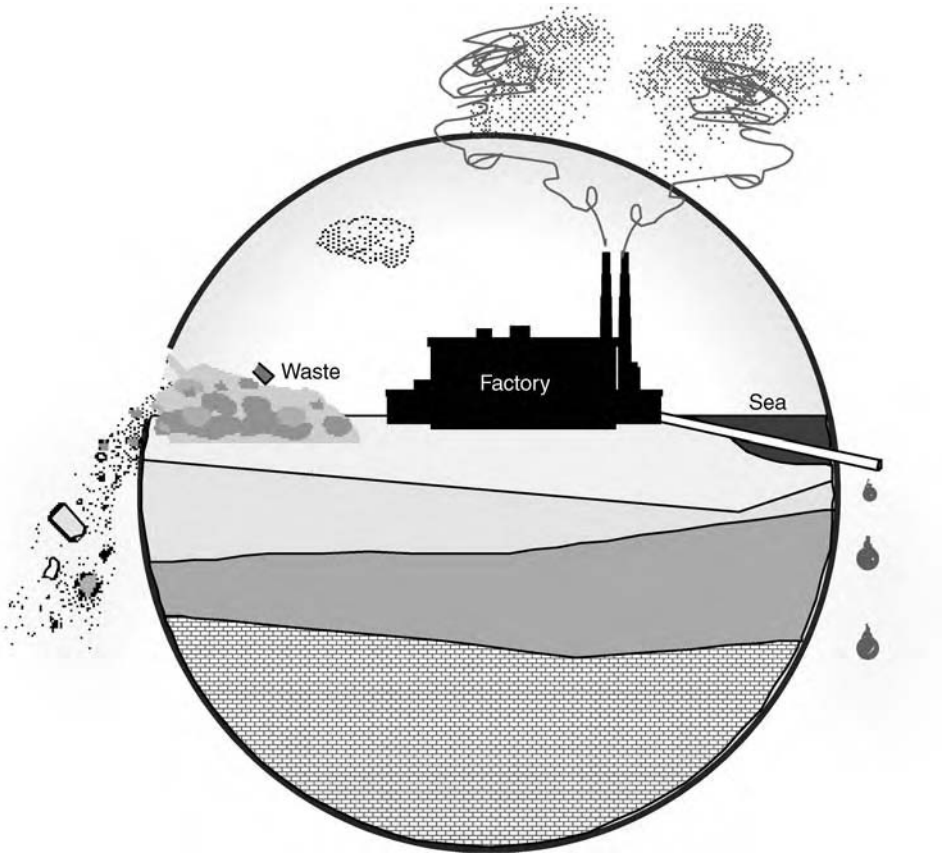

FIGURE 192.1 Nothing disappears from Earth. (*Source*: Adapted from KT Cullen & Co., training course material, Dublin, Ireland, 2000.)

including water treatment. Chances are, our food plant is either treating a contaminant that someone else introduced—maybe decades ago—or, we are contributing our own to the overall watershed by way of our wastewater effluent. Compounds like petroleum-based chemicals, pesticides and herbicides all too often make their way to water supplies either via run-off to rivers and streams, or down the well casing into groundwater aquifers. Pollution from such compounds can be a serious and costly matter for food companies in terms of consumer safety, adverse media attention, product recalls, remediation, loss of brand equity and regulatory concerns. Keep in mind that a very small amount of an organic pollutant can contaminate a very large amount of water. For example, the U.S. Environmental Protection Agency estimates that less than one gallon of gasoline can contaminate one million gallons of ground water to the point of losing potability.

1. Volatile Organic Compounds

Volatile Organic Compounds, or VOCs, are a category of compounds that includes many petroleum-based chemicals. For example, VOC compounds such as benzene, toluene, ethyl benzene and the xylenes (ortho-, meta- and para-xylene) are often implicated in the contamination of ground water by fuel (gasoline, kerosene, or some other petroleum-based energy source) (33–35). It is worth remembering that microbial soil mechanisms may transform the VOC contaminant in groundwaters. For example, under certain conditions, the common solvent tetrachloroethene (also known as tetrachloroethylene, perchloroethylene, PERC) can be transformed in soil first to trichloroethene, then to dichloroethene, and finally to vinyl chloride (monochloroethene). So, if vinyl chloride is detected in a groundwater sample, it might actually be the result of a tetrachloroethene spill from the dry cleaner several miles away!

The most common laboratory methods for analysis of VOCs use purge and trap gas chromatography using either a combination of photoionization detection (PID) and electrolytic conductivity (ELCD) detectors in series (36) or a mass spectrometer (MS) detector (37). With PID/ELCD, identification is by elution time only and can be partially confirmed by the use of a dissimilar chromatographic column. The MS detector provides more reliable identification.

2. Pesticides and Herbicides

Although the use of pesticides has led to many advances in agricultural output throughout the world, they have

been found to occur in surface and groundwater supplies all too frequently. Several of these compounds are bioaccumulative and reactively stable, as well as toxic or carcinogenic (8). Categories of pesticide residues include the organochlorine pesticides and the carbamate pesticides. Agricultural chemicals for weed control can also be routinely found in water supplies. Common types of these herbicides include chlorinated phenoxy acid herbicides, other types of carboxylic acid compounds and glycophosate herbicides (the latter is sold under registered trade names such as Roundup and Rodeo). Treatments such as granular activated carbon filtration, reverse osmosis, and to a lesser extent oxidation via chlorine and ozone, can play a vital role in controlling contaminant levels. However, it can be a challenge to food plant water treatment systems to meet the strict regulatory limits of some countries, especially if there are not controls governing the local use of pesticides and herbicides.

The type of test method utilized for pesticide and herbicide analysis in water often depends on the type of residue in question and the detection limit required. Sample preparation steps (which extract and concentrate the residue from water) and quality control checks can be time intensive. Analysis of organochlorine pesticides typically involve liquid-liquid extraction of water samples, followed by a capillary column gas chromatographic technique (38). Detection by either mass spectrometer (MS) or Electron Capture Detector (ECD) is commonplace. Degradation compounds of pesticides can also be detected by this method. Carbamate pesticides are heat sensitive and labile, and hence are not amenable to analysis by gas chromatography. Therefore, analysis of carbamate pesticides is often based on high performance liquid chromatography (HPLC) in conjunction with a post-column derivatization system and a fluorescence detector (39). A common method for measuring acidic herbicide compounds uses a micro liquid-liquid extraction method that is simpler than other extraction procedures and does not require large volumes of solvent extract (40). Glycophosate herbicides can be measured in water using liquid chromatography with a post column reaction/fluorometric method (41).

IV. MICROBIOLOGY

Typhoid, cholera, hepatitis A and E viruses, *Legionella* (often associated with piped water distribution systems) and *E. coli* O157 are examples of organisms that can cause infectious diseases by transmission through water. Others such as the protozoan organism *Cryptosporidium parvum* result in what are usually less severe, though uncomfortable, outcomes such as self-limiting diarrheal disease (8). According to the World Health Organization, "infectious diseases caused by pathogenic bacteria, viruses and protozoa or by parasites are the most common and widespread risk associated with drinking water (8). In addition to waterborne organisms of health concern, microorganisms can cause aesthetic and/or operational concerns. Despite these concerns, it is not practical to attempt to test all of these and other possible threats to a food plant water system. Consequently, the focus of the food industry, supported by most major regulatory organizations, is to monitor recognized "indicator organisms" of water quality.

A. Indicator Organisms

Total plate count bacteria testing provides a measure of the total number of viable bacteria. Proactively addressing increasing counts can avert microbial problems in the water treatment system. The corrective action(s) is dependent on the individual situation at each food plant. Areas that a plant might focus on include disinfectant residual levels, filtration operations, sanitation processes, ultraviolet radiation performance, materials used in water treatment operations, equipment performance and changes in the microbiologic quality of the incoming water.

Coliforms are rod-shaped bacteria that are widely found in the environment. Total coliform testing is widely used as an indicator of the general sanitary quality of treated drinking-water. The food industry is particularly interested in bacteria that may be present in excreted feces from the human gut, or from the gut of other mammals, which prosper in the condition found in the human digestive system. This is an acidic environment that has a temperature of approximately 98.6°F (37°C). The primary indicator tests of such fecal contamination in water are *Escherichia coli* (*E. coli*) or thermotolerant coliform bacteria.

Despite many benefits, coliforms do have shortcomings as indicator organisms. Among these is the fact that under certain circumstances (for example, following disinfection) they fail to indicate the presence of resistant pathogens such as viruses and protozoan parasites in treated drinking-water supplies. Keep in mind that total coliform bacteria and *E. coli* bacteria are part of the normal intestinal flora of healthy individuals, and are not always themselves implicated with adverse health effects. However, a pathogenic strain of *E. coli* known as *E. coli* O157 has received much recent discussion in the public domain. For example, an incident occurred in May 2000 where *E. coli* O157 contaminated the supply system of a farming community in Ontario, Canada. Five people died and 27 were hospitalized (42).

Mold is present throughout the environment (air, dust, soil, water) and can be transferred into a food manufacturing environment by people (direct contact with dirty hands, clothing, shoes, etc.), air ventilation systems, open doors and poor manufacturing practices in general. Sometimes mold issues in food or beverage products can be traced back to a water root cause. Although yeast is

rarely a problem with water, high yeast counts are occasionally detected and may be indicative of environmental issues at the plant. In addition to testing processed water, yeast and mold tests are sometimes conducted on sanitation rinse waters (assuming no disinfectant is present in the rinse water) to provide an early indication of the effectiveness of the plant sanitation process.

Membrane filtration techniques are commonplace for measuring microorganisms including total coliform bacteria, *E. coli*, thermotolerant coliform bacteria, yeast and mold. These techniques involve placing samples in a container (called a 'monitor'), using a membrane to capture microorganisms, adding the appropriate media to promote growth, incubating the samples in an oven for the appropriate time and temperature and counting the number of colonies that grow. Colisure, Colilert (both available from IDEXX Laboratories) and E*Colite (from Charm Sciences) are examples of rapid methods which are gaining increasing popularity within the food industry to detect the presence or absence of total coliform bacteria and *E. coli*.

B. Protozoa

The category of microorganisms known as the "emerging pathogens" has received a high level of scrutiny since a massive disease outbreak in Milwaukee, Wisconsin (U.S.), in 1993. Reports estimated at the time that 400,000 people became sick with gastrointestinal illness, and 100+ died (8). The cause of the outbreak was the protozoan parasite *Cryptosporidium parvum*. Since then, disease outbreaks due to protozoans such as "Crypto" and *Giardia lamblia* have become increasingly prevalent around the globe. *Cryptosporidium parvum* is particularly resistant to chlorine disinfection compared to bacteria. Part of this resistance is due to the fact that the organism forms protective shells, or oocysts, which make destruction difficult. A "multiple barrier" approach is generally recommended to protect against protozoan organisms. Coagulation with sand filtration, filtration to 1 micron absolute or less (e.g. reverse osmosis, nanofiltration, cartridge filters, etc.), ozone and UV can be effective "barriers" against *Cryptosporidium* and *Giardia*. The National Sanitation Foundation (NSF International) has published a standard for cartridge filters, Standard 53, which assures removal of a large percentage of oocysts ("cyst reduction filters").

Most water samples contain few oocysts and concentration techniques are required to obtain even a small number, many of which may be dead. As a result, the current test methods for protozoan organisms are neither precise nor accurate and monitoring results may contain false positives and false negatives.

C. Algae

At certain times of the year surficial supplies can undergo "inversion" leading to increased numbers of algae. Blooms, or scums, become easily visible across the water surface. In simplified terms, this phenomenon occurs where water at the surface reaches a temperature at which it is most dense (near 3.98°C, or 39.2°F), while the water below it has not yet reached this state. A density and temperature gradient are thus formed, with the denser water descending and displacing the water below it (hence the term "inversion"). The agitation brings sediment and unwanted components with it from the bottom to the surface.

Algae can produce physiologic breakdown products, such as geosmin and methyl-isoborneol, that are extremely sensory-active. They can cause off-odors in water (dirty, musty, moldy) at concentrations as low as nanograms/liter. These require extensive treatment to remove and can place a strain on the food plant water treatment system. Furthermore, some species of algae produce toxins that can be dangerous to people if they are consumed. To put this toxicity in perspective, *Microcystis*, a commonly found blue-green algae, produces a toxin called microcystin LR which is 200 times more toxic than cyanide (43).

Municipal water treatment authorities generally know of the taste, odor and toxicity problems associated with algae, and usually swiftly apply an algaecide. This kills the algae, but doesn't remove the "bodies." Sometimes, when conditions are just right, these algae (essentially silicate-laden diatomic skeletons) can make it through to food plant water supplies. If not effectively filtered by the plant water treatment system, this can result in issues with food products. The skeletons can be easily confirmed via electron microscopy.

V. RADIOLOGICAL PARAMETERS

Radiological contamination of drinking water can result from naturally occurring and man-made sources.

A prime example of a common naturally occurring radioactive species that can be found in water sources is uranium. More than 99% of natural uranium consists of the isotope U-238 which has a half life of 4,510,000,000 years. One gram of pure U-238 has a specific activity of 12,400 Bq, which means there are 12,400 atomic transformations every second, each of which releases an energetic alpha particle. Each atomic transformation produces another radioactive chemical: first U-238 produces thorium 234 (which has a half life of 24.1 days) and then thorium 234 decays to uranium 234 (which has a half life of 247,000 years). The Becquerel, or Bq, is the S.I. unit of radioactivity, where 1 Bq = one disintegration per second.

Man-made sources of radiological contamination include those from medical or industrial areas, from the disposal of radioactive materials (such as the mining and processing of mineral sands or phosphate fertilizer production), or from materials such as depleted uranium that are used in the manufacture of anti-tank missiles and other

weaponry. Depleted uranium has a lower or "depleted" U-235 content (0.2%) and higher U-238 content (99.8%) than naturally occurring uranium.

The process of identifying individual radioactive species and determining their concentration requires sophisticated and expensive procedures. A practical approach to monitoring for radioactivity in water is to use a screening technique. For example, the World Health Organization recommend a screening approach whereby the total radioactivity present in the form of alpha and beta radiation is determined without regard to the identity of specific radionuclides (8). If gross alpha and gross beta activity are within their threshold values, then the water is suitable from a radiological perspective. Only if either the gross alpha activity or the gross beta activity concentration thresholds are exceeded is it recommended to identify the specific radionuclides and measure their individual activity concentrations.

VI. DISSOLVED GASES

Water contains varying amounts of dissolved gases such as carbon dioxide, oxygen, ozone, hydrogen sulfide and ammonia. Dissolved gases contribute different attributes to the water. For example, carbon dioxide decreases the pH of un-buffered water and can contribute significantly to corrosion, oxygen can increase microbiologic activity, ozone provides oxidation and disinfection properties and can result in the formation of by-products such as bromate and chlorate, hydrogen sulfide imparts rotten egg-like odors at thresholds above 0.25–0.25 micrograms/l in clean water (44) and ammonia imparts off-odors, off-tastes and forms chloramines (commonly referred to as combined chlorine). The relationship between dissolved gases and the various species in water can be complex. For example, the relationship between carbon dioxide and carbonate in water is very pH dependent, as shown in the following equation:

$$CO_2 + H_2O <—> HCO_3^- + H^+ <—> CO_3^{2-} + 2H^+$$

The equation indicates why one typically sees a lower pH in reverse osmosis permeate than in feed-water. This is because the pH is always dictated by the ratios of bicarbonate and carbon dioxide found in the water. As these ratios change through the system, with much of the bicarbonate being rejected and much of the carbon dioxide passing through the reverse osmosis membrane (as gases are not effectively blocked), the pH will drop. Of course, if acid addition is employed as a pre-treatment to reverse osmosis membranes, then this will also contribute to the pH decrease. The presence of entrapped dissolved gases needs to be minimized for conventional coagulation treatment processes. They can result in floating floc or sludge which, in addition to causing operational difficulties, can potentially make its way to treated water used in food processing. Many de-aeration treatments are available to minimize the presence of entrapped gases.

If pH, temperature, alkalinity and total mineral content are known then the concentration of CO_2, and any or all of the alkalinity forms, can be calculated from charts, diagrams and nomographs (45). Another way to measure CO_2 content is by titration with either sodium carbonate or sodium hydroxide using phenolphthalein indicator (46). Dissolved oxygen is typically measured using a membrane electrode procedure, which is based on the rate of diffusion of molecular oxygen across the membrane (47). A simple colorimetric test for ozone uses indigo blue reagent (48). The blue color of indigo reagent is bleached in proportion to the amount of ozone present in the water sample. Alternatively, DPD (N,N-diethyl-p-phenylenediamine) reagent, the same reagent commonly used for free and total chlorine testing, may be used to measure ozone (49). Zinc acetate and sodium chloride solutions are often used to preserve the sample prior to hydrogen sulfide analysis (50). Several qualitative tests for hydrogen sulfide are available, and quantitative methods include the methylene blue colorimetric (51) and iodometric test methods (52). Ammonia can be measured using an ammonia-selective electrode method (53) or by titration against sulfuric acid using boric acid and mixed indicator solutions (54).

VII. IMPURITIES ADDED TO OR FORMED BY WATER TREATMENT

While the matter in water may render it unfit for human consumption, treatment can also adversely affect water quality by introducing pollutants, or by modifying chemicals that are harmless prior to water treatment.

A. Chlorine

Chlorine is widely used in water treatment. It has effective microbial disinfection properties, acts as an oxidant (e.g. for oxidation of dissolved iron and manganese to form insoluble products that can be removed as soluble precipitates) and it removes, or assists in the removal of, some chemicals e.g. decomposition of easily oxidized pesticides such as aldicarb (8). Chlorine is easy to apply, provides a strong residual, is relatively inexpensive and is easily removed from the water (typically via granular activated carbon filtration or sodium metabisulfite dosing prior to membranes). Disadvantages of chlorine include its reaction with natural organic material to produce disinfection by-products such as the trihalomethanes (discussed below) and that it provides relatively poor effectiveness for control of the protozoan parasite *Cryptosporidium parvum* (also discussed below).

The most common form of chlorine used in the food industry is sodium hypochlorite solution. Calcium

hypochlorite, available in granular form, is also commonly used. Chlorine gas is used mostly by municipal water treatment works, but may be used by very large food plants. A major drawback with chlorine gas is the regulatory prerequisites and paperwork usually needed for its safe storage, handling and use.

When chlorine dissolves in water, the hypochlorite anion (OCl^-) and hypochlorous acid (HOCl) form. Figure 192.2 illustrates the equilibrium between the three, with relative amounts varying depending on the pH. Very little molecular chlorine exists in solution at pH levels above 4 (or in dilute solutions). Hypochlorous acid is dominant at the low to moderate pH range. The hypochlorite anion is dominant at higher pH values. Hypochlorous acid is roughly 100 times more potent a germicide than the hypochlorite anion. This illustrates very effectively why the pH range of typical conventional lime treatment coagulation systems (9.6–10.5) renders the chlorine far less effective than at lower pHs. A pH in the range of 6 to 7.5 is generally preferred for chlorine disinfection. This provides a reasonable balance between hypochlorous acid and the hypochlorous anion, while not allowing the chlorine solution to become corrosive to piping and materials (as chlorinated water is more corrosive at low pH values). Chlorine effectiveness also varies with contact time (more contact time, more kill) and temperature (higher temperature, more kill).

Colorimetric methods are widely available to determine chlorine in water at concentrations ranging from 0.02–10 mg/l (49). When evaluating chlorine residuals, the distinction must be made between a "free" residual, and a "combined" residual. The "free" available chlorine residual is defined as that portion of the total residual chlorine which will react chemically and biologically as hypochlorous acid. It is in this form that chlorine exerts the most potent bactericidal effect. The "combined" available chlorine residual is defined as that portion of the total residual chlorine which will react chemically and biologically as chloramines or organic chloramines. In these forms, chlorine is a relatively mild bactericide and oxidizing agent. Analytically, using available test kits with prepared reagents, both the "free" chlorine and the "total" chlorine are measured. The assumption is made that the difference between these two represents the "combined" chlorine residual. The reagent N,N-diethyl-p-phenylenediamine (DPD) is most commonly used for both "free" and "total" chlorine testing (49). Orthotolidine has been used in the past (55), but has been found to be carcinogenic, and may pose other health risks. Food plants should therefore avoid it if at all possible. Oxidation-reduction potential (ORP) is another way to measure if chlorine or any other oxidizing agent is present in water (56). If you concentrate, you may remember from your school science classes that many chemical reactions around us are proton donor/acceptor in nature. However, with oxidation-reduction (redox) reactions, one chemical species loses, while another gains electrons. ORP is a value (number) defining how much gaining/losing of electrons a system might do (an oxidizing environment has a positive value). It is measured indirectly via conductivity or resistivity as the ability of water to conduct electricity, typically in millivolts. Shifts in ORP indicate chlorine breakthrough, contamination or that something has "changed" in the system.

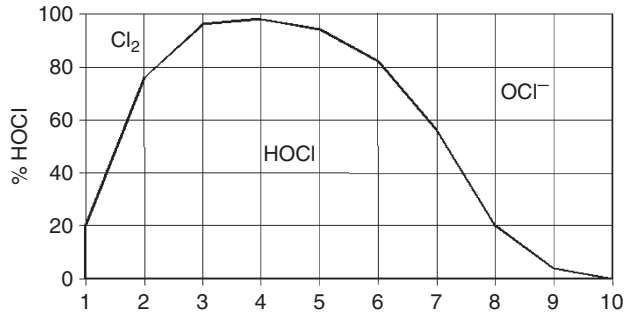

FIGURE 192.2 Relationship between chlorine, hypochlorous acid and the hypochlorite anion as a function of pH.

B. TRIHALOMETHANES

Trihalomethanes (THMs) are formed from the reaction of chlorine with natural organic matter precursors (humic and fulvic acids, for example). Surface supplies are most often implicated with respect to elevated levels of THMs. However, THMs may also be formed from ground water supplies, especially in cases where the well construction or integrity has been compromised. Four THMs are commonly found in water, namely chloroform, bromoform, bromodichloromethane and dibromochloromethane. They are closely controlled from a regulatory perspective as some THM species are known or suspect carcinogens above certain threshold levels.

THM formation is dependent on several factors including:

- Incoming raw water THM levels
- Incoming natural organic matter ("THM precursor") levels
- Water treatment conditions, such as conventional coagulation treatment systems
- Free chlorine concentration (increased chlorine levels can increase THM formation)
- pH (the higher the pH, the higher the THM formation potential)
- Chlorine contact time (the higher the contact time, the greater potential for forming THMs)
- Seasonal variations can create dramatic increases in THM precursors and subsequent THM formation

In most cases the food manufacturer's best defense against trihalomethanes such as chloroform is use and diligent maintenance of granular activated carbon (GAC) filters. Where conventional coagulation water treatment systems are in operation at a food plant, use of a "post-chlorination" technique is often employed where a high THM formation potential exists. This involves coagulating or otherwise removing the THM precursors, then chlorinating downstream. It is easier to remove the larger organic precursor molecules than the small THMs once they have been formed. For this reason, the best approach to THM control is to minimize their formation in the first place.

The same test procedures previously outlined in relation to Volatile Organic Compounds (VOC) testing may be used for THM testing (36,37). Although less precise, on-site THM test kits are offered by some companies which can be useful to track overall consistency of THM levels for some applications.

VIII. PROPERTIES OF WATER OF IMPORTANCE TO THE FOOD INDUSTRY

There are many properties of water that have particular importance for food industry applications. A number of the more common ones are described briefly below.

A. Taste, Odor and Appearance

Often, the human senses can detect contaminants in water at levels too low to be reliably measured by plant instrumentation, or in some cases the needed instrumentation may not be readily available. The concentrations at which such contaminants impact on food plant quality is dependent on individual and local plant factors, including the quality and consistency of the water available, the nature of the food products or processes with which the water is in contact and the sensitivity of the individual to the specific defect(s) that he or she is tasting.

A list of taste thresholds in water of commonly found constituents is provided in Table 192.2. Operational problems at a food plant facility can pose a major risk to the sensory profile of water and the food and beverage products it is used to prepare. One of the more common problems is the breakthrough of chlorine from a storage tank (perhaps due to the malfunction of a carbon filter). A noticeable "metallic taste" may point toward an overdose of coagulant, or an increase in metals due to an increase in the corrosivity of the water. If a carbon filter is utilized, carbon particles might sometimes penetrate the terminal polishing step of the process resulting in black specs in the treated water.

A rapid, coarse, taste, odor and appearance evaluation of water is routinely included as a step in overall food plant quality control. No chemical test is done, the tester merely relies on human senses. There should be no off-tastes, no off-odors, no turbidity (not cloudy), no suspended matter and no off-color in water used in the manufacture of food products.

TABLE 192.2
Taste Thresholds of Commonly Found Constituents in Water

Constituent	Approximate Taste Threshold
Inorganic Constituents	*mg/l*
Aluminium	0.2
Ammonia (at alkaline pH)	1.5
Calcium	100 to 300
Chloride	200 to 300
Hydrogen sulfide	0.05 to 0.1
Iron	0.3
Manganese	0.1
Sodium	200
Sulfate (highly cation specific)	250 to 1,000
Total dissolved solids	600 to 1,200
Zinc (as zinc sulfate)	4
Organic Constituents	*µg/l*
Toluene	40 to 120
Xylenes	300
Ethylbenzene	72 to 200
Chlorophenols	0.1 to 2

Source: Adapted from WHO Guidelines for Drinking Water Quality, 2nd Edition (1993).

B. Hardness

Hardness in water is caused by dissolved minerals, primarily those producing divalent, or double charged, cations including calcium (Ca^{2+}), magnesium (Mg^{2+}), iron (Fe^{2+}), strontium (Sr^{2+}), zinc (Zn^{2+}) and manganese (Mn^{2+}). Calcium and magnesium ions are usually the only ones present in significant concentrations in most waters. Hardness is, therefore, generally considered by the food and water treatment industries to be a measure of the calcium and magnesium content of water. The terms "hard" water and "water hardness" stem from the fact that it is "harder" to raise a lather when more calcium and magnesium are present, i.e., more soap, detergent, or shampoo is necessary. The term "soft water" developed as "soft" is obviously an antonym of "hard." Temporary or carbonate hardness is the hardness due to the bicarbonates of calcium and magnesium in the raw water. By classical definition, this type of hardness can be removed by boiling the water. Permanent or non-carbonate hardness is the hardness due to the chlorides and sulfates of calcium and magnesium in the raw water. This type of hardness cannot be removed by boiling the water.

High level of water hardness can result in scale deposition, particularly on heating, depending on factors such as pH and alkalinity. It is critical to ensure that maximum hardness levels required by manufacturers for the equipment they supply are satisfied. Boiler make-up water, in

particular, may require softening when the hardness goes above 50 mg/l or sometimes lower. Waters with a hardness of less than 100 mg/l have a low buffering capacity and may be more corrosive to water pipes than water with higher hardness levels. The acceptability to the food industry will depend on:

- Whether water might need to be softened to prevent scale deposition. e.g., water to be used in plant operations like heat exchangers, boilers, bottle washers, cooling tunnels, etc;
- Where high hardness causes interactions with individual products (for example, tea beverages that contain oxalic acid require low hardness levels to prevent calcium oxalate precipitation from the beverage).
- Where high hardness can directly impact sensory in water, and potentially food products.
- Where soft water has a low buffering capacity and so may be more corrosive for water pipes.
- For plants that utilize coagulation water treatment systems and have sodium alkalinity present in the food plant water supply (sodium alkalinity is indicated by the hardness concentration being less than that of alkalinity, both measured as calcium carbonate equivalents). Hardness and alkalinity testing can monitor the effectiveness of coagulation systems by gauging the need for addition of a calcium salt to the reaction tank (required where effective alkalinity reduction is desired from the treatment).

C. Alkalinity

The sum of the concentrations of bicarbonates, carbonates and hydroxides present in a water sample is commonly referred to in the food industry as its alkalinity. High levels can contribute significantly to the total dissolved solids present in the sample (discussed above). Alkalinity is a critically important measurement for the beverage industry because high levels will neutralize the acidity in many beverages, especially carbonated soft drinks. This can lead to a poor sensory experience for the consumer or microbial problems in trade.

There are two widely utilized methods for measuring the alkalinity of the water. One is a colorimetric method that uses indicators that change the color of the solution under test depending on its pH (57). The second is pH-metric method which is more precise since it removes the subjectivity of interpreting a color change by using a pH meter to determine the test result. The relationship between alkalinity components, free CO_2 and pH is outlined in Figure 192.3.

D. pH

pH is a measure of the relative acidity or alkalinity of water. The pH scale runs from 0 (acid) to 14 (alkaline), with a mid-point of 7.0 denoting neutrality. In more scientific terms, pH is defined as the logarithm of the reciprocal of the hydrogen ion activity expressed in moles per liter. Like the "logarithmic units" of the Richter scale which measures earthquakes, each number on the pH scale represents a 10-fold change in the acidity/alkalinity of the water. For example, water with a pH of 5 is 10 times more acidic than water having a pH of 6.

The pH of water is a composite reading of the balance between water, free carbon dioxide, carbonate, bicarbonate and hydroxide. A shift in any one of these species will produce a shift in the pH. Since pH can be affected by chemicals in the water, it is an important indicator of water that is changing chemically. In other words, the results of a single measurement of pH are usually less important than looking at how it varies over time.

The wide range of treatment processes that food plants employ brings with it an equally wide range in treated water pH values. Treated water in the 4 to 5 range is not uncommon where the treatment system is weak acid cation (WAC) ion exchange due to the displacement of calcium and magnesium ions in the water with hydrogen (H^+) ion. An acidic pH is also common for many systems which utilize reverse osmosis or nanofiltration. This is due to the pre-membrane acid dosing used to prevent scaling/fouling and to help maximize recovery, and also due to the changed ratios of bicarbonate and carbon dioxide found in the water, as was described above in the dissolved gases section of this chapter. Conventional coagulation water treatment systems are on the other end of the spectrum. Here, the operational pH range in the reaction tank is in the area of 9.6 to 10.5 where hydrated lime addition is used in the process for effective alkalinity reduction (via precipitation as calcium carbonate). The treated waters out of these systems are typically somewhere around the pH 8–9 range.

So, a pH 4–5 would not be a concern if the treatment were WAC ion exchange or reverse osmosis, but it might suggest a process control problem with conventional coagulation treatment. Conversely, the pH 10–11 would be a concern from a conventional coagulation operational perspective, since a pH of 9.6–10.5 is expected in the reaction tank, and decreases in pH with chlorination, dechlorination with granular activated carbon filtration and other unit operations. A high pH after this type of treatment usually indicates that the treatment is not being optimally controlled (for example, excess of hydrated lime, poor selection of or exhausted carbon bed, etc.). Likewise, a pH of 10–11 for WAC, reverse osmosis or nanofiltration treatment would be highly unusual and would warrant investigation.

E. Solubility and Corrosiveness

The solubility and corrosiveness of water are two closely related properties that are of much interest to the food

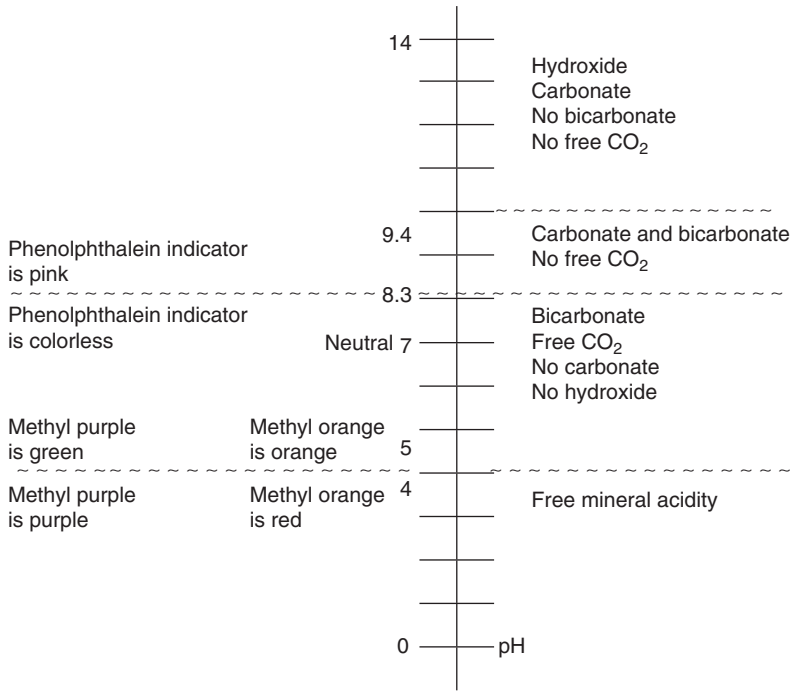

FIGURE 192.3 Relationship between alkalinity, free CO_2 and pH. (*Source*: Adapted from Pepsi-Cola training material, 2001.)

industry. The Langelier Saturation Index, or LSI, provides a measure of the solubility, or more specifically the scale forming tendency and corrosivity of water. The basic concept is that it indicates the degree of saturation of water with respect to calcium carbonate (58). LSI can also be understood as the pH change required to bring water to equilibrium. In order to calculate the LSI, it is necessary to know the alkalinity (mg/l as $CaCO_3$), the calcium hardness (mg/l Ca^{2+} as $CaCO_3$), the total dissolved solids (mg/l TDS), pH and the temperature of the water (°C). If the LSI testing result is negative, it can be interpreted that there is no potential to scale, the water will dissolve $CaCO_3$ and the water is corrosive. If the LSI test result is positive, it can be interpreted that scale can form, $CaCO_3$ precipitation may occur and the water is not corrosive.

193 Beverage Plant Sanitation

Daniel W. Bena
PepsiCo International

CONTENTS

I. INTRODUCTION

One part in 1,000,000,000,000,000 parts! Believe it or not, analytic measurements down to this detection level (parts per quadrillion, ppq) are quickly becoming routine for certain classes of organic compounds (for example, the polychlorinated dibenzo-dioxins and -furans). With the lightning-fast progress being made by chemists, physicists, and other scientists, we can only expect this trend to continue. Consequently, everyone involved with water in the food and beverage industries, either as an ingredient, product, or process chemical, will be forced to learn more about this often complex matrix—from its origin, through the paths it travels, the contaminants it meets along the way, to the point where it enters your production facility.

Water brings with it an inconceivable number of potential components—some considered contaminants, others considered therapeutic, and still others considered essential for life. The treatment technologist's challenge then becomes determining which components should be retained (and how), which should be reduced (and how)—and what the consequences of this selection might be. These consequences could potentially range from a minor, aesthetic defect in finished product, to a beverage or food

product which results in widespread public illness. The seriousness of a thorough understanding of water treatment is a unifying principle throughout this writing.

Over the past five years, the beverage industry's usable technology focus has moved from coagulation, ion exchange, filtration, carbon adsorption and ultraviolet disinfection to the use of membranes in technologies ranging from reverse osmosis, nanofiltration, ultrafiltration, and microfiltration; continuous electrodeionization, electrodialysis, selective exchangers and sophisticated controls and automation. Our quality focus has expanded to include organics, inorganics, and pathogens that are serious health concerns and present new treatment obstacles; and detection capability at a level to defy imagination which promises tighter and tighter regulatory guidelines. Our business focus is now largely driven and supported by regulatory guidelines and compliance requirements that demand in-house programs and reporting protocols. Over the next few years, millions of dollars will be spent on replacing or upgrading existing water treatment equipment or technology to keep pace with these new challenges. It will be a transition period of substantial turbulence, and we intend to offer insights into the advantages and shortcomings of all technology to aid the water technologist in making the most correct decisions for a given water supply.

II. WATER SOURCES

Perhaps the best place to begin a discussion of water sources is with an initial reference to the hydrologic cycle. As its name implies, the hydrologic cycle describes the continuous movement of water throughout its phases of state (solid, liquid, and vapor) within our hydrosphere, and is pictorially summarized in Figure 193.1. This "movement," or transformation, can be imagined in five major steps (1):

1. Water moving from the earth to the sky. In this part of the cycle, the movement of water from the earth to the sky involves a combination of three pathways: 1) evaporation, where water absorbs solar radiation which allows its transformation from water liquid to water vapor; 2) transpiration, where water is released to the atmosphere by plants as part of their normal physiologic processes; and 3) sublimation, where water (in its solid state as ice and snow) passes directly to the vapor state. The first two pathways above are often combined, and referred to simply as "evapotranspiration."
2. Water vapor forming water liquid. The active pathway in this step of the hydrologic cycle is one of condensation, due to temperature gradients within the atmosphere. Water vapor, which "moved from earth to sky," and which is currently stored in cloud formations, begins to form small droplets of water and/or small crystals of ice. As this condensing water continues to form, and eventually "saturates" the sky, the next step, below, is imminent.
3. Water falling back to earth, in the form of snow, ice, rain, sleet, and hail. The hydrologic cycle may be compared, on a much smaller and simplified scale, to a laboratory distillation. The aqueous sample in the "pot" is forced to move from liquid to vapor state, then the vapor is forced to condense back to liquid, and this purified liquid falls back to a collecting vessel. Ironically, despite the constant recycling of water through the hydrologic cycle, Table 193.1 illustrates that it may not be as pure as you think! These data, though reprinted in 1990 (2), were originally collected decades ago. A comparable analysis using today's environment and current analytic methodology would be interesting; unfortunately, it is likely that the table would need to be expanded, especially to include parameters as the result of acid precipitation, industrial discharge to the atmosphere, and emerging pathogens.
4. Water penetrating the ground. A single pathway describes this movement of water downward through the soil, but it is generally divided into two components: 1) infiltration, where water soaks into the soil and moves toward the root zones of area plant life. As part of the cycle, this water is then incorporated by the plants, and eventually re-introduced via transpirative processes; and 2) percolation, which describes a similar movement of water through the soil, but generally to greater depths—past the root zones and toward the aquifers, or water bearing geologic strata, which will be discussed in more

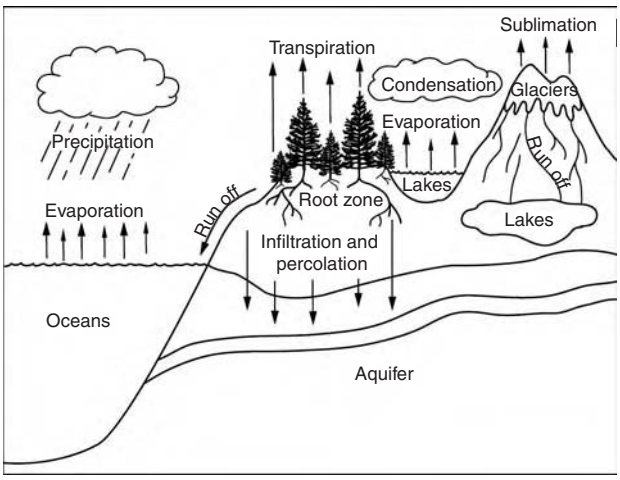

FIGURE 193.1 The hydrologic cycle.

TABLE 193.1
Chemical Analyses of Rain, Snow, and Hail

Parameter, in ppm	Rain, after 4 Hours	Rain, after 22 Hours	Snow	Hail
Total hardness, as $CaCO_3$	43	8	18	28
Calcium hardness	42	8	14	25
Magnesium hardness	1	11	4	3
Alkalinity	19	5	—	4
Sodium	5	0.11	5	—
Ammonia	1.5	2	6	1
Chloride	7	4	12	7
Sulfate	26	3	21	17
Nitrate	1	—	1	—

detail in the next sections. It is this movement of water through the soil that represents a "double-edged sword." On one hand, infiltration provides a perfect opportunity for the water to become contaminated on its journey—from underground storage tanks, septic systems, naturally occurring contaminants, and other sources. On the other hand, it also provides one of the most effective attenuative mechanisms for many contaminants. That is, through complex ion-exchange, adsorptive, and microbiologic processes in the soil, contaminants may be reduced in concentration, or completely transformed chemically into some other compound before reaching many groundwater supplies.

5. Water returning to the oceans. This explains the pathway of surface runoff. The soil becomes "saturated" (this term is used loosely here, since saturated and unsaturated zones have very specific meanings to hydrogeologists), and flows downhill (piezometrically, and usually downhill topographically—but not always) over the surface and near the surface. The moving water can incorporate anything in its path including physical debris, chemical contaminants, and microorganisms, as it moves toward the rivers, streams, etc., and on back to the oceans, where it again joins the evapotranspirative section of the hydrologic cycle.

Since this effect is cyclical, it may be entered at any point along its route, and followed through to some endpoint. Though the hydrologic cycle is often viewed as basic and fundamental, it does underscore the conservative and recyclable nature of these processes. As a result, the quality and safety of the water used in our products and processes is, to some extent, directly linked to how that water supply traverses the hydrologic cycle, and with which contaminants and impurities it comes in contact. Our knowledge of the basic and allied sciences is ever increasing, and the importance of water quality and overall water resources management increases in direct response. Now, the toxicologic and other health-related impacts of our ingredient water are under more study than ever before. As the skills of the analytic chemist lead to ever-decreasing lower limits of detection, the chemicophysical and microbiologic integrity of our water supplies will be under more scrutiny and of greater importance than at any other time in history. This chapter addresses the selection, treatment, and safety of this dynamic ingredient—water—as used in the beverage industry.

As an introduction, Table 193.2 affords an overall view of the world's water distribution (3). These numbers will vary depending on which source, and what year of publication, are cited. The overall illustration, however, is the same. The key things to glean from the table are these: 1) the vast majority of the world's water is trapped in the oceans, which are not yet considered economically feasible as useable drinking water supplies on a large scale; 2) if we remove the oceans from consideration, and we remove the water

TABLE 193.2
Estimated World Water Balance

Parameter	Surface Area ($km^2 \times 10^{-6}$)	Volume ($km^3 \times 10^{-6}$)	Volume (%)	Equivalent Depth (m)	Residence Time
Oceans and seas	361	1370	94	2500	~4000 years
Lakes and reservoirs	1.55	0.13	<0.01	0.25	~10 years
Swamps	<0.1	<0.01	<0.01	0.007	1 to 10 years
River channels	<0.1	<0.01	<0.01	0.003	~2 weeks
Soil moisture	130	0.07	<0.01	0.13	2 weeks to 1 year
Groundwater	130	60	4	120	2 weeks to 10,000 years
Icecaps and glaciers	17.8	30	2	60	10 to 10,000 years
Atmospheric water	504	0.01	<0.01	0.025	~10 days
Biospheric water	<0.1	<0.01	<0.01	0.001	~1 week

Source: Adapted from Nace (1971).

trapped in glaciers and the polar ice caps, only 1 to 5% of the world's water (depending on the source cited) is commonly considered treatable for use; and 3) of this small percentage, the vast majority of the supply (in some cases close to 100%) is found in the form of ground water.

Unfortunately, the citation of *available water*, alone, does not automatically mean that these supplies are *accessible*—or *safe*. According to Daniel A. Okun (4), in 1980, nearly two billion people did not have access to water supply and sanitation services. In 1990, it was estimated that more than 2.7 billion people in developing countries lacked access to these basic services (1.7 billion without access to sanitation, over 1 billion without access to water). Ten years later, at the first World Water Conference held at the Hague, a full 20% of the global population was cited as being without access to safe drinking water (5). Many feel that even these numbers are grossly underestimated due to the classification of exactly what water supply and sanitation "services" mean. As a country's geographic region, economic standing, and political infrastructure vary, so do the extent of what is "acceptable" in the provision of water supplies. Since we now know that the overall supply of water is a finite entity, let us examine the different water sources from which we may select our supply.

A. Water Source Categories

Water sources may be classified into two major categories: 1) ground water, and 2) surface water. Ground water examples include consolidated and unconsolidated aquifers (discussed later), artesian supplies, springs, etc. In short, water supplies that invade the saturated zone of the subsurface environment. Surface water examples include reservoirs, oceans, lakes, rivers, etc. The two categories differ greatly in the characteristics of the water they supply, as does water from groups even within the same category. Surface waters are usually higher in suspended solids, color, and turbidity than ground waters, and lower in total dissolved solids. The temperature of ground waters (depending on depth) is remarkably consistent—sometimes within a few degrees per year; in contrast, surface supplies, subject to the sun's radiation, are remarkably variable in temperature. As far as flow characteristics, surface waters are usually turbulent, while ground waters are usually laminar. "Typical" flows for ground water supplies may be one meter *per day*, in contrast to some surface water flows of one meter *per second*! Due to this wide variability, the often asked question of, "what does a 'typical' surface water look like in terms of its chemistry?" is impossible to answer with certainty. The best we can do is provide generalities, with the condition that there are truly exceptions to every rule. Table 193.3 was compiled by the author to present a relative comparison of surface and ground water supplies. Just when you think you have a thorough understanding of a particular supply—tread carefully—you may not!

TABLE 193.3
Relative Comparison of Ground and Surface Supplies

Parameter	Ground Water	Surface Water
Total dissolved solids	Higher	Lower
Suspended solids	Lower	Higher
Turbidity and color	Lower	Higher
Alkalinity	Higher	Lower
Total organic carbon	Lower	Higher
Microbiology:		
Protection from bacteria and viruses	Highly protected	Highly susceptible
Protection from protozoa	Almost completely protected	Highly susceptible
Presence of iron and/or manganese bacteria	Common	Rare
Hydrogen sulfide gas	Common	Uncommon
Aeration/dissolved oxygen	Lower	Higher
Temperature	More consistent	More variable
Flow rate	Very slow (1 m/day)	Very fast (1 m/sec)
Flow pattern	Laminar	Turbulent
Susceptibility to pollution through surface run-off	Low	High
Time for a contaminant plume to resolve	Very long—often decades, potentially centuries!	Usually short—day/months; sometimes years

Source: Developed by the author (1997).

1. Surface Water Supplies

In general, surface supplies can be highly variable in every respect—chemically (total dissolved solids, alkalinity, etc.), microbiologically (bacteria, viruses, etc.), and physically (turbidity, color, etc.). Many surface waters are easily subject to contamination which may present in many forms, including: 1) bacteria and other organisms from animal wastes via direct introduction (animals) or indirect introduction (poorly or untreated wastewater); 2) algae blooms, which are typically acute, seasonal events; 3) "natural" chemical contamination as evidenced by high levels of natural organic matter (primarily the humic substances from decaying vegetation and animal waste); and 4) "synthetic" chemical contamination from surface runoff (outflow) of agricultural chemicals (pesticides, herbicides, insecticides, etc.).

Again, it must be underscored that the characteristics above, and those that follow, are intended to provide general trends in terms of water composition and characteristics. During the author's industrial tenure, exceptions to virtually every characteristic described have been observed.

a. Streams

In general, streams are often of reasonable chemical/physical composition. Due to their locations and physical dimensions, they offer easy access for a multitude of animal life.

With this comes the frequent introduction of microorganisms of fecal origin, in addition to appreciable amounts of organic matter. This organic material is typically considered the precursor material of trihalomethanes and a host of other chemical by-products which can be formed once this water supply is disinfected. Smaller streams are often influenced by rain events, whereby their flows are increased, with subsequent increase in suspended solids and turbidity. Larger streams are generally at higher risk of having industrial waste (often poorly or inadequately treated) discharged into them. They are often more of a concern, due in part to their larger surface area, in terms of accepting surface runoff and subsurface drainage.

b. Lakes

Natural lakes, due to their relatively stagnant flow patterns, coupled with their long water residence time, are usually of consistent composition insofar as surface supplies are concerned. One major climatic event which may have drastic changes in lake water quality, is the phenomenon of seasonal inversion. This refers to the phenomenon whereby water at the surface of the lake reaches a temperature at which it is most dense (3.98ºC, or 39.2ºF). The water below it has not yet reached this state, therefore, a density and temperature gradient are formed. This "heavy" water then begins to descend, and displaces the water below it. This displaced water then inverts (hence the term "inversion"), and moves from the bottom of the lake toward the upper portion. This agitation brings with it much of the sediment, and associated unwanted components, which make municipal and industrial monitoring even more critical during this time. As you might imagine, this phenomenon of inversion and its related thermal stratification, are actually much more complex, and their effects on aquatic life and the eutrophication process (basically, the nutrient enrichment of a body of water, usually lakes or ponds, which results in certain forms of algae growth and some higher plant life) have been studied under many other scientific disciplines. Unfortunately, as is the case with many large streams, industrial waste effluent and sewage treatment plant discharge are often re-introduced into the same lake that originally supplied the influent water. These practices are coming under more scrutiny, and there is ever increasing political pressure for regulatory reform.

c. Reservoirs

Impounding reservoirs, or "man-made" lakes, are similar in overall characteristics to those described above for natural lakes. They are often regarded as huge storage reservoirs for municipal water supplies prior to treatment. As surface supplies go, reservoirs are of fairly consistent quality, reasonable turbidity (due in large part to natural oxidation and settling mechanisms), and often afford lower bacteria counts than other surface supplies (6). However, as a consequence of their relatively low flow patterns and lack of agitation, algae blooms are often a problem.

d. Rivers

Rivers represent perhaps the most difficult of the surface supplies to address. In general, they are of highly inconsistent quality, very high turbidity and suspended solids, prone to considerable temperature fluctuations, and vary widely with respect to their flow patterns (that is, areas of excessive turbulence, and areas of minimal movement may exist within close proximity to each other). Rivers, as a result of their great length and flows, are recipients of surface runoff from many types of areas. For example, a river might flow across areas of agrarian activity, with the potential to incorporate pesticides, herbicides, nitrate, and other contaminants along its route. This same river might later flow through an industrial zone, pick up run-off from poorly contained chemical storage tanks, drains, sewers, etc., and possibly even meet the discharge of one or more municipal waste treatment plants! Imagine the contaminant "soup" that would result. For this reason, any methods of treatment for river water must be preceded by thorough characterization of the supply. The treatment itself must be capable of addressing a wide range of quickly changing water quality.

2. Ground Water Supplies

In comparison to surface supplies, ground water supplies are generally more consistent in every respect—thermally, microbially, chemically, and physically. They have historically been considered a much safer supply, or one which produces "purer" water. Two hundred years ago, this blanket statement might have been more universally true. Along with the development of the chemical and related industries came the increased potential for ground water contamination. Prior to this, the concerns over ground water were few—maybe the well was dug a little too close to the septic tank or cess pool, and incidences of diarrhea and other gastrointestinal ailments were increasing (so "let's dig another one farther away," or "let's dig this one a little deeper" were the seeming solutions). Possibly the well was under the influence of a salt water or brackish supply, and intrusion of high levels of salts were becoming evident (usually noticed by taste). In many cases, the two former solutions would have applied here as well.

Though this previous discussion has been a gross over-simplification, the facts remain that, with increasing industry, came increasing underground chemical storage—increasing contaminant spills—increasing numbers of poorly located and/or poorly constructed septic systems, along with a host of other problems for the ground water environment that needed to be addressed (and, in fact, many still do).

As with surface water supplies, there are different classifications of ground water—some more preferred than others. A brief discussion of each, in terms understood by the novice hydrogeologist (which is a discipline becoming increasingly important for anyone involved with water operations to know), follows below.

a. Aquifers and the underground environment

An aquifer (7) is defined as "a geologic formation with sufficient interconnected porosity and permeability to store and transmit significant quantities of water under natural hydraulic gradients." Critical terms in this description are "store," "transmit," and "significant quantities." All three should be satisfied to consider a supply an aquifer. The first two are straightforward—huge amounts may be stored, but unable to be transmitted—in which case, this supply, however large, should not be considered an aquifer. The third term, "significant quantities" is more nebulous and linked to the intended use of the supply—for example, a residential well, a large municipality, or multiple industrial users tapped into a community well. Clearly, "significant quantities" would be defined differently for these three applications. Before discussing aquifers in more detail, Figure 193.2 which follows should be reviewed. It describes the different layers or zones encountered as we move downward from the surface of the ground to the water bearing strata below it.

As we move from the surface, the first zone encountered is the "unsaturated zone" (also referred to as the "vadose zone"). In this area, the geologic media (dirt, clay, sand, etc.) contains a mixture of water and void spaces with air—hence, the terms "unsaturated" or "variably saturated." Continuing downward, we reach the "capillary fringe," which is generally considered the beginning of the "saturated zone," but is sometimes considered a distinct entity. This interface between unsaturated and saturated zones is not completely understood, and is the subject of much study with regard to movement of certain contaminants within it. The "saturated zone" is the area where air is at a minimum, and water is at a maximum. The geologic media here are saturated with water. Dissolved oxygen in the saturated zone is extremely rare; many deep ground water formations exist under anaerobic or hypoxic conditions. It is within the saturated zone where actual ground water supplies are found, and where most production wells are placed. Throughout the saturated zone, many strata of varying permeability will be found. Most importantly, this is where we find our aquifers.

b. Unconfined and confined aquifers

Aquifers may be grouped into two broad categories: 1) unconfined aquifers, and 2) confined aquifers. Unconfined aquifers (sometimes referred to as "water table aquifers") are those water bearing, geologic formations which are under atmospheric pressure at their upper boundary. The "water table" (sometimes referred to as the "phreatic surface") is the upper boundary of the saturated zone. Water levels in wells which tap unconfined aquifers should be the same as the level of the water table. The plane which connects the upper levels of water in all wells which penetrate unconfined aquifers is known as the "potentiometric surface." Confined aquifers (sometimes called "artesian aquifers") are those water bearing, geologic formations whose upper and lower boundaries are comprised of geologic material of low permeability, and which are under pressure greater than atmospheric. Older definitions may describe the boundary layers (or "confining layers") of a confined aquifer as being of no permeability (that is, "impermeable"). This is inaccurate, as

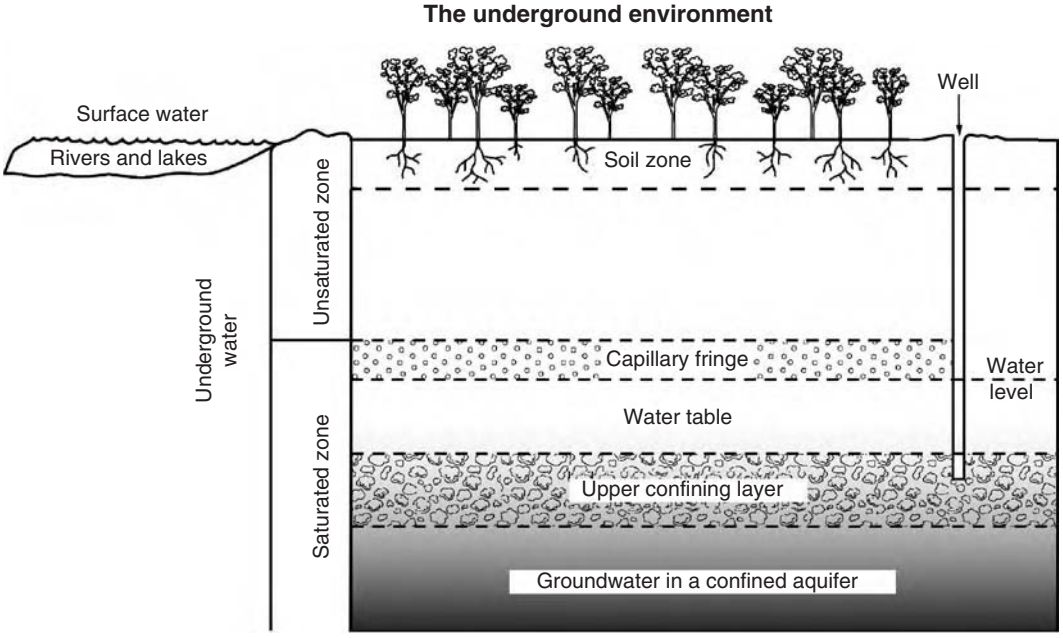

FIGURE 193.2 The underground environment.

even the least permeable geologic materials still exhibit some degree of permeability. Some hydrogeologists further classify these confining layers accordingly, as aquitards, aquicludes, and aquifuges. While all three exhibit very low permeabilities, aquitards are the most permeable of the three, followed by aquicludes, and finally aquifuges, which are as close to impermeable as we know. Confined aquifers are sometimes further described as "semiconfined" (also, "partially confined," or "leaky confined") or "highly confined" (also, "fully confined"), depending on the leakage or seepage through the confining layers.

Just as the water in unconfined aquifers will form a potentiometric surface, or water table plane, the water levels in wells tapping confined aquifers will also form a plane. It may still be referred to as a "potentiometric surface," but, intuitively, not a "water table plane." In the case of confined aquifers, due to the internal pressures, the water levels in wells which tap them may often exceed the level of the water table (which may result in a "flowing artesian well"). In the beverage industry, conversational knowledge of confined and unconfined aquifers will account for nearly all of the hydrogeologic discussions into which a beverage technologist might become engaged. For purposes of completeness, two more topics will be briefly addressed below.

In addition to aquifers being classified as confined or unconfined, the geologic material of the aquifer may be described as consolidated or unconsolidated. "Unconsolidated" deposits are formed from loose geologic material, such as sand, clay, silt, gravel, and even sea shell remains. "Consolidated" deposits are formed by mineral particles combining from heat and pressure, or via chemical mechanisms. They include sedimentary (previously unconsolidated) rocks, such as limestone, dolomite, shale, and sandstone; igneous (formed from molten) rocks, such as granite and basalt; and metamorphic rocks, such as limestone and gneiss (8). Fractured rock formations almost always refer to fractures or fissures in consolidated deposits. Ground water and contaminant flows through this type of formation are highly unpredictable, since it is difficult to determine which route the water will take through this hard rock maze. Carbonate aquifers (also "karstic formations") are formations of limestone and other water-soluble rocks whose fractures have been widened by erosion to form sinkholes, caves, or tunnels (9). As you might expect, with such little resistance, the flows through fractured and carbonate formations can be rapid enough to rival surface water sources. Flows, though rare, have been reported up to 1500 feet per day.

B. Source Selection Considerations

The categories above briefly discussed the major sources of supplies for potable water. Obviously, there are others (oceans, lagoons, glaciers, etc.), and many possible combinations of supplies. Remember, the keys to any consideration of a water source are:

1. First and foremost, its sanitary quality, wherever possible. In some areas of the world, the potability of a supply—even a municipal supply—may not be guaranteed.
2. Chemical/physical quality—is it safe? Is it too high a risk to even consider? Can it be treated economically and within regulatory guidelines? These questions must be answered on a case-by-case basis, and will depend on the degree of due diligence desired by a parent company, presiding regulations, corporate policies, and the risk assessment of the impurities themselves.
3. Consistency of composition—is it consistent? Will it vary beyond the capability of the proposed treatment? Gathering any and all available data will aid in answering this question. Make use of municipal monitoring data, rainfall data, hydrogeologic or surface water surveys, etc.
4. Volumes/supply—can it currently meet your needs? Will it in the future? In addition to the quality and safety components, supply is a key parameter to help ensure that the volume of water will be available for the long-term needs of the business. In many areas, the volume of withdrawal of water from an aquifer falls under government control or guidance, and this must be considered.
5. Its recharge—is run-off a concern? This is related to the previous discussion in this chapter of the hydrologic cycle. The volume of recharge, or replenishment, of the aquifer is important, as is the quality and origin of the water being used for that recharge.
6. Future plans for the source or surrounding areas—is a municipality planning to develop the source and treat it? Are there multiple taps? Is there planned construction or industrial entry to the area? These questions highlight the value of considering water a dynamic ingredient throughout its supply chain. Many beverage plant issues have resulted from municipal water treatment plant operators effecting a change to the municipal treatment without alerting the beverage plant personnel. For example, if polyphosphate use is instituted by a municipality for corrosion control within their distribution system, this could result in a gross upset to the floc formation in conventional lime treatment systems.

Water, unlike virtually any other raw material, often does not provide an opportunity for sourcing from an

alternate supplier. Consequently, selection of a source after thorough characterization is paramount, and subsequent treatment design is critical to helping assure that only a safe, consistent, high quality treated water is used by food and beverage plants.

C. Specifications and Guidelines

Frankly, in the Unites States, Canada, the European Union, and most other first-world countries, the expectations for water treatment are clearly delineated by the regulatory agency having jurisdiction. That is, drinking water must meet the National Primary Drinking Water Standards (10, 11) promulgated by the Unites States Environmental Protection Agency, the Directive of the European Union on the Quality of Water Intended for Human Consumption (12), or some analogous drinking water standard. Indeed, many of these standards are founded, to varying degree, on the Guidelines for Drinking Water Quality established by the World Health Organization (13, 14). Packaged water, or the water used to make carbonated beverages, usually has corresponding regulations. In the US, for example, the Food and Drug Administration established a bottled water standard of identity, which, with only a few exceptions, mirrors the EPA's Drinking Water Standards.

The challenges come when we establish our beverage businesses in second- and third-world countries where the regulatory standards are perhaps not as refined as for those countries mentioned previously. In these countries, the beverage producer is not afforded the luxury of knowing that the water entering their plant will consistently meet USEPA drinking water standards—or the EU Standards for water intended for human consumption. In these situations, it becomes even more critical that rigorous water source assessment, careful treatment selection, and conscientious long-term monitoring are performed with even greater diligence.

Table 193.4 was compiled by the author for informational purposes only to compare the major standards for drinking water around the globe. The National Primary Drinking Water Standards of the USEPA are compared to the EU Standards for Water Intended for Human Consumption, and finally with the Guidelines for Drinking Water Quality of the World Health Organization.

For a beverage producer, as is likely the case with any of our food industry allies, we cannot—and should not—rely on any external body to assure the quality and consistency we require for the production of our trademark products. Certainly, a conscientious municipal monitoring scheme established by the EPA or analogous regulatory organization often increases our confidence that a particular water supply will reach our plant with some level of safety and consistency, but this should not be expected; rather, it should be viewed as an added benefit to complement our already-dependable in-plant treatment system.

III. WATER TREATMENT

A. Goals of Treatment

In light of the mounting scientific evidence for the myriad chemical compounds related to their adverse health effects—at a time when carcinogen, mutagen, and teratogen are practically becoming part of the vernacular—the primary reason for water treatment is to safeguard public health and safety. All other reasons for treatment fall second, and include the following:

1. To assure compliance with all levels of regulatory guidelines and mandates. The product water for carbonated soft drinks has historically had to meet not only the primary drinking water standards of the U.S. Environmental Protection Agency (in the United States), but all applicable local standards as well. This same philosophy of multiple levels of compliance holds true as we look at the international arena as well. Here, compliance will be driven not only by national standards (often founded to varying degree on the World Health Organization Guidelines for Drinking Water), but also by local (state, regional, etc.) regulations and codes germane to each product category (bottled water, natural mineral waters, juice drinks, teas, etc.).
2. To achieve specific product characteristics and improve product shelf-life. Certain soft-drink products require ingredient water of varying composition. By utilizing a variety of water treatment unit operations, the requisite composition can be achieved (for example, ion-exchange demineralization for those products sensitive to the profile of dissolved ionic solids). In addition, the shelf-life of the individual product is often prolonged by removal of troublesome components that could potentially result in aesthetically displeasing precipitation (for example, preventing the precipitation of calcium oxalate salts in tea by limiting the incoming calcium load).

As mentioned above, the wide range of chemicophysical characteristics required of our ingredient water mandates the utilization of a variety of water treatment technologies. Selection of the appropriate treatment chain is based upon several factors, including, but not limited to: 1) water source—aquifer and watershed characteristics, municipal supply/consistency, location, etc.; 2) proposed technology capability relative to raw water analyses and desired product characteristics—removal of organics, inorganics, disinfection/inactivation, color and odor control, etc.; 3) recommended support technology—filtration, preozonation, iron/manganese removal, etc.; 4) costs vs. finished water profile—initial investment, operating costs,

Notes and abbreviations:

- Blank cells indicate the absence of a standard for that parameter
- Chemicals that have been assigned a "provisional guideline" value by the WHO, or a "proposed MCL" by USEPA, are included in the table above, and are followed by the letter "P."
- Chemicals listed by WHO as "not of health significance at concentrations normally found in drinking water" are designated with the letter "U."

(*Continued*)

TABLE 193.4 (*Continued*)

- Chemicals evaluated by WHO and assigned the status of having "no adequate data to permit recommendation of a health-based guideline value are designated with the letters "NAD."
- 1° refers to the primary maximum contaminant levels (MCL) established by EPA, which are enforceable limits.
- 2° refers to the secondary maximum contaminant levels (SMCL) established by EPA, which are generally not enforceable on a federal level.
- MCLG = Maximum contaminant level goal
- GV = Guideline Value, a maximum level recommended by WHO for the provision of safe drinking water
- MRDL = Maximum Residual Disinfectant Level, established by the USEPA
- WHO = World Health Organization
- EPA = United States Environmental Protection Agency
- EU = Member States of the European Union
- TT = Treatment technique, an approach developed by EPA to provide direction to municipalities as to which parameters require installation of an acceptable treatment technique to demonstrate reduction of the respective contaminant(s).
- TCU = Total Color Units
- Co-Pt = Cobalt Platinum Color Units
- NTU = Nephelometric Turbidity Units
- TON = Threshold Odor Number
- uS/cm = microsiemens per centimeter, a standard expression of conductivity
- mSv/year = milliSievert per year, a standard expression of committed effective dose of radiation
- pCi/L = picoCurie per liter, the U.S. expression of the activity of ionizing radiation
- Bq/L = Becquerel per liter, the Standard International (SI) system of expressing activity for ionizing radiation:

  1 Curie = 3.7×10^{10} Becquerel

  1 pCi = 10^{-12} Ci

  therefore, pCi/L $\times$ 0.037 = Bq/L
- mrem/year = milliroentgen equivalent man per year, the U.S. expression of radiation dose; applies to total body and individual organ exposure, calculated on the basis of a two liter per day drinking water intake.
- In most cases, standard IUPAC chemical nomenclature was applied, so the unsaturated alkene family of compounds will end in the suffix "-ene." Be aware that some regulatory agencies continue to use the older common names, which bear the suffix "-ylene." So, for example, "trichloroethene" and "trichloroethylene" are the identical compound.

equipment serviceability/parts accessibility, etc.; and 5) contribution to plant effluent—total dissolved solids, water volume to drain, etc.

Where ingredient water for production of soft drinks is concerned, the typical "fleet" of treatment technology available to the beverage industry includes:

1. Conventional Lime Treatment Systems (CLTS)—coagulation/flocculation, hydrated lime, superchlorination. This treatment chain represents the majority of most beverage treatment armadas worldwide. Historically, and as little as 25 years ago, this combination of treatment was regarded as the "ideal" treatment for raw water of virtually any quality. Indeed, this system, coupled with the required support technology—fine sand filtration, granular activated carbon, polishing filtration, and ultraviolet irradiation—does address a broad range of water contaminants.
2. Ion-exchange. This technology is routinely utilized for partial or complete demineralization,

softening, dealkalization, or can be customized for selective removal of a specific contaminant (for example, denitratization).

3. Membrane technology. Clearly, this has seen the most growth in recent years with the advent of more resistant membrane materials of construction and more flexible rejection characteristics. Included in this category is the prototype of the cross-flow, polymeric membrane filtration systems—reverse osmosis, along with nanofiltration and ultrafiltration (both polymeric and ceramic). Also among this group is electrodialysis technology for removal of ionic species in water, and continuous electrodeionization.

B. Primary Treatment Technology

1. Conventional Lime Treatment Systems

Conventional Lime Treatment Systems (CLTS), sometimes also referred to as traditional coagulation or the cold lime process, remains one of the most common treatment techniques employed in the carbonated beverage industry. Five years ago, one estimate placed approximately 85% of beverage water systems using conventional lime treatment (personal communication, Harry Delonge, 1996), but this number has been steadily decreasing over the years, with this treatment modality being replaced by membrane systems. Operationally, at its most fundamental level, CLTS involves mixing three chemicals—a chlorine source, a coagulant, and hydrated lime—together in a reaction tank, and allowing a contact time of at least two hours for the ensuing reactions to proceed. The hydrated lime (traditionally called "lime," even though calcium oxide is rarely used) increases the pH of the water in the reaction tank to above 9.6, thereby converting the naturally occurring bicarbonate alkalinity components to carbonate alkalinity. This is a critical reaction, since at this pH, calcium carbonate is virtually insoluble in water, and begins to precipitate from solution. At the same time, the coagulant, aided by steady, non-turbulent mixing, is overcoming the repulsive negative charges present on natural organic debris in the water supply. This charge neutralization and subsequent destabilization allows the coagulant to form a floc of ever-increasing size and density. As it forms, it incorporates the precipitating calcium carbonate, along with a host of other particulates present in the incoming water. The chlorine source in conventional systems serves a dual purpose: 1) oxidation—both of the soluble ferrous sulfate coagulant to the insoluble ferric form, and of metallic contaminants like iron, manganese, arsenic, and others; and, 2) disinfection of the water in the reaction tank. The efficiency of disinfection in these systems will be discussed in more detail at a later point in this chapter. However, at high pH values (typically the range used in CLTS), the dissociated chlorine equilibrium favors the existence of the hypochlorite anion, which is approximately 100 times less effective as a germicide than the dominant species at lower pH (hypochlorous acid). From a microbial safety perspective, if the adequate free chlorine dosage is maintained in the reaction tank over the entire course of the two-hour contact time, this will afford excellent bacterial and viral destruction. The protozoans, like *Cryptosporidium* and *Giardia*, being more resilient to chlorine, will be less affected by the chlorine at the high pH employed in conventional lime treatment systems. However, the chlorine, aided by the physical entrapment and removal of these organisms during the coagulation process, will still typically result in a substantial reduction in their numbers. Indeed, conventional coagulation is one of the effective barriers in a multiple barrier approach against protozoans.

This floc that forms over the course of the two-hour reaction time in conventional systems continues to grow in size and bulk, enmeshing suspended solids, particulates, oxidized metals, organic debris, and a host of other impurities, and eventually settles toward the bottom of the reaction tank. The settled floc comprises the "sludge" associated with these conventional lime treatment systems, which must be frequently discharged in order to keep this system in equilibrium. As the impurity-laden floc is discharged from the bottom of the reaction tank, the treated water—now free of debris, low in alkalinity, sanitized, and of a generally high quality—is withdrawn from the top of the reaction tank to undergo further treatment through support processes prior to being used for final product. Table 193.5 summarizes the advantages and disadvantages of these treatment systems. From a water safety perspective, conventional lime treatment continues to offer excellent removal of a variety of water impurities.

TABLE 193.5
Advantages and Disadvantages of Conventional Lime Treatment Systems

Advantages	Disadvantages
Removes alkalinity and hardness	Does not effectively reduce nitrate, sulfate, or chloride concentration
Removes organic debris, particulates, and natural organic matter (NOM)	Sludge formation and disposal requirements
Reduces metal concentrations (iron, manganese, arsenic, others) and some radionuclides	May promote the formation of disinfection by products (trihalomethanes) under certain conditions
Reduces some color compounds (tannins), off-tastes, and off-odors	Often difficult to operate consistently in waters with very low dissolved solids
Reduces bacteria, virus, and protozoan populations	Relatively large space requirements on plant floor ("foot print")

It is often adequate as a primary treatment for many beverage water purification applications, but may also be used as a superb pretreatment for membrane processes, ion-exchange, or electrodialysis.

2. Membrane Technology

Membrane technology, in the application of water treatment for the beverage industry, encompasses a broad range of polymeric and ceramic impurity removal techniques. This may range from the use of a simple ten-micron microfilter to help remove granular activated carbon fines to employment of the prototype polymeric membrane technology—reverse osmosis. Figure 193.3 depicts the Filtration Spectrum, which provides a visual representation of the relative particle size removal which may be expected of the common membrane processes, including—in order of decreasing pore size—microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. As we can see from the spectrum, particulate filters may be used for the removal of relatively large suspended matter, and are often employed at the end of a water treatment chain as a "polishing filter" to remove any small floc particles, oxidized iron, carbon, or precipitated calcium carbonate that might have carried over from the primary treatment process. Microfilters are often used for their controlled pore size distribution (when absolute rated), which makes mechanical removal of bacteria from water streams commonplace. Often, for this application, a stepped removal approach is employed which will include filters of decreasing pore size oriented in series, so as to minimize the plugging potential of the smallest pores (for example, a five or ten micron particulate filter, followed by a 0.45 micron microfilter, and finally as low as a 0.2 micronfilter to help assure adequate bacterial reduction). Ultrafiltration (either polymeric or ceramic) is an excellent tool for the removal of particulates, large organicmatter (for example, the humic and fulvic acids which comprise natural organic matter in water supplies), and many types of microorganisms, including viruses, bacteria, and protozoa. However, for removal at the level of dissolved inorganic salts, nanofiltration and reverse osmosis are our only two feasible options. Table 193.6 comparesthe typical removal percentages of reverse osmosis, nanofiltration, and ultrafiltration for a variety of water impurities (15).

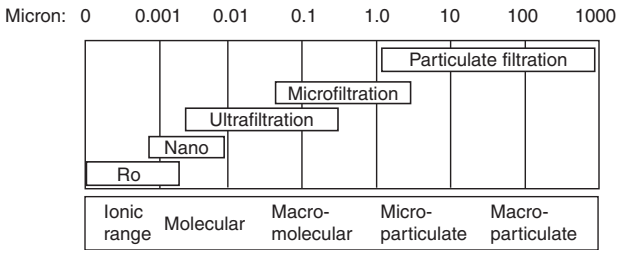

FIGURE 193.3 The Filtration Spectrum.

TABLE 193.6
Comparison of Reverse Osmosis, Nanofiltration, and Ultrafiltration Membrane Processes

Component	Reverse Osmosis	Nano Filtration	Ultrafiltration
Alkalinity	95 to 98%	50 to 70%	None
TDS	95 to 98%	50 to 70%	None
Particulates	nearly 100%	nearly 100%	nearly 100%
Organic matter	most >100 MW	most >200 MW	some >2000 MW
THM precursors	90+%	90+%	30 to 60%
Sodium	90 to 99%	35 to 75%	None
Chloride	90 to 99%	35 to 60%	None
Hardness	90 to 99%	50 to 95+%	None
Sulfate	90 to 99%	70 to 95+%	None
Nitrate	90 to 95%	20 to 35%	None
Protozoa	near 100%	near 100%	near 100%
Bacteria	near 100%	near 100%	near 100%
Viruses	near 100%	near 100%	near 100%
Operating pressure	200 to 450 psi	100 to 200 psi	80 to 150 psi

Approximate removal percentages. Actual performance is system-specific.

The driving force behind the membranes used in water treatment applications for the beverage industry is pressure, which is applied across the membrane to force the filtered or purified water through the membrane, leaving the unwanted impurities behind. This concept becomes even more critical when describing the operation of a reverse osmosis membrane system. To understand "reverse" osmosis, we must first understand "osmosis." According to The Drinking Water Dictionary (16), osmosis is a "natural phenomenon whereby water (or some other solvent) diffuses from the lower-concentration side to the higher-concentration side of a permselective (semipermeable) membrane barrier in a process of equalizing concentrations on both sides." The corresponding osmotic pressure is the pressure exerted on the solution at equilibrium as a result of osmosis. This is illustrated in Figure 193.4.

In "reverse" osmosis, we apply a pressure to the concentrated side which is greater than the osmotic pressure, which thereby reverses the osmotic flow. The result is that the water now flows across the reverse osmosis membrane in the opposite direction to what was just described above with osmosis. The water is forced from areas of high to low solute concentration, thereby leaving a very concentrated salt stream behind on the waste side of the membrane, and a very dilute, purified water stream on the product or permeate side of the membrane. This is depicted in Figure 193.5. This is an important concept to visualize, since it is this osmotic pressure control which

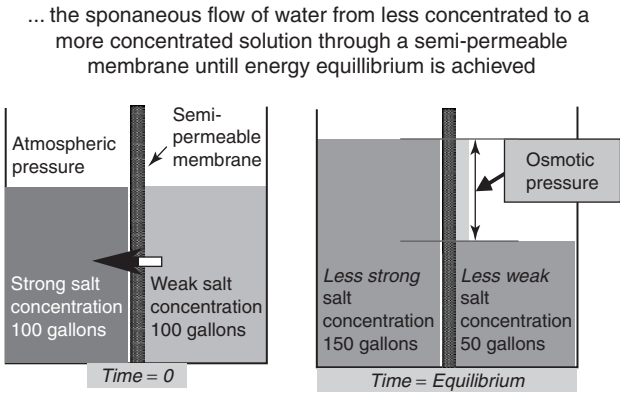

FIGURE 193.4 Osmosis.

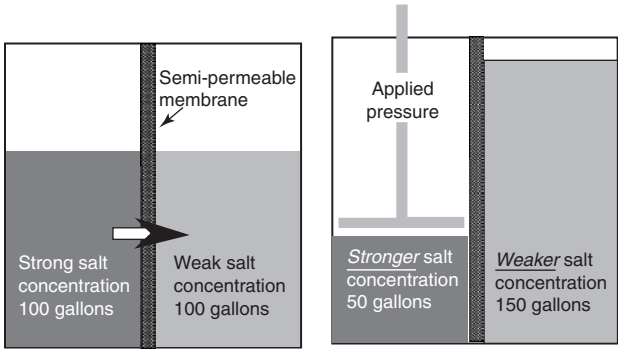

FIGURE 193.5 Reverse osmosis.

allows reverse osmosis to remove impurities from water down to the level of dissolved ionic species. In fact, reverse osmosis can afford removal of from 95 to greater than 99% of many dissolved salts, resulting in a treated water exiting the system with a total dissolved solids (TDS) concentration often below 10 mg/L, within the range of many distilled water products.

Though ultrafiltration, nanofiltration, and reverse osmosis all afford efficient removal of many microbial impurities, a critical point which must be understood is that none of these processes—not even reverse osmosis—produces a commercially sterile water. This is still a common misconception among many in the beverage and allied industries. Owing to the nature of cross-flow technology, the high pressures used, integrity of the seals, and variability in the pore structure of the membrane materials, these membrane treatment operations will remove a large percentage of the microorganisms to which they are introduced, though not all. If these processes are used as a primary treatment, this should not preclude the need for additional disinfection of the water supply.

Key considerations when selecting and designing nanofiltration and reverse osmosis treatment systems are the choice of proper pre- and post-membrane treatment operations. The primary goal of pretreatment processes is to protect the integrity of the membranes, since they often represent a substantial portion of the capital cost. These polymeric membranes, usually some form of polyamide, though traditionally also available as cellulose acetate, are susceptible to a variety of processes and impurities which may foul or degrade them, thereby rendering them inefficient, ineffective, or, in the worst case, totally destroyed. In general, the pretreatment processes will involve reducing the silt density index (plugging potential) of the feed water to the membrane. This is often accomplished by filtration through sand or mixed media, or via in-line coagulation. Pretreatment also includes some form of chlorine control—either assuring that it is removed (in the case of polyamide membranes), or assuring that it is present to prevent biologic degradation of cellulose acetate membrane materials. Finally, the pretreatment processes will normally include the in-line dosing of acid, antiscalant, or both. These steps help prevent a loss of membrane performance due to metal oxide fouling, scaling, or related processes which might occlude the membrane pores. Table 193.7 summarizes the various processes which may cause fouling (usually partially or completely reversible) or degradation (usually irreversible) of nanofiltration and reverse osmosis membranes. Potential solutions are also listed.

The post-treatment of water exiting nanofiltration and reverse osmosis membrane systems is also important, and should be carefully considered. Unlike prior to treatment, once the water has passed the membrane modules, it will be considerably more pure than when it entered. As a result, much of the microbial load is gone, as are many of the chemico-physical impurities. However, as we stressed previously, these membrane processes should not be relied upon to produce a consistently commercially sterile water. Consequently, post-treatment operations may include chemical or ultraviolet disinfection, granular activated carbon treatment, and polishing filtration. In-plant process monitoring is as critical with membrane processes as it is for any other treatment modality, and will usually include microbial monitoring to help gauge biofouling of the membranes, total dissolved solids or conductivity to assess the gross rejection of the membranes toward inorganic salts, pH, silt density index, chlorine residuals, and any other parameters assigned by the parent beverage company or suggested by the equipment supplier.

The advantages and disadvantages of reverse osmosis, as the "gold standard" of membrane removal processes, are summarized in Table 193.8

3. Ion-Exchange

The process of ion-exchange, like conventional lime treatment systems, has been known to the beverage industry for decades. However, its early applications did not typically include the water to be used for product, but rather

TABLE 193.7
Causes of Fouling and Degradation of Reverse Osmosis and Nanofiltration Membranes, Along with Possible Solution

FOULING		DEGRADATION	
Problem	**Potential Solutions**	**Problem**	**Potential Solutions**
Suspended solids (in feed water)	• Multimedia filtration (sand, greensand, carbon) • Ultrafiltration • Microfiltration • Plate and frame filtration with diatomaceous earth • Cartridge filtration • In-line coagulation • Coagulation	Oxidation	• Proper membrane selection • Disinfectant removal if required by membrane (carbon, bisulfite) • Proper dosing and feedback controls
Oxidation of metallic components (iron, manganese, etc.)	• Oxidation (aeration, ozonation, chlorination, etc.); filtration • Greensand filtration • Coagulation/lime treatment • Acid feed	Hydrolysis (membrane break down at low pH)	• Proper membrane selection • pH control (both operating range and cleaning range) • Controlled acid feed
Precipitation/scaling (sulfates, carbonates, silicates, etc.)	• Limit recovery (in design phase) • Antiscalant addition • pH control • Lime softening • Ion-exchange	Bacterial attack (especially for unprotected cellulose acetate membranes)	• Proper membrane selection • Periodic membrane cleaning and sanitizing • Proper pretreatment
Microbial growth (biofilm formation)	• Chemical disinfection • Ultraviolet disinfection • Periodic membrane cleaning and sanitizing	Solubilization (not very common in the beverage industry, but due to high concentrations of organic compounds with solvent properties)	• Removal of compounds prior to membrane contact; usually via aeration or granular activated carbon

Source: Developed by the author (1996).

involved softening of the water (removal of calcium and magnesium) used for auxiliary plant purposes in order to prevent scaling or avoid loss of efficiency in heat exchangers, boilers, and bottle washers. Today, with the advent of many categories of resin materials, ion-exchange is another of the valuable tools used by the beverage water technologist to help assure that the treated water used meets all of the applicable standards and guidelines expected.

In its most fundamental form, ion-exchange, as the name implies, involves replacing an ion which is less desirable in a particular application with one that is more desirable. In the case of the early softeners mentioned above, natural ion-exchange materials (called zeolites) were employed to exchange the hardness components (calcium and magnesium) in water with sodium. The rationale here was that calcium and magnesium salts may often precipitate as scale inside equipment; the corresponding sodium salts, however, were much more soluble, and hence did not pose a scaling concern. In this example, the supply of sodium on the zeolite to be exchanged for calcium and magnesium is not present in endless supply. Therefore, once the resin material is exhausted, it must be replenished—or "regenerated"—with a new supply of the appropriate ion; in this case, the sodium zeolite softeners are typically regenerated with brine (sodium chloride solution). Here the excess of sodium overcomes the calcium and magnesium attached to the resin, and they are washed to the drain. The resin, now fully regenerated, is again ready to be put into service. Figures 193.6 and 193.7 illustrate the exchange of sodium for calcium and magnesium, and the regeneration of the resin, respectively.

Ion-exchange applications have broadened far beyond zeolite softening, and include complete demineralization (reduction of the total dissolved solids to near zero, if desired), dealkalization (removal of alkalinity and hardness at the same time), anion or cation exchange alone, denitratization (nitrate removal), and a variety of other specialty applications, which include removal of silica, natural organic matter, iron, and other targeted impurities. The specific application depends largely on the structure of the resin material used, the characteristics of the water being treated, and the desired treated water profile.

Ion-exchange resins for most beverage water treatment operations may be divided into two major categories:

TABLE 193.8
Advantages and Disadvantages of Reverse Osmosis Systems

Advantages	Disadvantages
Removes nearly all suspended material, and greater than 99% of dissolved salts in full-flow operation	Pretreatment must be carefully considered, and typically involves operating costs for chemicals (acid, antiscalant, chlorine removal)
Significantly reduces microbial load (viruses, bacteria, and protozoans)	Does not produce a commercially sterile water
Removes nearly all natural organic matter (NOM)	Membranes still represent a substantial portion of the capital cost, and may typically last 3-5 years
May be designed as a fully automated system with little maintenance	Low solids water may be aggressive toward piping and equipment, so this must be considered for downstream operations
Relatively small space requirements on the plant floor ("footprint")	High pressure inlet pump is required

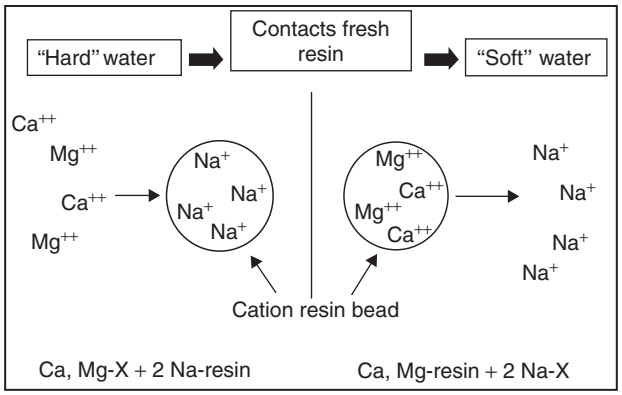

FIGURE 193.6 Ion-exchange reactions (softening).

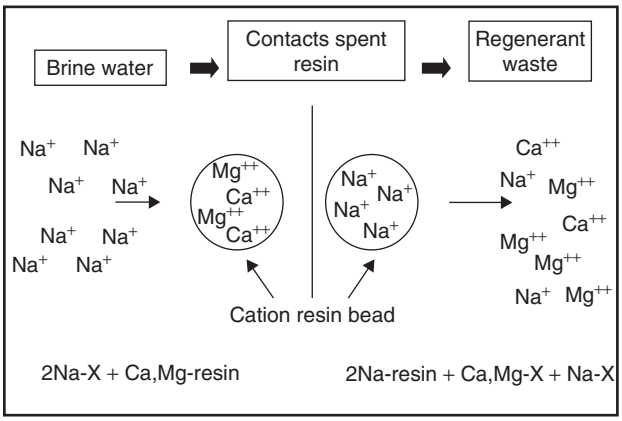

FIGURE 193.7 Ion-exchange regeneration (softening).

1) cation resins, which remove positively charged ions (cations) like calcium, magnesium, and sodium, and which require regeneration with brine or a mineral acid; and, 2) anion resins, which remove negatively charged ions (anions), like nitrate, sulfate, and chloride, and which require regeneration with brine or alkali. Each of these categories may be further divided into "weak" and "strong" subdivisions—that is, weak acid and strong acid cation exchange resins; and weak base and strong base anion exchange resins. Due to the nature of the chemistry at work, the "cation" and "acid" belong together, as do the "anion" and "base." The term "weak" refers to the functional moiety on the resin itself, and the fact that these resins will remove the "weakly" bonded ions in their respective class, whereas the "strong" resins will remove both weakly and strongly bonded ions in their groups.

An increasingly popular ion-exchange application for the beverage industry involves the use of a weak acid cation exchange resin. This resin is typically charged with acid, and, instead of sodium (as in the zeolite softener) these resins will exchange the acid proton, or hydrogen ion for weakly bonded cations in the water. The predominant cations removed are those that comprise hardness, calcium and magnesium. In addition, some sodium may be removed in the process, but only after the hardness is removed. As the hardness is removed, and exchanged for hydrogen ions, these hydrogen ions combine with the naturally occurring bicarbonate alkalinity in the water to form carbonic acid (H_2CO_3). This newly formed carbonic acid quickly dissociates into water and carbon dioxide, and the carbon dioxide is usually removed with a downstream degasifier. By forming the carbonic acid and removing the carbon dioxide, the alkalinity of the water is reduced proportionately. Hence, the weak acid cation exchange resin, in the acid form (as opposed to the sodium form, as the zeolites), removes both hardness and alkalinity in one treatment unit. The caution with this application is that, if used alone, other operations must accompany the ion-exchange—for example, disinfection, filtration, activated carbon, etc.—since softening and alkalinity removal are the major benefits of this treatment. If anion impurities are a problem in the water supply (nitrate, chloride, sulfate), then these weak acid resins will have no effect on these contaminants. Some companies, where the water source is of a demonstrated, consistent supply, use weak acid cation exchange resins preceded by in-line coagulation. This combination affords the removal of turbidity, suspended solids, and some protozoans (from the coagulation), along with the removal of alkalinity and hardness by the resin itself.

Ion exchange alone affords no disinfection or microbial protection, unlike conventional lime treatment systems and

membrane processes already discussed. Consequently, they must be augmented by the appropriate additional treatment to result in the final water quality profile desired. In some cases, the resin beds themselves may promote the growth of bacterial populations, and, once established, may be very difficult to fully overcome. Some suppliers recommend the installation of an ultraviolet disinfection loop to help protect the resin unit from microbiologic proliferation during periods when not in use. In general, cation resins are more resilient materials, and may be disinfected with a variety of sanitizers, including chlorine solutions, permanganate, peracetic acid, and formaldehyde. This is usually not true for anion resins, which may be more prone to osmotic shock from changes in ionic strength, water temperature, or pH extremes. In some cases, anion resins—usually strong base anion material—have been implicated in causing off-odors ("fishy") in the treated water exiting their beds, which may be due to the methylamine breakdown products of some anion resins. In all cases, the supplier of the resins should be consulted for the proper operational, regeneration, and disinfection procedures to be used with their particular resin.

C. Support Technology

"Support technology" is a term used to describe the ancillary unit operations which are typically not considered primary treatment. Rather, they are intended to augment the primary treatment to result in a robust, complete treatment chain designed to deliver the quality of treated water we require for food and beverage plant applications. Given this definition, a wide variety of unit operations may be grouped into this category, but this section will only address two of the more common support technologies—media filtration, and activated carbon purification.

1. Media Filtration

Media filtration, in the simplest terms, involves the passage of water through any of a variety of coarse filtration materials. Traditionally, the most common medium for beverage water treatment was simple filtering sand, supported by a bed of gravel. The major intent of these sand filters was—and still is—to provide a coarse straining of the water stream. Sand filters may be located at different points in the treatment chain, but for conventional lime treatment systems, the industry practice is to locate the sand filter downstream of the reaction tank. Logically, this was done to capture any loose floc carryover, precipitated calcium carbonate, or other particulates that might not have settled adequately in the reaction tank. In some applications, like in-line coagulation, the deep bed sand filter which is used serves not only to filter the floc which is intentionally formed in line, but to provide part of the contact time of the water with the chlorine disinfectant.

As the choice of primary treatment technologies available to the beverage technologist has increased over time, so has the choice of support operations. In addition to sand, other media are commercially available to suit a variety of applications. For example, some reverse osmosis and nanofiltration membrane systems might incorporate "greensand" as one of the pretreatment operations. Greensand is a naturally occurring mineral that consists largely of dark greenish grains of glauconite, possesses ion-exchange properties (17), and is used for the removal of soluble iron and manganese from water streams to prevent fouling of downstream membrane systems. Other media used include garnet, anthracite, and diatomaceous earth, each having its own niche application. These media may also be combined in dual media or mixed media filters. Regardless of the medium selected, the fundamental objectives of media filtration include 1) removal of particulates from the overflow of reaction tanks, 2) preventing the occlusion of carbon pores, 3) avoiding the surface occlusion or fouling of ion-exchange resins, and, 4) providing the required contact time for chlorine and coagulant. In general, the supplier of water treatment equipment will routinely suggest media with which they have had positive operating and quality histories.

Media filtration, like virtually all water treatment processes, requires diligent maintenance in order to help assure its on-going performance. Since media filters remove particulate matter from the water, these impurities must then somehow be removed from the filter itself. This is accomplished by frequent backwashing of the filter medium, often with treated water, to suspend and expand the filter bed into the freeboard of the filter vessel, thereby allowing collected impurities to be washed to the drain. Some media filters, more commonly in municipal applications, augment the water backwash by the injection of air. This air scouring also helps suspend the bed, and allows conserves the overall volume of water necessary for the backwash cycle. The frequency and conditions of backwash depend on the filter media, vessel design, supplier recommendations and corporate policies, although the range of operating conditions usually includes a frequency of anywhere from daily to monthly, and a backwash rate of from two to five times the normal flow. Intimately linked with the maintenance described above is the routine sanitation of the media filters. Several methods may be used, including heat and chemical sanitizers, but this critical operation must not be overlooked. It is possible for bacterial populations to become established in media filter beds, and subsequent mucilagenous biofilms to form in and on the filter media which may be extremely resistant to removal.

2. Carbon Purification

In the field of water treatment, carbon purification is arguably the single unit operation that provides the broadest protection against the widest range of possible contaminants. In fact, the United States Environmental Protection Agency has routinely identified activated carbon as the "best available technology" for the removal of a wide variety of volatile

and semi-volatile organic impurities (18), which are summarized in Table 193.9. In addition to these, thousands of other organic compounds show some degree of removal by activated carbon. This application of organic impurity removal is relatively new to the beverage industry, despite the fact that activated carbon has been a part of beverage water treatment systems for many decades. The primary use of activated carbon in this field has been to effect the removal of the chlorine species used to disinfect the treated water. Here, a critical distinction must be drawn between the adsorptive mechanisms of contaminant removal by carbon, and the catalytic mechanisms carbon employs to dechlorinate. Adsorption refers to the adhesion, bonding, and other chemical attractive forces which retain impurities on the surface of the carbon and within its pores. This is usually a reversible process, to varying degree. The catalytic mechanism refers to the formation of a surface oxide on the activated carbon medium as a result of the reaction of the carbon with the hypochlorous acid, according to the following reaction:

$$HOCl + C^* \rightarrow HCl + C^*O$$

Hypochlorous acid + carbon = hydrochloric acid + carbon surface oxide

TABLE 193.9
Organic Contaminants for Which Activated Carbon Has Been Identified as the Best Available Technology for Their Removal

Alachlor	Aldicarb
Aldicarb sulfone	Aldicarb sulfoxide
Atrazine	Benzene
Benzo[a]pyrene	Carbofuran
Carbon tetrachloride	Chlordane
Dalapon	2,4-D
Di (2-ethylhexyl) adipate	Di (2-ethylhexyl) phthalate
Dibromochloropropane (DBCP)	o-Dichlorobenzene
para-Dichlorobenzene	1,2-Dichloroethane
1,1-Dichloroethylene	cis-1,2-Dichloroethylene
trans-1,2-Dichloroethylene	1,2-Dichloropropane
Dinoseb	Diquat
Endothall	Endrin
Ethylbenzene	Ethylene Dibromide (EDB)
Heptachlor	Heptachlor epoxide
Hexachlorobenzene	Hexachlorocyclopentadiene
Lindane	Methoxychlor
Monochlorobenzene	Oxamyl (Vydate)
Pentachlorophenol	Picloram
Polychlorinated biphenyls (PCB)	Simazine
Styrene	2,3,7,8-TCDD (Dioxin)
Tetrachloroethylene	Toluene
Toxaphene	2,4,5-TP (Silvex)
1,2,4-Trichlorobenzene	1,1,1 –Trichloroethane
1,1,2-Trichloroethane	Trichloroethylene
Xylene	

Source: EPA (1999).

Unlike adsorption, the catalytic reaction is not reversible, and, in fact, carbon bulk is destroyed in the process.

Carbon may be obtained from a variety of different starting materials—for example, coal, wood, peach pits, coconut shells. The carbon is activated either thermally (steam) or chemically. Steam activation, the more common, involves two steps: 1) carbonization, and, 2) activation. Carbonization involves the conversion of the raw material into a disordered carbon structure with a very low volatile content. Carbonization is done at elevated temperatures in an oxygen-lean environment which keeps it from burning. In activation, some carbon atoms are vaporized, leaving behind the highly porous structure. Steam activation is carried out in temperatures of approximately 1800°F. (982°C). At these conditions, carbon reacts with steam to form carbon monoxide and hydrogen, which exit as gases. The result: a highly porous carbon material. Chemical activation is used to produce very high pore volume in wood-based carbons, particularly in the medium-size pore range. The most common process consists of mixing wood dust or some other cellulose-based material with a strong dehydrating agent and then heating to a designated temperature. The activating agent not only extracts moisture but helps prevent collapse of the pore structure during activation (19).

Activated carbon is generally available in the powdered or granular form, but granular activated carbon (GAC) is used for the vast majority of water treatment applications in the beverage industry. In addition to the volatile organic impurities mentioned above, and the removal of chlorine and chloramine, GAC also affords treated water protection against adversely sensory-active compounds, like the microbial metabolites geosmin and 2-methyl isoborneol. These compounds may be odor active in nanogram per liter concentrations, and represent a substantial proportion of off-odor complaints to municipal water treatment works (20).

Operationally, perhaps even more so than for media filtration, the activated carbon unit operation must be diligently maintained and sanitized. Many microbial complaints and sensory excursions in the beverage industry have been linked, at least in part, to inadequate carbon bed management practices. One of the reasons for this required diligence is that the core of the GAC bed has the potential to provide optimal conditions for the growth of troublesome microorganisms—specifically, the chlorine is absent, the environment can vary in its level of air or dissolved oxygen, and, in most cases, the organic microbial nutrients abound (since GAC is so proficient at removing organic compounds, including natural organic matter, from water supplies). These conditions combine to make carbon an excellent medium for the support of microbial growth. Once established, the extremely large

surface area within the carbon pores can make control of an unwanted microbial population a daunting task. As is the case with media filters, routine and diligent backwashing and sanitization of the carbon bed should be viewed as an absolute requirement for any beverage plant water treatment system. Hot water, steam, or a combination are generally employed to sanitize the carbon filters, provided their material of construction can withstand the temperature needed. When performed regularly, this helps prevent a biofilm from becoming firmly established in the bed, and helps avoid the problems often associated with poor carbon maintenance, including high bacteria counts, off-odor production within the bed, poor dechlorination or chlorine breakthrough, and loss of adsorptive capacity.

D. Disinfection

At the beginning of this chapter, the food and beverage producer's commitment to consumer and employee safety was stressed as being a paramount goal of water treatment in our industry. Microbiologic contamination, in addition to resulting in spoilage of the beverage, represents an acute potential threat to the quality of our products and the integrity of our trademarks. Therefore, overall microbial management is critical to the success of any beverage producer. In this section, we will focus on the major techniques employed for disinfection as it specifically relates to the water used for beverage products. As an introduction to this section of the chapter, a distinction between cleaning, sanitizing, and sterilizing must be drawn.

"Cleaning" may be described as the removal of soil particles from surfaces by rinsing and washing through the use of physical and chemical action. "Sanitizing," in our industry, refers to treating a cleaned surface to destroy contaminant organisms and reduce the total vegetative cell population to a safe level. Finally, "sterilizing" is the complete destruction of all organisms, including spores, through the use of chemical agents, heat, radiation, or other means. These are largely intuitive, yet critical concepts to recognize. Unlike many pharmaceutical or ultra clean room applications which may require commercially sterile water, the beverage industry does not. Our requirements, in nearly all cases, dictate a "sanitary" treated water supply, not a "sterile" one. That is, we diligently "control any contaminant organisms…to a safe level."

1. Primary Organisms of Concern

The specific organisms of concern for the water treatment system of a beverage producer must be identified by the corporate research and development functions, with probable guidance by any applicable drinking water and food regulations. The World Health Organization asserts that "infectious diseases caused by pathogenic bacteria, viruses, and protozoa or by parasites are the most common and widespread health risk associated with drinking water" (21). It would be impossible and irrational to attempt to test all potential microbial threats to a water supply. Consequently, the focus of most major regulatory bodies is on testing and monitoring recognized "indicators" of water quality. Perhaps the most notable and widely accepted group of indicator organisms is the coliform group, which refers to Gram-negative, rod-shaped bacteria capable of growth in the presence of bile salts or other surface-active agents with similar growth-inhibiting properties and able to ferment lactose at 35–37°C with the production of acid, gas, and aldehyde within 24–48 hours. They are also oxidase-negative and non-spore-forming. By definition, coliform bacteria display beta-galactosidase activity (22).

The real threat to public health and safety is from those waterborne organisms transmitted as a result of direct contact with fecal contamination. Because not all coliform organisms are of fecal origin, other indicator tests are used to help detect the possibility of unsanitary conditions in a water supply. These include fecal or thermotolerant coliform, with *Escherichia coli* being the most prominent member (23), fecal *Streptococci*, and anaerobic, spore-forming bacteria, the target of which is primarily *Clostridium perfringens*. The most common bacterial measurement in municipal water supplies and in beverage plant water treatment monitoring remain total coliform and *E. coli*. In addition, a total bacterial plate count is commonplace for routine monitoring, but more as an indicator of acceptable "good manufacturing practices" (GMPs) rather than as an indicator of the presence of fecal organisms. One notable exception to this industry practice is in the production and packaging of a natural mineral water. In most countries where regulations for natural mineral waters exist, disinfection is realistically not allowed for these products. Instead, the focus is on impeccable selection and monitoring of a source as close to pristine as possible. Part of this rigorous monitoring may include all of the organisms mentioned above, in addition to others (like *Pseudomonas aeruginosa*, for example). The rationale is to help assure optimal confidence that the natural mineral water being abstracted from the source and subjected to minimal treatment, at best, is as microbially risk-free as feasible.

Another organism that has recently become a threat to both the municipal and industrial water treatment arenas is the protozoan, *Cryptosporidium parvum*. *Cryptosporidium* is a protozoan parasite affecting the gastrointestinal tract of humans and animals. It is shed in the feces in the form of an "oocyst," which has a hard shell to protect it from the environment. This also makes it highly resistant to disinfection by chlorine and ozone; although, UV disinfection has proven to be extremely effective at its inactivation. Waterborne *Cryptosporidium* outbreaks have occurred in

both large and small communities, with the largest outbreak occurring in Milwaukee, Wisconsin in 1993, affecting an estimated 403,000 people. Such outbreaks have caused major disruption to residents, businesses, and government. Infection with the *Cryptosporidium* organism may also have contributed to the premature deaths of immunosuppressed individuals in these outbreaks. Because of this, the finding of *Cryptosporidium* oocysts in many drinking water sources (rivers, lakes, and reservoirs), and occasionally even in municipal treated water, has been a source of considerable concern to drinking water and public health officials, as well as to the public and the news media (24).

In addition to waterborne organisms of health concern, like those discussed above, water supplies may also be subject to inhabitation by "nuisance organisms." These organisms, as their name implies, are typically not associated with any direct health effects, but, rather, are known to cause aesthetic or operational concerns to the water treatment plant or distribution network. In reality, most beverage producers will not test for these nuisance organisms unless a problem is known to exist (which is usually detected initially by an off-odor in the water plant, or by metallic particles in the system). Bacteria in this broad category include the following (25):

1. Iron bacteria. These bacteria incorporate ferrous iron as part of their normal physiologic processes, and oxidize it to the insoluble ferric form. Genera include *Leptothrix, Clonothrix*, and *Gallionella*.
2. Manganese bacteria. Instead of iron, these bacteria may incorporate manganese and oxidize it. Genera include *Hyphomicrobium* and *Caulobacter*.
3. Sulfur bacteria. Many subgroups of sulfur bacteria exist, depending on the specific sulfur form utilized as a nutrient substrate. The more troublesome group to the beverage water treatment plant is the sulfate-reducing bacteria (SRB), since they produce the malodorous hydrogen sulfide. These include the genera *Desulfovibrio* and *Desulfotomaculum*. Some species of *Pseudomonas* have also been implicated in producing organo-sulfur compounds in water.

2. The "CT" Concept

A critical concept when forming the foundation for any discussion of disinfection is the "CT" concept. In this mathematic product, the "C" refers to the final residual concentration of a particular chemical disinfectant, in mg/L, and the "T" refers to the minimum contact time, in minutes, with which the material being disinfected has been in contact with the disinfectant. Therefore, the units of CT are expressed in mg-min/L. To explore this in more detail, we must first recognize that every water supply has a natural disinfectant "demand." The demand may be described as the utilization of a disinfectant by components in the water which must first be satisfied before a residual disinfectant concentration may be established. Impurities like soluble metals, particulates, natural organic matter, microorganisms, etc., all contribute to the demand of a particular water supply. Before we can confidently begin to disinfect this supply, we must first provide the water with enough disinfectant to react with these components. Once this is accomplished, we may then establish a "residual" disinfectant concentration. After this residual is established and confirmed via testing, we must then maintain this residual in contact with the water over the course of the required contact time. This concept explains why in a conventional lime treatment system, a chlorine dose as high as 12−20 mg/L is often required to result in a free chlorine residual of between 6 and 8 mg/L. The dose must be adequate to satisfy the demand, and then establish a residual. Simply put, the residual is equivalent to the arithmetic difference between the dose and the demand.

Many regulatory and industry organizations have adopted the CT concept to express relative values of a disinfectant's effectiveness against a particular organism under a defined set of conditions (temperature, pH, etc.). Often, published tables of CT data will include a subscript, for example, $CT_{99.9}$, which describes the log removal of a particular organism when tested against a particular disinfectant. The 99.9 subscript in this example indicates that for this particular CT data, a three-log, or 99.9% reduction in the target organism has been demonstrated.

Table 193.10 provides further illustration of the CT concept using real data from the United States Environmental Protection Agency. The table values include CT_{99}, or the CT ranges within which 99% of the target organisms were inactivated by the disinfectant. A bacterium, virus, and protozoan are compared insofar as their susceptibility to free chlorine, preformed chloramine, chlorine dioxide, and ozone. Many conclusions may be drawn

TABLE 193.10
Comparison of CT Values for Inactivation at 5°C (mg-min/L)

Organism	Free Chlorine pH 6–7	Preformed Chloramine pH 8–9	Chlorine Dioxide pH 6–7	Ozone pH 6–7
E. coli (bacteria)	0.034–0.05	95–180	0.4–0.75	0.02
Polio 1 (virus)	1.1–2.5	770–3740	0.2–6.7	0.1–0.2
G. lamblia (protozoan)	47–150+	—	—	0.5–0.6

Source: Langlais (1991).

from this single tabulation, which will summarize the discussion of CT:

1. Compared to the other disinfectants, preformed chloramine is virtually ineffective at inactivating polio 1 virus (note the very high CT value of 770–3740 mg-min/L).
2. In general, ozone is the most effective disinfectant against all categories of the organisms studied (note the very low CT values in the ozone column).
3. Except for preformed chloramine, the other disinfectants are markedly effective against *E. coli* and polio 1 (in most cases, CT values are well below one).

Critical concepts with regard to CT data include: 1) the disinfectant demand must first be satisfied; 2) the disinfectant residual must then be established; 3) this residual must be maintained for the minimal contact time specified in order to provide adequate protection; and 4) "dose" and "residual" must not be confused or equated.

3. Major Disinfectants

A variety of disinfectants are currently available for use in beverage water treatment applications, but this section will focus on the three most common: chlorine species, ozone, and ultraviolet irradiation. The perspective presented will be from that of direct disinfection of the water to be used for beverage production. Note, however, that the disinfection of surfaces and equipment in the water treatment room and throughout the beverage plant is often treated as a separate topic, and additional sanitizing techniques may be used for these applications, with one of the most effective being heat. However, surface and plant disinfection are beyond the scope of this chapter.

a. Chlorine species

Chlorine is commercially available to the beverage industry as compressed chlorine gas, solid calcium hypochlorite pellets, and sodium hypochlorite solution of various concentrations. The traditional and likely the most commonly used form for disinfection of treated water is the last, sodium hypochlorite solutions, although the others are also employed. Chlorine gas is usually reserved for large-volume beverage plants, and considerable drawbacks to its use are the strict transport, handling, storage, metering, permitting, and use requirements being enforced by many regulatory agencies. Calcium hypochlorite is utilized, although, in many markets, is more costly than sodium hypochlorite. Irrespective of which form is chosen, once in aqueous solution, the chlorine chemistry becomes essentially the same.

The chlorine species, when dissolved in water, will eventually dissociate into primarily two active forms: 1) hypochlorous acid (HOCl); and, 2) the hypochlorite anion (OCl^-). The ratio of these two chlorine species varies as a function of pH, with hypochlorous acid predominating at acidic pH, and the hypochlorite anion predominating at alkaline pH (26). Figure 193.8 depicts the relative equilibria, as a function of pH, for chlorine, hypochlorous acid, and the hypochlorite anion. One critical concept to link with this chlorine equilibria is that hypochlorous acid (predominant at lower pH) has been described as 80 to 100 times more potent a germicide than the hypochlorite anion (predominant at higher pH). As a result of this, the World Health Organization suggests a pH of less than 8.0 to help assure effective disinfection of water with chlorine. In conventional lime water treatment systems, where the operating pH in the reaction tank is often above 10.0, the chlorine equilibrium favors the existence of hypochlorite anion, which is why, in addition to allowing adequate floc settling time, a minimum two hours of retention must be designed in these systems.

In summary: 1) chlorine is an effective disinfectant against bacteria and viruses, although is less effective against protozoan organisms like *Giardia* and *Cryptosporidium*; 2) the effectiveness of chlorine varies markedly with pH, owing to the distribution between the more effective hypochlorous acid, and the less effective hypochlorite anion; and, 3) the preferred operating range for chlorine disinfection is roughly pH 6.0 to 7.5; below this, corrosion may occur, above this, its effectiveness declines. Though the actual disinfection criteria for your application must be decided within your own corporation, a long-standing industry practice for water disinfection using chlorine in conventional treatment systems is to maintain a free chlorine residual of 6 to 8 mg/L over the course of a two-hour contact time. For other treatments, where the pH is lower, this CT is often decreased.

b. Ozone

Ozone (O_3) is an unstable, gaseous, allotrope of oxygen (O_2). It has a distinctive pungent odor, from which its name is derived (from Greek *ozein*, "to smell"). It is formed locally in air by the ionizing effects of environmental lightning, and in the earth's stratosphere by ultra-

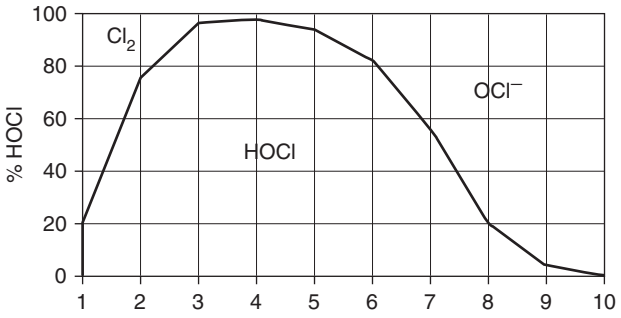

FIGURE 193.8 Chlorine species as a function of pH.

violet irradiation. It also safeguards us from the damaging effects of the sun by inhibiting the penetration of much of the sun's UV waves, and preventing them from reaching the planet's surface. It is also formed during combustion in automobile engines, and thereby contributes to the troublesome phenomenon of "photochemical smog."

Following the lead from many municipal drinking water companies that have used ozone for decades, the beverage industry more formally recognized its use in 1981 by the publication of "Ozone Treatment of Beverage Water" in the Proceedings of the International Society of Beverage Technologists (27), and then again in its 1987 Proceedings: "Applications of Ozone in Soft Drink Bottling Plants" (28). The major applications then—which continue to be currently valid—are the use of ozone as an oxidant and as a disinfectant. The major use of ozone in the beverage industry currently is the treatment of bottled water. Its use in the treatment of water for carbonated soft drinks is still uncommon.

Commercially, ozone is produced via the Corona Silent Arc Discharge process (29). The major drawback with the use of ozone, due to its very short half-life, is that it cannot be efficiently stored—it must be produced on-site at the point of use. With the Corona Discharge, a feed gas (oxygen or air) passes through an electrode pair (high and low voltage) where free electrons are of sufficient energy to split the diatomic (i.e., two atoms) oxygen molecules apart. The "single" atomic oxygen species then recombine with other diatomic oxygen to form a molecule with three atoms of oxygen—ozone (O_3). When compressed purified oxygen gas is used as the feed, in place of treated air, roughly twice the amount of ozone is produced for the same energy input. For most bottled water applications (where ozone is frequently used), even despite the increased output, the cost of the compressed oxygen usually makes its use uneconomical. There are many designs of ozone generators—tubular, plate, water-cooled, refrigerated air-cooled, etc.—but the most important design characteristic is the treatment of the feed gas. The ozone generator must include modules for: air compression and pressure regulation; cooling; particulate filtration; water vapor removal (dryers); gas impurity removal (methane, ammonia, etc.); and oil (hydrocarbon) removal. Along with the ozone generator should come some form of ozone destruct device (usually thermal or catalytic) to destroy the excess ozone "off-gas."

As a water disinfectant, the effectiveness of ozone varies widely with the specific organism of interest. For example, at 5°C, and a pH of 6–7, to obtain the same degree of inactivation (99%), the following "CT" conditions must be used (30):

1. *E. coli* bacteria: CT=0.02 mg-min/L
2. Polio 1 virus: CT=0.1–0.2 mg-min/L
3. *Giardia lamblia* cysts: CT=0.5–0.6 mg-min/L
4. *Giardia muris* cysts: CT=1.8–2.0
5. *Cryptosporidium parvum* cysts: 5–6 mg-min/L, estimated (unpublished data; personal communication)

As with any chemical disinfectant, when ozone is used for disinfecting water supplies, the ozone demand must first be met, and then a residual ozone concentration established, and maintained for the desired contact time. An industry practice, which dates back to data nearly four decades old, is to utilize an ozone CT value of 1.6 mg-min/L. This is generally done by maintaining a residual of 0.4 mg/L ozone for 4 minutes. You will notice from the data above, that a CT of 1.6 mg-min/L is adequate to provide at least a two-log reduction in bacteria, virus, and *Giardia lamblia* populations. However, as with chlorine, *Cryptosporidium parvum* remains resilient to inactivation, so higher CT values will be necessary to address this organism.

Operationally, the two major drawbacks to the more widespread application of ozone to our industry include the fact that: 1) it must be generated and used immediately on-site and cannot be stored, and, 2) due to its short half-life, it does not provide adequate residual disinfectant activity. As with other disinfectants, the dose and half life of ozone will vary as a function of pH, temperature, organic matter, and other variables, but somewhat unique to ozone is its behavior at varying levels of total dissolved solids (TDS). Table 193.11 illustrates the time, in minutes, for the disappearance of initial ozone doses of 0.64, 0.32, and 0.16 ppm in waters of varying levels of total dissolved solids (31). Note the magnitude of the inverse relationship between ozone half-life and total dissolved solids. The lower the level of total dissolved solids, the longer the

TABLE 193.11
Ozone Half-Life as a Function of Total Dissolved Solids, 70°F

		Time for Disappearance of an Initial Ozone Concentration of		
Total Dissolved Solids	**Ozone Half-Life**	**0.64 ppm O_3**	**0.32 ppm O_3**	**0.16 ppm O_3**
500 ppm	5.7 minutes	28.5 minutes	22.8 minutes	17.1 minutes
400–450 ppm	29 minutes	222 minutes	174 minutes	132 minutes
1 ppm	119 minutes	594 minutes	474 minutes	360 minutes

Source: Adapted from IBWA Technical Manual (1995).

ozone residual will last. Finally, ozone is very powerful chemical oxidant, and can be extremely aggressive toward equipment, both in air and in aqueous phase. Care must be taken to ensure that all materials used are suitable for ozone contact, and that all employee safety precautions are observed.

C. Ultraviolet irradiation

The last of the major disinfectants used for water treatment in the beverage industry is ultraviolet irradiation. UV radiation energy waves are the range of electromagnetic waves 100 to 400 nm long (between the x-ray and visible light spectrums). The division of UV radiation may be classified as Vacuum UV (100−200 nm), UV-C (200−280 nm), UV-B (280−315 nm) and UV-A (315−400 nm). In terms of germicidal effects, the optimum UV range is between 245 and 285 nm. UV disinfection utilizes a mercury source in the form of either: 1) low-pressure lamps that emit maximum energy output at a wavelength of 253.7 nm; 2) medium-pressure lamps that emit energy at wavelengths from 180 to 1370 nm; or, 3) lamps that emit at other wavelengths in a high intensity "pulsed" manner. Pulsed UV is a relatively new technology to the beverage industry, and is not widely employed at present. While both low and medium pressure designs have their own advantages and disadvantages, they have both proven to be adequate for water disinfection applications.

The degree to which the destruction or inactivation of microorganisms occurs by UV radiation is directly related to the UV dose. The UV dosage, D, is calculated as the arithmetic product of intensity, I, in milli- or micro-watt seconds per square centimeter, and time, t, in seconds. Internationally, the dose is often expressed in millijoules per square centimeter, which is exactly equivalent to milliwatt-seconds per square centimeter (1 mJ/cm^2 = 1 mW-s/cm^2 = 1000 microW-s/cm^2). Research indicates that when microorganisms are exposed to UV radiation, a constant fraction of the living population is inactivated during each progressive increment in time. This dose-response relationship for germicidal effect indicates that high intensity UV energy over a short period of time would provide the same kill as a lower intensity UV energy at a proportionally longer period of time. The UV dose required for effective inactivation is determined by site-specific data relating to the water quality and log removal required (32).

The mechanism of inactivation of microorganisms by UV is complicated, but has been reported many times in the literature. Fundamentally, the organism's genetic material (for example, bacterial deoxyribonucleic acid, or DNA) absorbs the UV radiation, which results in a chemical disruption of the DNA's chemical bases. Though many various photoproducts form as a result of this, the major rearrangement is the dimerization of the thymine base. This change renders the organism unable to replicate their DNA, and, therefore, cannot reproduce. As you might expect, ultraviolet disinfection does not provide any residual disinfectant activity.

Just as with ozone and chlorine, ultraviolet energy also has an accepted industrial "rule of thumb" which has been established for decades. A typical UV system used for the disinfection of beverage plant water treatment is sized to deliver a dose of at least 30 mJ/cm^2 at the end of its service life (typically 8,000 hours). To achieve this, since UV intensity naturally decreases over time as the lamp ages, the initial dose design is usually on the order of 60 mJ/cm^2. This design has traditionally been credited with providing at least a three-log (99.9%) inactivation of bacteria, yeast, and virus populations. Data published in late 1999 (33), and confirmed since then in several industry journals, suggest that the same 30 mJ/cm^2 dose also provides at least a three-log inactivation of *Cryptosporidium parvum*, a protozoan organism highly resistant to disinfection by chlorine and ozone. Table 193.12 summarizes the relative effectiveness of a variety of disinfectants against *Cryptosporidium parvum*. This is promising news for the water treatment industry, since it now adds UV to our armamentarium of weapons to help ensure the microbial safety of our water supplies.

4. The Multiple Barrier Approach

The "Multiple Barrier Approach," as the term implies, refers to the installation of any combination of multiple barriers in a water treatment chain to help decrease the risk of microbial contamination. These barriers may be physical (RO, microfiltration, coagulation, etc.), chemical (ozone, chlorine, UV, etc.) or a combination of the two. Multiple barrier design, though it applies correctly to the protection against any microbial threat, was the subject of increased interest after the Milwaukee *Cryptosporidium* outbreak in 1993. That outbreak, and the research done in its wake, helped demonstrate the resilience of that protozoan organism to traditional disinfection—an alternate approach was needed. That alternate approach became the multiple barrier concept. The Milwaukee outbreak also, arguably, spurred a heightened focus on the area of "emerging pathogens," with the hope of being able to

TABLE 193.12
Relative Comparison of Various Methods for 99% *Cryptosporidium* Inactivation

Disinfectant	Effectiveness	Estimated CT-99
Free chlorine	Poor	7200 mg-min/L
Chloramine	Poor	7200 mg-min/L
Mixed oxidants	Fair	1000 mg-min/L
Ozone	Good	5–15 mg-min/L
Chlorine dioxide	Good	80 mg-min/L
UV Irradiation	Excellent	2–5 mJ/cm^2

Source: Aquionìcs UV Systems, Inc. (2001).

proactively identify troublesome microorganisms, and apply appropriate treatment technology to address them.

The multiple barrier concept is becoming more recognized by both regulatory agencies and members of industry. This trend is likely to continue, since, intuitively, it should be able to address—at least to some degree—most microbial threats in the future. Considering the wide range of chemical and physical unit operations, and combinations thereof, available to the beverage water treatment technologist, we should be well-armed to design a robust treatment system to address many of the future threats which might face us in the future. The key is to work with municipalities, researchers, the private sector, and other resources to build and sustain network of expertise. Then, when a "new" pathogen arises, the industry should draw from this "skills reservoir" to take the necessary precautions to continue to protect public and consumer health, and the integrity of our brands.

In the beverage industry, many plants can confidently apply at least three microbial barriers—coagulation (conventional lime treatment systems), chlorine (primary disinfection), and UV (secondary disinfection, and extremely effective against *Cryptosporidium*). In general, the more barriers in place, the greater our confidence that we are providing treated water with adequate protection against microbial impurities. This is a simple concept, but far-reaching in implication.

IV. TESTING AND MONITORING

To keep pace with the changes in today's regulatory environment, the food and beverage industries must recognize a two-pronged approach as it relates to the testing of water in their facilities. The first prong incorporates testing required from a "regulatory" perspective. In this case, "regulatory" not only includes formal bodies like the Environmental Protection Agency or the Councils of the European Union, but also our own corporate "regulatory" departments. This type of testing is typically quite rigorous, and is concerned primarily with the protection of the consumer and the environment. The second prong incorporates the "day-to-day" testing required to keep our treatment processes functioning effectively, and to assure that our final treated water used in product consistently meets acceptable standards. This section is intended as a primer, to stimulate more in-depth investigation by the individual company, rather than a complete treatise of analytic methodology that might be employed.

What should you test? An anecdote paraphrased from a supposedly "ancient un-named philosopher" was once credited with the quotation, "To some extent, water can dissolve every naturally occurring substance on earth. Proof of this is limited only by our ability to detect species." (34) As modern analytic chemistry continues to evolve, this philosopher must be heralded as the visionary he must have been. For example, Environmental Protection Agency (EPA) Method 1613B allows the quantitation of polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) down to part-per-quadrillion levels (35). As the levels of detection improve, the question will no longer be, "is this compound in our water?" Rather, it will become, "we know it's there, but what level is acceptable?" To try to simplify this complex and case-specific area, the food or beverage plant should consider dividing water related testing into five categories:

1. Testing for new plant site qualification;
2. Testing for regulatory compliance;
3. In-plant testing;
4. Testing to incorporate individual company requirements;
5. Troubleshooting

A. Testing for New Plant Site Qualification

This category of testing is usually considered the most rigorous, and typically encompasses testing for the broadest range of potential contaminants. It is often driven by the federal and local regulations that apply to the transaction of commercial real estate during a due diligence period. In the United States, this may include a simple "transaction screen," which is categorized by obtaining data primarily through visual inspection, surveys and interviews, and previous testing; or may range through a Phase III Environmental Site Assessment, which is a data-based quantitation of an identified site hazard. For more information, the American Society for Testing and Materials has published "Standard Practices for Environmental Site Assessments" (36), and should be reviewed by anyone involved in this initial phase of testing.

B. Testing for Regulatory Compliance

This category of testing is also rigorous, and has the primary function of protecting public health and safeguarding the corporate trademark. It typically represents an appreciable cost to the food or beverage manufacturer. The expense may be due to the capital investment needed for compliance (for example, a gas chromatograph with mass spectrometric detector to monitor trihalomethanes and other volatile organic compounds in potable water), or may be due to the on-going operating costs of external third party laboratories or contracted companies to manage a plant's overall compliance. The food and beverage manufacturer must be aware that regulatory compliance rarely, if ever, involves a *single* regulatory agency. Two is a common number in the United States; for example, the EPA for jurisdiction over potable water as it enters the food or beverage processing plant, and the Food and Drug Administration (FDA) for jurisdiction over a finished packaged water. Outside the United States, the maze of

presiding regulatory bodies may be even more complicated. For example, some years ago, at a natural mineral water facility in Poland, the plant was expected to comply with (1) the Council Directive of the European Union (since the country followed E.U. trends); (2) the Federal Regulations for Poland; (3) the regional Codes of the Vovoidship of Radom; and (4) the local laws as promulgated by the Warsaw authorities. The chemical, physical, microbiologic, and radiologic testing had to, therefore, follow suit.

Tracking regulatory trends is best left to the experts, and virtually all major food and beverage companies have entire departments devoted to doing just that. Historically, compliance monitoring has been criticized for the tedium and analyst sophistication necessary in the official analytic methods. Also, though the water-related agencies of the federal government have been doing a laudable job, they have been doing so with ever-dwindling resources. This has led to an official documentation system which is sometimes months or years behind the most current developments. However, the future is bright for regulatory compliance monitoring as many regulatory bodies join the Internet age (37).

C. In-plant Testing

This category should include the more routine, "plant floor friendly" testing that is required to operate a food or beverage plant on a day-to-day basis. It is generally intended for use as a surrogate system for fast, easy monitoring; the parameters measured should serve as a "red flag" assessment for when the next phase of more intensive testing is warranted.

For example, in beverage water treatment systems, especially for those utilizing polymeric membrane technology (i.e., reverse osmosis or nanofiltration), the measurement of total dissolved solids (TDS) is an excellent aggregate parameter to use as a surrogate measure of the overall rejection performance of the membrane. Simply put, TDS provides a fast, easy, in-line, reproducible method by which to monitor how effectively your membrane is rejecting dissolved salts. If the TDS changes suddenly, it raises a "red flag" that further data collection is necessary (for example, visual inspection of the membrane elements; speciation of the components of TDS—sulfate, chloride, sodium, etc.; among others). From the standpoint of normal daily operation, however, we may not need to measure all the anions and cations that comprise TDS. The decision as to which parameters should be included on an in-plant testing protocol will vary with the type of industry, the specific application of the process, an assessment of the potential risks associated with a process or product, hazard analysis and critical control point (HACCP) evaluation, the presiding regulations and guidelines that apply, and the company's own internal mandates.

D. Testing to Incorporate Individual Company Requirements

This category is often a hybrid of the other testing categories included in this section. The testing may be driven by: 1) regulatory mandates or voluntary ascription to impending regulatory trends; 2) "historical lessons" learned; 3) product- or process-specific testing (for example, individual stability or sensory standards, consumer-driven requirements, etc.); and, 4) parameters that may affect plant effluent treatment (for example, pH, TDS, biochemical oxygen demand, etc.)

Most of the points above are self-explanatory, but, in the author's experience, the "historical lessons" category is often the most worthwhile when it comes to monitoring parameters of importance. Every food and beverage company must be replete with anecdotes, for example, from a Principal Scientist with 40 years of corporate tenure, which describe problems that occurred decades ago. Though some might scoff at these "war stories," most will admit that there is empirical validity to the quote, "those who do not learn from their mistakes are destined to repeat them."

E. Troubleshooting

This category may be the most encompassing of all, and cannot be distilled to a few concise guidelines. The testing performed as a result of a troubleshooting exercise is often not planned; is often forcibly undertaken under the threat of an impending plant shut down; may potentially mean the difference between a minor, easily-remedied plant operations issue, and a serious breach which warrants a product recall; and must always be performed in a scientific, methodical fashion to maintain the integrity of the data and the value of the conclusions which will be drawn.

As we continue to develop the *ability* to detect compounds at lower levels than ever thought possible, we must also face the reality that we will undoubtedly *find* them in many of the places we look. As contaminants move more toward ubiquity, this makes the thoughtful development of appropriate testing protocols, acquisition of accurate and precise data, formulation of valid conclusions, and data-based action plans key to the future success of food, beverage, pharmaceutical, and municipal water treatment industries.

I. INTRODUCTION

Contrary to popular consumer perception about the risk of chemicals in foods, major hazards associated with foodborne illness are clearly of biological origin (1). The Centers for Disease Control and Prevention (CDC) has published summaries of foodborne diseases by etiology for the years 1993 through 1997 (Table 194.1) (2). CDC groups foodborne disease agents in four categories; bacterial, parasitic, viral, and chemical. Greater than 95% of all reported outbreaks foodborne illnesses are caused by microorganisms or their toxins. Fully 97% of reported cases are likewise linked to a microbial source. Only around 3% of the outbreaks and less than 1% of cases can be truly linked to chemical (heavy metals, monosodium glutamate, and other chemicals) contamination of foods. Furthermore, 97% of reported deaths are due to microbial sources. These data are from reported outbreaks. CDC estimates for the actual number of cases of foodborne disease caused by microbial agents is much higher due to under reporting (Table 194.2).

Bacterial agents are by far the leading cause of illness, with total numbers estimated as high as 76 million cases per year and deaths as high as 5,000 annually in the U.S. (3). Costs are estimated to be $9.7 billion annually in medical expenses and lost productivity in the U.S. (3). The high

incidence of foodborne disease is paralleled in other developed countries (4). Enteric viruses are now recognized as the leading cause of foodborne infections, although the bacteria are better known. Predominant bacterial agents are *Campylobacter* spp., *Salmonella* spp., *Shigella* spp., and *Clostridium perfringens*. Foodborne bacterial hazards are classified based on their ability to cause infections or intoxications. Foodborne infections are usually the predominant type of foodborne illness reported. Foodborne outbreaks most often occur with foods prepared at food service establishments and at home (Table 194.3). Improper holding temperatures and poor personal hygiene are the leading factors contributing to reported outbreaks (Table 194.4).

Bacterial hazards are further classified based upon the severity of risk (5). Severe hazards are those capable of causing widespread epidemics. Moderate hazards can be

those that have potential for extensive spread, with possible severe illness, complication, or sequelae in susceptible populations. Mild hazards can also cause outbreaks but have limited ability to spread. Those involved with food production, processing, and service should pay careful attention to controlling these biological hazards by: 1) destroying or minimizing the hazard, 2) preventing contamination of food with the hazard, or 3) inhibiting growth or preventing toxin production by the hazard. Control steps will follow in later sections of this chapter.

When investigating foodborne disease outbreaks, the most important factor is time (6). Prompt reporting of an outbreak is essential to identifying implicated foods and stopping potentially widespread epidemics. Initial work in

the investigation should be inspection of the premises where the outbreak occurred. Look for obvious sources, including sanitation and worker hygiene. Food preparation, storage, and serving should be carefully monitored. Interview those involved in the outbreak. Obtain case histories of victims and healthy individuals. Discuss health history and work habits of food handlers. Collect appropriate specimens for laboratory analysis, including stool samples, vomitus, and swabs of rectum, nose, and skin. Attempt to collect suspect foods, including leftovers or garbage if necessary. Specific tests for pathogens or toxins will depend on potential etiological agents and food type. Analysis of data should include case histories, illness specifics (incubation time, symptoms, and duration), lab results, and attack rates. All foodborne disease outbreaks should be reported to local and state health officers and to the CDC.

II. BACTERIAL INFECTIONS

Predominant bacterial infections transmitted via foods are salmonellosis, campylobacteriosis, yersiniosis, vibriosis, and shigellosis (7). Most causative agents are Gram-negative rod shaped bacteria that are inhabitants of the intestinal tract of animals. Indeed, federal and most state regulatory agencies consider foods of animal origin (meat, poultry and eggs, fish and shellfish, and milk and dairy products) potentially hazardous foods. One look at epidemiological data confirms this suspicion. That said, fresh produce (fruits and vegetables) is increasingly being implicated in outbreaks of both bacterial and viral agents.

A. SALMONELLOSIS

Salmonella resides primarily in the intestinal tract of animals (humans, birds, wild animals, farm animals, and insects) (8). Many people are permanent, often asymptomatic carriers. Salmonellosis varies with species and strain, susceptibility of host, and total number of cells ingested. Several dozen serotypes cause foodborne outbreaks. Incubation time is 24–36 hours, which may be longer or shorter. Symptoms include nausea, vomiting, abdominal pain, and diarrhea, which may be preceded by headache, fever, and chills. Weakness and prostration may occur. Duration is 1 to 4 days with a low mortality rate (0.1%). High risk very young and elderly may have a considerably higher mortality rate (3.8%) (9). The condition needed for an outbreak is the ingestion of live cells (10,000) present in the food. For high fat foods such as chocolate, 50 cells may be a sufficient infectious dose due to protective enrobement of cells by fat allowing survival in high acid gastric fluid during intestinal transit. Foods primarily involved in outbreaks include meat, poultry, fish, eggs, and milk products. *S. enteritidis* is present in raw uncooked eggs even with sound shells (10). Most often the bacterium is transferred from a raw food to a processed food via cross contamination. Control of *Salmonella* in foods can be accomplished in several ways. Avoidance of contamination by using only healthy food handlers and adequately cleaned and sanitized food contact surfaces, utensils, and equipment works best. Heat treatment of foods by cooking or pasteurization is sufficient to kill *Salmonella*. Refrigeration temperatures at or below 5°C are sufficient, as the minimum temperature for growth is 7 to 10°C. The prevalence of salmonellosis as a foodborne disease has prompted regulatory agencies to adopt a zero tolerance for the genus in ready-to-eat foods. Presence of the bacterium in these foods (luncheon meats, dairy products, pastries, produce, etc.) renders them unwholesome and unfit for consumptions. These foods must then be destroyed or reprocessed to eliminate the pathogen.

B. SHIGELLOSIS

Four species are associated with foodborne transmission of dysentery, *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei* (11). The disease is characterized with an incubation period of 1 to 7 days (usually less than 4 days). Symptoms include mild diarrhea to very severe with blood, mucus, and pus. Fever, chills, and vomiting also occur. Duration is long, typically 4 days to 2 weeks. *Shigella* spp. have a very low infectious dose of around 10 to 200 cells. Foods most often associated with shigellosis are any that are contaminated with human fecal material,

with salads frequently implicated. Control is best focused on worker hygiene and avoidance of human waste.

C. Vibriosis

Most vibrios are obligate halophiles that are found in coastal waters and estuaries (12). Consequently most foodborne outbreaks are associated with consumption of raw or undercooked shellfish (oysters, crabs, shrimp) and fish (sushi or sashimi) (13). *V. parahaemolyticus* causes most vibriosis outbreaks in developed countries and is primarily foodborne. *V. cholerae* is primarily waterborne, but has been associated with foods from aquatic origin (14). Because *V. cholerae* is halotolerant it can survive and grow in non-salt foods. Hence, the bacterium has been spread through foods of terrestrial origin in addition to nonsaline fresh water. *V. vulnificus* is capable of causing very serious infections leading to septicemia and a high mortality rate (30–40%) (15). This very high mortality rate is the highest of all foodborne infectious agents. Fortunately the incidence of *V. vulnificus* infections is extremely low. Consumption of raw oysters harvested from warm waters (U.S. Gulf Coast) among high risk individuals (chronic alcoholics, severely immunocompromised) are factors involved with fatalities (16). Several other *Vibrio* species may be pathogenic (16). Incubation period for vibriosis is 2 to 48 hours, usually 12 hours. Symptoms include abdominal pain, watery diarrhea, usually nausea and vomiting, mild fever, chills, headache, and prostration. Duration is usually 2 to 5 days. Cholera typically expresses profuse rice water stools as a characterizing symptom. *V. vulnificus* infections can include septicemia and extremity cellulitis. Prevention of vibriosis includes cooking shellfish and fish, harvesting shellfish from approved waters, preventing cross contamination, and chilling foods to less than 10°C (17).

D. *Escherichia coli*

There are six pathogenic types of *E. coli* associated with foodborne illness (18). The infectious dose for most strains is high (10^6 to 10^8 cells), although enterohemorrhagic strains may be much lower (2–45 cells). Enteropathogenic (EPEC) strains are serious in developing countries but rare in the U.S. These strains are a leading cause of neonatal diarrhea in hospitals. Likewise, diffusely adherent (DAEC) and enteroaggregative (EAEC) *E. coli* strains are associated with childhood diarrhea. Enteroinvasive (EIEC) strains have an incubation period of 8 to 24 hours, with 11 hours most often seen. Symptoms are similar to *Shigella* infections, with bloody diarrhea lasting for several days. Enterotoxigenic (ETEC) strains are a notable cause of traveler's diarrhea. Onset for illness by these strains is 8 to 44 hours, 26 hours normal. Symptoms are similar to cholera, with watery diarrhea, rice water stools, shock, and maybe vomiting lasting a short 24 to 30 hours. Enterohemorrhagic or verotoxigenic strains (EHEC) are the most serious *E. coli* found in foods, especially in developed countries. *E. coli* O157:H7 is the predominant serotype among these shiga-like toxin producing bacteria, although other serotypes are found. EHEC cause three syndromes (19,20). Hemorrhagic colitis (red, bloody stools) is the first symptom usually seen. Hemolytic uremic syndrome (HUS), which is the leading cause of renal failure in children, is characterized by blood clots in kidneys leading to death or coma in children and the elderly. Rarely, individuals may acquire thrombotic thrombocytopenic purpura (TTP), which is similar to HUS but causes brain damage and has a very high mortality rate. Verotoxic strains have an incubation period of 3 to 4 days. Symptoms include bloody diarrhea, severe abdominal pain, and no fever. Duration ranges from 2 to 9 days. Vehicles of transmission include untreated water, cheese, salads, raw vegetables, and water. For 0157:H7, ground beef, raw milk, and raw apple juice or cider are common vehicles. Prevention of *E. coli* outbreaks includes treatment of water supplies and proper cooking of food. Complete cooking of hamburgers is necessary for destruction of verotoxigenic strains.

E. Yersiniosis

Most environmental *Yersinia enterocolitica* strains are avirulent; however, pathogenic strains are often isolated from porcine or bovine foods (21). The disease is predominately serious to the very young or the elderly and is more common in Europe and Canada compared to the U.S. Incubation period for the disease is 24 hours to several days with symptoms including severe abdominal pain similar to acute appendicitis, fever, headache, diarrhea, malaise, nausea, vomiting, and chills. It is not uncommon for children involved in outbreaks to experience unnecessary appendectomies. Duration is usually long 1 week to perhaps several months. The majority of foods involved in yersiniosis outbreaks are pork and other meats. Milk, seafood, poultry, and water may also serve as vehicles. Control is achieved by adequate pasteurization and cooking and avoiding cross-contamination. Refrigeration is not adequate because the bacterium is psychrotrophic.

F. Campylobacteriosis

Three species are linked to foodborne diseases, *C. jejuni*, *C. coli*, and *C. laridis* (22). *C. jejuni* is most often associated with poultry, *C. coli* with swine, and *C. laridis* with shellfish. *C. jejuni* gastroenteritis is the most frequent infection among the bacterial agents of foodborne disease (Table 194.1). Campylobacters and related pathogens *Arcobacter* spp. and *Helicobacter pylori* are microaerophilic and are thus sensitive to normal atmospheric oxygen concentrations (21% O_2) and very low oxygen concentrations (less than 3%). Growth is favored by 5% O_2. Disease characteristics

are an incubation period of 1 to 10 days, 3–5 days normal. Symptoms include fever, abdominal pain, vomiting, bloody diarrhea, and headache, which last for 1 day to several weeks. Relapses are common. The infectious dose is low, 10 to 500 cells. Foods linked to outbreaks include raw milk, animal foods, raw meat, and fresh mushrooms. Control is achieved by adequate cooking, pasteurization, and cooling and by avoiding cross-contamination. Although gastroenteritis is the predominant clinical presentation of campylobacteriosis, chronic sequelae may occur. Guillian-Barré syndrome, which is a severe neurological condition, and Reiter's syndrome, which is reactive arthritis are rare but serious consequences of campylobacteriosis. *H. pylori* is associated with chronic peptic ulcers.

G. Listeriosis

Listeria monocytogenes emerged as a cause of foodborne disease in 1981 (23,25). Susceptible humans include pregnant women and their fetuses, newborn infants, the elderly, and immunocompromised individuals due to cancer, chemotherapy, and AIDS. The disease has a high 30% mortality rate. Incubation period is variable, ranging from 1 day to a few weeks (25). In healthy individuals, symptoms are mild fever, chills, headache, and diarrhea. In serious cases septicemia, meningitis, encephalitis, and abortion may occur. The duration is variable. The infectious dose is unknown, but for susceptible individuals it may be as low as 100 to 1000 cells. Foods associated with listeriosis are milk, soft cheeses, meats, and vegetables. Like *Y. enterocolitica*, the bacterium is psychrotrophic and will grow at refrigeration temperatures, though slowly. Control is best done by avoiding cross-contamination and adequately cooking food.

H. Clostridium perfringens

C. perfringens is a moderate thermophile showing optimal growth at 43 to 47°C, with a maximum of 55°C (26). Large numbers of viable cells ($>10^8$) must be consumed, which then pass through the stomach into the intestine. The abrupt change in pH from stomach to intestine causes sporulation to occur, which releases an enterotoxin. Furthermore, the bacterium can grow in the intestine leading to a toxicoinfection. The illness is characterized by an incubation period of 8 to 24 hours. Symptoms are abdominal pain, diarrhea, and gas. A cardinal symptom is explosive diarrhea. Fever, nausea, and vomiting are rare. Duration is short, 12 to 24 hours. Because of the large infectious dose foods often associated with outbreaks are cooked meats and poultry that have been poorly cooked, such as gravy (anaerobic environment at bottom of pot), stews, and sauces. Outbreaks frequently occur in food service establishments where large quantities of food are made and poorly cooled. Control is best achieved by rapidly cooling cooked food to less than 7°C, holding hot foods at greater than 60°C, and reheating leftovers to greater than 71°C.

I. Other Bacterial Foodborne Infections

Many other bacteria have been linked to foodborne diseases including *Plesiomonas shigelloides* (raw seafood), *Aeromonas hydrophila* (raw seafood), *Arizona hinshawii* (poultry), *Streptococcus pyogenes* (milk, eggs), and perhaps *Enterococcus faecalis* (27). Their contribution to foodborne illness appears to be minimal but they may contribute to opportunistic infections.

III. NON-BACTERIAL FOODBORNE INFECTIONS

Numerous infectious viruses and parasitic worms are capable of causing foodborne illness. All are easily controlled by proper heat treatment of foods. Difficulty with laboratory confirmation of viral agents as causes of foodborne illness leads to probable under reporting (28,29).

A. Infectious Hepatitis

Hepatitis A virus is a fairly common infectious agent having an incubation period of 10 to 50 days, mean of 4 weeks (30). Symptoms include loss of appetite, fever, malaise, nausea, anorexia, and abdominal distress. Approximately 50% of cases develop jaundice that may lead to serious liver damage. The duration is several weeks to months. The infectious dose is quite low, less than 100 particles. The long incubation period and duration of the disease means that affected individuals will shed virus for a prolonged period. Foods handled by an infected worker or those that come in contact with human feces are likely vehicles (raw shellfish, salads, sandwiches, and fruits). Filter feeding mollusks concentrate virus particles from polluted waters. Control is achieved by cooking food, stressing personal hygiene, and by avoiding shellfish harvested from polluted waters.

B. Enteroviruses

Norwalk-like viruses in the calicivirus family (Coxsackie, ECHO, Norwalk, Rotavirus, Astrovirus, Calicivirus, Parvovirus, and Adenovirus) are now considered the leading cause of foodborne gastroenteritis in the U.S. (1). Other viruses most certainly are involved but our ability to isolate them from infected consumers and foods is limited. Incubation period is typical for infectious organisms, 27 to 72 hours (30). Symptoms are usually mild and self limiting and include fever, headache, abdominal pain, vomiting, and diarrhea. Duration is from 1 to 6 days. The infectious dose for these agents is thought to be very low, 1 to 10 particles. Foods associated with transmission of viral agents are raw shellfish, vegetables, fruits, and

salads. Control is primarily achieved by cooking and personal hygiene.

C. Parasites

Nematodes (roundworms) linked to foodborne illness in humans include *Trichinella spiralis, Ascaris lumbricoides, Trichuris trichiura, Enterobius vermicularis, Anisakis* spp., and *Pseudoterranova* spp. (31). *T. spiralis* can invade skeletal muscle and cause damage to vital organs leading to fatalities. Incubation period of trichinosis is 2 to 28 days, usually 9 days. Symptoms include nausea, vomiting, diarrhea, muscle pains, and fever. Several days duration is common. Foods linked to the disease are raw or undercooked pork and wild game meat (beaver, bear, and boar). Control in pork is accomplished by: 1) cooking to 60°C for 1 minute, 2) frozen storage at −15°C for 20 days, −23°C for 10 days, or −30°C for 6 days, or 3) following USDA recommendations for salting, drying, and smoking sausages or other cured pork products. *Anisakis simplex* and *Pseudoterranova decipiens* are found in fish and are potential problems for consumers of raw fish. The incubation period is several days with irritation of throat and digestive tract as primary symptoms. Control of these nematodes is by thoroughly cooking fish or by freezing fish prior to presenting for raw consumption. *A. lumbricoides* is commonly transmitted by use of improperly treated water or sewage fertilizer on crops.

Cestoda (tapeworms) are common in developing countries. Examples include *Taenia saginata* (raw beef), *Taenia solium* (raw pork), and *Diphyllobothrium latum* (raw fish) (31). Incubation period is 10 days to several weeks with usually mild symptoms including abdominal cramps, flatulence, and diarrhea. In severe cases weight loss can be extreme. Control methods are limited to cooking and freezing. Salting has been suggested as an additional control technique.

Protozoa cause a large number of foodborne and waterborne outbreaks each year. *Entamoeba histolytica, Toxoplasma gondii, Cyclospora cayetanensis*, *Crytosporidium parvum*, and *Giardia lamblia* cause dysentery-like illness that can be fatal (31). Incubation period is a few days to weeks leading to diarrhea. Duration can be several weeks, with chronic infections lasting months to years. Those foods that contacted feces or contaminated water are common vehicles. Control is best achieved by proper personal hygiene and water and sewage treatment.

D. Prions

Prions are small proteins found in animal nervous tissues (brain, spinal cord) (30). They are capable of forming holes in brains of affected animals leading to neurological deficits. In cattle, prions are associated with bovine spongiform encephalopathy (BSE) and consumers of beef from affected animals are at risk of obtaining the human form of the disease called variant Creutzfeldt-Jakob disease (vCJD). Although this link is tenuous, a few human cases in Europe are thought to be based on consumption of contaminating nervous tissue in beef. The disease is characterized by progressive brain dysfunction ultimately leading to death. Little is known about the incubation period or the infectious dose, as this is a newly emerged condition. Meat and milk from affected animals are not considered a transmission risk.

IV. FOODBORNE BACTERIAL INTOXICATIONS

Foodborne microbial intoxications are caused by a toxin in the food or production of a toxin in the intestinal tract. Normally the microorganism grows in the food prior to consumption. There are several differences between foodborne infections and intoxications. Intoxicating organisms normally grow in the food prior to consumption, which is not always true for infectious microorganisms. Microorganisms causing intoxications may be dead or nonviable in the food when consumed; only the toxin need be present. Microorganisms causing infections must be alive and viable when food is consumed. Infection-causing microorganisms invade host tissues and symptoms usually include headache and fever. Toxins usually do not cause fever and toxins act by widely different mechanisms.

A. *Staphylococcus aureus* Enterotoxin

Certain strains of *S. aureus* produce a heat stable enterotoxin that is resistant to denaturation during thermal processing (cooking, canning, pasteurization) (32). The bacterium is salt (10 to 20% NaCl) and nitrite tolerant, which enables survival in cured meat products (luncheon meats, hams, sausages, etc.). Conditions that favor optimum growth favor toxin production, i.e. high protein and starch foods. *S. aureus* competes poorly with other microorganisms, so if competitors are removed by cooking and *S. aureus* is introduced, noncompetitive proliferation is possible. The toxin affects the vagus nerve in the stomach causing uncontrolled vomiting shortly after consumption (1 to 6 hours). Other symptoms include nausea, retching, severe abdominal cramps, and diarrhea, which clear in 12 to 48 hours. Fortunately, fatalities are rare. Sources of the bacterium are usually from nasal passages, skin, and wound infections of food handlers. Hence, suspect foods are those rich in nutrients, high in salt, and those that are handled, with ham, salami, cream filled pastries, and cooked poultry common vehicles. Control is accomplished by preventing contamination, personal hygiene, and no hand-food contact. Refrigeration below 5°C prevents multiplication, and heating foods to greater than 60°C will not destroy the toxin but will kill the bacterium. Prolific

growth of the bacterium is possible in the 5 to 40°C range. Problems with the bacterium occur most frequently with foods prepared at home or at food service establishments, where gross temperature abuse has occurred.

B. *Bacillus cereus* Enterotoxin

This spore-forming bacterium produces a cell-associated endotoxin that is released when cells lyse upon entering the digestive tract (33). There are two distinct types of disease syndromes seen with this bacterium. The diarrheal syndrome occurs 8 to 16 hours after consumption. Symptoms include abdominal pain, watery diarrhea, with vomiting and nausea rarely seen. Duration is a short 12 to 24 hours. Foods linked to transmission of this syndrome are pudding, sauces, custards, soups, meat loaf, and gravy. The second, emetic syndrome, is similar to *S. aureus* intoxication. The incubation period is very short, 1 to 5 hours. Symptoms commonly are nausea and vomiting, with rare occurrence of diarrhea. Duration again is short, less than 1 day. This syndrome is commonly linked to consumption of fried rice in Oriental restaurants. Other foods include mashed potatoes and pasta. The infectious dose for both is thought to be at least 500,000. Because the bacterium forms spores, prevention of outbreaks is by proper temperature control. Hot foods should be held at greater than 65°C, leftovers should be reheated to greater than 72°C, and chilled foods should be quickly cooled to less than 10°C.

C. Botulism

This rare disease is caused by consumption of neurotoxins produced by *Clostridium botulinum* (34). This spore-forming bacterium grows anaerobically and sometimes produces gas that can swell improperly processed canned foods. The bacterium produces several types of neurotoxins that are differentiated serologically. The toxins are heat-labile exotoxins. Two main food poisoning groups (proteolytic and nonproteolytic) are found in nature. Nonproteolytic strains can be psychrotrophic and grow at refrigeration temperatures without the food showing obvious signs of spoilage (no swollen cans or off odor). Incubation period is 12 to 48 hours, but may be shorter or longer. Early symptoms, which may be absent, include nausea, vomiting, and occasionally diarrhea. Other symptoms are dizziness, fatigue, headache, constipation, blurred vision, double vision, difficulty in swallowing, breathing, and speaking, dry mouth and throat, and swollen tongue. Later, paralysis of muscles followed by the heart and respiratory system can lead to death due to respiratory failure. Duration is 3 to 6 days for fatal cases, several months for non-fatal cases. Treatment of suspect cases is by immediate administration of antisera, which can be useful if given early. Respiratory assistance is usually required.

Foods frequently linked to botulism are inadequately home canned foods, primarily low-acid vegetables, preserved meats, and fish (more common in Europe), cooked onions and leftover baked potatoes. The bacterium generally will not grow at a pH of less than 4.6 or at a water activity below 0.85. Thus, high-acid foods, like tomatoes and some fruits, generally are safer than low-acid foods, like corn, green beans, peas, muscle foods, etc. Control is by applying a minimum botulinum cook (12 D) to all thermally processed foods held in hermetically sealed containers. Each particle of food must reach 120°C (and be held at that temperature for 3 minutes to reach a 12 D process). Consumers should reject swollen or putrid cans of food. Properly cured meats hams, bacon, luncheon meats should not support growth and toxin production by the bacterium.

A related illness caused by *C. botulinum* is infant botulism. The bacterium can colonize and grow in the intestinal tract of some newborn infants who have not developed a desirable competing microflora. The toxin is then slowly released in the intestines leading to weakness, lack of sucking, and limpness. Evidence suggests that infant botulism may be associated with sudden infant death syndrome. Consumption of honey by young infants has been linked to this type of disease.

V. CHEMICAL INTOXICATIONS

Chemical hazards are minimally important as etiological agents of foodborne disease (Table 194.1). It should be noted that a number of chemicals, whether naturally occurring or intentionally added, have tolerance limits in foods. These limits are published in the Code of Federal Regulations, Title 21. Informal limits are available through FDA Compliance Policy Guidelines (Center for Food Safety and Applied Nutrition, Washington, D.C.). Prohibited substances (CFR 21, Part 189) are not allowed in human foods either because they have been shown to be a public health risk or they have not been shown to be safe using sound scientific data (36). Safe food additives are oftentimes referred to as Generally Recognized as Safe (GRAS) substances. There are no documented occurrences of foodborne disease associated with the proper use of insecticides, herbicides, fungicides, fertilizers, food additives, package material migration chemicals, and other industrial use chemicals.

Most human-made chemicals associated with foodborne disease find their way into foods by nonintentional means. Accidental or inadvertent contamination with heavy metals, detergents, or sanitizers can occur (36). Although infrequently reported to CDC, most chemical intoxications are likely to be short in duration with mild symptoms. CDC does not attempt to link exposure to these chemicals with chronic diseases. There are measurable levels of pesticides, herbicides, fungicides, fertilizers, and veterinary drugs and antibiotics in most foods.

The vast majority of instances where these residues are found, levels are well below tolerance. Heavy metal poisonings have occurred primarily due to leaching of lead, copper, tin, zinc, or cadmium from containers or utensils in contact with acidic foods. Although usually considered minor contributors to human illness, toxic chemicals in foods may be significant contributors to morbidity and mortality of consumers. A number of toxic chemicals found in foods are of microbial origin. For example, mycotoxins are secondary metabolites produced by fungi (37). The aflatoxins were the first fungal metabolite in foods regulated by the U.S. government. Grains and nut products are common carriers of these and other mold toxins. Other fungal toxins not associated with microscopic molds include toxic alkaloids associated with certain mushrooms. In this case direct consumption of wild mushrooms that are frequently confused with edible domesticated species can lead to acute toxicity (38). There are no current food processing or sanitation methods that can render these mushrooms acceptable as human food.

A number of seafood toxins are naturally associated with shellfish and some predatory reef fish (39). Again, the ultimate cause of these intoxications is traced to the presence of microorganisms. Under favorable environmental conditions, populations of planktonic algae (dinoflagellates) are high (algal bloom) in shellfish growing waters. The algae are removed from the water column during filter feeding of molluscan shellfish (oysters, clams, mussels, cockles, and scallops). The shellfish then concentrate the algae and associated toxins in their edible flesh. Four primary shellfish intoxications have been identified: amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP), neurotoxic shellfish poisoning (NSP), and paralytic shellfish poisoning (PSP). ASP has been linked to mussels, DSP with mussels, oysters, and scallops, NSP with oysters and clams, and PSP with all mentioned shellfish. Control of shellfish toxins is best accomplished by monitoring harvest waters for the toxic algae. Post-harvest control is not presently possible; however, depuration or relaying may be of some use.

Some marine fish harvested from temperate or tropical climates may contain toxic chemicals. Scombroid fish (anchovy, herring, marlin, sardine, tuna, bonito, mahi mahi, tuna, mackerel, bluefish, and amberjack) under time/temperature abuse during storage can support growth of bacteria that produce histidine decarboxylase (39). This enzyme releases free histamine from the fish tissues. High histamine levels lead to an allergic response among susceptible consumers. Prompt and continued refrigeration of these fish after harvesting will limit microbial growth and enzyme activity. Fish most often associated with histamine scombrotoxicity are mahi mahi, tuna, mackerel, bluefish and amberjack. Another form of naturally occurring chemical food poisoning found in tropical and subtropical fish is ciguatera. Like shellfish toxicity, ciguatera results when fish bioconcentrate dinoflagellate toxins through the food chain. Thus, large predatory fish at the top of the food chain can accumulate enough toxin to give a paralysis-type response among consumers. Fish associated with ciguatera poisoning are grouper, barracuda, snapper, jack, mackerel, and triggerfish. Again, monitoring of harvest waters is the essential control step to avoid human illness.

VI. PHYSICAL HAZARDS

Consumers frequently report physical defects with foods, of which presence of foreign objects predominate (8). Glass is the leading object consumers report and is evidence of manufacturing or distribution error. Most physical hazards are not particularly dangerous to the consumer, but their obvious presence in a food is disconcerting. Most injuries are cuts, choking, and broken teeth. Control of physical hazards in foods is often difficult, especially when these hazards are a normal constituent of the food, such as bones and shells. Good manufacturing practices and employee awareness are the best measures to prevent physical hazards. Metal detectors and X-ray machines may be installed where appropriate.

VII. SUMMARY

Because of the predominance of hazardous biological contaminants found in raw foods most food processing unit operations are designed to reduce or eliminate these hazards. Successful implementation of these processing steps can greatly minimize the risk of foodborne disease transmission. Unsuccessful implementation or failure to recognize the need for interventions sets the stage for production of potentially dangerous products. Because of the varied nature of foods it is imperative that prudent processors understand the inherent risks of their products and ensure the proper application of interventions to reduce these risks. This fundamentally sound recommendation will help keep processed foods competitive in the marketplace and will help maintain and enhance consumer confidence in the safety of their food supply.

195 Personal Hygiene

Kenneth W. McMillin
Department of Animal Sciences, Louisiana State University Agricultural Center

CONTENTS

I. INTRODUCTION

More than 215 million cases of infectious disease are caused by foodborne illness in industrialized countries each year, but the true incidence is difficult to determine because actual illness cases are probably underreported (1,2). The five major risk factors related to employee behaviors and preparation practices in retail and food service establishments that have been identified as contributing to foodborne illness are improper holding temperatures, inadequate cooking, contaminated equipment, food from unsafe sources, and poor personal hygiene (3). The five key public health interventions to protect consumer health are demonstration of knowledge, employee health controls, controlling hands as a vehicle of contamination, time and temperature parameters for controlling pathogens, and the consumer advisory notices (3). Three of the important interventions rely directly or indirectly on the employee and individual personal hygiene.

Personal hygiene refers to the cleanliness of a person's body, with skin, hands, hair, eyes, mouth, nose, nasopharynx, respiratory tract, and excretal organs as body parts that can potentially contaminate food (4). Poor personal hygiene contributed 38% of foodborne illness outbreaks in the U.S. from 1973 to 1987 (5) and 36% of outbreaks from 1988 to 1992 (6). From 1983 to 1992, 79% of outbreaks were bacterial in origin, with disease incidence contributed most by improper holding temperature and poor personal hygiene of food handlers (7). This trend continued in the U.S. from 1993–1997, with 75% of foodborne outbreaks from bacterial pathogens, 33% being attributed to improper holding temperature, and 15% to poor personal hygiene (8). The most common factors contributing to outbreaks in England and Wales between 1992 and 1996 were improper cooking, inadequate storage, cross-contamination, and raw ingredients in prepared foods, with 63% of outbreaks involving foods of animal origin (9). A key concept in proper personal hygiene is that appropriate individual behavior and actions can prevent transmission of pathogenic microorganisms from the body or from contaminated surfaces to food by the food handler. The recommended practices of sanitation and personal hygiene are similar in food processing plants, foodservice preparation establishments, and home kitchens, indicating a common goal in preventing foodborne illnesses. Personal hygiene forms the basis for effective food processing sanitation programs and manufacture of safe food products. Good Manufacturing Practices (GMPs), Sanitation Standard Operating Procedures (SSOPs), Sanitation Performance Standards (SPSs), Sanitation Control Procedures (SCPs), and Hazard Analysis Critical Control Point (HACCP) programs all depend upon the consistent application of desirable habits by employees. HACCP is a preventive system of food control that relies upon the other prerequisite programs for success (10).

II. SOURCES AND TYPES OF FOOD CONTAMINATION

Contamination of food can be categorized into three hazard areas of physical, chemical, and biochemical sources. A hazard is an agent that is reasonably likely to cause illness or injury in the absence of its control (11) or any biological, chemical, or physical property that may cause an

unacceptable consumer health risk (12). Physical hazards are usually considered to cause less severe or shorter durations of illness than the other types of hazards, but may be caused by human activities or behaviors. Physical hazards include foreign objects or extraneous materials not normally found in food, such as wood, plastic, glass, and metal that might be contributed by lack of personal hygiene regarding toothpicks, jewelry, bottles, eating utensils, and other objects not desired in food areas. Finding these items in foods causes discomfort or personal injury to the consumer, but usually does not result in death (13). Physical hazards that are less likely to be contributed by improper personal hygiene are materials like bone fragments in meat or poultry, insects or insect fragments, and sand or soil due to improper harvesting or processing practices.

Chemical hazards are substances that may cause toxicity or acute diseases. The actual risk of illness or injury to consumers from many of the chemicals used in food production and processing is controversial (14). Some chemicals may be used in processing, such as cleaners, detergents, sanitizers, lubricants, and water treatment chemicals (14). Other chemicals are used for specific purposes, ingredients in food products, antimicrobial solutions on carcasses, or as processing adjuncts (14). Other sources of chemical hazards might be pesticides, herbicides, antibiotics, hormones, or heavy metals from raw materials; personal care-related materials such as cosmetics, perspiration, and medicines; or naturally occurring substances such as myotoxins, allergens, or color extractives. Foodborne illness may be caused by chemical poisoning, but illnesses caused by microorganisms are more common than from chemicals (15). Generally, biological hazards are considered the most serious of the foodborne agents. These include bacteria, viruses, fungi, and parasites as well as the toxins from those biological sources (16,17). Humans have been regarded as an excellent harbor for most of the pathogenic microorganisms, with human disease conditions linked to the contamination of foodstuffs. Gram-negative pathogenic microorganisms (*Salmonella*, *Shigella*, *Escherichia coli*, *Campylobacter*, and *Vibrio* species) may be present in the intestines and feces of humans, animals, and birds (18). These microorganisms are not heat resistant and cause problems because of poor sanitation, inadequate personal hygiene, and cross-contamination (18).

The major classifications of biological foodborne illnesses are intoxication caused by ingestion of toxins produced by microorganisms, infection caused by growth of microorganisms or parasite, and toxin-mediated infection that arise from toxin production by pathogenic microorganisms introduced to the intestinal tract through consumption of contaminated foods (15,16,17). Pathogenic microorganisms that cause foodborne illnesses include *Campylobacter*, *Clostridium*, *Escherichia*, *Listeria*, *Salmonella*, *Shigella*, *Staphylococcus*, *Streptococcus*, *Vibrio*, and *Yersinia* bacteria species; viruses such as Hepatitis, Noroviruses (Norwalk), and Rotavirus; molds and fungi that produce ergotoxins, alkaloids, and aflatoxins; and parasites such as *Anisakis*, *Cryptosporidium*, *Cyclospora*, *Giardia*, *Toxoplasma*, and *Trichinella* (6,15,16,17,19,20,21,22). Minimum growth temperature for most pathogenic bacteria is 4°C or above (16,17). Incubation times for foodborne illnesses range from a few hours with *S. aureus* and *V. parahemolyticus* to several weeks for *L. monocytogenes* and Hepatitis A (6,22). An individual may be infected with foodborne illness vectors and contaminate food-contact surfaces or other individuals, even if clinical symptoms of the illness are not evident (23). Food handlers may not always recognize when they are ill and may cause contamination by handling food.

Food workers who were ill either prior to or at the time of the outbreak, depending upon the specific microorganism involved, were implicated in 93% of foodborne illness outbreaks from 1975 to 1998 (23). Staphylococcal food poisoning, shigellosis, and typhoid fever were most highly contributed by colonized persons handling the implicated foods (5). *Campylobacter* in retail chicken and lamb shared identical subtypes as those strains found in humans, which indicates the potential role of food to human foodborne illness through hand-to-mouth transmission (24). The incidence of *Campylobacter* spp. in broiler feces and corresponding processed carcasses decreased by 1 logarithmic unit from 1995 to 2001, which may have contributed to the reduction in the frequency of human disease during the same time period (25). However, *Campylobacter* was not detectable on carcasses after overnight chilling, even though it was readily recovered from composite rectal and individual colon samples from swine, indicating that the microorganism did not progress through the slaughtering operation and other means of transmission to pork should be considered (26).

Campylobacter jejuni and *Salmonella* spp. are easily transferred from raw chicken to food contact surfaces and hands and then to other foods or food contact surfaces through cross-contamination (27). *Salmonella* and *Campylobacter* were implicated in 72% of laboratory-diagnosed cases of foodborne diseases in the U.S. in 2001 (22). *Salmonella* species isolated from domestic and imported food products were resistant to rifampin antibiotic, and 49% of isolates were resistant to one or more antimicrobial agents, giving a baseline for antimicrobial-resistant *Salmonella* in the U.S. food supply (28). The incidence of *L. monocytogenes* was increased after chilling and cutting of pork and beef, with contamination originating from the processing environments of the chilling or cutting room, and the incidence of *L. monocytogenes* was lower in bovine cutting and processing than in porcine cutting and processing (29). Viral foodborne infection can be transmitted to humans and food-contact surfaces by

contaminated human hands (30,31). There are health risks of contaminated hands contacting the mouth through smoking or eating or the further contamination of ready-to-eat foods by contaminated hands (27). Foodservice employees can contribute to foodborne illness by mishandling food or as direct sources of illness (32). The infectious doses for many pathogenic microorganisms are relatively low, especially in susceptible individuals, which indicates that all measures possible should be implemented to prevent contamination of food from any source. Governmental health agencies have implemented guidelines and regulations required of personnel and their managers regarding the cleaning and composition of facilities and equipment and the health and hygienic practices expected of employees for all sectors of the food industry (2). The recognition that food handlers served as the source of infection in foodborne outbreaks and that hand contact with food was a mode for pathogen contamination has been responsible for changes in governmental oversight of food production and handling practices (23).

III. PERSONAL HYGIENE REGULATIONS

Most governments have agencies that prescribe sanitation and sanitary practices because there is potential for food handlers to transfer pathogenic microorganisms to food. The European Union (EU) European Food Safety Authority, United States Food and Drug Administration (FDA), and United States Department of Agriculture (USDA) have enacted directives and regulations that identify the need for sanitation and cleanliness of facilities, equipment, and personnel (3,33,34,35,36). The EU passed Council Directive 93/43/EEC in 1993 to harmonize general rules of hygiene for foodstuffs to protect human health through movement of foodstuffs throughout all stages of preparation, processing, manufacturing, packaging, storing, transportation, distribution, handling, and sale or supply to the consumer (33). These incorporated the use of hazard analysis, risk assessments, and other management techniques, including microbiological criteria and temperature control when those were adopted in accordance with scientifically accepted general principles. In addition, the guides to good hygiene practice based on the Recommended International Code of Practice, General Principles of Food Hygiene of the Codex Alimentarius were developed (34). In the U.S., the Food, Drug and Cosmetic Act was enacted in 1906 and amended in 1997 and the Federal Meat Inspection Act was enacted in 1906 and substantially amended by the Wholesome Meat Act of 1967. The Food and Drug Administration of the Department of Health and Human Services and the Food Safety and Inspection Service of the Department of Agriculture are agencies responsible for ensuring the wholesomeness of food products in the U.S. (3,35,36). The many requirements for personal hygiene that are common among different country jurisdictions are summarized in Table 195.1 to show the common concerns for personal hygiene.

The common concerns for prevention of food contamination and maintenance of personal hygienic conditions are reflected by the regulatory preambles to ensure that food is safe and unadulterated, that food-contact surfaces are cleaned and maintained in an uncontaminated condition, that facilities provide for cleaning and continuation of hygienic conditions, and that employees practice appropriate hygienic behaviors in food areas. Additionally, most agency regulations describe appropriate facilities for cleaning equipment; necessary personal hygiene, training, and knowledge of food sanitary practices by employees and managers; and requirements for personal habits of individuals in food areas and manufacturing facilities. A difficulty in quantifying the role of personal cleanliness in control of infectious diseases is that other factors, including improved public services, waste disposal, water supplies, commercial food handling, and nutrition, have also changed (37).

The implementation of HACCP plans and improvements in Good Manufacturing Practices have reduced microbial contamination on equipment surfaces and educational programs that continually reinforce food safety principles have reduced total aerobic and coliform counts (38). Complex etiological relationships in food products are due to interactions among food, environment, and the food handler (39). The role of hands in disease transmission and the accompanying importance of handwashing in preventing foodborne disease has been well established (40).

IV. HAND CLEANLINESS

The aim of hand sanitation is to prevent transmission of pathogenic microorganisms from the hands through food or from food to food transferred through the handler's hands (41). Cross-contamination of bacterial and viral pathogens was thought to be a major contributing factor for sporadic and epidemic foodborne illness (42,43). The FDA database of 17,477 observations by compliance officers indicated that lack of hand washing accounted for 30 to 45% of the noncompliance observations (44). Resident bacteria are those normally present on the skin and are usually not harmful while transient bacteria are microorganisms transferred to the skin (45). Bacteria can change their status from transient and become permanent residents on the skin (39). The pathogens most commonly transmitted by hands in healthcare settings are nosocomial bacterial pathogens and lipophilic viruses, which are different than the fecal pathogens transmitted through fecal-oral routes from contaminated hands to food items in retail and food service settings (46).

Skin and hand hygiene are primary means to reduce contact and fecal-oral transmission of infectious agents (37). Removal of the bioload from the hand is a key focus

TABLE 195.1
Sanitary and Personal Hygiene Requirements in International and United States Regulations

Sanitary Guideline or Requirement	Codex (34)	Food Code (3)	21CFR (36)	9 CFR (35)	EU 93/43 Directive (33)
Ensure food is safe and suitable for intended purpose	Section III	2-102.11	110.5; 110.80	416.1	Article 2
Protect food and ingredients from contamination	3.3; 4.4.4		110.10	416.1	Article 3

in proper hand washing (47,48). Frequent hand washing has been cited as a critical component for safe food serving in the retail industry to prevent spread of disease (49,50,51). Numerous pathogenic microorganisms can survive up to 90 minutes when artificially inoculated on the fingertips (52). Thorough hand drying is also important to reduce the incidence of sporadic infections (53). A review of the efficacy of hand washing using literature and experimental data to determine risk assessment ended with the conclusion that proper hand washing can reduce the risk of bacterial contamination on hands, with sanitizer use, soap use, and drying method being primary factors influencing final bacterial counts on hands (54). Hand washing and drying efficacy against resident microbial flora is 35% to 60% (55). Levels of microbial contamination vary with worker and type of work in food and non-food industries (56). Heavily soiled hands of meat cutters had higher bacterial levels, even after hand washing, than workers in meat packaging areas (57).

More frequent hand washing will affect the number of bacteria on the skin (58). After washing with water for one minute with rubbing, but without soap, food handler hand samples had 6,200 to 16,000,000 microorganisms per mL, which was indicative of the problem of hand hygiene among food handlers (59). Comparisons of bacterial baseline levels on hands of workers in the food industries and non-food occupations showed a correlation between the flora on the hands and that of the food that was contacted

(39). Fecal coliforms and enterococci on hands of employees increased with increased degree of food contact (39). Bacterial transfer rates among hands, foods, and food preparation surfaces are highly variable, but it is likely that contamination of hands and various surfaces occurs following the preparation of contaminated foods (43).

Microorganisms were transferred in sufficient numbers by contact of fingers or clean surfaces with contaminated surfaces or cloths to represent a potential hazard if hands then contacted food (60). Cleaning of cloths with detergent increased contamination of cloths and surfaces while quaternary ammonium disinfectant plus EDTA significantly reduced contamination of surfaces and cloths (61). After handling meat contaminated with *Enterobacter aerogenes*, hands had lower microbial counts, but microorganisms were transferred to water faucet spigots (43). Hand washing reduced microorganisms enumerated on the hands, but not to an absolute level of zero, and so the transfer rate of microorganisms by hand to food must be considered a dynamic phenomenon (43). *Campylobacter* are unlikely to survive for long periods outside the body, but transmission from contaminated hands to mouth may occur when food handlers process raw food and from cross contamination of foods and utensils when cooked food is handled immediately after uncooked food (42). The risk of foodborne illness associated with cross-contamination depends upon the level of contamination on the surfaces and the probability of contamination transfer to the foods that will be consumed (42).

Inoculum level of microorganisms is critical in transmission of foodborne pathogens by the hands (58). In one study, all beef samples became positive when food handler fingertips were inoculated with more than 600 *Salmonella*, but lower levels of inocula on fingertips yielded variable microorganism counts on beef samples (62). The efficacy of hand disinfectants and hand washing practices can be determined using several different techniques, but the major areas of contamination are the fingertips and perimeter of the palm (63). Most bacteria identified on hands are resident rather than transient-type skin microorganisms (64). Transient microorganisms represent the major concern in cross-contamination and may not act like resident or normal skin flora in a washing process (64). Hand washing by workers with low initial contamination did not eliminate transient microorganisms that contaminated the hands (57). Cleaning compounds will remove transient bacteria and sanitizers will subsequently destroy the microorganisms, but antimicrobial agents must have a contact time of more than five seconds during hand washing to reduce microbial load on the hands (45). An antibacterial agent for hands should not be chosen on the basis of activity against staphylococci and Gram-positive bacteria, but should control transient organisms by killing a wide variety of pathogenic microorganisms, have sufficient residual concentration to exert control throughout the day, and be non-irritating to the skin (41). Detergents or agents that irritate the skin may damage the stratum corneum and impair the barrier properties by removing normal skin oils (65).

Bacteria are not readily transferred from person to person through use of bar soaps, which do not support growth of bacteria under usage conditions and are inherently antibacterial by their physical-chemical nature (66). Bacteria from previously used soap bars were not transferred to the hands of individuals by routine handwashing (49). Some antimicrobial agents (0.5% 2,4,4'-trichlor-2'-hydroxy diphenyl ether, 0.5% tribromosalicylanilide, 0.325% parachloro-meta-xylenol, PCMX) did not decrease the numbers of bacteria released from hands more than a non-germicidal soap control while iodophor with 0.75% available iodine and 4% chlorhexidine gluconate gave significant reductions during short exposure times (64). Higher concentrations of 2,4,4'-trichlor-2'-hydroxy diphenyl ether and PCMX did not improve reduction in microorganisms released from fingertips (67). Iodine was the only agent that killed bacteria, had residual effect, and was not irritating to skin compared with bisphenols and quaternary ammonium compounds (41). Other studies showed that non-antibacterial liquid soap, hand wash containing PCMX, and an alcohol gel sanitizer gave equivalent reductions in microbial populations on hands after 30 seconds of washing and 30 seconds of rinsing while the combination of antibacterial lotion soap and alcohol gel sanitizer caused greater reductions in microorganisms (68). Automated hand washing systems are used in some food establishments. Manual hand washing with soap for 5 seconds gave the same relative results as automated hand cleansing for 10 seconds with 2% chlorhexidine gluconate (69). The major advantage of hand wash machines is consistency of the hand washing procedure (70). Hand washing machines improved hand-washing compliance from 22% to 38%, but nurses preferred manual hand washing and contamination of sleeves sometimes occurred in a healthcare study (71). Washing of hands is generally preferable to dipping of hands in antimicrobial agents.

Manual hand washing with soap for 5 seconds or automated hand cleansing for 10 seconds with 2% chlorhexidine gluconate resulted in greater microbial reduction than an iodine dip for 2 seconds (69). Hand dip treatments with 25% available iodine, 50 ppm available chlorine, or 930 ppm benzalkonium chloride were generally less effective than hand wash treatments, particularly those with 0.75% available iodine or 4% chlorhexidine gluconate (72). Of hand dip agents, only quaternary ammonium (930 ppm benzalkonium chloride) resulted in significant microorganism decreases compared with sodium hypochlorite (50 ppm available chlorine) and iodophor (25 ppm available iodine) (64). USDA requires that hand sanitizing compounds for dips have equivalency of 50 ppm chlorine (73). Hand sanitizer and sanitizing solutions used as a hand dip should have approved antimicrobial ingredients (3).

Different antimicrobial agents influence different types of microorganisms. Widespread use of antimicrobial products that are superior to plain soap have caused concerns about bacterial strains resistant to the agents and the alterations of skin flora (37). Iodophors and chlorhexidine gluconate reduced *E. coli* more than *P. fluorescens* (72). *S. aureus* had better tolerance to sodium hypochlorite than *Salmonella enteritidis* (74). Hepatitis A virus was highly resistant to a variety of commercial disinfectants, with 12% sodium hypochlorite most effective at inactivating the virus on food contact surfaces (31). Antiseptics like alcohols and iodophors have instant microbial killing while chlorhexidine gluconate, cloroxylenol, and triclosan have less rapid action, but a residual effect (75). Some protective and antiseptic lotion products applied after hand washing may give a residual antibacterial effect and reduce skin irritation, particularly with glove use (75). Barrier creams are widely used for skin protection, creating a thin, water repellent layer over the skin, which may decrease the effectiveness of germicidal agents (76). The benefits of hand washing are enough to require hand washing even when gloves are used (77).

The FDA Food Code requires that there be no hand contact with ready-to-eat food, reflecting the premise that use of a physical barrier such as gloves or utensils minimizes the transfer of pathogens to food (3). Plastic glove use offers benefits and disadvantages because intact gloves prevent bacteria from the skin from entering product, but the skin inside the glove may be occluded and may promote resident microorganism growth (45). Use of gloves is well established for infection control in healthcare environments (77). A vinyl or latex barrier that is intact will provide protection from transmission of bacteria contaminating the hands (78). Vinyl food-grade gloves frequently have pinhole punctures that compromise the barrier protection (77). Gloves can be easily ripped, torn, or punctured as workers perform their normal duties in food handling (78). Studies are conflicting on the necessity of glove use when food is handled. Microbiological counts on ungloved hands washed hourly were lower at 3.5 log cfu/g than on gloved hands with no hand washing and hourly glove changes (6.1 log cfu/g) after a three-hour time (79). Transfer of microorganisms from food to hands and from hands to food was 0.01% when subjects wore gloves and 10% without gloves (80). Gloving is generally recognized as an adjunct and not a replacement for hand washing (77). The frequency of glove changes depends upon length of time gloves are worn, types of food handled, material and thickness of gloves, type of work activity, and chemicals contacting the gloves (56).

Hourly glove changes with hand washing between changes and hourly washing and sanitizing of bare hands after handling of ground beef contaminated with *E. coli* were similar in minimizing microbial levels on hands after 3 hours (81). Bare hands had the greatest level of contamination while bare hands with hourly washing, but no sanitizing, and hourly glove changes with no hand washing minimally reduced microbial loads on hands (81). Knitted gloves (polyester and cotton cloth) could reduce the transfer of bacteria from hands to meat, but increased the transfer of microorganisms among meat pieces (82). Cloth gloves should not be used in direct contact with food unless the food is subsequently cooked to destroy pathogenic microorganisms (3). Cloth gloves must be laundered before being used with a different type of raw animal food (3). Rubber gloves could almost prevent transfer of bacteria from hands to meat and would greatly reduce transfer of microorganisms among meat pieces (82). Heavy contamination of hands is rare when knitted or rubber gloves are worn by meat plant workers (83). Decontamination of glove surfaces can be accomplished by washing. Washing with water, non-medicated soap, or several antimicrobial agents eradicated *S. aureus* loads from vinyl glove surfaces, but water was ineffective with latex gloves (84). Use of 4% clorhexidine gluconate and 70% ethanol was more effective in decontaminating latex gloves than non-medicated soap or sodium hypochlorite with 6,000 and 10,000 ppm available chlorine (84). The routine washing of gloved hands could not be recommended for healthcare workers (84). It should be noted that glove use may promote complacency about hand hygiene so effective hand washing must be conducted with or without the use of gloves (45). Use of gloves does ensure that fingernails and fingertips, major sites of contamination, are not exposed.

Microbial counts of 2 to 3 log CFU frequently occur beneath nails and are often more difficult to remove than from other locations on hands (85). Inoculated microbial populations were reduced the greatest by washing with liquid soap plus a nailbrush (86). Counts recovered from hands with artificial nails were higher before and after hand washing than with natural nails (86,87). Best practices for fingernail sanitation are maintaining short fingernails and scrubbing of fingernails with soap and nailbrush when hands are washed (86). The residual effectiveness of hand washing to prevent cross-contamination of foods and hand-to-mouth contamination is also affected by other factors (53). Residual moisture after washing is an important factor in cross-contamination (79). Washing hands with soap and water or water alone combined with drying on paper towels can remove a heavy inoculum of *Campylobacter* from the fingertips (53). Paper towels were the most effective way to reduce residual moisture after washing (79). Wiping of hands with a paper towel seemed to physically remove bacteria from the hand (42). Hot air driers were viewed to be safe from a bacteriological view, but a 30-second cycle time was insufficient to dry hands thoroughly (88). Electric air drying was shown to reduce the most test microorganisms on finger pads, with paper intermediate and cloth drying the least effective regardless

of washing agents among 70% isopropanol, medicated liquid soap, unmedicated liquid soap, or tap water (89). Hot air driers may create undesirable aerosols when used in processing areas or accumulate microorganisms from toilet areas when used in rest rooms (56,90).

Transfer of Hepatitis A virus from contaminated finger pads could be interrupted by hard-water rinsing and towel drying, application of a topical agent followed by water rinsing and towel drying, and exposure to a hand gel with 62% ethanol (91). Variability in virus transfer rates following water rinsing indicated that volume of water might influence virus removal from the finger pads differently (91). The studies discussed in this section verify that effective hand hygiene is highly dependent upon the habitual behavior of food handlers and the available supporting facilities and items for hygienic practices.

V. RECOMMENDED PERSONAL HYGIENIC PRACTICES

Food workers should follow several fundamental practices to maintain themselves, facilities, equipment, and the food hygienically. Personal hygiene concerns include physical health maintenance, exclusion of individuals with illnesses or disease from contact with food, development of hygienic work habits, proper washing of hands, and maintenance of personal cleanliness (45). Proper personal hygiene at a food establishment involves hand washing following any act that even remotely might cause hand contamination, covering of cuts and abrasions, and designated areas for smoking (58). Personal cleanliness should be maintained through daily bathing, frequent hair washing, daily fingernail cleaning, use of a hat or hairnet, and clean underclothing (45). The sanitary and personal hygiene requirements of controlling regulatory agencies, such as those in Table 195.1, should be used as a guide in establishing food handler and personal hygiene rules and monitoring procedures. Employees should be given adequate training, supervision, and supporting items to promote and maintain desired personal hygiene when handling food.

Managers should check each employee before each shift begins to ensure healthfulness (4). All workers should be trained to report when they are ill or have suffered from an illness. Sick employees may have food poisoning bacteria that can be spread to food (4). Workers should advise the supervisor if they feel ill, especially if there is diarrhea, sore throat, discharge from ears, eyes, or nose; if there are cuts, boils, or skin infections; or if they have been in contact with someone who has been ill (4). Employees with open lesions that cannot be adequately covered, with signs of illness such as coughing or colds, or who have been in contact with other individuals who are ill should be placed in work that does not require contact with food or food-contact surfaces (3,92).

The clothing worn by food workers should be clean (3). Food handlers should also wear appropriate head and face coverings, gloves when applicable, and boots or other cleanable footwear when floors are contaminated (92). They should maintain cleanliness of themselves, particularly their hands and exposed arms, utensils, equipment, facilities, and other food-contact surfaces that might cause food contamination (3). Hand washing should be frequent to prevent hand-to-food or food-surface-to-food-contamination, with a minimum of 20 seconds washing with soap and warm water (3).

It has been suggested that hand washing procedures may vary with activity, double hand washing when initially entering food handling areas and single hand washing frequently during the food handling operations (73). The suggested procedures for double hand washing requires wetting of hands, soap application to form a lather that is spread uniformly on all hand surfaces, use of a nailbrush on all sections of the hand, fingers, and nails, rinsing with warm water, repeat of soap lathering and physical abrasion, second rinse, and towel drying (45). Recommended double washing procedures are shown in Figure 195.1 (73). Double hand washing is used to reduce high levels of pathogens to a safe level upon beginning a work shift, after using toilets or after breaks, after contact with vomit or any fecal material, and after touching any open sores (73). Increased friction through rubbing hands together or use of a fingernail brush with the soap will reduce a larger number of transient and resident microorganisms than quick hand washing (4). The single wash procedure omits use of nailbrush, second soap lathering, and second rinsing and is recommended for use during food handling operations to reduce lesser amounts of microbial or other contamination of the hands (56). Food employees should use vigorous friction on the surfaces of lathered fingers, finger tips, areas between fingers, hands, and arms by rubbing for at least 10 to 15 seconds followed by thorough rinsing under clean and running warm water and thorough drying of cleaned hands and arms (3). Contact with antimicrobial agents less than 5 seconds will have little effect on reducing the microbial load (4).

Hands should be washed before starting work, after touching bare human body parts other than clean hands and arms, after using the toilet, after coughing, sneezing, and use of a handkerchief or disposable tissue, after using tobacco products, following eating or drinking, after handling soiled equipment or utensils, during food preparation as often as needed to remove soil and contamination, to prevent cross-contamination when changing tasks, when switching work between raw and ready-to-eat foods, before donning gloves for working with food, and after engaging in activities that contaminate the hands (3). Hands should be washed often throughout the working day and most particularly when specific activities are changed to another type of task. It is highly advisable that

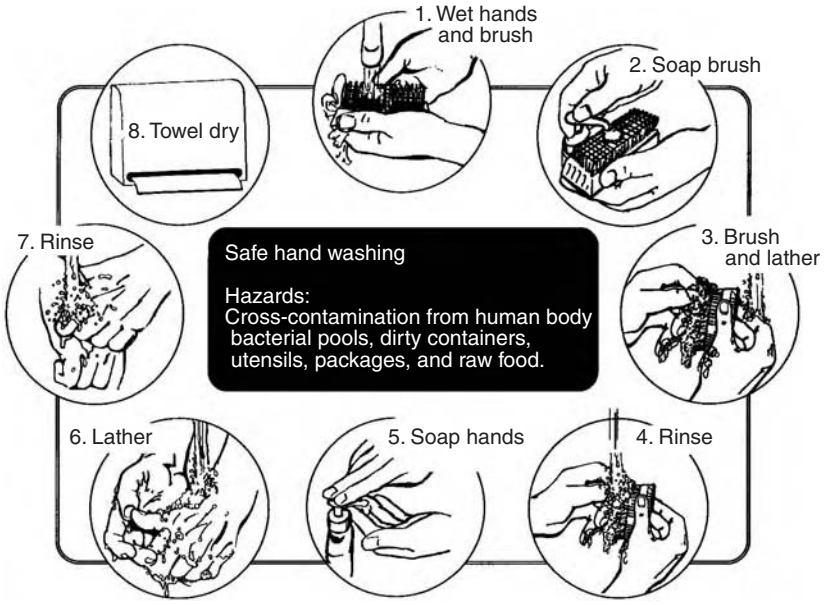

FIGURE 195.1 Double hand washing procedure advocated for elimination of pathogenic microorganisms from hands. Used with permission by OP Snyder, Jr., Ph.D., reference 73.

hand washing be conducted after each absence from the post of duty or work station, after handling cleaning chemicals or equipment, and after putting on a waterproof dressing over wounds or sores (92). Particular attention should be given to cleaning under the fingernails during hand washing (3).

Nails should be clean and short with no biting with the teeth, no nail varnish or polish, and no false nails. Artificial nails and nail polish should not be used by food workers (92). Nails and cuticles should be smooth and neatly trimmed (3,93). Workers should not wear any jewelry, such as earrings, hairgrips, rings, bracelets or wristwatches, or other items that might carry bacteria on them or be lost and cause physical contamination of food products (3). Jewelry should be removed because it interferes with hand washing and may become a physical contaminant if lost in food (89,93).

Hair should be kept clean, tidy, and covered when working with food. Hair restraints are absolutely necessary for all individuals in food processing and preparation areas (3,4). It is preferable to use disposable bouffants, hoods, or snoods to keep hair and hair contaminants from contaminating food, even with helmets, hard hats, or caps. Loosely woven hairnets should be avoided because there is inadequate control of hair (90). Individuals with facial hair should wear disposable paper beard nets. Adequate and clearly marked containers for disposal of head coverings should be immediately outside work areas and near locker and rest room areas (90).

If gloves are to be used, a means to keep them hygienic while workers are washing their hands immediately before beginning work should be available. Hands must be washed properly before gloving (3). Clean gloves should be issued at each break or when employees perform tasks other than food handling. Workers should be required to change gloves whenever they become excessively soiled or contaminated or when changing from one task to another activity (3). It is highly advisable that utensils, tools, and equipment be used to contact food rather than hands or gloves. Gloves should be chosen carefully. Green gloves frighten animals in meat processing facilities (94). Latex gloves should be avoided because latex in glove materials might be transferred to food and cause allergic reactions in the approximately 6% of U.S. consumers who are allergic to latex (94). If latex gloves are used, gloves should not be powdered since the powder, often corn starch, will bind the latex protein and increase glove contact with the skin (94). Alternatives to natural latex rubber gloves are polychloroprene (neoprene), styrene butadiene, styrene ethyl butadiene, and synthetic latex, which lack the protein that initiates allergic reactions (94).

Smoking and gum chewing should be avoided during the day (93). Workers should never eat, drink, chew gum, or use tobacco products in any room or adjacent areas where food is handled or stored. Workers must always wash their hands after eating, drinking, chewing gum, using tobacco products, or handling money before resuming activities in food areas (4). Workers should not cough, sneeze, or touch the mouth and nose during working with food and should wash their hands using the double wash technique if the mouth or nose is contacted. Sanitation training and education should be ongoing and continuous to maintain personal and environmental hygienic conditions (78).

VI. TRAINING, FACILITIES, AND SUPPORT FOR PERSONAL HYGIENE

Appropriate equipment and supplies are needed for personal hygiene (4). Survey instruments have indicated that knowledge of food safety by food service managers did not correlate with hand washing habits, with only 75% always washing hands after using the toilet (40). As many as 60% of foodservice personnel neglect to wash their hands after use of toilets (40,55). Hand washing behavior was ranked by an expert panel as the highest behavior for prevention of shigellosis while other factors such as keeping food at safe temperatures and avoidance of cross-contamination ranked more highly for prevention of other forms of foodborne illnesses (95). Hand washing should be made a part of the operation, and not treated as a separate issue apart from the food preparation (48). This may be difficult because of the location of hand wash and sanitary facilities. Barriers to frequent hand washing have been identified as understanding the necessity for frequent hand washing and the amount of time needed for hand washing (51). The solution lies in improved hand washing compliance and management of hand washing through effective and consistent training (47).

Teaching workers to wash their hands properly involves learning by doing through repetition and observing actual hand washing results (48). An effective teaching tool is to use colored spice in cooking oil or a safe fluorescent compound spread on the hands before washing and to observe the hands carefully, particularly around the fingernails and between the fingers, after washing (using UV light for fluorescent compounds) (48,55). Employees should scrub hands whenever contaminated, as may occur after touching food, contact surfaces, or the mouth, and always before performing the next or a different job function (93). Washing for 30 seconds, using a nail brush and lather to scrub fingernails, knuckle creases, backs of finger joint, and deep creases in palms is required (93).

Hand washing sinks should be located near all work and food preparation areas to encourage washing of hands frequently during work and to allow convenient use by employees (3,93). Separate sinks are required for hand washing and for food preparation or utensils (3). Hand washing sinks should have foot or knee-operated faucets to prevent contamination of faucet handles with contaminated hands (4). Hand washing lavatories should be equipped to provide water at least 38°C with a self-closing, slow-closing, or metering faucet to provide a flow of water for at least 15 seconds without reactivation (3). It is desirable that water be 43–50°C (4). Automatic hand washing facilities may be substituted for hand washing lavatories in food establishments that have at least one hand-washing lavatory (3). Each hand washing lavatory or group of adjacent lavatories should have a supply of hand cleaning liquid, powder, or bar soap and individual disposable towels, a continuous towel system that supplies the user with a clean towel, or a heated-air hand drying device (3). A sign or poster that notifies employees to wash their hands should be provided and clearly visible at all hand washing lavatories (3).

Welfare facilities must be clean, free of debris, well lighted, and conveniently located away from production areas. There should be a locker or changing area where employees change from street clothing to work garments (3). Work clothes should not be worn to work, but stored in a locker at work or carried to work in a garment bag (93). Lockers should be neat and well ventilated, with sufficient size to store clothing and other personal items (3,90). Laundry services are preferable to in-plant laundry for supply of clean clothing (90). It is highly recommended that uniforms be provided to workers to ensure that clothing is clean each day (90,94). This may be especially important when protective clothing is necessary to keep employees dry, warm, and comfortable in cold work environments (94). The choice of durability or disposability, relative weight of garments, and barrier capacity of garments depends upon the activities of the food handler (94). An effective means of reducing human contamination to food and contact surfaces in ready-to-eat facilities is clean, sanitized clean room work apparel to provide a protective barrier between employee and product (96). Clean room apparel is designed to capture and trap particles to prevent them from dispersing into the processing environment (96). Clean room clothing fabrics vary in weight, pore size, moisture vapor transmission rate, and air permeability (96).

Selection of uniforms and uniform provider services should involve consideration of garment segregation to prevent cross-contamination, a wash process formulated to decontaminate and remove particles, an efficient one-pass drying process, complete inspection process, garment packaging to maintain cleanliness, and distribution of required garment quantities (96). Cleaning of food handler clothing is a multi-step process, removing organic material first and then using sequential washing and rinsing cycles (94). Reusable uniforms should be durable and cleanable, achieving a six-log reduction of pathogens (94). Clothing of 100% polyester garments lasts longer than with cotton (94). Effective bacterial destruction relies on water temperature higher than 70°C and pH of 11 or 12 (94). Clothing should have no pockets or pockets only on the lower part of the body to prevent physical contamination by items falling from pockets (90). Pockets should have flaps that close securely, and all clothing should be routinely examined for loose buttons, snaps, closures, and frayed edges (90). Work clothing should be light in color to reveal stains and contamination (90,93). Food handlers should be encouraged to change their clothing when it becomes soiled or contaminated. Employers must anticipate the demand for

different sizes of clean garments, the purchase of replacement clothing, repair of damaged clothing, and adequate cleaning and sanitation of soiled clothing.

Rubber boots with steel toes are recommended in food processing areas to promote proper foot hygiene and prevent cross-contamination in food processing areas (92). Boot wash stations and footbaths with antimicrobial agents should be located at strategic locations, especially at entrances and exits to areas of food production. If leather boots are used in areas of the plant where food is not handled, dirt and debris should be rinsed from boots with plain water or a mild soap solution using a soft-bristle brush, damp cloth, or sponge rather than detergent or oil soap (94).

Rest room facilities should be clean at all times and adjacent to, but separated from, locker rooms and work areas. There must be at least one toilet provided and a hand washing facility in or immediately adjacent to toilet rooms (3). Toilet tissue supplies must be available at each toilet (3). Rest rooms should have self-closing doors (4). Shower areas must be kept absolutely sanitary with daily or more often cleaning and adequate ventilation (90). An area separate from lockers, changing rooms, and rest rooms should be provided for employees to store food (90). Designated areas for eating, drinking, use of tobacco products and other non-work activities should be provided away from work areas (3).

VII. SUMMARY

A major risk factor in contributing to foodborne illness is personal hygiene because food handler training and practices determine the effectiveness of eliminating and preventing contamination of food. Personal hygiene is keeping all parts of the body in a healthful and clean condition. Governmental agencies have established directives, regulations, and rules necessary for personal hygiene practices and support. Hand washing and attention to hand hygiene on a frequent basis and when hands are contaminated with pathogenic microorganisms will prevent transfer of contaminants from humans and surfaces to food. Effective hand washing depends upon rubbing of hands in warm water, preferably with an antimicrobial agent, for at least 20 seconds followed by sufficient rinsing and drying. Hands that are heavily soiled or contaminated with pathogenic bacteria should be double washed using a hand brush for nails, fingers, and creases in the hand. Sufficient numbers of hand washing facilities with knee or foot operation, soap, and towels should be located where workers enter and leave work areas and close to work activities so hands can be washed before and after handling food and when contaminated during work activities. Other hygienic practices include food handling only by healthy individuals; daily personal bathing; clean clothing; hair restraint; gloves and boots when applicable; and proper welfare facilities for toilets, lockers, and breaks for eating, drinking, and tobacco use. Proper training, constant reinforcement, and careful supervision of personal hygienic habits and supporting sanitary facilities and equipment are essential for prevention of foodborne illnesses.

ACKNOWLEDGMENTS

Appreciation is expressed to D.L. Marshall, A.P. Brock, D.M. Price, and N.J. Honeycutt for their assistance with the manuscript. This was approved for publication by the Director of the Louisiana Agricultural Experiment Station as manuscript 04-18-0034.

196 Cleaning a Processing Plant

Gianna M. Durán and Douglas L. Marshall
Department of Food Science, Nutrition, and Health Promotion, Mississippi State University

CONTENTS

I. INTRODUCTION

Technological advances have resulted in processing and packaging methods that produce higher quality, less expensive food (1). However, this increased productivity has also led to problems due to food contamination and waste disposal. As the food industry has expanded, sanitary practices have become more complex and regulations have become more strictly enforced (1,2). In addition, inspection has become more stringent as modern testing methods become more precise (3).

In processing food, one of the objectives should be to make it cleaner and more wholesome (2). Proper sanitation results in a better, more competitive product, a more efficiently operating plant, greater employee productivity, and fewer accidents. In addition, having a clean plant engenders employees to practice higher standards of cleanliness and hygiene (4).

An effective sanitation program can control problems due to food spoilage, can improve product quality, prolong shelflife, and ensure product safety. Such a program includes regular cleaning and sanitizing of the whole

processing plant including environmental heating and cooling equipment, ventilation ducts, and the refrigeration and storage equipment (1,2). Major effort should be expended on cleaning and sanitizing processing equipment and the plant floor. In addition, all equipment in a plant should be cleaned and sanitized before each use.

Maintaining environmental equipment is important in order to prevent the spread of dirt and microorganisms through the ventilation system and into the plant environment. As a bonus, well maintained heating and cooling equipment will run more efficiently and will thus reduce overhead costs (1,3).

II. GMPS AND REGULATIONS

Good Manufacturing Practice (GMPs) regulations were established by the U.S. Food and Drug Administration in 1969. The "umbrella GMPs" broadly cover maintenance of the facilities, cleaning and sanitizing equipment and utensils, pest control, proper use and storage of chemical compounds in the plant, and basic guidelines for restroom facilities. There are also more specific GMPs for safe food manufacturing. These are directed towards individual food industries (5,6). GMPs do not specify how often cleaning and sanitizing is to occur. This is a decision of the sanitation managers, and is based on the equipment, its frequency of use, its potential for food contact, and the type of cleaning it requires (2). International regulations by the Codex Alimentarius (FAO/WHO) are similar to GMPs. Their Recommended Codes of Practice (RCPs) make general recommendations about hygiene, and producing safe food (7).

Federal authorities have regulatory responsibility over food industries that ship their products across state lines. These companies are regulated by the federal government, with assistance from state regulatory bodies. Some states have their own local ordinances, which apply to both the food that is produced for local consumption as well as for interstate consumption (2). The majority of local regulations are in the form of GMPs. In addition, the U.S. Food, Drug and Cosmetic Act, which was established in 1938, also regulates the national food industry. This Act provides general regulations for food quality standards and identity as well as general guidelines on tolerances and specific prohibitions on what can and cannot be used as food additives (3).

III. CLEANING

Cleaning is a process where dirt, food debris, and other soils are removed from surfaces. This is a prerequisite to sanitation as the ability of sanitation routines is affected by how clean a surface is prior to application. The removal of biofilm materials from all equipment and food contact surfaces will enable best control of both spoilage and pathogenic microbes that may cross contaminate foods. Although some microbes are removed during cleaning, this is not the primary purpose of this step.

A. Types of Soil

In order to select the correct cleaning compound one has to know what type of soil is present. In a food plant the most common types of organic soils are food deposits, such as salts, sugars, lipids, and proteins. Salts are soluble in water and acid but may react with other compounds when exposed to heat and become difficult to remove (8). Sugar is soluble in water but may caramelize in the presence of heat and become more adhered to the surface. Lipids (fats and oils) are insoluble in water but soluble in alkali. The sources of lipids may be the food being processed or petroleum deposits from lubricants used to grease plant equipment (1). Both lipid sources can be removed using solvent cleaners. Protein is insoluble in water, slightly soluble in acid, and soluble in alkali. Proteins are very difficult to remove because heat denatures the protein molecules allowing them to adhere tightly to surfaces (3).

One other type of organic soil is biofilm. Biofilms are matrices of microbial cells adhering to a surface. These usually occur in areas where liquids are constantly in contact with surfaces, but they may also occur on moist surfaces, such as the exterior of meats (9,10,11,12). Biofilms inoculate any fluids passing over the colonized surfaces and are more resistant to sanitizers than planktonic (non-attached) cells because the sanitizing agent is unable to penetrate the organic matrix (9,13,11,12). Eliminating biofilms requires mechanical cleaning of the surfaces. Chlorinated alkaline detergents help detach biofilms, but scrubbing surfaces and using high-pressure jets is more effective. Acid detergents are ineffective (9).

Inorganic soils include hard water deposits or scale, rust, and alkaline film deposits from previously used cleaners. When water with bicarbonates (calcium and magnesium bicarbonate are the common sources of water hardness) is heated, the bicarbonates transform into carbonates that have low solubility and as a result precipitate out of solution and form a scale on exposed surfaces. This scale can reduce heat transfer and if allowed to build-up will also reduce pipe diameters (1,2,4). Water pretreatment systems, such as using ion exchange resins that capture calcium and magnesium ions, can prevent problems due to hardness. If no pretreatment is used, then the cleaning routine must also include an acid cleanser and an abrasive compound to remove scale build-up (1).

Rust commonly occurs near boilers or in other areas where condensation is prone to settle. Adequate ventilation and proper maintenance of plant humidity can go a long way in preventing rust. Surfactants and abrasives can help to remove rust, but will not prevent it from returning.

Any equipment that has food contact surfaces should be replaced when rust forms. Modern equipment is primarily made of rustproof aluminum and stainless steel.

B. Cleaning Basics

A properly kept plant and plant grounds will not only improve the quality of the product but will also improve the morale of the employees and serve as a reflection to the public of the quality of the food produced by the plant (4). Both the exterior and the interior of the plant need to be constantly cleaned and maintained. GMPs maintain that any grass or hedges on the exterior of the building should be properly trimmed to ensure that they do not serve as breeding ground for rodents or insects. In addition, all openings into the building should have screens to prevent animals from entering (1,5,7).

The interior of the building should be constructed in a manner that facilitates cleaning. Floors should be smooth so that any soil or food particles may be easily dislodged. In addition, drains should be present approximately every 3 meters so that water may be easily removed (1,4). Processing plants need to be well ventilated as the area may become very humid due to steam produced while processing and because large quantities of water are regularly used while cleaning. Poorly ventilated areas may facilitate microorganism growth resulting in an unsanitary and odorous plant (1,5,7).

Processing equipment used in a food plant should be designed in a manner that facilitates cleaning and sanitizing (4). Difficult to clean equipment should be disassembled to facilitate removal of debris. Improperly cleaned equipment will harbor microorganisms and serve as a reservoir of contamination of the plant. Small parts, chains, cutters, grinders, and conveyor belts are examples of equipment that tend to be difficult to clean, and as a result are conducive to biofilm formation. Despite claims by detergent manufacturers, difficult to clean equipment must be taken apart and the individual pieces must be scrubbed. Gels and foams are not abrasive, and as a result will not remove adhered material from equipment. Detergents with silicates are somewhat abrasive, but without scrubbing, they are not abrasive enough to remove food particles and biofilms (1,9,11).

When cleaning, gross dirt must be removed first. This can be done by using air jets or vacuums, by sweeping, or spraying with low-pressure water hoses. Compressed air or vacuums are good options for removing dry material. Use of compressed air is usually done at the beginning of the cleaning session as the material may be blown onto surrounding equipment. Vacuums are especially useful in storage areas, where excess humidity is undesirable. At this point, any water used should be cold as hot water is more expensive. In addition, hot water may gel or bake on food particles, making them even more difficult to remove (1,4).

While high-pressure jets can efficiently remove dirt, if used incorrectly they can simply spread loose dirt around. The resultant spray may also disseminate microbes throughout the plant in aerosols. These aerosols can also condensate on ceilings, walls, and overhanging structures, which can serve as harborages of microorganisms. For loose dirt, low-pressure sprayers and brooms are recommended. High-pressure sprayers are better recommended for difficult to reach areas and dirt that is stuck on surfaces. Keep in mind that high-pressure sprayers are more likely to have strong recoil and the water is likely to splash on the operator (1,2,3).

Cleaning should be carried out in planned stages. When planning, the operators should take into account the order in which the equipment and plant areas are being cleaned in order to prevent spreading dirt or dirty water onto surfaces that have been previously cleaned. Cleaning should be carried out in a top down manner, from the highest level of the equipment moving down towards the floor. The floors should be the last surface cleaned (1).

Cleaning equipment, including, brushes, brooms, buckets and hoses must also be cleaned after each use to prevent them from becoming sources of plant contamination. They must be washed and allowed to dry before storage. Hoses should be drained before storage. Processing plants normally have suspended hoses for use on the processing floor, and use portable hoses for cleaning the exterior of the plant or the non-processing areas of the plant. These should not be introduced into the plant, as they may have picked up dirt and microorganisms. All the cleaning and sanitizing equipment must be maintained in proper working order, and must be replaced when they start showing wear, as these old brushes, frayed brooms, and broken hoses, for example, will be less effective and will make the operators less efficient (1).

C. Cleaning Compounds

1. Detergents

An ideal detergent is water-soluble and will not leave deposits on cleaned surfaces. A good detergent is non-corrosive and should assist in conditioning (softening) the water. It should also be able to penetrate the surface of soils in order to remove them more effectively. The ideal detergent should also be able to emulsify fats and break the bonds between soil and the surface. In addition, it must be easily rinsed off after use (1). As yet, no single detergent has all the listed properties, so mixtures of detergents and other compounds are used. Most of the detergents used in food plant applications are synthetic detergents, which usually will not react with minerals in hard water.

2. Alkaline Cleaners

Alkaline cleaners have a pH above 7 and are used primarily for their abilities to dissolve protein-based soils and emulsify fats (1,3). Unfortunately, alkaline cleaners also tend to

be corrosive to metals and skin, and will also corrode glass if heated. In addition, they may also leave a film on surfaces. There are three different types of alkaline cleaners, strong, heavy duty, and mild (3).

Strong alkaline cleaners have strong dissolving properties, but are corrosive and can burn skin. In addition, the fumes they release may cause respiratory problems. These cleaners may precipitate calcium and magnesium from hard water, thereby depositing scale on the equipment surfaces. Strong alkaline cleaners are used to remove heavy, mixed soils such as those deposited on walls and equipment of smoke houses. These soils may consist of fats, sugars, and proteins and as a result require a cleaner that has strong penetrating and emulsifying properties. Examples include sodium hydroxide, sodium orthosilicate, and sodium sesquisilicate (1,2,3).

Heavy-duty alkaline cleaners are less corrosive than strong alkaline cleaners; however, prolonged exposure to skin may cause irritation. These are usually used in conjunction with high pressure cleaning. Examples include sodium carbonate and sodium metasilicate (1,2,3).

Mild alkaline cleaners are usually used for manual cleaning of equipment. These cleaners are general purpose and can be used on any surface. Examples include sodium bicarbonate and tetrasodium pyrophosphate (1,2,3).

3. Acid Cleaners

Acid cleaners are not as commonly used as alkaline cleaners. They are mainly used to remove mineral buildup (scale) and other encrusted deposits on surfaces. These cleaners are naturally corrosive, but low-corrosion formulations have been created for plant use (1). The acid cleaners react chemically with mineral deposits, making them soluble and easily removable. These chemicals are extremely corrosive and are not used as all-purpose cleaners. They are not very effective against lipid and protein soils. Their cleaning activity is mainly limited to removal of mineral and alkaline deposits (1,2,3). The most commonly used acid cleaners are hydrochloric (muriatic) acid, nitric acid, phosphoric acid, sulfuric acid, and sulfamic acid. Sulfamic acid is distributed in crystalline form and is therefore easier to transport and easier to mix with powdered detergents.

Strong acid cleaners are corrosive to most metals and even concrete. When heated they release toxic fumes. In addition, if the acid solution is at too high of a temperature, the solution will redeposit the minerals onto the equipment surfaces. Therefore, use of these cleansers has to be done in a strictly controlled manner. Examples of strong acids include hydrochloric acid, sulfuric acid, and sulfamic acid. Phosphoric acid, which is also classified as a strong acid cleaner, is the least corrosive of the strong acid cleaners (1,2,3).

Mild acid cleaners are only mildly corrosive. Examples include acetic acid, gluconic acid, and hydroxyacetic acid. These can be used in manual applications but tend to be of higher cost than the strong acid cleaners. As a result they are less popular than the strong acids.

4. Chelating Agents

Chelating agents are also called sequestrants. These additives prevent minerals from being deposited on equipment surfaces and forming scale. Chelators act by binding mineral ions to prevent precipitation and adherence to equipment surfaces. Commonly used chelators include polyphosphates or amine derivatives. Examples include ethylenediaminetetraacetic acid (EDTA), sodium acid pyrophosphate, and sodium tripolyphosphate. EDTA is more effective than the polyphosphates (1,2,3).

5. Surfactants

Surfactants are used to improve the wetting and penetrating abilities of a detergent by reducing the surface tension between water molecules and soils. Surfactants are also able to emulsify lipids with water, which results in easier removal of fats from surfaces.

Surfactants usually dissociate in solution to give positively charged ions and negatively charged ions. There are three types of surfactants, negatively charged anionic, positively charged cationic, and amphoteric in which the most active ion is determined by the pH of the solution. If the solution is alkaline, an amphoteric surfactant will behave anionically. If the solution is acidic, the surfactant will behave cationically.

Anionic surfactants are usually high foaming cleaners and are affected by water hardness. Common anionic surfactants include sodium and potassium salts of fatty acids, and sodium, potassium and ammonium sulfates, sulfonates, and sulfosuccinates. Cationic surfactants are not affected by water hardness and usually have bactericidal properties. These two advantages make cationic surfactants the most commonly used surfactants.

Surfactants that do not dissociate in solution are called non-ionic. They are not affected by water hardness. These are low foaming and can be combined with other surfactants (1,2,3).

6. Abrasive Agents

Abrasive agents are normally inert materials that are added to detergents to physically scour equipment surfaces. Abrasives can scratch smooth surfaces of stainless steel equipment leaving pockets where biofilms or miniscule food particles can accumulate. In addition, they can corrode surfaces over time. Abrasive use should be carefully monitored. Examples of abrasives include borax, volcanic ash, pumice, and feldspar. They are available in powder or paste forms and are usually used to remove baked on or encrusted material. They may also be used to

remove mineral scale in areas where the use of acid cleaners is undesirable (1,2,3).

IV. SANITIZING

Once surfaces have been cleaned they are ready for a sanitization step. The purpose of sanitization is to kill any residual microbes that may be present on surfaces. Because the efficacy of many sanitizers is affected by soils, properly cleaned surfaces will be more readily sanitized than dirty surfaces.

A. Heat

Sanitizing using heat is the oldest method used. Unfortunately heat is economically inefficient because of substantial energy requirements for production of hot water or steam. Sanitation by heat should not be carried out on surfaces that are not heat tolerant. Heat also should not be used on sectors of equipment that are lubricated as steam can melt grease. In addition, high temperatures can cause scale deposition. The most common heat sanitizing methods use steam and hot water (14).

1. Steam

Steam is not recommended for sanitizing because operators frequently mistake steam for water vapor, resulting in high probability for worker injury. In addition, steam can condense on surfaces and provide a water source for microbe proliferation (14). Water droplets from condensed steam can help spread microorganisms on food contact surfaces. This may only be a problem in plants that are inadequately ventilated. Guthrie (2) recommends steam, citing that the high temperature allows the surfaces to dry quickly.

2. Hot Water

Hot water (76°–85°C) is frequently used as a sanitizing rinse. This is a non-selective sanitizing method. The temperature of the water needs to be maintained; as a result one cannot simply pour hot water over equipment. Hot water sanitization requires the use of thermostat-controlled tanks, which will circulate the water and maintain the desired temperature (2,5,14).

3. Time-Temperature Relationships

Since heat historically has been the most widely used method of killing microorganisms, several studies have been carried out to determine the most advantageous heat treatment. It has been established that the temperature of the heat source determines the time of exposure required to sanitize a surface (14). For example, equivalent treatments can be achieved using hot water at 85°C for 15 minutes or 80°C for 20 minutes. According to Guthrie (1988), steam is more efficient at killing microorganisms than hot water because of its higher temperature. This reduces the time required to sterilize equipment making the sanitation process quicker and also reduces deterioration of equipment, as it is exposed to high temperatures for less time than it would be if hot water was used (2,5,14).

B. Chemicals

Chemical sanitizers are usually more desirable than thermal sanitizers because they reduce the likelihood of burns and require less labor and less energy input. Chemical sanitizers have various modes of activity and each is appropriate for different situations. Chemical sanitizers do not penetrate below the surfaces of the soil and as a result will only sanitize the exterior. The effectiveness of chemical sanitizers depends primarily on the initial microbial load, the exposure time, and the sanitizer concentration (3,14).

1. Chlorine

Hypochlorite solutions are the most common and most effective chemical disinfectants. Other common sources of chlorine are potassium chloride, trichlorisocycamuric acid, and dichloroisocycamuric acid. The latter two are available in granulated form in concentrations of up to 60% available chlorine. Sodium and potassium chloride are usually only available in liquid forms. Commercial solutions are available with any of these formulations in concentrations of up to 12% available chlorine. In contrast, solutions for household use are only available with up to 6.0% sodium hypochlorite. Solutions with 200 ppm or less of free chlorine do not have to be rinsed. Chlorine compounds are desirable because they can kill a wide variety of microorganisms and because they can be used in concentrations that do not need to be rinsed, which cuts down on cleaning time.

One disadvantage of chlorine is that it corrodes metal. In addition, chlorine reacts with all proteinaceous material resulting in inactivation by organic material present on surfaces. Because of this, all surfaces should be cleaned before chlorine sanitizing is attempted. Chlorine also tends to lose strength in storage and should not be purchased in amounts larger than will be used within a few months. Storage conditions will determine how quickly the chlorine will become inactivated. Temperatures above 60°C and excess light will hasten deterioration (2,3,4,14).

2. Iodine Compounds

Iodine is effective against a wide variety of microorganisms. However, iodine is of limited use in the food industry because it is extremely corrosive, toxic, and stains equipment and food. Instead, iodophors, which are iodine in

complex with a nonionic surface-active agent, are more useful in the food industry. Iodophors are less irritating than chlorine compounds and are mostly employed as skin sanitizers or in solutions used for manual washing of equipment. Iodophors are also able to remove scale build-up on equipment.

Iodophors are available in solution with surfactants and acids such as phosphoric acid. This gives them detergent properties, which allows them to be used as a sanitizing cleaning agents. Iodophors are usually used in concentrations of up to 50–70 mg/L free iodine. They have higher bactericidal activity in acid conditions and are more stable than chlorine in the presence of organic matter. However, they are more expensive than chlorine solutions and when heated above 43°C will release free iodine resulting in the negative characteristics of iodine (2,3,4,14).

3. Quaternary Ammonium Compounds

These compounds have a different mode of action than other sanitizing compounds in that they form a bacteriostatic film on surfaces. As a result, their use is usually limited to physical plant surfaces such as floors and walls, but not processing equipment. In addition, they penetrate surfaces and are very effective for porous surfaces. Quaternary ammonium compounds (QACs) are only mildly corrosive, non-irritating, and of low toxicity. They are less susceptible to inactivation by organic matter than chlorine and iodine based sanitizers. They are, however, easily inactivated by the presence of detergents (2,3,4,14).

4. Peroxyacetic Acid

This type of sanitizer is popular because it can combine an acid cleaning rinse with sanitization in one step. It is a rapid acting, broad-spectrum sanitizer. Despite being acid based, it is less corrosive than iodine. The normal, application rate is 125–250 ppm. The disadvantages of peroxyacetic acid are that its effectiveness is reduced in the presence of organic material and it is expensive. However, it is useful for automated cleaning equipment, because it is low foaming and heat stable, pH tolerant, and effective against biofilms (2,3,4,14).

V. DESIGNING CLEANING AND SANITIZING ROUTINES

A. Sanitation Standard Operating Procedures

Sanitation should not be delegated to the employee who has nothing else to do, as it requires dedication and knowledge of what needs to be done and why it needs to be done (4). The sanitary engineer or the sanitation department is responsible for the development and maintenance of a sanitation program. In addition, they must secure the support and compliance of the management and employees (3,4).

Sanitation Standard Operating Procedures (SSOPs) are closely linked to GMPs as they both are guidelines on how to maintain sanitary plant conditions. SSOPs describe the specific steps required to clean different equipment or areas of the plant. They cover the preoperational and operational procedures that must be followed to prevent contamination of the food products. In addition, SSOPs should specify: 1) the frequency and method for cleaning, 2) the frequency and method for sanitization, 3) the cleaners/disinfectants to be used, 4) the specific equipment that will make the process more efficient and effective, and 5) the employee responsible for cleaning and sanitation (3,4,7).

B. Designing Schedules

The most efficient sanitation program is accomplished by establishing a routine that is preventative (2). Having a designed schedule facilitates cleaning and avoids problems or downtime. The workers are aware of what their assignments are and what equipment they will need, which makes cleaning more efficient. Schedules should show who has been designated for each specific job. In addition, these schedules should also have a space for the workers signature. This can serve as proof that the particular assignment was carried out. Schedules should be prepared for every cleaning and sanitizing task in the processing plant (2,3).

C. Stop Production and Continuous Production Processing Plants

Stop production plants are those that process for a specific number of hours daily. In these plants all the equipment is cleaned and sanitized after the last shift. Continuous production plants process 24 hours a day, 7 days a week. There is no time when the plant is shut down for cleaning and maintenance. In these situations, a carefully constructed cleaning and sanitation schedule must be prepared and rigorously adhered to on a daily basis. In continuous plants, the preferred cleaning methods are those that will reduce downtime. Thus, use of sanitizing detergents, acid sanitizers, and sanitizers that do not need to be rinsed are widely used (2).

D. Cleaning out of Place and Cleaning in Place

Cleaning out of place (COP) is the traditional cleaning method. Equipment is dismantled and the parts are washed. First, gross pieces of dirt are removed using brushes. Then the pieces are manually cleaned using water, detergent, and brushes to scrub the parts. Scrubbing may

also be carried out in tanks or vats — this saves water, but the operators also have to be aware to regularly change the water. Then the parts are rinsed with hot water (76°C–85°C), which would rinse, sanitize, and help the parts dry quickly. Parts can also be rinsed with cold water first then immersed in sanitizers. Concentrations of sanitizers to be used should be carefully monitored using test kits or a Bactometer as sanitizer effectiveness is dependent on concentration (15). In addition some sanitizers degrade with time, with exposure to light or exposure to organic material (15). Some sanitizers may need to be rinsed off. This should be done with hot water if possible to facilitate drying. If not, then special areas of the plant will have to be designated for drying. Drying ovens, which circulate warm dry air, are useful for quickly drying equipment or utensils. Drying cloths are not recommended as they can easily contaminate the equipment if dirty (3,14).

Small parts can also be washed using commercial dishwashers, which usually have a sanitizing cycle. If the dishwasher does not sanitize, then the parts must be manually sanitized as described above. Circulation cleaners may also be used to wash parts. These are tanks that circulate detergent solutions. The cleaning solutions in circulation tanks are usually held at higher temperatures than for manual cleaning. In addition more caustic detergents may be used, as no employees will actually be handling the solution. This has to be followed by manual rinsing and sanitizing (2,3).

Cleaning in place (CIP) is used more frequently now. In this system, a tank containing detergent solution is connected to the processing equipment, and the solution is piped into the equipment lines and pumped through. The proper concentration of chemicals, the required temperature, and the pressure must be maintained in order to effectively clean using CIP (14). CIP can reduce downtime and requires less man-hours than COP as the equipment does not have to be taken apart. The drawback, however, is that it is initially expensive to refit existing equipment to CIP (1,2,3,14).

VI. SUMMARY

Sanitation programs, no matter how well designed, are only as good as the operators who implement them. As a result, regular testing of cleaned and sanitized equipment is recommended. Common tests include the use of sterile swabs, replicate organism detection and counting plates (Rodac), and ATP bioluminescence tests. Testing with swabs simply requires dipping a sterile swab in a sterile buffer solution and swabbing the test area. The swab is then returned to the buffer solution and swirled to deposit bacteria into the solution, and the buffer solution is plated and incubated. Rodac plates are surface contact plates that are simply pressed against the area being tested, then incubated. Plate counts are used as a measure of sanitation, for both the swab tests and the rodac tests. ATP bioluminescence test measures adenosine triphosphate (ATP), which is the energy store in living cells. When ATP comes into contact with luciferin, luciferase catalyzes a chemical reaction that produces light. ATP bioluminescence tests will measure the amount of light produced, which is directly related to the amount of ATP present, which in turn is related to the amount of cellular debris on surfaces. All these testing methods can be used to evaluate the sanitation operators, but can also be used when a plant adopts new sanitation procedures or equipment. Sanitation programs are never complete. Managers must constantly look for ways to improve their sanitation program and make it more efficient.

197 Sanitation of Food Processing Equipment

Nanna Cross
Chicago, IL

CONTENTS

I. GENERAL CONSIDERATIONS

The information in this chapter have been derived from the following sources:

1. Food and Drug Administration (FDA) documents: Code of Federal Regulations, Current Good Manufacturing Practices (CGMPs), the Food Code, Hazard Analysis and Critical Control Point (HACCP) programs;
2. Department of Agriculture (USDA) documents: Code of Federal Regulations, HACCP programs, inspection manuals, directives, etc.;
3. Recommendations developed and distributed by major trade associations representing food, warehousing, and transport and related industries.

Food processing equipment used in all food plants (meat and non-meat) is "predetermined" under usual circumstances:

1. FDA and USDA mandatory specifications. Most of those used in processing low acid (acidified, etc.) foods in hermetically sealed containers (thermal processing) and meat and poultry products are directly regulated by regulations promulgated by the FDA and USDA, in relation to safety and sanitation.
2. New establishments. Equipment intended for use in newly constructed establishments should take into consideration all aspects of good manufacturing practices before their construction or purchases.
3. Most specialty equipment (for bakery, dairy, pasta, oil, etc.) is under voluntary/mandatory requirements established and distributed by trade associations such as the American Institute of Baking, Dairy and Food Industries Supply Association, American Oil Chemical Society, and the National Sanitation Foundation. Again, such equipment is in compliance with FDA/USDA GMP provided that all instructions relating to maintenance and repair are adhered to.
4. With built-in designs to comply with FDA/USDA GMP, this equipment saves food processors time and money in looking for the "right" equipment.
5. Custom made equipment. Plant personnel may build their own equipment or have an outside contractor fabricate equipment for them. Even though it is custom made and not intended for resale, such equipment should be built to comply with good manufacturing practices. The same standards are applicable to custom made equipment as are applicable to commercially available equipment.
6. Many food processing plants require some equipment that is custom made for particular operational requirements. It may not be possible to comply with certain good manufacturing practices in the same way as other conventional equipment. If so, it is always advisable to inform the appropriate state and federal regulators of the circumstances.
7. All other food processing equipment that is commercially available.

The bottom line is that all food processing equipment, no matter how they are "predetermined," must comply with FDA, USDA and State GMP.

Some equipment manufacturers or brokers are sometimes not interested in complying with FDA/USDA GMP. In such events, equipment is considered the same as custom made and food establishment operators should be aware of this responsibility before they purchase any equipment.

All food processors using a variety of equipment, especially custom made ones, should focus on correcting problems during the initial development of equipment instead of resolving problems which may result when improperly designed or constructed equipment is put into widespread use. This preventive mode of action benefits equipment manufacturers, food processors, state and federal regulators, and American consumers.

In general, the following basic and standard equipment is usually considered to comply with good manufacturing practice or their compliance is of minor significance:

1. Simple hand tools.
2. Equipment used to prepare packaging materials.
3. Equipment used on fully packaged product.
4. Equipment used on operations involving inedible products that will not be mixed with edible ones.
5. Central cleaning system.
6. Utensil and equipment cleaning machinery.
7. Pails, buckets, etc.
8. Pallets for packaged product.
9. Picking fingers.
10. Tanks for fully finished oils.
11. Simple can openers.
12. Chutes, flumes, hangback racks, supporting stands, and brackets.
13. Vegetable cleaning equipment (not applicable to spin type washers/dryers.)
14. Insect control units.
15. Shipping containers.
16. Pressure storage vessels for refrigerants (not applicable to CO_2 snow making equipment).
17. Water softeners, water heaters, water meters, and chemical dispensers.
18. Can and jar washers/cleaners.
19. Mixing equipment.
20. Hot air shrink tunnels.

21. Air and water filters.
22. Devices for measuring physical characteristics (temperature, pressure, etc.).
23. Rubber floor mats.

The product contact area of this equipment must be made up of approved materials.

II. MATERIALS FOR CONSTRUCTION AND REPAIR

A. Characteristics

Materials that are used in the construction of utensils and food-contact surfaces of equipment may not allow the migration of deleterious substances or impart colors, odors, or tastes to food and under normal use conditions should be:

1. Safe;
2. Durable, corrosion-resistant, and nonabsorbent;
3. Sufficient in weight and thickness to withstand repeated warewashing;
4. Finished to have a smooth, easily cleanable surface; and
5. Resistant to pitting, chipping, crazing, scratching, scoring, distortion, and decomposition.

Multi-use equipment is subject to deterioration because of its nature, i.e., intended use over an extended period of time. Certain materials allow harmful chemicals to be transferred to the food being prepared which could lead to foodborne illness. In addition, some materials can affect the taste of the food being prepared. Surfaces that are unable to be routinely cleaned and sanitized because of the materials used could harbor foodborne pathogens. Deterioration of the surfaces of equipment such as pitting may inhibit adequate cleaning of the surfaces of equipment, so that food prepared on or in the equipment becomes contaminated. Inability to effectively wash, rinse and sanitize the surfaces of food equipment may lead to the buildup of pathogenic organisms transmissible through food. Studies regarding the rigor required to remove biofilms from smooth surfaces highlight the need for materials of optimal quality in multi-use equipment.

It must be emphasized that each food processing operation is unique which applies to the equipment used. The acceptability and non-acceptability of any food processing equipment or its component materials occasionally depends on the operation itself. This must be taken into consideration when evaluating an item of equipment in relation to the GMP.

B. Cast Iron, Use Limitation

1. In general, cast iron may not be used for utensils or food-contact surfaces of equipment.
2. It may be used as a surface for cooking.
3. It may be used in utensils for serving food if the utensils are used only as part of an uninterrupted process from cooking through service.

Cast iron is an alloy of iron and heavy metals which may leach into food if left in contact with acidic foods for extended periods of time. Heavy metal poisoning has resulted from such situations. The temporary or incidental contact that results from using cast iron as a cooking surface and for dispensing utensils used as part of an uninterrupted, short-term process is acceptable because of the brief contact time involved.

C. Some Acceptable Materials

Equipment should be constructed of materials that will not deteriorate from normal use under the anticipated environment. For example, equipment must be constructed of materials that will withstand one category of environment, e.g., generally humid operating environment and high pressure, hot water cleaning with strong chemical cleaning agents. Of course, there are other categories of food processing environments. In addition, all equipment surfaces should be smooth; corrosion and abrasion resistant; shatterproof; nontoxic; non-absorbent; and not capable of migrating into food product (staining). The following lists some acceptable food processing equipment and/or their component materials.

1. The Series 300 (18-8) Stainless Steel

The Series 300 (18-8) stainless steel is acceptable for general use. Other series have been used for construction of food equipment, but their use is limited because they tend to rust or discolor in certain applications. The abbreviation “S/S” is used throughout this publication to denote stainless steel construction.

2. Aluminum

Aluminum may pit and corrode when exposed to certain chemicals. When friction occurs between aluminum and fats a black oxide is produced which discolors the product. Anodizing the aluminum does not eliminate this problem. Therefore, the use of aluminum is limited to applications where the metal does not contact the product or in which the product is suspended in water.

3. Surface Coatings and Platings

Surface coatings and platings may be used if the base material is non-toxic and rendered non-corrosive and the plating material is USDA/FDA acceptable. Chrome, nickel, tin, and zinc (galvanization) platings will generally be acceptable for most appropriate applications. USDA/FDA clearance of other plating materials and processes can he obtained by

receiving a favorable opinion for the intended use from the FDA, Office of Premarket Approval. Surface coatings and platings must remain intact. If a surface coating or plating begins to peel or crack, the FDA/USDA inspection will request correction from the management and may even disallow the use of the equipment.

4. Hardwood

Hardwood may be used for dry curing. In addition, solid (unlaminated) pieces of hardwood are acceptable as removable cutting boards provided the wood is maintained in a smooth, sound condition and is free from cracks. Hardwood cutting boards must be of the shortest dimension which is practical preferably not exceeding 3 or 4 feet (.91 or 1.22m.).

D. Some Unacceptable Materials

Cadmium. antimony. and lead are toxic materials that cannot be used as materials of construction either as a plating or the plated base material. Lead, however, may be used in acceptable alloys in an amount not exceeding 5%.

Enamelware and porcelain are not acceptable for handling and processing food product unless a food plant management provides reasons why they are needed.

Copper, bronze, and brass are not acceptable for direct product contact. These materials may be used in air and water lines or for gears and bushings outside the product zone. Brass is acceptable for potable water systems and direct contact with brine, but not for brine, or any solution, that is recirculated.

Leather and fabric are not acceptable materials unless a food plant management provides reasons why they are needed.

E. Nonfood-Contact Surfaces

Nonfood-contact surfaces of equipment that are exposed to splash, spillage, or other food soiling or that require frequent cleaning should be constructed of a corrosion-resistant, nonabsorbent, and smooth material.

Nonfood-contact surfaces of equipment routinely exposed to splash or food debris are required to be constructed of nonabsorbent materials to facilitate cleaning. Equipment that is easily cleaned minimizes the presence of pathogenic organisms, moisture, and debris and deters the attraction of rodents and insects.

III. DESIGN AND CONSTRUCTION

A. Durability and Strength

1. Equipment and Utensils

Equipment and utensils should be designed and constructed to be durable and to retain their characteristic qualities under normal use conditions.

Equipment should be designed so that all product contact surfaces can be readily and thoroughly cleaned with high temperature, high pressure water and caustic soap solution. Components such as electric motors, electric components, etc., which cannot be cleaned in this manner should be completely enclosed and sealed. Other considerations are:

a. All product contact surfaces should be visible (or easily made visible) for inspection.
b. All product contact surfaces should be smooth and maintained free of pits, crevices, and scale.
c. The product zone should be free of recesses; open seams; gaps; protruding ledges; inside threads; inside shoulders; bolts; rivets; and dead ends.
d. Bearings (including greaseless bearings) should not be located in or above the product zone. In addition, bearings should be constructed so that lubricants will not leak or drip or be forced into the product zone.
e. Internal corners or angles in the product zone should have a smooth and continuous radius of 1/4 inch (6.35 mm.) or greater. (Lesser radii may be used for proper functioning of parts or to facilitate drainage provided these areas can be readily cleaned).
f. Equipment should be self-draining or designed to be evacuated of water.
g. Framework of equipment (if not completely enclosed and sealed) should be designed to use as few horizontal frame members as possible. Furthermore, these components should be rounded or of tubular construction. Angle is not acceptable except as motor supports.
h. Equipment should be designed, constructed, and installed in a manner to protect personnel from safety hazards such as sharp edges, moving parts, electric shocks, excessive noise, and any other hazards. Safety guards should be removable for cleaning and inspection purposes.
i. All welds, in both product and non-product contact areas, should be smooth, continuous, even, and relatively flush with the adjacent surfaces.
j. Equipment should not be painted on areas which are in or above the product zone.
k. External surfaces should not have open seams, gaps, crevices, and inaccessible recesses.
l. Where parts must be retained by nuts or bolts, fixed studs with wing nuts should be used instead of screws to a tapped hole.
m. Gasketing, packing materials, 0-rings, etc., must be nontoxic, nonporous, nonabsorbent, and unaffected by food products and cleaning compounds.

Equipment and utensils must be designed and constructed to be durable and capable of retaining their original characteristics so that such items can continue to fulfill their intended purpose for the duration of their life expectancy and to maintain their easy cleanability. If they can not maintain their original characteristics, they may become difficult to clean, allowing for the harborage of pathogenic microorganisms, insects, and rodents. Equipment and utensils must be designed and constructed so that parts do not break and end up in food as foreign objects or present injury hazards to consumers. A common example of presenting an injury hazard is the tendency for tines of poorly designed single service forks to break during use.

2. Food Temperature Measuring Devices

Food temperature measuring devices may not have sensors or stems constructed of glass, except that thermometers with glass sensors or stems that are encased in a shatterproof coating such as candy thermometers may be used.

Food temperature measuring devices that have glass sensors or stems present a likelihood that glass will end up in food as a foreign object and create an injury hazard to the consumer. In addition, the contents of the temperature measuring device, e.g. mercury, may contaminate food or utensils.

B. Cleanability

1. Food-Contact Surfaces

Multi-use food-contact surfaces should be:

a. Smooth;
b. Free of breaks, open seams, cracks, chips, pits, and similar imperfections;
c. Free of sharp internal angles, corners, and crevices;
d. Finished to have smooth welds and joints; and
e. Accessible for cleaning and inspection by one of the following methods:
    i. Without being disassembled,
    ii. By disassembling without the use of tools, or
    iii. By easy disassembling with the use of only simple tools such as mallets, screwdrivers, or wrenches that are kept near the equipment and are accessible for use.

The purpose of the requirements for multi-use food-contact surfaces is to assure that such surfaces are capable of being easily cleaned and accessible for cleaning. Food-contact surfaces that do not meet these requirements provide a potential harbor for foodborne pathogenic organisms. Surfaces which have imperfections such as cracks, chips, or pits allow microorganisms to attach and form biofilms. Once established, these biofilms can release pathogens to food. Biofilms are highly resistant to cleaning and sanitizing efforts. The requirement for easy disassembly recognizes the reluctance of food employees to disassemble and clean equipment if the task is difficult or requires the use of special, complicated tools.

2. Clean-In-Place (CIP) Systems

Clean-In-Place or CIP is defined as follows:

a. "CIP" means cleaned in place by the circulation or flowing by mechanical means through a piping system of a detergent solution, water rinse, and sanitizing solution onto or over equipment surfaces that require cleaning, such as the method used, in part, to clean and sanitize a frozen dessert machine.
b. "CIP" does not include the cleaning of equipment such as band saws, slicers or mixers that are subjected to in-place manual cleaning without the use of a CIP system.

Sanitation procedures for CIP systems must be as effective as those for cleaning and sanitizing disassembled equipment. Only equipment that meets the following criteria may be cleaned in place. Any equipment or portions of equipment not meeting these requirements should be disassembled for daily cleaning and inspection.

a. CIP equipment should meet the characteristics as specified.
b. Cleaning solutions, sanitizing solutions, and rinse water should circulate throughout a fixed system and contact all interior surfaces of the system.
c. All internal surfaces should be either designed for self draining (of cleaning and sanitizing solutions) or physically disassembled for draining after rinsing. CIP equipment that is not designed to be disassembled for cleaning should be designed with inspection access points to assure that all interior food-contact surfaces throughout the fixed system are being effectively cleaned.
d. Pipe interiors should be highly polished (120–180 grit abrasive) stainless steel or some other acceptable, smooth surfaced material which is easy to inspect.
e. Easily removable elbows with quick disconnect mechanisms should be located at each change of direction.
f. All sections of the system should be capable of being completely disassembled for periodic inspection of all internal surfaces.

g. All sections should be available for inspection without posing any safety hazard to the inspector.

Certain types of equipment are designed to be cleaned in place (CIP) where it is difficult or impractical to disassemble the equipment for cleaning. Because of the closed nature of the system, CIP cleaning must be monitored via access points to assure that cleaning has been effective throughout the system.

The CIP design must assure that all food-contact surfaces of the equipment are contacted by the circulating cleaning and sanitizing solutions. Dead spots in the system, i.e., areas which are not contacted by the cleaning and sanitizing solutions, could result in the buildup of food debris and growth of pathogenic microorganisms. There is equal concern that cleaning and sanitizing solutions might be retained in the system, which may result in the inadvertent adulteration of food. Therefore, the CIP system must be self-draining.

3. "V" Threads Use Limitation

"V" type threads may not be used on food-contact surfaces. This section does not apply to hot oil cooking or filtering equipment.

V-type threads present a surface which is difficult to clean routinely; therefore, they are not allowed on food-contact surfaces. The exception provided for hot oil cooking fryers and filtering systems is based on the high temperatures that are used in this equipment. The high temperature in effect sterilizes the equipment, including debris in the "V" threads.

4. Hot Oil Filtering Equipment

Hot oil filtering equipment should meet the characteristics of cleanability and should be readily accessible for filter replacement and cleaning of the filter.

To facilitate and assure effective cleaning of this equipment, cleanability requirements must be followed. The filter is designed to keep the oil free of undesired materials and therefore must be readily accessible for replacement. Filtering the oil reduces the likelihood that off-odors, tastes, and possibly toxic compounds may be imparted to food as a result of debris buildup. To assure that filtering occurs, it is necessary for the filter to be accessible for replacement.

5. Can Openers

Cutting or piercing parts of can openers should be readily removable for cleaning and for replacement.

Once can openers become pitted or the surface in any way becomes uncleanable, they must be replaced because they can no longer be adequately cleaned and sanitized. Can openers must be designed to facilitate replacement.

6. Nonfood-Contact Surfaces

Nonfood-contact surfaces should be free of unnecessary ledges, projections, and crevices, and designed and constructed to allow easy cleaning and to facilitate maintenance.

Hard-to-clean areas could result in the attraction and harborage of insects and rodents and allow the growth of foodborne pathogenic microorganisms. Well-designed equipment enhances the ability to keep nonfood-contact surfaces clean.

7. Kick Plates, Removable

Kick plates should be designed so that the areas behind them are accessible for inspection and cleaning by being:

a. Removable by one of the methods specified under cleanability or capable of being rotated open; and
b. Removable or capable of being rotated open without unlocking equipment doors.

The use of kick plates is required to allow access for proper cleaning. If kick plate design and installation does not meet the above requirements, debris could accumulate and create a situation that may attract insects and rodents.

C. Accuracy

1. Food Temperature Measuring Devices

a. Food temperature measuring devices that are scaled only in Celsius or dually scaled in Celsius and Fahrenheit should be accurate to ±1°C (1.8°F).
b. Food temperature measuring devices that are scaled only in Fahrenheit should be accurate to ±2°F.

The Metric Conversion Act of 1975 (amended 1988) requires that all federal government regulations use the Celsius scale for temperature measurement. The Fahrenheit scale is included here for all other sectors of the country using Fahrenheit equivalents. The Fahrenheit equivalent will also help those jurisdictions that require Celsius readings to make the transition from Fahrenheit. Since 1°C is equivalent to approximately 2°F (1.8°F), an accuracy of ± 1°C is required.

The small margin of error specified for thermometer accuracy is due to the lack of a large safety margin in the temperature requirements themselves. The requirement for Fahrenheit thermometers to be accurate to 2°F is due to the lack of 1° increment scaling in Fahrenheit thermometers currently being used such as the metal stem thermometer.

2. Ambient Temperature Measuring Devices

a. Ambient temperature measuring devices that are scaled in Celsius or dually scaled in Celsius and Fahrenheit should be designed to be easily readable and accurate to ±1.5°C (2.7°F) at the use range.
b. Ambient temperature measuring devices that are scaled only in Fahrenheit should be accurate to ±3°F at the use range.

A temperature measuring device used to measure the air temperature in a refrigeration unit is not required to be as accurate as a food thermometer because the unit's temperature fluctuates with repeated opening and closing of the door and because accuracy in measuring internal food temperatures is of more significance.

The Celsius scale is the federally recognized scale based on The Metric Conversion Act of 1975 (amended 1988) which requires the use of metric values. The ±1.5°C requirement is more stringent than the 3°F previously required since ±1.5°C is equivalent to ±2.7°F. The more rigid accuracy results from the practical application of metric equivalents to the temperature gradations of Celsius thermometers.

If Fahrenheit thermometers are used, the 3°F requirement applies because of the calibrated intervals of Fahrenheit thermometers.

IV. FUNCTIONALITY, DESIGN AND CONSTRUCTION

A. Ventilation Hood Systems, Drip Prevention

Exhaust ventilation hood systems in food preparation and warewashing areas including components such as hoods, fans, guards, and ducting should be designed to prevent grease or condensation from draining or dripping onto food, equipment, utensils, linens, and single-service and single-use articles.

The dripping of grease or condensation onto food constitutes adulteration and may involve contamination of the food with pathogenic organisms. Equipment, utensils, linens, and single service and single use articles that are subjected to such drippage are no longer clean.

B. Equipment Openings, Closures and Deflectors

1. A cover or lid for equipment should overlap the opening and be sloped to drain.
2. An opening located within the top of a unit of equipment that is designed for use with a cover or lid should be flanged upward at least 5 millimeters (two-tenths of an inch).
3. Fixed piping, temperature measuring devices, rotary shafts, and other parts extending into equipment should be provided with a watertight joint at the point where the item enters the equipment. This assumes that a watertight joint is not provided:
4. If a watertight joint is not provided:
   a. The piping, temperature measuring devices, rotary shafts, and other parts extending through the openings should be equipped with an apron designed to deflect condensation, drips, and dust from food openings; and
   b. The opening should be flanged (see Item 2 above).

Equipment openings and covers must be designed to protect stored or prepared food from contaminants and foreign matter that may fall into the food. The requirement for an opening to be flanged upward and for the cover to overlap the opening and be sloped to drain prevents contaminants, especially liquids, from entering the food-contact area.

Some equipment may have parts that extend into the food-contact areas. If these parts are not provided with a watertight joint at the point of entry into the food-contact area, liquids may contaminate the food by adhering to shafts or other parts and running or dripping into the food.

An apron on parts extending into the food-contact area is an acceptable alternative to the watertight seal. If the apron is not properly designed and installed, condensation, drips, and dust may gain access to the food.

1. Bearings and Gear Boxes, Leakproof

Equipment containing bearings and gears that require lubricants should be designed and constructed so that the lubricant cannot leak, drip, or be forced into food or onto food-contact surfaces.

It is not unusual for food equipment to contain bearings and gears. Lubricants necessary for the operation of these types of equipment could contaminate food or food-contact surfaces if the equipment is not properly designed and constructed.

2. Condenser Unit, Separation

If a condenser unit is an integral component of equipment, the condenser unit should be separated from the food and food storage space by a dustproof barrier.

A dust-proof barrier between a condenser and food storage areas of equipment protects food and food-contact areas from contamination by dust that is accumulated and blown about as a result of the condenser's operation.

3. Temperature Measuring Devices

1. In a temperature regulated storage unit (cool for refrigerator or warm/hot for a storage room/equipment), the sensor of a temperature measuring device should be located to measure the air temperature in the warmest part of a mechanically refrigerated unit and in the coolest part of the storage unit.
2. Cold or hot holding equipment used for edible products should be equipped with at least one integral or permanently affixed temperature measuring device that is located to allow easy viewing of the device's temperature display. There are exceptions.
3. Item 2 does not apply to equipment for which the placement of a temperature measuring device is not a practical means for measuring the ambient air surrounding the edible product because of the design, type, and use of the equipment, such as calrod units, heat lamps, cold plates, bainmaries, steam tables, insulated food transport containers, and salad bars.
4. Temperature measuring devices should be designed to be easily readable.
5. Food temperature measuring devices should have a numerical scale, printed record, or digital readout in increments no greater than 1°C or 2°F.

The placement of the temperature measuring device is important. If the device is placed in the coldest location in the storage unit, it may not be representative of the temperature of the unit. Food could be stored in areas of the unit that exceed requirements. Therefore, the temperature measuring device must be placed in a location that is representative of the actual storage temperature of the unit to assure that all potentially hazardous foods are stored at least at the minimum temperature required for the specific foods.

A permanent temperature measuring device is required in any unit storing potentially hazardous food because of the potential growth of pathogenic microorganisms should the temperature of the unit exceed requirements. In order to facilitate routine monitoring of the unit, the device must be clearly visible.

The exception to requiring a temperature measuring device for the types of equipment listed is primarily due to equipment design and function. It would be difficult and impractical to permanently mount a temperature measuring device on the equipment listed. The futility of attempting to measure the temperature of unconfined air such as with heat lamps and, in some cases, the brief period of time the equipment is used for a given food negate the usefulness of ambient temperature monitoring at that point. In such cases, it would be more practical and accurate to measure the internal temperature of the food.

The importance of maintaining potentially hazardous foods at the specified temperatures requires that temperature measuring devices be easily readable. The inability to accurately read a thermometer could result in food being held at unsafe temperatures.

Temperature measuring devices must be appropriately scaled per stated requirements to assure accurate readings.

The required incremental gradations are more precise for food measuring devices than for those used to measure ambient temperature because of the significance at a given point in time, i.e., the potential for pathogenic growth, versus the unit's temperature. The food temperature will not necessarily match the ambient temperature of the storage unit; it will depend on many variables including the temperature of the food when it is placed in the unit, the temperature at which the unit is maintained, and the length of time the food is stored in the unit.

4. Case Lot Handling Equipment, Moveability

Equipment, such as dollies, pallets, racks, and skids used to store and transport large quantities of packaged foods received from a supplier in a cased or overwrapped lot, should be designed to be moved by hand or by conveniently available equipment such as hand trucks and forklifts.

Proper design of case lot handling equipment facilitates moving case lots for cleaning and for surveillance of insect or rodent activity.

V. EQUIPMENT AND WATER USAGE

A. Water Wasting Equipment

Water wasting equipment should be installed so that waste water is delivered into the drainage system through an interrupted connection without flowing over the floor, or is discharged into a properly drained curbed area. Waste water from cooking tanks, soaking tanks, chilling tanks, and other large vessels may be discharged for short distances across the floor to a drain after operations have ceased and all product has been removed from the area.

B. Protection of Water Supply

An air gap should be provided between the highest possible level of liquids in equipment and a directly connected water supply line(s). The air gap must be at least twice the diameter of the supply side orifice. If submerged lines are unavoidable due to design considerations, then the equipment must include a functional vacuum breaker which will, without fail, break the connection in the event of water pressure loss.

C. Re-circulation of Water

Equipment which re-circulates water as part of its intended function should be equipped with sanitary re-circulating

components if the water directly or indirectly contacts food product or the product contact surfaces. For examples, recirculating pumps should be accepted for direct product contact and piping must be easily demountable with quick disconnect mechanisms at each change of direction.

In addition, establishment operators using equipment or systems which re-use water may be required to have written approval of a water re-use procedure. However, the requirement is mandatory for meat and poultry processors by the USDA. Although the FDA does not require a written approval at this stage, its GMP regulations make it clear that there must be built-in safeguards in the reuse of water in a food plant.

D. Valves

Valves on drainage outlets should be easily demountable to the extent necessary for thorough cleaning. Overflow pipes should be constructed so that all internal and external surfaces can be thoroughly cleaned.

VI. PIPING SYSTEMS

Piping systems used to convey edible product (including pickle solutions) should be readily disassembled for cleaning and inspection. Pumps, valves, and other such components should comply with the sanitary requirements of good manufacturing practices promulgated by USDA/FDA. Piping systems must be designed so that product flow will be smooth and continuous, i.e., no traps or dead ends. Pipes must be either 300 series stainless steel or a USDA/FDA acceptable plastic.

Clear demountable rigid plastic piping may be used for two-way flow provided it is chemically and functionally acceptable. Opaque plastic piping may be used for one way purposes only.

The above requirements apply to systems for conveying raw fat and to re-circulate cooking and frying oils. Black iron pipes with threaded or welded joints are acceptable for conveying completely finished, rendered fats. Continuous rendering is not considered complete until after the final centrifuge.

Pipeline conveying systems for aseptic processing and packaging should comply with the requirements promulgated by the FDA and USDA in the U.S. Code of Federal Regulations.

VII. MAGNETIC TRAPS AND METAL DETECTORS

The extensive exposure of some products to metal equipment such as grinders, choppers, mixers, shovels, etc., causes the possibility of metal contamination. Magnetic traps have been found effective in removing iron particles from chopped or semi-liquid products. However, these magnetic traps are not useful for removing nonmagnetic metals such as stainless steel or aluminum. Therefore, the use of electronic metal detectors is highly recommended for sausage emulsions, can filling lines (especially baby foods), etc. Metal detectors are usually installed so an alarm (either a bell or light or both) is activated when a metal fragment is in the detection zone. The production line should stop automatically when the detector is activated. Alternatively, some systems are arranged so that the nant(s) is automatically removed from the production line.

The FDA and USDA do not currently regulate the use of metal detectors for normal production. The agencies do encourage food plant operators to voluntarily use metal detectors whenever possible. The agencies review and evaluate metal detectors using the same sanitary standards applied to other types of equipment.

The sensitivity and reliability of metal detectors varies depending on aperture size, type of food product, frequency and method of calibration, and numerous other variables. Since many of the involved factors are not related to the design of the unit itself, the agencies do not currently classify metal detectors. However, the following classification standard is offered on a voluntary basis.

Classification*	Spherical Diameter	Type of Metal
A	1/32 inch (.794 mm)	316 stainless
B	1/16 inch (1.588 mm)	316 stainless
C	1 / 8 inch (8.175 mm)	316 stainless
D**		

*To test a metal detector, a metal sphere of the size and type indicated (generally imbedded in an acceptable, non-metallic material) is passed through the center of the aperture. The detector must detect in at least 9 of the 10 pass through to qualify for the applicable classification.

**The "D" classification identifies those detectors which are either not sensitive to the 1/8 inch (3.175 mm) level or are installed in a manner that prevents testing in the described fashion.

VIII. CONVEYOR BELTS

Conveyor belts used in direct contact with food product must be moisture resistant and nonabsorbent. Convey belts should have the edges sealed with the same material as is used for the food contact surface. In addition, belting material must be chemically acceptable and approved by the FDA/USDA. Conveyors with trough like sides and bed should have a quick belt tension release device to allow cleaning under the belt.

IX. JET-VACUUM EQUIPMENT

Equipment used for cleaning jars or cans should have safety devices to indicate malfunction of either jet or

vacuum elements. If necessary, vents to the outside should be provided to control exhaust currents and to prevent dust and/or paper particles from being blown back into cleaned containers.

X. HOSES

Hoses used for product contact should comply with recommendations of trade associations or be accepted by both FDA/USDA. The hose material must be installed in a manner that allows for inspection of the interior surface. Sanitary connectors can be installed at appropriate intervals to allow breakdown for visual inspection or use of inspection devices, such as, boroscopes.

Hoses without sanitary connectors are acceptable for steam and water lines where breakdown for cleaning and inspection is not necessary. However, hoses used for re-circulating water into and out of product contact areas must satisfy the requirement for product contact hoses.

XI. PICKLE LINE

Pickle lines should be either stainless steel or some other USDA acceptable material. If re-circulated, pickle line should be filtered and re-circulated through a system that can be disassembled to the extent necessary for thorough cleaning and inspection.

XII. SMOKEHOUSES, OVENS

Smokehouses or ovens must be designed for easy cleaning and inspection of all inner and outer surfaces. Ducts should be designed to be easily disassembled to the extent necessary for thorough cleaning and inspection. Spray heads for dispensing liquid smoke must be mounted below the level of the rails and trolleys. If liquid smoke is to be recirculated, the pump and pipelines must be of sanitary type construction. Liquid smoke cannot be re-circulated if product is on rack trucks.

XIII. SCREENS AND FILTERS

Screens and straining devices should be readily removable for cleaning and inspection and should be designed to prevent incorrect installation. Permanent screens should be constructed of non-corrosive metals. Synthetic filter materials should have clearance from trade associations. The same applies to filters intended for direct product contact. Filter paper should be single service. Filter cloths should be washable. Asbestos is not acceptable for use as filtering material or for any other purpose.

XIV. VENT STACKS FROM HOODS

Vent stacks from covered cooking vats or hoods over cook tanks and CO_2 equipment should be arranged or constructed so as to prevent drainage of condensate back into the product zone.

XV. ULTRAVIOLET (UV LAMPS)

Ultraviolet lamps which generate ozone are restricted for use as described under Ozone Producing Equipment. UV lamps which do not produce ozone may be used in any area provided shields are used to prevent exposure of workers to direct or reflected UV rays. Otherwise, rooms where unshielded UV lights are used should be equipped with switches at all entry points so the units may be turned off before workers enter. These switches should be identified with suitable placards such as, “Ultraviolet Lights.” Employees should not enter areas where unshielded UV lights are burning because of possible damage to skin and eyes.

XVI. HEAT EXCHANGERS

Heat exchangers may be used to heat or cool product. Heat exchangers may also be used to heat or cool gases or liquids which directly contact product. However, extreme caution should be exercised to prevent contamination. Inspectors and plant personnel should be alert to the following conditions and requirements.

1. Only heat exchanger media authorized by trade associations, FDA, USDA and other standardization bodies in the U.S. can be used for applications involving food product. Common materials such as brine or ammonia need not be submitted for review. Under no circumstances can toxic materials be used.
2. Heat exchangers should be routinely pressure tested to ensure that pinholes, hairline cracks, loose fittings, or other similar defects are not present. Presence of off-color, off-odor, and/or off-flavor may indicate leakage. Frequent depletion of heat exchange media may also indicate leakage.
3. Pressure on the product side should be higher than the media side.

XVII. IN-PLANT TRUCKS

Trucks used to transport product within the plant should be constructed of stainless steel. However, galvanized metal is acceptable provided it is maintained in a good state of repair and is re-galvanizcd when necessary. Trucks should be free of cracks and rough seams. Metal wheels should be avoided as they cause deterioration of the floor surfaces. All trucks should have some means of affixing a tag. This can be accomplished by drilling two

holes approximately 1 inch (25.4 mm) apart in the lip of the truck to accommodate string or wire.

XVIII. AIR COMPRESSORS

Compressed air may be used to directly contact product and/or product contact surfaces provided the air is filtered before entering a compressor and it is clean and free of moisture, oil, or other foreign material when contacting product or product contact surfaces. Lubricants and coolants directly contacting air should be authorized by trade associations, FDA, USDA and other standardization bodies in the U.S.

Compressed air storage tanks should have a drain. Water and oil traps must be located between storage tanks and the point of use. Spent air must be exhausted in a manner to prevent product contamination.

Air directly contacting product or product contact surfaces should be filtered as near the air outlet as feasible. Filters should be readily removable for cleaning or replacement and should be capable of filtering out 50 micron particles (measured in the longest dimension). Air intake on votators should also be filtered.

XIX. PRODUCT RECONDITIONING EQUIPMENT

Product which is accidentally soiled may be cleaned on a separate, conveniently located wash table or sink. This wash station should be properly equipped with sprays and a removable, perforated plate to hold product off the bottom. The station should be identified as a "product wash station" and cannot be used for hand or implement washing.

XX. ELECTRIC CORDS

Accepting the use of electric cords should be based on both sanitary and safety considerations. Drop cords suspended from the ceiling may be retractable and used to connect portable equipment on an as needed basis if the cords are properly wired to the power source. Electric cords should not be strung across the floor even on a temporary basis.

XXI. ELECTRIC INSECT TRAPS

Electric insect traps may be used in edible product handling and storage areas provided the following conditions are met.

1. The equipment should be made of acceptable non-corrosive materials.
2. The traps must not be placed above uncovered product or above uncovered product traffic ways.
3. The electrified components are either apparent or properly identified; insulated from non-electrified components; and covered with a protective grille to prevent electric shock hazard.
4. The equipment should have a removable shelf or drawer which collects all trapped insects.
5. The equipment is designed and constructed so that all dead insects are trapped in the removable shelf or drawer. (Insects must not collect on the protective grille.)

Removable drawers or shelves should be emptied as often as necessary. If the drawer or shelf becomes full of dead insects, then the fourth requirement above cannot be met so the equipment should be rejected for use. Dead insects must be removed from the unit before they create an odor problem. They cannot be left in the unit as "bait."

XXII. INEDIBLE PRODUCT EQUIPMENT

Containers for handling and transporting inedible products should be watertight; maintained in a good state of repair (no rust or corrosion); and clearly marked with an appropriate identification. All inedible product containers in the plant should be uniformly identified. Inedible product containers should be cleaned before being moved into an edible products department.

Metal barrels, tanks, or trucks may be used for holding inedible poultry products in specially designated inedible product rooms. Alternatively, the containers may be stored outside the building provided the storage area is paved, drained, and conveniently located. These storage areas should also be equipped with nearby hose connections for cleanup.

XXIII. BLOW-OFF EQUIPMENT USING COMPRESSED AIR

Filters used on the compressed-air line should be readily removable for cleaning or replacement and should be capable of filtering out 50 micron particles.

The air-pressure must be measured and recorded with appropriate devices and must be set to deliver 75 to 125 psi (5.27 to 8.79 Kg/sq. cm).

The blown air must be confined so that it is captured by a water curtain or by an exhaust system that has a suction of at least 1500 cfm (425 Hectoliters/min) at the point of exhaust.

XXIV. OZONE PRODUCING EQUIPMENT

Equipment which produces ozone may be used only in coolers designated for certain types of products, e.g., aging meat. The ozone concentration in the air must be measured and recorded with appropriate devices and cannot exceed 0.1 ppm. Ozone generating equipment should be turned off and the ozone permitted to dissipate before any in-house or external inspection is performed.

XXV. OZONE WATER TREATMENT AND RECYCLING EQUIPMENT

Equipment used to ozonize and recycle water should be constructed from non-corrosive type material with safe and easy access for cleanup and sanitary inspection of all component parts. Pumps and piping should be of acceptable sanitary type, demountable, with quick disconnect mechanisms at each change of direction. Tanks, funnels, ozone generators, filter housings and filter media should have FDA/USDA acceptance and approval and they should be easily demountable for cleanup and sanitary inspection. A written approval of a water re-use procedure may be needed by state and federal regulators. There should also be written procedures for measuring and recording the total bacteria count and the total organic carbon level (TOC) in the ozone treated water returning to the source of use. [Established guidelines: a total aerobic plate count of less than 1000/mL, coliform less than 10/mL, and E. coli less than 2/mL.] All systems should have monitoring devices online:

1. to measure and record the ozone level and concentration in the immediate area (ozone concentration cannot exceed 0.1 ppm);
2. to measure and record ozone level and range of turbidity in the water being returned to the source of use; all ozone must be dissipated at this time and turbidity must be within the range of 0.5–5.0 NTU (nephelometric turbidity units); and
3. to automatically interrupt the water flow if the quality of the ozone treated water does not comply with established NTU guidelines.

XXVI. SANITIZING SOLUTIONS, TESTING DEVICES

A test kit or other device that accurately measures the concentration in mg/L of sanitizing solutions should be provided. Testing devices to measure the concentration of sanitizing solutions are required for two reasons:

1. The use of chemical sanitizers requires minimum concentrations of the sanitizer during the final rinse step to assure sanitization; and
2. Too much sanitizer in the final rinse water could be toxic.

XXVII. LOCATION AND INSTALLATION

1. Fixed Equipment, Spacing or Sealing

A unit of equipment that is fixed because it is not easily movable should be installed so that it is:

a. Spaced to allow access for cleaning along the sides, behind, and above the unit;
b. Spaced from adjoining equipment, walls, and ceilings a distance of not more than 1 millimeter or 1/32 inch; or
c. Sealed to adjoining equipment or walls, if the unit is exposed to spillage or seepage.

Table-mounted equipment that is not easily movable should be installed to allow cleaning of the equipment and areas underneath and around the equipment by being: (a) sealed to the table; or (b) elevated on legs as specified.

When the weight of the equipment exceeds 14 kg (30 pounds), it is no longer considered by the definition to be easily movable. Consequently, the following guide is noted:

a. Allows accessibility for cleaning on all sides, above, and underneath the units or minimizes the need for cleaning due to closely abutted surfaces;
b. Assures that equipment that is subject to moisture is sealed;
c. Prevents the harborage of insects and rodents; and
d. Provides accessibility for the monitoring of pests.

2. Fixed Equipment, Elevation or Sealing

Floor-mounted equipment that is not easily movable should be sealed to the floor or elevated on legs that provide at least a 15 centimeter (6 inch) clearance between the floor and the equipment. However, if no part of the floor under the floor-mounted equipment is more than 15 centimeters (6 inches) from the point of cleaning access, the clearance space may be only 10 centimeters (4 inches).

The above suggestions do not apply to display shelving units, display refrigeration units, and display freezer units located in the consumer shopping areas of a retail food store, if the floor under the units is maintained clean.

Table-mounted equipment that is not easily movable should be elevated on legs that provide at least a 10 centimeter (4 inch) clearance between the table and the equipment. However, the clearance space between the table and table-mounted equipment may be:

a. 7.5 centimeters (3 inches) if the horizontal distance of the table top under the equipment is no more than 50 centimeters (20 inches) from the point of access for cleaning; or
b. 2.5 centimeters (2 inches) if the horizontal distance of the table top under the equipment is no more than 7.5 centimeters (3 inches) from the point of access for cleaning.

3. Summary

Stationary equipment or equipment not easily moveable (i.e., no casters) should be installed far enough from walls

and support columns to allow thorough cleaning and inspection. In addition, there must be ample clearance between the floor and the ceiling. If these clearances are not possible, then equipment should be sealed watertight to the surfaces. All wall mounted cabinets, electrical connections, and electronic components should be at least 1 inch from the wall or sealed watertight to the wall.

The inability to adequately or effectively clean areas under equipment could create a situation that may attract insects and rodents and accumulate pathogenic microorganisms that are transmissible through food.

The effectiveness of cleaning is directly affected by the ability to access all areas to clean fixed equipment. It may be necessary to elevate the equipment. When elevating equipment is not feasible or prohibitively expensive, sealing to prevent contamination is required.

The economic impact of the requirement to elevate display units in retail food stores, coupled with the fact that the design, weight, and size of such units are not conducive to casters or legs, led to the exception for certain units located in consumer shopping areas, provided the floor under the units is kept clean. This exception for retail food store display equipment including shelving, refrigeration, and freezer units in the consumer shopping areas requires a rigorous cleaning schedule.

XXVIII. MAINTENANCE AND OPERATION

A. Equipment

1. Good Repair and Proper Adjustment

a. Equipment should be maintained in a state of repair and condition that meets the requirements specified in this chapter.
b. Equipment components such as doors, seals, hinges, fasteners, and kick plates should be kept intact, tight, and adjusted in accordance with manufacturers' specifications.
c. Cutting or piercing parts of can openers should be kept sharp to minimize the creation of metal fragments that can contaminate food when the container is opened.

Proper maintenance of equipment to manufacturer specifications helps assure that it will continue to operate as designed. Failure to properly maintain equipment could lead to violations of the associated requirements that place the health of the consumer at risk. For example, refrigeration units in disrepair may no longer be capable of properly cooling or holding potentially hazardous foods at safe temperatures.

The cutting or piercing parts of can openers may accumulate metal fragments that could lead to food containing foreign objects and, possibly, result in consumer injury.

Adequate cleaning and sanitization of dishes and utensils using a warewashing machine is directly dependent on the exposure time during the wash, rinse, and sanitizing cycles. Failure to meet manufacturer and stated requirements for cycle times could result in failure to clean and sanitize. For example, high temperature machines depend on the buildup of heat on the surface of dishes to accomplish sanitization. If the exposure time during any of the cycles is not met, the surface of the items may not reach the time-temperature parameter required for sanitization. Exposure time is also important in warewashing machines that use a chemical sanitizer since the sanitizer must contact the items long enough for sanitization to occur. In addition, a chemical sanitizer will not sanitize a dirty dish; therefore, the cycle times during the wash and rinse phases are critical to sanitization.

B. Cutting Surfaces

Surfaces such as cutting blocks and boards that are subject to scratching and scoring should be resurfaced if they can no longer be effectively cleaned and sanitized, or discarded if they are not capable of being resurfaced.

Cutting surfaces such as cutting boards and blocks that become scratched and scored may be difficult to clean and sanitize. As a result, pathogenic microorganisms transmissible through food may build up or accumulate. These microorganisms may be transferred to foods that are prepared on such surfaces.

XXIX. CLEANING OF EQUIPMENT AND UTENSILS

A. Objectives

1. Equipment, Food-Contact Surfaces, Nonfood-Contact Surfaces, and Utensils

a. Equipment food-contact surfaces and utensils should be clean to sight and touch. The food-contact surfaces of cooking equipment and pans should be kept free of encrusted grease deposits and other soil accumulations.
b. Nonfood-contact surfaces of equipment should be kept free of an accumulation of dust, dirt, food residue, and other debris.

The objective of cleaning focuses on the need to remove organic matter from food-contact surfaces so that sanitization can occur and to remove soil from nonfood contact surfaces so that pathogenic microorganisms will not be allowed to accumulate and insects and rodents will not be attracted.

B. Frequency

1. Nonfood-Contact Surfaces

Nonfood-contact surfaces of equipment should be cleaned at a frequency necessary to preclude accumulation of soil residues.

The presence of food debris or dirt on nonfood contact surfaces may provide a suitable environment for the growth of microorganisms which employees may inadvertently transfer to food. If these areas are not kept clean, they may also provide harborage for roaches, flies, mice, and other pests.

C. Methods

1. Dry Cleaning

a. If used, dry cleaning methods such as brushing, scraping, and vacuuming should contact only surfaces that are soiled with dry food residues that are not potentially hazardous.
b. Cleaning equipment used in dry cleaning food-contact surfaces may not be used for any other purpose.

Dry cleaning methods are indicated in only a few operations, which are limited to dry foods that are not potentially hazardous. Under some circumstances, attempts at wet cleaning may create microbiological concerns.

2. Precleaning

a. Food debris on equipment and utensils should be scrapped over a waste disposal unit, scupper, or garbage receptacle or should be removed in a warewashing machine with a prewash cycle.
b. If necessary for effective cleaning, utensils and equipment should be preflushed, scrubbed with abrasives, or presoaked.

Precleaning of utensils, dishes, and food equipment allows for the removal of grease and food debris to facilitate the cleaning action of the detergent. Depending upon the condition of the surface to be cleaned, detergent alone may not be sufficient to loosen soil for cleaning. Heavily soiled surfaces may need to be presoaked or scrubbed with an abrasive.

3. Wet Cleaning

a. Equipment food-contact surfaces and utensils should be effectively washed to remove or completely loosen soils by using the manual or mechanical means necessary such as the application of detergents containing wetting agents and emulsifiers; acid, alkaline, or abrasive cleaners; hot water; brushes; scouring pads; or high-pressure sprays.
b. The washing procedures selected should be based on the type and purpose of the equipment or utensil, and on the type of soil to be removed.

Because of the variety of cleaning agents available and the many different types of soil to be removed it is not possible to recommend one cleaning agent to fit all situations. Each of the different types of cleaners works best under different conditions (i.e., some work best on grease, some work best in warm water, others work best in hot water). The specific chemical selected should be compatible with any other chemicals to be used in the operation such as a sanitizer or drying agent.

XXX. SANITIZATION OF EQUIPMENT AND UTENSILS

A. Objective

1. Food-Contact Surfaces and Utensils

Equipment food-contact surfaces and utensils should be sanitized.

Effective sanitization procedures destroy organisms of public health importance that may be present on wiping cloths, food equipment, or utensils after cleaning, or which have been introduced into the rinse solution. It is important that surfaces be clean before being sanitized to allow the sanitizer to achieve its maximum benefit.

B. Frequency

1. Before Use and After Cleaning

Utensils and food-contact surfaces of equipment should be sanitized before use and after cleaning.

Sanitization is accomplished after the warewashing steps of cleaning and rinsing so that utensils and food-contact surfaces are sanitized before coming in contact with food and before use.

C. Methods

1. Hot Water and Chemical

After being cleaned, equipment food-contact surfaces and utensils should be sanitized in:

a. Hot water manual operations by immersion for at least 30 seconds as specified in standard manuals;

b. Hot water mechanical operations by being cycled through equipment that is set up as specified elsewhere and achieving a utensil surface temperature of 71°C (160°F) as measured by an irreversible registering temperature indicator; or

Chemical manual or mechanical operations, including the application of sanitizing chemicals by immersion, manual swabbing, brushing, or pressure spraying methods, using a solution as specified in a standard manual, FDA/USDA regulations, and trade recommendations by providing:

1. An exposure time of at least 10 seconds for a chlorine solution,
2. An exposure time of at least 30 seconds for other chemical sanitizer solutions, or
3. An exposure time used in relationship with a combination of temperature, concentration, and pH that, when evaluated for efficacy, yields sanitization as defined elsewhere.

Efficacious sanitization is dependent upon warewashing being conducted within certain parameters. Time is a parameter applicable to both chemical and hot water sanitization. The time that hot water or chemicals contact utensils or food-contact surfaces must be sufficient to destroy pathogens that may remain on surfaces after cleaning. Other parameters, such as temperature or chemical concentration, are used in combination with time to deliver effective sanitization.

XXXI. PROTECTION OF CLEAN ITEMS

A. Drying

1. Equipment and Utensils: Air-Drying Required

a. After cleaning and sanitizing, equipment and utensils may not be cloth-dried.
b. Equipment and utensils may be air-dried or used after adequate draining as specified in FDA regulations (21 CFR 178.1010 Sanitizing solutions), before contact with food.
c. Utensils that have been air-dried may be polished with cloths that are maintained clean and dry.
d. Items must be allowed to drain and to air-dry before being stacked or stored. Stacking wet items such as pans prevents them from drying and may allow an environment where microorganisms can begin to grow. Cloth drying of equipment and utensils is prohibited to prevent the possible transfer of microorganisms to equipment or utensils.

B. Lubricating and Reassembling

Lubricants should be applied to food-contact surfaces that require lubrication in a manner so that food-contact surfaces are not contaminated.

Equipment should be reassembled so that food contact surfaces are not contaminated.

C. Storing

Cleaned equipment and utensils should be stored:

1. In a clean, dry location;
2. Where they are not exposed to splash, dust, or other contamination; and
3. At least 15 cm (6 inches) above the floor.

Further, equipment and utensils should be stored:

1. In a self-draining position; and
2. Covered or inverted.

Clean equipment and multi-use utensils which have been cleaned and sanitized can become contaminated before their intended use in a variety of ways such as through water leakage, pest infestation, or other insanitary conditions.

Cleaned and sanitized equipment and utensils may not be stored:

1. In locker rooms;
2. In toilet rooms;
3. In garbage rooms;
4. In mechanical rooms;
5. Under sewer lines that are not shielded to intercept potential drips;
6. Under leaking water lines including leaking automatic fire sprinkler heads or under lines on which water has condensed;
7. Under open stairwells; or
8. Under other sources of contamination.

The improper storage of clean and sanitized equipment, and utensils may allow contamination before their intended use. Contamination can be caused by moisture from absorption, flooding, drippage, or splash. It can also be caused by food debris, toxic materials, litter, dust, and other materials. The contamination is often related to unhygienic employee practices, unacceptable high-risk storage locations, or improper construction of storage facilities.

XXXII. CONCLUSION

For any food processor, the sanitation of equipment is a permanent problem. Contamination of food or food ingredients by unclean equipment has been the cause of

foodborne diseases in human population throughout the history of modern civilization.

It is important that a food processor comply with good manufacturing practices to reduce the potential of equipment being the source of human pathogens or poisonous chemicals.

198 Frozen Food Plant Sanitation

Nanna Cross
Chicago, IL

CONTENTS

I. INTRODUCTION

The Departments of Agriculture of most states in this country have issued some basic regulations governing frozen food processing plants. Such regulations have, among others, a major objective of assuring that the frozen food products are safe for public consumption.

This chapter has provided a modified version of those regulations issued by the Pennsylvania Department of Agriculture. The modification transforms a legal document into an easy-to-read scientific discussion. Consult the Pennsylvania Code for a copy of the original legal document [Title 7 Agriculture, Part III Bureau of food safety and laboratory services, Chapter 37, Frozen foods, Subchapters B-G, Sections 37.11–37.216.].

A. Definitions

Accessible. Easily exposed for cleaning and inspection with the use of simple tools, such as those normally used by maintenance personnel.

Air temperature. The equilibrated temperature of the air environment in question.

Break-up room. Any area, or space within a warehouse, used primarily for the purpose of organizing cased frozen food into lots for individual consignment on route delivery.

Display case. Any case, cabinet or other facility used for displaying frozen food for sale.

Food product zone. Those surfaces with which food is normally in contact and those surfaces with which food may come in contact during processing, conveying, holding, refrigeration and packing, and which may drain onto product contact surfaces or into the product.

Freezing cycle. Lowering the internal product temperature of a food product to a temperature of 0°F or lower.

Frozen food. Any article used for food or drink by man or other animal which is all of the following: processed; packaged and preserved by freezing in accordance with good commercial practices; intended for sale in the frozen state.

Internal product temperature. The equilibrated product temperature of frozen food.

Operator. (1) Any person, firm or corporation operating or maintaining a frozen food plant or warehouse for the purpose of commercially preparing or storing frozen food. (2) Any person, firm, or corporation, operating or offering to operate, a vehicle for the purpose of transporting frozen food.

Readily (or easily) accessible. Easily exposed without the use of tools, for cleaning and inspection.

Readily removable. When a component part shall be capable of being separated from the principal part without the use of tools.

Ready to eat frozen food. A frozen food product which has been factory processed to the point at which it is ready for use as a food and may or may not require further heating before use.

Removable. When a component part shall be capable of being separated from the principal part with the use of simple tools, such as those normally used by maintenance personnel.

Retail outlet. Any building, room, or parts thereof, where the sale of frozen food is conducted to the ultimate consuming purchaser.

Route delivery. The transportation of frozen food, with frequent stops for partial unloading.

Sale. Any and every transaction including the dispensing, giving, delivering, serving, exposing, storing or any other possessing of frozen food wherein frozen food is subject to transfer to another person.

Storage room or facility. Any area or space within a warehouse used for the purpose of storing frozen food.

Transportation. The physical movement, or the acceptance for physical movement, of frozen food by a carrier.

Vehicle. Any van, truck, trailer, automobile, wagon, ship, barge, freight car, airplane or other means for transporting frozen food.

Warehouse. Any structure, room or part thereof, used for the purpose of storing commercially processed or manufactured frozen food.

B. Temperatures

1. Air Temperature

All frozen food should be held at an air temperature of 0°F or lower, except for defrost cycles, loading and unloading or for other temporary conditions beyond the immediate control of the person under whose care or supervision the frozen food is held. Only those frozen foods destined for further processing or repackaging in smaller units should be defrosted for such purposes. All such defrosting should be in accordance with good sanitary precautions.

2. Internal Product Temperature

The internal product temperature of frozen food should be maintained at 0°F or lower except when the product is subjected to the conditions provided and relating to air temperature. When the frozen food is subjected to such conditions the internal product temperature should not exceed 10°F except during further processing. In all cases the product should be returned to 0°F as quickly as possible.

When an accurate determination of internal product temperature of any case of frozen food fails without having sacrificed the packaged frozen food, representative packages or units should be opened to allow inserting of the sensing element to the approximate center of the packages in question.

Internal product temperature of cases of consumer packages of frozen food should be determined in the following manner:

1. Open the top of the case and remove two corner packages.
2. Punch a hole in the case from the inside. The stem of the thermometer should not be used for punching. The hole should be positioned so that when the thermometer stem is inserted from the outside it fits snugly between packages.
3. The temperature may be read after 5 minutes.
4. Thermometers or other temperature measuring devices should have an accuracy of plus or minus 2°F.

II. GENERAL REQUIREMENTS

A. Separation from Living Quarters and Objectionable Conditions

Frozen food preparation plants should be completely separated from areas used as living quarters by solid, impervious floors, walls and ceilings, with no connecting openings.

Food processing plants should be located in areas reasonably free from objectionable odors, smoke, fly ash and dust or other contamination. Objectionable conditions are often prevalent in the environs of the following facilities, though not limited to such facilities:

1. Oil refineries.
2. City dumps.
3. Chemical plants.
4. Sewage treatment plants.
5. Dye-works.
6. Paper pulp mills.

B. Accessways; Parking Areas; Expansion

Adequate, dust-proof accessways for all vehicular traffic, connecting loading and unloading areas of the plant to the public streets, should be available. Employee parking areas and access roads close by the food processing plant should be hard surfaced with a binder of tar, cement or asphalt.

When planning a plant, due consideration should be given to providing for an arrangement of buildings and necessary space to permit future expansion. Coolers, freezers, and the various processing departments should be so located that they may be enlarged without adversely affecting other departments.

C. Potable Water; Nonpotable Water

The plant should have an ample supply of potable water available from an approved public or private source as specified

Whenever a nonpotable water supply is necessary it should not be used in a manner which will bring it into contact with the product or product zone of equipment. Nonpotable water systems should be kept entirely separate from the potable water supply. The nonpotable water lines should be positively identified by paint of a distinctive color.

D. Equipment Installation; Hot and Cold Water; Clean-Up; Sewage Systems

Equipment should be so installed and used that back siphonage of foreign liquids into the potable water lines is impossible.

Hot and cold water in ample supply should be provided for all plant cleanup needs. Hoses used for cleanup should be stored on racks or reels when not in use.

Disposal of liquid wastes should be through the public sewage system, if available and permitted by local ordinances, or by a properly designed and installed private facility. Private liquid waste treatment facilities should be approved by the health authority having jurisdiction.

III. PLANT LAYOUT

A. Product Preparation and Processing; Preparatory Operations Areas

Product preparation and processing (including freezing) departments should be of sufficient size to permit the installation of all necessary equipment with ample space for plant operations, and with unobstructed truckways for conveyances of raw materials and processed products. The plant should be so arranged that there is a proper production flow of materials, without undue congestion or backtracking, from the time raw materials are received until the frozen, packaged article is shipped from the plant.

Raw material storage rooms and areas where preparatory operations, such as washing and peeling of fruits and vegetables and the evisceration of poultry, are carried on should be separate from areas where frozen food is formulated, processed and packaged. Doors connecting various rooms or openings to the outside should be tightly fitted and kept in a closed position by self-closing devices.

B. Refrigeration Facilities; Quick Freezing Facilities; Waste Storage Rooms

Facilities for holding products under refrigeration until processed should be provided.

Whenever facilities for quick freezing the processed product are used, they should be so located as to be convenient to the food processing and packaging departments. Ample freezer storage should be provided, located conveniently to the quick freezing facilities. Freezer storage should not, however, be required if the frozen products are immediately removed from the establishment.

Separate rooms for storing inedible materials such as fruit and vegetable peels, and feathers and bones pending removal from the plant, should be provided in a location convenient to the various preparation and processing areas.

Waste storage rooms should be of sufficient size to permit the proper storage of filled and empty metal or other relatively nonabsorbent refuse containers and their lids. Waste storage rooms should be equipped with efficient power exhaust ventilation systems, hot and cold water outlets, and adequate floor drainage. The discharge from the exhaust system should be located well away from fresh air inlets into the plant.

C. Storage of Packaging and Labeling Materials; Facilities for Inedible Products; Cleaning Room; Dockage Areas

Packaging and labeling materials should be stored in an area separate from but convenient to the packaging department, except that small quantities of such supplies which are necessary for maintaining continuity of operations may be stored in the processing and packaging departments.

Facilities for inedible products and catch basins, should be located so as to avoid objectionable conditions affecting the preparation and handling of edible products.

A separate room or area and the proper facilities for cleaning equipment such as trays, hand trucks and implements, should be provided in a location convenient to the processing department. A power exhaust system should be provided to dispel steam and vapors from the room.

Dockage areas should be of adequate size, constructed of impervious materials and so drained as to minimize the entrance into the plant of dust, dirt and other contaminants from the receiving and shipping operations. If live animals are received a separate dock should be provided for this purpose.

D. Dressing Rooms; Toilet Rooms; Eating

Well located, properly ventilated dressing rooms and toilet rooms of ample size should be provided for employeees. Dressing rooms should be separated from adjoining toilet rooms by tight, full height walls or partitions. Toilet rooms should not be entered directly from a work room but through an intervening dressing room or a properly ventilated toilet room vestibule.

Standard building codes should govern such matters as the following:

1. Ventilation and lighting of toilet and dressing rooms.
2. Ratio of toilet, handwashing facilities, and urinals to the number of employees using such facilities.
3. Type of fixtures used.
4. Manner of installation of plumbing in such rooms.

Employees should not eat in food processing or packaging areas.

IV. PLANT CONSTRUCTION

A. Floors; Walls; Ceilings; Window Ledges; Rodents; Vermin

Floors should be constructed of durable material which is easily cleaned and skid resistant. Where floors are wet cleaned, they should be sloped to drain.

Regarding the walls of the plant:

1. Interior walls should be constructed of smooth, cleanable, surfaces applied to a suitable base.
2. Dressed lumber should be used for exposed interior woodwork. Exposed wood surfaces should be finished with nontoxic oil or plastic paint or treated with hot linseed oil or clear wood sealer.

3. Coves with radii sufficient to promote sanitation should be installed at the juncture of floors and walls in all processing rooms.

Ceilings should be of adequate height and of smooth, cleanable material.

Window ledges should be sloped at least 45° to the interior to promote sanitation.

Frozen food plants and warehouses should be so constructed as to be rodent resistant. Exterior window and door openings should be equipped with effective insect and rodent screens. Where doors in outside walls of food handling areas are used for loading or unloading, fly chaser; fans and ducts or other effective means should be provided at such doors to prevent the entrance of insects.

B. Stairs; Refrigerator Doors; Variations from Requirements

Stairs in product handling departments should be constructed with solid treads and closed risers and should have side curbs of similar material, which should be 6 inches high as measured at the front edge of the tread.

Regarding the refrigerator doors:

1. Refrigerator doors and jambs should be covered with rust-resisting metal securely affixed to the doors and jambs.
2 Joints necessary for installation should be welded, soldered or otherwise effectively sealed.
3 The juncture of the metal covering on jambs and walls should be sealed with a flexible sealing compound.
4. Doorways through which the product is transferred, either on overhead rails or on hand trucks, should be sufficiently wide to permit free passage of the largest trucks or the widest suspended products without contact with the jambs.

The requirements for building materials listed in this chapter represent minimum requirements. Variations should be acceptable provided the substitutions are equal to or exceed minimum requirements.

V. PLUMBING AND FLOOR DRAINAGE

A. Wet Processing Areas; Hand Washing Facilities; Sterilizers

Floors should be sloped and drains functionally located to provide adequate drainage. In wet processing areas the type and size of floor drains and sanitary sewage lines used and the method of installing such facilities and other plumbing equipment should conform to Commonwealth or local regulations.

Hand washing facilities should be located conveniently to all locations where products are prepared and processed. Lavatories should be supplied with the following:

1. Hot and cold or warm running water.
2. Powdered or liquid soap in a suitable dispenser.
3. An ample supply of single service towels or electric air dryers.
4. A suitable receptacle for used towels.

Where sterilizers are required they should be large enough to allow complete immersion of tools and other implements. Sterilizing facilities should have the following:

1. A water line.
2. A means of heating the water.
3. An overflow outlet.
4. A means of emptying the receptacle.

VI. LIGHTING; VENTILATION

A. Work Rooms and Dressing Rooms; Fresh Air Intakes; General Light Intensities

Work rooms and dressing rooms:

1. Work rooms and employee dressing rooms should have means for furnishing adequate natural light, which may be accomplished by having windows or skylights of an area approximately 25% that of the floor area.
2. Ventilation or efficient air conditioning or a mechanical ventilation system should be provided.
3. Adequate artificial light should be provided.

Fresh air intakes:

1. Fresh air intakes for mechanical ventilation systems should be equipped with effective replaceable filters to prevent the entrance of airborne contaminants.
2. Fresh air intakes should be located well away from power exhaust system discharges and other sources of airborne contaminants.

General light intensities:

1. The general light intensities in product preparation, processing and packaging areas should be not less than 20 foot-candles as measured 30 inches above the floor.

2. Where detailed visual tasks are required to assure a safe, wholesome product, the intensity of light on the surfaces of the product or product container should be not less than 50 foot-candles.
3. At least ten foot-candles of light should be provided in all dressing rooms and at least 5 foot-candles in all other areas of the plant.

VII. FROZEN FOOD PROCESSING EQUIPMENT: CLASSIFICATION

These specifications should apply to the design, materials, construction and installation of equipment used in the processing, holding, and packaging of ready-to-eat frozen food and the processing and holding of gravies, coating batters, and other food ingredients containing eggs, milk, broth and other food components capable of supporting rapid bacterial growth.

Design, materials, construction and installation of frozen food equipment should be easily accessible for cleaning and sanitizing.

In order to encourage the cleaning of equipment, the time factor and the ease of disassembly are important considerations. The unit of equipment should contain the fewest number of parts to permit easy reassembly by unskilled labor following cleaning.

A. Group A

Equipment in Group A should be used for the processing, conveying, holding, refrigeration and packaging of gravies, coating batters or other food ingredients containing eggs, milk or broth, alone or in combination with other food ingredients, which are capable of supporting rapid bacterial growth. This group includes, but is not limited to, the following:

1. Pumps.
2. Valves.
3. Pipelines and fittings.
4. Heat exchangers.
5. Homogenizers.
6. Containers.
7. Hoppers.
8. Fillers.

B. Group B

Equipment in Group B should be used in the processing, holding and conveying of foods or food ingredients which are intended to be incorporated in ready-to-eat frozen food. This group includes, but is not limited to, the following:

1. Reservoirs.
2. Holding tanks.
3. Kettles.
4. Mixers for liquids.
5. Mixers and blenders for powders.
6. Dough mixers.
7. Flour handling equipment.
8. Fryers.
9. Cutters.
10. Dicers.
11. Slicers.
12. Cutting boards.
13. Pumps.
14. Valves.
15. Tanks.
16. Lines and fittings for liquid sugar.
17. Lines and fittings for oil and shortening.

C. Group C

Equipment in Group C should be used in the manufacture of ready-to-eat frozen food, but applicable standards are not available.

VIII. FROZEN FOOD PROCESSING EQUIPMENT: MATERIALS, DESIGN AND CONSTRUCTION: GROUPS A AND B

Specifications and published standards for food equipment have been developed by official agencies and voluntary organizations other than those specifically mentioned in this chapter. These standards may be worthy of consideration in the evaluation of certain equipment items. The development organization and the area in which standards are published are the following:

1. National Sanitation Foundation. Food preparation and service equipment.
2. United States Department of Agriculture, Meat Inspection Division, Meat processing equipment.
3. United States Department of Agriculture, Poultry Inspection Division, Poultry processing equipment.
4. United States Department of Commerce, National Marine Fisheries Service, Fishery products handling and processing equipment.

A. Group A

Effort should be made to have equipment in Group A conform to 3A Sanitary Standards. Standards are as follows:

1. Pumps. 3A Sanitary Standards for Pumps for Milk and Milk Products, including both centrifugal and rotary pumps
2. Valves. 3A Sanitary Standards for Inlet and Outlet Leak Protector Plug Valves for Batch Pasteurizers.

3. Milk and milk products equipment. 3A Sanitary Standards for Fittings and Connections Used on Milk and Milk Products Equipment.
4. Heat exchangers. 3A Sanitary Standards of Plate Type Heat Exchangers for Milk and Milk Products.
5. Pasteurizers. 3A Accepted Practices for the Sanitary Construction, Installation, Testing, and Operation of High-Temperature, Short-Time Pasteurizers.

B. Group B

Effort should be made to have equipment in this group conform to B.I.S.S.C. standards, which are promulgated by the Baking Industry Sanitation Standards Committee. Standards (always check for the latest version) are as follows:

1. Mixers or blenders for powders. B.I.S.S.C. Standards pending.
2. Horizontal and vertical dough mixers. B.I.S.S.C. Sanitary Standard No. 6, for Horizontal Mixers and Vertical Mixers.
3. Flour handling equipment. B.I.S.S.C. Sanitation Standard for Flour Handling Equipment.
4. Liquid sugar handling equipment. B.I.S.S.C..
5. Liquid oil and shortening handling equipment. B.I.S.S.C.
6. Fryers. B.I.S.S.C. Sanitation Standard No. 16, for Doughnut Equipment.
7. Depositors, fillers. B.I.S.S.C., Sanitation Standard No. 5, for Cake Depositors, Fillers and Icing Machines.
8. Conveyors. B.I.S.S.C., Sanitation Standard No. 7, for Conveyors.
9. Homogenizers, emulsifiers. B.I.S.S.C., Sanitation Standard No. 18, for Emulsifiers and Homogenizers.

IX. FROZEN FOOD PROCESSING EQUIPMENT: MATERIALS, DESIGN AND CONSTRUCTION: GROUP C

A. Materials

1. Food surfaces:
   a. Surfaces within the food product zone should be smooth, free from pits, crevices and loose scale, and should be relatively nonabsorbent. Furthermore, surfaces should be nontoxic and unaffected by food products and cleaning compounds.
   b. Sponge rubber, stone slab, linoleum, flannel and unglazed ceramic material are basically objectionable and should not be used.
   c. Wood and cloth, if used, should be indicated under specific application.
2. The finish of corrosion-resistant surfaces such as stainless steel or nickel alloy should be of 125 grit, and properly applied.
3. Finishes of cast iron, cast and forged steel, and cast nickel alloy should not exceed a surface roughness of American Standard #125 or its equivalent.
4. The use of galvanized surfaces should be minimal and where used should be of the smoothness of high quality commercial hot dip.
5. Copper and its alloys should not be used in equipment where edible oils, liquid shortening, chocolate liquor and other fatty food products come in contact with the metal.
6. Cadmium should not be used in any manner or form on the food equipment.
7. Lead should not be used within or adjacent to the food product zone, with the exception of its inclusion in dairy solder, in an amount not to exceed current specification.
8. Plastics should be in conformity with federal regulations.
9. Gasketing and packing materials should be relatively non-porous, relatively non-absorbent, and installed in a manner that results in a true fit to prevent protruding into the product zone of the creation of recesses or ledges between the gasketed joints.
10. Coatings used in the food product zone as a lining to prevent corrosion of the base material of food equipment should be in conformity with federal regulations.

B. Design and Construction in the Food Product Zone

1. All parts of the product zone should be readily accessible or should be readily removable for cleaning and inspection.
2. All parts of the food product zone should be free of recesses, dead ends, open seams and gaps, crevices, protruding ledges, inside threads, inside shoulders and bolts or rivets which form pockets and patterns.
3. Permanent joints of metal parts should be butt welded. Dissimilar metals should not be used in equipment construction if their contact with liquid products might create deleterious chemical or electrolytic action.
4. Welding within the food product zone should be continuous, smooth, even and flush with the adjacent surfaces.

5. Interior corners should be provided with a minimum radius of 1/4 inch except where a greater radius is required to facilitate drainage or cleaning.
6. Equipment should be constructed and installed to provide sufficient pitch so as to be completely self-draining.
7. Equipment which introduces air into the food product or uses air to convey the food product should be fitted with filters capable of withholding particles 50 microns or larger in size. Such filters should be readily removable for cartridge replacement or cleaning.
8. Bearings should be located outside the food product zone or outboard, and should be of the sealed or self-lubricated type. Those intended for use with a dry granular or a dry pulverized product directly adjacent to the food product zone should be of the sealed type without grease fittings. The bearings should be installed flush to eliminate any recessed areas around the shaft within the food product zone.
9. Shaft seal assemblies and packing glands should be outboard and should be readily removable. The shaft seal or packing should be retractable within a space between the assembly and bearing to facilitate easy removal of the sealing assembly and materials for cleaning and inspection.
10. Permanent screening and straining devices and surfaces
    a. All permanent screening and straining devices should be readily removable for cleaning and inspection. They should be designed to prevent replacement in an improper position.
    b. Permanent screening and straining surfaces intended for use with a liquid or a semi-liquid product should be fabricated from perforated metal.
    c. Permanent screening and straining surfaces for use with a dry granular or a dry pulverized product should be designed with sufficient strength for its intended use, and be sized to efficiently remove foreign material.
11. Filtering process
    a. Filtering surfaces should be readily removable for cleaning and inspection.
    b. Filter papers should be of the single-service type.
    c. Filter cloths and spun glass filters should be launderable.
12. Hinges and latches should be of the simple take-apart type.
13. Motors should be of the totally enclosed finless type and should be mounted on the equipment whenever possible.
14. Covers should be provided on reservoirs, hoppers or other vessels and should be readily removable and fitted with drip protective devices or facilities to prevent foreign substances from falling into the product.

C. Design and Construction in the Nonfood Products Zone

1. Safety and gear guards should be removable for cleaning and inspection.
2. External surfaces should be free of open seams, gaps, crevices, unused holes and inaccessible recesses.
3. Horizontal ledges and frame members should be kept to a minimum. External angles should be rounded and internal angles should be avoided.
4. Where lubrication of equipment is required provision should be made to prevent leaking or dripping into the food product zone.

D. Installation of Equipment

1. Equipment should be installed on a foundation of durable, easily cleaned material.
2. Equipment should be placed at adequate distance from walls, ceilings and floors for cleaning and maintenance, or sealed watertight thereto. The preferred minimum space between walls or ceilings should be 30 inches.
3. Whenever equipment passes through walls or floors it should be sealed to that partition, or sufficient clearance should be allowed to permit inspection, cleaning and maintenance.
4. Wherever there is spill or drip, drains and catch pans should be provided and should be of such dimensions to collect all spill and drip. They should be easily accessible or easily removable for cleaning.
5. Where pipes pass through ceilings of processing areas pipe sleeves should be inserted in the floor above so that their upper periphery is at least 2 inches above the floor.

E. Connections

All electrical connections, such as switch boxes, control boxes, conduits and box cables, should be installed a minimum of 3/4 inch away from the equipment or walls or be completely sealed to the equipment or walls.

X. OPERATING PRACTICES FOR THE COMMERCIAL MANUFACTURE OF FOOD

A. Handling and Storage of Materials

Requirements for food should be as follows:

1. All food ingredients received at the plant should be wholesome.
2. Storage conditions should protect against contamination from rodents, insects and other sources.
3. Storage temperature should be in accordance with the following practices:
   a. Ingredients requiring refrigeration should be stored at an air temperature of 40°F or lower. Only areas where the temperature does not exceed 40°F should be considered refrigerated.
   b. Frozen ingredients not in process should be stored at an air temperature of 0°F or lower.

Storage of packaging materials should be separate and set apart from food preparation and processing operations under conditions which should protect against contamination from rodents, insects and other sources.

General housekeeping should be conducted so that the plant and premises present a neat and orderly appearance at all times.

B. Personnel Hygiene

The services of an employeee with any open sore on an exposed portion of the body or one afflicted with an infectious or contagious disease should not be used except that services of employees with finger cuts or with bandages, finger cuts and similar type coverings may be utilized on the condition that the employeee wears rubber gloves. Any employeee with an upper respiratory infection should be assigned duties outside of the areas of food preparation, processing and packaging. Visitors to food preparation, processing and packaging areas should comply with employee requirements.

Practices for employees handling unpackaged food should be as follows:

1. Employees should wear head covering and should keep clothing in a clean condition consistent with the duty being performed.
2. Before beginning work, after each absence from post of duty and after contact with non-sanitized surfaces, each employee should:
   a. Wash his hands with liquid or powdered soap and warm water dispensed from a foot or elbow operated device (Existing faucet facilities need to be changed to a foot or elbow operated device only when a new hand washing facility is installed.).
   b. Rinse his hands in a chlorinated spray or other approved sanitizing agent, unless a bacteriostatic soap is used in washing.
   c. Dry his hands with single service towels or with electric hot air dryers.
3. Hand contact with food products should be minimized.
4. Use of a common dip bowl or tank is prohibited.
5. Whenever rubber gloves are used they should be cleaned and sanitized in accordance with hand washing specifications.
6. Use of tobacco in any form, chewing gum or eating in rooms where food products are stored, handled or prepared should not be permitted.

C. Plant and Equipment Sanitation

1. Plant and equipment should be clean when put into service.
2. All floors, tables, splash boards, work surfaces, equipment and utensils should be maintained in a clean and sanitary condition at all times. Critical areas and all food contact surfaces should be cleaned and sanitized whenever necessary or at scheduled intervals.
3. Equipment such as pipes, pumps, fillers and valves should be dismantled for cleaning and sanitizing, unless in-place cleaning and sanitizing methods are effective. Suggested criteria for acceptance of clean-in-place (CIP) systems areas are as follows:
   a. The arrangement should allow cleaning and bactericidal solutions to be circulated through the system.
   b. Solutions should touch all surfaces.
   c. The system should be self-draining or otherwise completely evacuable.
   d. The cleaning procedure should result in thorough cleaning of the equipment.
4. A thorough rinse with potable water should follow any sanitizing operation that has been completed with a chemical sanitizing agent.

D. Preparation and Processing

1. Fans, blowers or air cooling systems should not move unfiltered air from raw material or preparation rooms into processing rooms.
2. Only adequately cleaned, prepared raw materials should be introduced into areas where frozen precooked foods are cooked and subsequently handled in processing operations.

3. Preparatory operations feeding to the packing line should be so timed to permit efficient handling of consecutive packages in production, and under conditions designed to prevent contamination, loss of quality or spoilage.
4. When batter, egg wash or milk wash is an ingredient, it should be maintained at a product temperature not to exceed 45°F, except when the process temperatures required for manufacturing the product are higher. Cracked or flaked ice used to refrigerate batters should meet bacterial standards for potable water. Batter remaining in machines and equipment at cleanup time should be discarded.
5. Breading materials that have come in contact with batter and have been removed by screening should be discarded.
6. Food ingredients or mixtures that are capable of supporting rapid bacterial growth should be maintained either at a product temperature above 160°F or below 45°F, except when processing temperatures falling in this range are an integral part of the product manufactured, such as, yeast.
7. Cooked food such as meat, poultry, sauces and gravies should be all of the following:
   a. Refrigerated or incorporated into the finished product within 1 hour following preparation.
   b. Refrigerated within 30 minutes following preparation at an air temperature of 50°F or less if the product is to be held from 1 to 8 hours after preparation.
   c. Refrigerated within 30 minutes following preparation such that the internal temperature of the food product will be 40°F or lower, within 2 hours of refrigeration if the food product has been comminuted, sliced or is a liquid, and if the food is to be held more than eight hours. Large solid food components such as those that must be cooled before slicing should be refrigerated at an air temperature of 40°F or lower.
8. Trays, pans or other containers of ingredients destined for incorporation into the finished product should be protected with a clean cover unless these ingredients are used within 30 minutes of preparation. The cover should not be made from porous material.
9. Permanently legible code marks should be placed on each immediate container or package at time of packing. The code marks, as devised by management, should include date of packing and establishment where packed.
10. Packaged products should be placed in the freezer according to good commercial practice. Placement of packages in cases before freezing is prohibited unless the wholesome quality of the product is fully protected by prior processing.
11. Waste disposal:
    a. Refuse from the food operations should be promptly placed in containers that are prominently marked REFUSE and equipped with lids.
    b. The handling of refuse should be done in such a manner as not to cause a nuisance.
    c. All refuse should be removed from the premises on a daily basis and in such a manner as not to contaminate food products being manufactured within the plant.
    d. Refuse containers should be thoroughly cleaned immediately after each emptying.

E. In-Plant Freezing

1. During the freezing cycle products should be cooled to 50°F or lower within 2 hours.
2. Products should then be reduced to 0°F by approved commercial practice.
3. When necessary products should be protected so that dehydration and discoloration will not occur during the freezing cycle.
4. The freezer should be precooled to an air temperature of 0°F before loading. During loading, however, the freezer may rise to temperatures above 0°F for short periods of time.
5. If cold air is used as the freezing medium the product should be arranged by staggering the individual items or by employing dunnage, spacers or other suitable methods to permit satisfactory circulation of cold air around the products. The cold air should be circulated by a positive method; natural air circulation should not be satisfactory.
6. The freezer and associated equipment used for handling the product should be maintained in a clean and sanitary condition at all times.
7. A suitable indicating or recording instrument should be used to measure the temperature of the cooling medium, that is, air, liquid, refrigerated plates or pipe coils.
8. Packaged items should be frozen in a manner that will result in a minimum amount of bulging or distortion.
9. After the freezing cycle the frozen product should be transferred to a storage facility as quickly as possible.

XI. TRANSPORTATION EQUIPMENT

Vehicles used for transportation should be equipped with insulation and mechanical refrigeration systems, or other

refrigeration methods or facilities capable of maintaining an air and product temperature of 0°F, or lower, while loaded with frozen food.

Vehicles used for transportation should be equipped with a thermometer or other appropriate means of temperature measurement, indicating air temperature inside the vehicle. The dial or reading element of the thermometer should be mounted on the outside of the vehicle.

Vehicles used for route delivery should comply with all equipment provisions specified in this chapter for vehicles used for transportation, and should in addition be equipped with curtains or flaps in the doorway area, or with port doors, or with portable insulated chests to maintain required temperature during distribution.

XII. HANDLING PRACTICES FOR OVER-THE-ROAD TRANSPORTATION

Vehicles should be precooled to an air temperature of 20°F or lower before loading.

Frozen food shipments should not be accepted for transportation when the internal product temperature exceeds 0°F, except that shipments in transit at a higher temperature should not be considered in violation of this section if the bill of lading, signed by the shipper, specifies that the product is consigned to a warehouse or other facility for further freezing, or if the product is to be sold as fresh and is to be defrosted when offered for use or for sale.

Frozen food should be loaded in a transportation vehicle so as to provide free circulation of refrigerated air at the front, rear, top, bottom and both sides of the load, except for vehicles of envelope construction in which refrigerated air circulates within the walls of the vehicles.

The mechanical refrigerating unit of vehicles should be turned on and doors of vehicles should be kept closed or curtained during any time interval when loading or unloading operations cease.

The average product temperature of any shipment of frozen food should be determined during loading and unloading by adequate temperature readings.

XIII. HANDLING PRACTICES FOR ROUTE DELIVERY

Lots for individual consignment which are to be sold in a frozen state should be refrigerated by means of mechanical refrigeration, dry ice, or by any other means capable of maintaining an air and product temperature of 0°F or lower.

Insulated containers should be precooled to a temperature of 20°F or lower before being loaded with frozen food.

Doors of vehicles should be kept closed during any time interval that loading or unloading operations cease.

XIV. SANITARY REQUIREMENTS DURING TRANSPORTATION

Interior surfaces of vehicles and devices used for transporting frozen food should be clean and free of objectionable odors before being loaded with frozen food.

Frozen food should be securely packaged or wrapped in a sanitary manner before it is accepted for transportation.

XV. WAREHOUSING EQUIPMENT

Regarding refrigeration capacity and minimum temperature:

1. Warehouses should be equipped with suitable mechanical refrigeration capacity to maintain, under extreme outside temperature and peak load conditions, an air temperature of 0°F or lower.
2. Storage rooms and all their parts should be maintained at an air temperature of 0°F or lower.

Regarding the use of thermometers:

1. Each storage room should be equipped with a thermometer or some other temperature measuring device which is easily visible.
2. The sensing element of thermometers and other temperature measuring and recording devices should be located not more than 6 feet nor less than 5 feet from the floor and not in a direct blast of refrigerated air or near entrance doors.
3. When indicating thermometers alone are used they should be read and recorded at least once every 24 hours during each calendar day.
4. Recording thermometers equipped with charts should have a range of at least 15° above and 10° below, 0°F in graduations of 1°.
5. The use of electric or handwound clocks as well as 24-hour or 7-day charts for recording thermometers should be optional at the discretion of the operator.
6. Each chart or record of observed temperatures should be dated to show the time interval covered and should be kept on file for at least 1 calendar year.

Break-up rooms should be maintained at temperatures not in excess of 20°F.

XVI. WAREHOUSING HANDLING PRACTICES

The operator of a warehouse should not accept custody of a lot or shipment of frozen food if internal product temperature exceeds 0°F (except as relating to air temperature; and

internal product temperature). When frozen food is accepted pursuant to such exception the operator should make a written record of the incident.

Notwithstanding the above, custody of lots with an internal product temperature not in excess of 10°F may be accepted by the operator on request of the owner of the lot in question if the foods are detained from sale at retail and the temperature of such product is promptly returned to and maintained at 0°F or lower.

Before lots of frozen food are placed in storage they should be given lot numbers for effective identification.

Regarding the storage of frozen food:

1. Frozen food in storage should be placed on dunnage, pallets, racks or skids and should be stored no closer than 18 inches to the ceiling and otherwise stored so as to permit free circulation of refrigerated air.
2. Frozen food should be stored under good sanitary conditions that preclude injury and contamination from or to other food held within the warehouse.

During the defrosting of overhead coils in storage rooms stacks of frozen food should be effectively protected from contamination by condensation, drip or leakage.

Break-up rooms should not be used for storage unless the temperature is kept below 0°F.

At time of removal from warehouse custody the internal product temperature of frozen food should not exceed 0°F unless authorized by the owner to begin a defrost cycle.

XVII. WAREHOUSING SANITARY PRACTICES

Floors, walls and ceilings of a warehouse should be maintained in a good sanitary condition. Premises of a warehouse should be maintained in a good sanitary condition.

Warehouses should have water flush toilets so located as to be convenient to all employees. Toilet rooms should be well lighted and ventilated and should be maintained in a sanitary condition. The doors of all toilet rooms should be full-length and self-closing.

Adequate hand washing facilities, including hot and cold or warm running water, powdered or liquid soap in a suitable dispenser, and single service towels or hot air dryers, should be provided adjacent to all toilet rooms. Wash rooms should be well lighted and ventilated, and should be maintained in a sanitary condition. The use of a common towel is prohibited.

Warehouses should have a dressing room or rooms for the changing and hanging of wearing apparel. If individual lockers are provided, they should be well vented and maintained in a clean, sanitary condition, and should be free from disagreeable odors. The dressing room or rooms should be adequately lighted and ventilated and should be maintained in a clean, sanitary condition.

XVIII. RETAIL EQUIPMENT

Storage facilities should be equipped with suitable mechanical refrigeration capacity to maintain, under extreme outside temperature and peak load conditions, an air temperature of 0°F or lower.

When storage facilities of cabinet type are used they should be all of the following:

1. Defrosted as frequently as necessary to maintain refrigeration efficiently as specified.
2. Equipped with a thermometer indicating a representative air temperature.

When storage facilities of walk-in freezer type are used the following requirements should apply:

1. Frozen food in storage should be on dunnage, pallets, racks or skids, and should be stored so as to permit free circulation of refrigerated air.
2. The facility should be equipped with a thermometer, the sensing element of which should be located within the upper third of the distance between floor and ceiling. The sensing elements should not be placed in a direct blast of air from cooling units, cooling coils and heat exchange devices, or near the entrance door.
3. The facility should be equipped with an automatic mechanism for defrosting refrigerated coils when forced air blower refrigeration is used.

Frozen food display cases should be designed, constructed and equipped with mechanical refrigeration facilities capable of maintaining an air temperature of 0°F or lower.

Frost on refrigerator coils and in air passages of display cases should be removed as frequently as necessary to maintain refrigeration efficiency of 0°F or below.

Each display case should be equipped with a thermometer, the sensing element of which should be located in an appropriate place within the path of refrigerated air being returned to the coils.

The product load line should be designated by a distinctive line at inside terminal ends of each display case, and such lines should be at the highest point of discharge and return of refrigerated air.

Separators in display cases should be located a minimum of 1/2 inch from terminal ends to provide for free circulation of refrigerated air between the terminal ends and the displayed product.

Display cases in retail outlets should be so placed as to be relatively free of all of the following:

1. Air current resulting from door drafts, electric fans, and other factors that adversely deflect the current of refrigerated air within the display case.
2. Heat elements such as lights, heating units, and related devices that tend to raise the temperature of refrigerated air within the display case.

XIX. RETAIL HANDLING PRACTICES

Frozen food should not be accepted for delivery by a retail outlet when the internal product temperature exceeds 0°F, except as relating to air temperature; and internal product temperature. When frozen food is accepted under this exception the retail outlet should duly record that fact, preferably on the bill of lading or the delivery ticket.

The receiving of frozen foods should follow the following recommendations:

1. All frozen food received at a retail outlet should be placed in storage facilities without undue delay.
2. Retail outlets should employ the first-in, first-out basis of inventory.

Retail outlets should be equipped with storage facilities of sufficient cubic displacement to accommodate the storage of frozen food.

Regarding storage and display:

1. Frozen food should not be placed above the product food lines within any display case.
2. Frozen food in retail outlets should be stored and displayed under good sanitary conditions.

Obligations for compliance with this retail requirement should cease at the time of retail sale or when the ultimate purchaser takes custody of the product.

A product should be understood to be in the custody of the purchaser when some one else takes a delivery from a retail outlet at the request of the purchaser.

A. Preordered Frozen Foods

Frozen food that is preordered by the ultimate consumer may be sold at internal temperatures exceeding 0°F but not exceeding 45°F provided all of the following are met:

1. A pickup time and date is announced to potential customers.
2. Potential customers are advised on the sales invoice that food is subject to possible quality and perishable degradation when internal product temperature exceeds 0°F and the products are not to be resold.
3. Frozen foods are limited to foods that do not support the rapid and progressive growth of pathogenic micro-organisms.
4. Foods are not to be resold to other parties.
5. Frozen foods arrive at the pickup location with an internal temperature of 0°F or below except as relating to minimum temperature requirements.

XX. FROZEN PRE-COOKED FOODS: ESTABLISHMENT INSPECTION

The United States Food and Drug Administration has issued the following guides regarding the inspection of establishing manufacturing frozen pre-cooked foods.

1. Check for presence of rodents, birds, insects, or for other possible sources of contamination.
2. Check what tests are conducted on incoming raw materials (e.g., filth, mold, decomposition, bacterial load, etc.) if they are they received under a *Salmonella* free guarantee and if tested for *Salmonella* and other pathogens.
3. Determine the adequacy of cleaning and sanitizing steps for equipment.
4. Watch for time-temperature abuses in processing, particularly where product may be hung up in equipment or in cooling and storage processes.
5. Be sure that cooking, cooling and storage conditions are adequate and do not merely produce incubation temperatures for bacteria.
6. Consider employee hygiene and sanitary practices, mainly handwashing and sanitizing, but including health, wounds, sores or disease conditions.
7. Check food and color additives used to ascertain if permitted and used at proper levels.
8. Check labeling and net weights for compliance.

During a comprehensive inspection of frozen precooked foods establishment, cover.

A. Raw Materials

1. Examine raw materials in storage for evidence of contamination with filth (insects, rodents, birds, etc.), mold, and possible routes of other microbiological contamination.
2. Determine if raw materials are stored and handled properly (i.e., frozen products kept frozen, etc.).

3. Examine raw material area for possible misuse of pesticides, rodenticides and other dangerous chemicals.
4. Determine if critical raw materials; e.g.: NFDM, frozen eggs, dried eggs, etc., are received under a *Salmonella* free guarantee and are tested for *Salmonella* and other pathogens.
5. Check food and color additives in storage and determine if they are allowed for use.

B. Processing

1. List product flow in detail, including a flow plan.
2. Ascertain if manufacturing equipment is suitable for its intended use and is in good state of repair.
3. Check if equipment is cleaned and sanitized properly before use, as necessary during the day (i.e.: at breaks, etc.), and after use.
4. Obtain manufacturing process in detail including the conditions under which products are held prior to process, handled during process, and handled after process.
5. If applicable to the process, determine the time\temperature parameters of the manufacturing operation. Include:
   a. Temperature of raw materials prior to process.
   b. Temperatures during the process.
   c. Time\temperature during and holding periods between steps.
   d. Time\temperature of final heat treatment.
   e. Temperature of product at final packaging.
6. Check for any undue delays between final heat treatment and packaging.
7. Determine freezing process to include:
   a. Freezing equipment and process.
   b. Holding time and temperature prior to freezing.
   c. Time taken to reach hard frozen condition.
8. Check finished product handling and storage.
9. Evaluate the use of food and color additives to ascertain if permitted and used at the proper level.
10. Check use of pesticides and rodenticides to preclude their becoming incidental food additives.

C. Sanitation

1. Evaluate firms operation for compliance with GMPRs (Sanitation).
2. Check employee practices which could lead to the comtamination of the products with filth, bacteria and/or mold.
3. Determine if employees use hand dip and sanitizing solutions when necessary.

D. Economics

1. Check firm's net weights to ascertain proper container fill.
2. Review labeling for compliance with FPLA, etc.
3. Obtain significance of firm's coding system.

199 Sanitation and Safety for a Fats and Oils Processing Plant

Richard D. O'Brien
Fats and Oils Consultant

CONTENTS

I. INTRODUCTION

Fats and oils have been recovered for thousands of years from oil bearing seeds, nuts, beans, fruits, and animal tissues. These raw materials have and continue to be important ingredients for foods, cosmetics, lubricants, and chemicals. The extracted fats and oils vary from pleasant smelling products that contain few impurities to very offensive smelling, highly impure materials. Fortunately, researchers have developed technologies for processing the fats and oils products to make them more suitable for foods and other applications. Developments in lipid processing technology have produced ingredients that have been instrumental in the development of many of the current food products available that provide the functional and nutritional requirements of discerning and better informed consumers. Processes have been developed to make them flavorless and odorless, lighter in color, modify the melting behavior, rearrange the molecular structure, remove potential disease causing impurities, capture possible harmful materials, and other changes to make them more desirable for the intended application.

Process control is practiced during fats and oils processing to assure that safe, nutritious, pleasant, cost effective products that perform as intended are produced. These products must meet all of the applicable legal requirements for a food product and the customer's standards of quality, performance, economics, and aesthetics. Each fat and oil's process has individual critical control requirements that contribute to the quality assurance of the finished product. In practice, fats and oils critical control points fall into the areas of safety, quality, compliance, and economics. Hazard Analysis Critical Control Points (HACCP), a part of the process control system, is a method that assesses and monitors food safety.

The basic concept of HACCP can be stated by the maxim "An ounce of prevention is worth a pound of cure." The HACCP system is based on the principle that food safety issues can be eliminated or minimized by prevention during production rather than by detection in the finished product. Development of a HACCP plan focuses on the identification of critical control points, and procedures or activities that will adequately control them to ensure safe production of a food product. Food safety hazards include all microbiological, chemical, and foreign materials that, if consumed could cause injury or harm [8].

II. EDIBLE FATS AND OILS COMPONENTS

The primary constituents of the extracted fats and oils are triglycerides but they also contain varying amounts of nonglyceride materials. Some of the nonglyceride components are undesirable, and can be considered a food safety hazard, while others are very beneficial. Therefore, the objective in all of fats and oils processing is to remove the objectionable materials with the least possible damage to the desirable constituents. In most cases, free fatty acids, phospholipids, moisture, color pigments, oxidation products, waxes trace metals, proteins, pesticides, meal, dirt, and other gross impurities are the materials that need to be removed. Most vegetable oils contain tocopherols, which are natural antioxidants that protect the oils from oxidation and should be retained. For some products, neither the color pigments nor waxes are detrimental and need not be removed. The major product quality concerns are with free fatty acids, phospholipids, oxidation products, proteins, and trace metals; all materials that affect the odor, flavor, and flavor stability of edible fats and oils products. In the U.S., fats and oils color is usually a major concern from a cosmetic sense to include pigments adsorption as a major impurities concern especially for products marketed directly to consumers. The major food safety concerns are with residual pesticides, mold, bacteria, and impurities developed during processing or with mishandling.

A. Pesticides

Pesticides have been used for increased agriculture production throughout the world. Studies have shown that the majority of the pesticides applied eventually reach the soil surface where they gradually spread, translocate to other environments, or eventually degrade. Translocation to oil-bearing plant seeds has also been demonstrated by studies. Processing studies have shown that neither solvent extraction nor bleaching affected the pesticide levels in vegetable oils. However, it was found that pesticides were removed by volatilization during hydrogenation and/or deodorization [1,2,7]. U.S. government agencies have recognized that the insecticides are distilled from edible oils during the deodorization process and have forbidden the use of deodorizer distillates in animal feeds.

B. Mold and Bacteria

Moisture content is one of the most important factors in determining the storability of oil seeds, fruits, nuts, and animal fats. Both molds and bacteria have critical moisture levels for proliferation and enzymes function in an aqueous substrate. Micro-toxins, or mold-derived toxins, can infest oil seeds, nuts, and fruits that are routinely used as an oil source. Only a small portion of the toxin is retained in the separated oil received during normal processing. Filtration of the extracted oil lowers the aflatoxin level, and conventional refining and bleaching effectively removes any residual aflatoxin [5].

C. In-process Tank Impurities

Storage tanks throughout the process are normally dedicated to a particular source oil or modified product. Even so these tanks are emptied and cleaned on a regular frequency to remove the sludge which collects on the tank bottoms. This sludge is composed of polymerized oils, burnt particles, acid salts, high melting oil fractions and other impurities which develop and settle out of the oils during storage. Cleaning equipment using high-pressure jets rotating horizontally and vertically are effective in the large tanks ranging from 40 thousand to million pound capacities. High temperatures, in the range of 185°F or 85°C, and an appropriate detergent suitable for use in food plants are used for washing before rinsing with clear water and finally the tanks are sweetened with freshly processed oil.

D. Separation of Impurities

From the time that crude vegetable oils are expressed from the bean, nut, fruit, or seed, and meat fat rendered from the fatty tissues, until the finished oil product is packaged, edible fats and oils pass through clarification or filtration steps in almost every stage of the processing sequence.

Even finished oils are subjected to a final filtration before packaging or loading into tank cars and trucks. The three generally used methods of separating impurities from oils are distillation, centrifugation and filtration. Pesticides and other impurities are removed from fats and oils with the deodorization which is a steam distillation process. Centrifuges are utilized to separate fines from solvent extracted and screw pressed vegetable oils and to separate the saponified materials after caustic refining and the gums participated with degumming processes. Filtration is employed as well in these processes and in all of the other major fats and oils processes to remove impurities.

Filtration is the process of passing a fluid through a permeable filter media in order to separate particles from the fluid. The particles may be either in suspension or solution. A filter medium is a porous material and one which allows a fluid to pass through yet retain the particles to be removed. Examples of filter media are filter paper, filter cloth, and filter screens. Filters of various types are used in through fats and oil processing beginning with clarification of the oils after extraction or rendering. Oils are filtered after bleaching to remove the bleaching earth which has adsorbed the color pigments and secondary oxidation products; after hydrogenation to remove the nickel catalyst which promoted the reaction, and after deodorization to remove minute quantities of burnt and polymerization particles which can develop during the high temperature process. Polish filters are utilized through the fats and oils process after movement of the product from one location to another to ensure that any impurities developed during that particular process are removed immediately.

III. PROCESSING FLOW SEQUENCE

A HACCP process hazard analysis begins with a detailed examination and evaluation of the processing and handling facilities for the purpose of identifying the location and severity of food safety hazards. Hazard analysis begins with a current flowchart of the production process which provides a means to evaluate potential hazards. A complete HACCP analysis encompasses all processes from the field to the final consumer. This evaluation reviews each process or operation for situations that could result in adulteration with injurious materials, which fall into one or more of three categories, microbiological, foreign material, and chemical. After determining the location of potential hazards, the next step is to determine where critical control points exist. Critical control points are the positions in the process flow where inadequate control would result in a contamination for which there are no downstream provisions to correct. After the critical control points are identified, it is essential to establish safe operating standards, monitoring procedures, frequencies, and responsibilities.

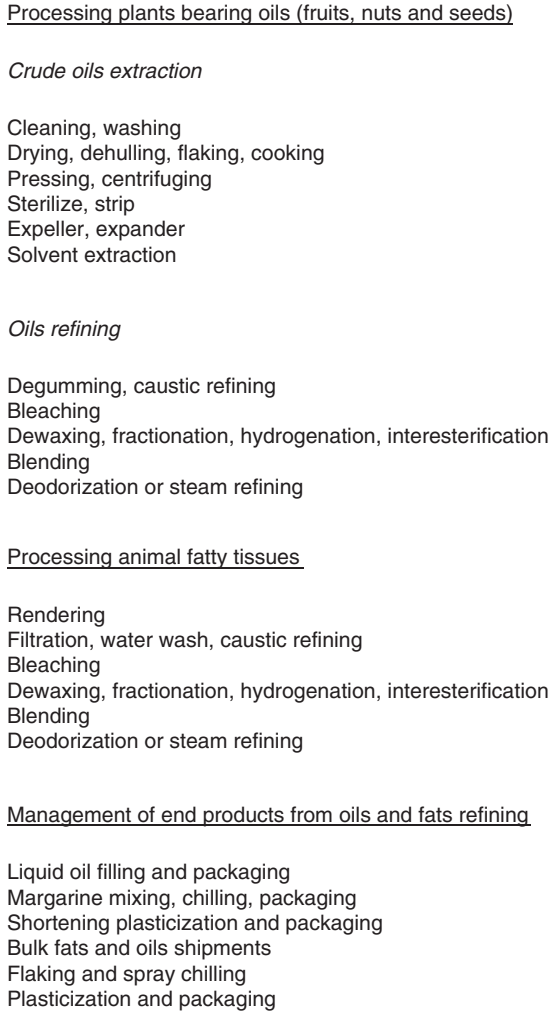

FIGURE 199.1 General steps in processing oils and fats in plant and animal products.

Edible fats and oils processing involves a series of processes in which both physical and chemical changes are made to the raw material. Figure 199.1 illustrates most of the potential processing flow sequencing to produce the various fats and oils products. The sanitation concerns for fats and oil's processing plants are similar to those of any other food processor; for example: rodent, insect and bird control, broken windows, leaking walls or roofs, unsecured doors, screened doors, dirty floor drains, cracks in floors, etc. But, the risks are somewhat lessened since all of the processing is performed within closed systems. Many of these systems are protected from the atmosphere with vacuum, pressure, or nitrogen. Practically, the only time that fats and oils products are exposed to the atmosphere is during filling into a package or a tanker for shipment. Therefore, the major product hazards concerns with fats and oils processing are the removal of impurities which

have gained access to the product prior to processing, added as a processing aid, or developed during processing.

Processing of fats and oils is initiated by an extraction or rendering process to remove the fat or oil from the seed, bean, nut, fruit, or fatty tissues. Vegetable oil's processing after extraction almost always includes neutralization or refining, bleaching, and deodorization with the major differences being the choice of equipment and techniques utilized. Rendered animal fats are normally clarified to remove impurities, bleached and deodorized, again with differences in equipment and techniques providing the major differences. Clairification, neutralization, bleaching and deodorization are all purification processes which affect the flavor, flavor stability and appearance of the fat or oil product while removing harmful impurities.

Vegetable oils and animal fats are natural products with variable characteristics contributed by nature. The fats and oils products selected for a particular application are made on the basis of functionality. Each source oil or fat has characteristic functionality traits which can be modified with the hydrogenation, interesterification, or fractionation processes. The natural or modified fats and oils products can also be blended to change the melting profiles, solidification points, crystal tendencies, and other physical characteristics of the fats and oils ingredients. A review of the major fats and oils processes follows with an emphasis on the critical control points for food safety.

A. Extraction

Cleaning is the first step in the processing of vegetable oils. Typically, oilseeds contain stems, pods, leaves, broken grain, dirt, sand, small stones, and other extraneous seeds. These foreign materials reduce the oil content, adversely effect oil quality and increase the wear and damage potential to the extraction equipment. Shaker screens are used to separate the particles on the basis of size, whereas aspiration separates on the basis of density and buoyancy in a stream of air. Tramp iron, extraneous metal acquired during harvesting, storage or transportation is removed to prevent damage to the equipment by the placement of magnets in chutes just ahead of vulnerable processing equipment.

Extraction of oil from materials of plant origin is usually done by pressing with the use of a continuous screw press or by extraction with volatile solvents. Prior to 1940, mechanical pressing was the primary method used. Mechanical pressing had limits because the oil recovery is poorer than with solvent extraction and the high temperatures generated damaged both the oil and the meal. Solvent allows a more complete oil extraction at lower temperatures. Solvent extraction plants can be either batch or continuous. The continuous extraction plants can be percolation, immersion or direct extraction plants. Generally, the oilseeds may be divided by oil content; above and below 20% oil content. In most cases, oilseeds with a low oil content are subjected to both continuous and batch solvent extraction. High oil content seeds are normally extracted in two stages; first pressing and then solvent extraction; however, many single step continuous direct solvent extraction systems are in current use.

To be used legally in the United States, oilseed extraction solvents and food processing substances must have been subjected to an approval by the U.S. Food and Drug Administration (FDA) or the U.S. Department of Agriculture (USDA), be generally recognized as safe (GRAS) for this use, or be used in accordance with food additives regulation promulgated by the U.S. FDA. Commercial hexane has been in major use since the 1940s as an oilseed extraction solvent on the determination that it is GRAS, and it may also be subject to a prior sanction. Like many other food-processing substances, there is no U.S. FDA regulation specifically listing n-hexane as GRAS or having prior sanction. However, it has been cleared in as a solvent in a number of other food products, one of them a cocoa butter substitute with a 5 ppm maximum limit. Because edible fats and oils are subjected to deodorization and other purification processes as a part of the manufacturing process before being used as a food product, they should not contain any of the extraction solvent, if proper practices are followed [9].

B. Rendering

The fatty tissue from meat animals which is not a part of the carcass or that trimmed from the carcass in preparation for sale is the raw material for which lard and tallow is obtained. Separation of fat from the fatty tissues of animals is called rendering. The rendering process consists of two basic steps. First, the meat by-product is heated to evaporate the moisture, to melt the fat present and to condition the animal fibrous tissue. Two alternative cooking temperatures are used: fat temperatures below 120°F and fat temperatures above 180°F. A more complete separation of the fat and protein is accomplished with the higher temperature processing but a better quality protein is obtained with the lower temperature processing. Normally, the value of the protein dictates that the lower temperature poorer separation technique be used which probably leaves trace quantities of protein in the rendered lard or tallow. After cooking, the fat is separated from the solid proteinaceous material. In batch rendering the cooked material is allowed to separate and the fat to drain followed by filtration to complete the separation. Continuous rendering, introduced to replace the batch systems, normally consists of a continuous cooker which requires less cooking time and is more energy efficient with better quality control [6].

C. Refining Systems

Processors have the option of approaching edible oil purification in two ways: either chemical or physical refining. The two systems utilize very similar processes with the major difference being the method used for free fatty acid removal. Chemical refining, the conventional method used

for removal of the nonglyceride impurities from edible fats and oils, consists of optional degumming, caustic neutralization, bleaching and deodorization. The alkali refining process produces good quality oil and is flexible with the ability to treat different oils and different qualities of individual oils. However, caustic refining has three major drawbacks: (1) the soap produced promotes a tendency for emulsion formation which will occlude neutral oil to increase oil losses, (2) oil losses are particularly high when processing oils with free fatty acids over 3.0%, and (3) disposal of the soapstock produced has become more difficult.

The second process, which has become known as physical refining, consists of removing the fatty acids from the oil by steam distillation under vacuum after the phosphatides have been removed by a degumming process followed by a pretreatment process before bleaching. The major advantages for physical refining are the elimination of soapstock, lower capital costs and fewer processes to operate and maintain. The objective of the initial processing step in either refining method is the removal of phosphatides, color bodies, and trace metals. Removal of these nontriglyceride impurities is crucial to ensure good product quality. Herein lies the major drawback for the physical refining system; i.e., complete phosphatide removal with degumming and bleaching is very difficult. Some of the other problems with physical refining systems can be: (1) additional bleaching earth usually required, (2) pesticides are co-distilled with the fatty acids during steam refining, (3) phosphoric acid treatment may darken the gums produced and incomplete removal can produce off flavors in the oil after deodorization, (4) steam distillation or deodorizer units must be designed to handle higher concentrations of free fatty acids, (5) cottonseed oil cannot be physically refined because the gossypol pigment must be removed with alkali refining, and (6) it may be necessary to steam refine before hydrogenation or other processing to adjust melting characteristics and deodorize again following these processes. Physical refining is favored for processing high free acidity oils with low phosphatide contents; it has been demonstrated to produce good quality product from coconut, palm kernel, palm, lard, tallow, and some of the seed oils [10].

D. Degumming

Degumming is the treatment of crude vegetable oils with water, salt solutions. or dilute acids such as phosphoric, citric, or maleic to remove phosphatides, waxes, and other impurities. Degumming converts the phosphatides to hydrated gums, which are insoluble in oil for separation as a sludge by settling, filtering, or centrifugal action. Phosphatide removal is the first process for the physical refining system and can also be for chemical refining. However, with chemical refining the processor has the option of removing the phosphatides for their by-product value as lecithin or treating them as impurities to be removed along with free fatty acids during caustic neutralization.

E. Caustic Neutralization

The conventional caustic neutralization process is the most widely used and most well known purification system. The addition of an alkali solution to a crude oil brings about a number of chemical and physical reactions: (1) the alkali combines with the free fatty acid present to form soaps, (2) the phosphatides absorb alkali and are coagulated through hydration, (3) pigments are degraded, absorbed by the gums, or made water soluble by the alkali, and (4) the insoluble matter is entrained with the other coagulable material. Efficient separation of the soapstock from the neutralized oil is a significant factor in caustic neutralization which is usually accomplished with centrifugal separators. The conventional caustic soda neutralization systems have the flexibility to efficiently refine all of the crude oils presently utilized for food products [4].

Caustic neutralization is ordinarily accomplished by treating the fat or oil with diluted sodium hydroxide. This treatment forms soapstock with the free fatty acids, phosphatides, trace metals, pigments, and other nonglyceride impurities that can be separated by settling or centrifugal force from the neutralized oil. The neutral oil is usually water washed and again separated by settling or centrifuged to remove trace impurities and residual soaps from the neutralization and separation processes. After water washing, the oil is either dried with a vacuum dryer or immediately bleached to remove the trace quantities of water remaining.

F. Bleaching

Edible fats and oils bleaching is popularly and correctly regarded as the partial or complete removal of color; however, bleaching is also an integral process in both the chemical and physical refining systems. Bleaching is relied upon to clean up the traces of soap and phosphatides remaining after caustic neutralization and water washing for the chemical refining system. For physical refining, the technical feasibility depends upon bleaching as a pretreatment to remove phosphatides, trace metals, waxes, and the color pigments. Another, very important function of bleaching, in both refining systems, is the removal of peroxides and secondary oxidation products.

The usual method of bleaching is by adsorption of the pigments and other nonglyceride impurities on bleaching earth. In a typical process, the bleaching materials are added to the oil in an agitated vessel either at atmospheric pressure or under a vacuum. The oil is heated to bleaching temperature and held to allow contact time with the bleaching earth. After the adsorbent has captured the color pigments, soap, phosphatides, trace metals, and polar

materials, it becomes an impurity which must be removed from the oil with a filtration system. Control point impurities analysis are used to monitor the removal of the potential food safety hazard.

G. Animal Fat Purification Systems

Traditionally, the method used to purify meat fats has been a form of physical refining. The two main impurities in meat fats are proteins carried over from the rendering process and free fatty acids. The pretreatment phase for meat fats is the removal of the proteinaceous materials. Typically this is easily accomplished by adding small amounts of diatomaceous earth and/or bleaching earth followed by filtration. An alternative clairification or pretreatment method is to water wash the fat to remove the proteins. This method also requires bleaching or at least drying to remove the moisture remaining in the oil after water washing. A third method for meat fat clarification is caustic refining. Chemical refining is usually reserved for poor quality animal fats or for specialty products used undeodorized to preserve the characteristic meat fat flavor. The caustic refining system consists of caustic neutralization, water washing and vacuum drying.

H. Hydrogenation

The hydrogenation process is an important tool for the edible fats and oils processor. With hydrogenation, liquid oils can be converted into plastic or hard fats more suitable for a particular food product. There are two reasons to hydrogenate a fat or oil: (1) to change the physical form for product functionality improvement, and (2) to improve oxidative stability. Hydrogenation involves the chemical addition of hydrogen to the double bonds in the unsaturated fatty acids. The reaction is carried out by mixing heated oil and hydrogen gas in the presence of a catalyst. After the hydrogenation endpoint has been achieved, the hardened oil is cooled and filtered to remove the nickel catalyst.

Most hydrogenations are preformed in batch reactors due to the variation in raw materials and the desired end products. Normally, batch hydrogenation are performed in an agitated tank reactor with heating and cooling capabilities designed to withstand pressures of 7 to 10 bar. First, the catalyst is suspended in the oil. Then, hydrogen gas, dispersed as bubbles, must be dissolved in the oil to reach the surface of the catalyst. The three reaction variables, pressure, temperature, and rate of agitation are controlled to reduce batch to batch variation for preparation of the desired hydrogenated product or basestock. The typical analytical evaluations for endpoint control which measure consistency are refractive index, iodine value, and various melting points. A food safety control point would be the incomplete removal of the nickel catalyst after the reaction is completed; however, this is not a critical control point because the post bleaching process immediately following hydrogenation is designed to remove the remaining trace catalyst impurities.

I. Post-Bleaching

A separate bleaching operation, immediately following the hydrogenation process, has three purposes: (1) insurance that all traces of the prooxidant hydrogenation catalyst that have escaped the filtration system after hydrogenation have been removed, (2) to remove undesirable colors generally of a greenish hue accentuated during hydrogenation by heat bleaching of the red and yellow pigments, and (3) removal of peroxide and secondary oxidation products. Post-bleach systems are usually batch systems for the same reasons as for hydrogenation systems; production of a wide variety of hydrogenated basestocks.

J. Fractionation

Edible fats and oils are fractionated to provide new materials more useful than the natural product. Fractionation may be practiced to remove an undesirable component, which is the case with dewaxing and winterization, or to provide two or more functional products from the same original fat or oil as is the case with cocoa butter equivalents or substitutes and high stability oils.

The three fractionation process types practiced commercially to produce the value added products are: (1) dry fractionation. (2) solvent fractionation, and (3) aqueous detergent fractionation. Dry fractionation, which includes winterization, dewaxing, hydraulic pressing, and crystal fractionation processes, is probably the most widely practiced. Solvent or aqueous detergent fractionation process provide better separation of specific fractions for the more sophisticated fats and oils products. All of these fractionation process practice the three successive stages of fractionation: (1) cooling the oil to supersaturation to form the nuclei for crystallization, (2) progressive growth of the crystalline and liquid phases, and (3) separation of the crystalline and liquid fractions. A food safety control point identified for the solvent fractionation system would naturally be removal of the solvent used. Complete solvent removal is assured with steam distillation in the deodorization process which is downstream.

K. Interesterification

The interesterification process can alter the original order of distribution of the fatty acids in the triglyceride-producing products with melting and crystallization characteristics different from the original oil or fat. Unlike hydrogenation, interesterification neither affects the degree of saturation nor causes isomerization of the fatty acid double bond. It does not change the fatty acid composition of the starting material but rearranges the fatty acids on the glycerol molecule. The process of interesterification can be considered as the removal of fatty acids

from the glyceride molecules, shuffling them, and then replacement on the glyceride molecules at random. This change in the distribution of the fatty acids affects the structural properties and melting behavior of the fats and oils. Commercially, the interesterification process has been utilized for the production of confectionery fats, margarine oils, cooking oils, frying fats, shortenings, and other special application fats and oils products.

Two types of chemical interesterification process are practiced: random or directed. Random rearrangement of fats and oils can be accomplished using either a batch or continuous process. Both random interesterification processes perform the three important rearrangement steps: (1) pretreatment of the oil, (2) reaction with the catalyst, and (3) deactivation of the catalyst. In the directed rearrangement process, one or more of the triglyceride products of the interesterification reaction is selectively removed from the ongoing reaction. Continuous processes are normally used for directed rearrangements for better control. Trisaturated glycerides are crystallized and separated from the reaction which upsets the reaction equilibrium so that more trisaturated glycerides are produced.

L. Blending

Different stocks are blended to produce the specified composition, consistency, and stability requirements for the various fats and oils products, such as shortenings, frying fats, margarine oils, specialty products, and even some salad or cooking oils. The basestocks may be composed of hydrogenated fats and oils, interesterified products, refined and bleached vegetable oils, purified animal fats, and/or fractions from winterization, dewaxing, or another form of fractionation. The products are blended to meet both the composition and analytical consistency controls identified by the product developers and quality assurance. The consistency controls frequently include analytical testing for solids fat index, iodine value, various melting points, fatty acid composition, and other evaluations designed to insure compliance with customer requirements. The blending process requires scale tanks and meters to proportion the basestocks accurately for each different product. The blend tanks should be equipped with agitators and heating to assure a uniform blend for consistency control [4].

M. Deodorization

With conventional edible oil processing, deodorization is the last in a series of process steps used to improve the taste, odor, stability, and the food safety of the fats and oils by the removal of undesirable substances. In this process, the fats and oils products are steam-distilled under vacuum. The object is to remove the volatile impurities from the oil. The foremost concern from a quality aspect is the volatile impurities are the objectionable flavors and odors; however, deodorization is also very important from a food safety aspect. Steam distillation removes any trace pesticide and "heavy" metals contents obtained during the growing process. Deodorization is primarily a high-temperature, high-vacuum, steam distillation process to remove volatile, odoriferous materials present in edible fats and oils. It is the last major processing step through which the flavor and odor and many of the stability qualities of a fat or oil product can be changed. From this point forward, efforts must directed toward retaining the quality that has been built into the fat and oil product with all of the preceding processes [4].

The odoriferous substances in fats and oils are generally considered to be free fatty acids, peroxides, aldehydes, ketones, alcohols, and other organic compounds. Experience has shown that the removal of flavor, odor, and other undesirables correlates well with the reduction of free fatty acids. Therefore, all commercial deodorization consists of steam stripping the oil for free fatty removal. Currently, batch, semicontinuous, and continuous systems of various designs are utilized by edible fats and oils processors to produce deodorized oil. All of the systems utilize steam stripping with four interrelated operating variables: (1) vacuum, (2) temperature, (3) stripping steam rate, and (4) holding time.

N. Liquid Oil Filling and Packaging

Most salad and cooking oils are packaged shortly after deodorization in containers for home, restaurant, or large food processor use. The processing necessary for most oils is oxidative stability preservation measures such as nitrogen protection, temperature control, light avoidance, and the addition of any additives required by the individual products. The oil is filtered for a final time in-line to the bottle filler. The effectiveness of this final filtration is monitored with laboratory filterable impurities testing of packaged product samples obtained utilizing a statistical sampling plan. Food safety concerns for retail liquid oils were lessen with the packaging change from glass to plastic containers. Glass breakage and contamination of other containers were major concerns when glass bottles were used. Exposure of the oil to the atmosphere is limited to a micro-second for most filling lines with a tamper-evident seal applied to the container before the cap is applied.

O. Shortening Plasticization and Packaging

Plasticized shortening products can be defined as fats with a consistency that can be readily spread, mixed, or worked. Considerably more is involved in the plasticization of shortening and margarine than merely lowering the temperature to cause solidification. Slow cooling of these products produces a grainy, pasty, non-uniform mushy product that lacks the appearance, texture, and functional

characteristics associated with plasticized products. Development of these characteristics are a function of controlled crystallization or plasticization. The final consistency of a shortening is the culmination of all the factors influencing crystallization and plasticization: chilling, working, tempering, pressure, and gas incorporation.

The plasticization process involves the rapid chilling and homogenization of shortening mixture. Most shortenings are quick-chilled in closed thin-film scraped-wall heat exchangers with extrusion valves to deliver a smooth homogeneous product to the package at 17 to 27 atm pressure. Nitrogen is injected at 13 ± 1% into most shortenings to increase the product's workability and provide a white, creamy appearance. After packaging, many processors temper shortenings at temperatures slightly above the packaging temperature to allow the crystal structure of the hard fraction to reach equilibrium and form a stable matrix. After tempering, shortenings are usually stored and shipped at controlled temperatures of 70 to 80°F (21.1 to 26.7°C) to avoid crystal change and loss of the plastic properties [3].

Shortenings are only exposed to the atmosphere during the actual filling of the product into the container which is less than 15 seconds for the slowest filling lines. Protection from contamination from the atmosphere is provided at the filling lines with covers and other protective devices. As in most of the other fats and oils processes the oil is filtered for a final time while being pumped to the plasticization equipment. Laboratory filterable impurities testing of the packaged product will determine if this filtration effectively removed any particles of polymerized or charred oil that may have developed during storage or movement to the shortening filling department. A positive finding at this point is only resolved by reworking the packaged product involved. This necessitates a remelting of the product reprocessing that may include bleaching and deodorization. Shortenings free of impurities and that meet all of the other quality requirements are released for shipment after the product has crystallized to the predetermined consistency.

Plasticization provides a safety risk that requires careful control; metal contamination from the plasticization equipment. The scraped wall heat exchangers have very tight tolerances between the floating metal scraper blades and the chilling surface. A malfunction of this equipment can distribute shreds of metal into the product. Protective devices such a magnetic traps downstream of the plasticization equipment, screens to filter the product, and metal detection after packaging are used on almost all shortening and margarine packaging lines. The magnetic traps and the screens need to be inspected on a routine basis, probably daily, to ensure that no problem developed since the last inspection. Metal particle findings necessitate a hold on the release of the product filled on that particular line during the period covered by the last inspection. Packaged product metal detectors usually isolate the package with a positive detection. Inspection of these packages must include the package itself because the detection levels must be set to very sensitive levels. At these levels the equipment will alarm with the tramp metal contained in many packages. The package metal detectors should be tested hourly with a test wand or package with metal contents at the lowest detection level.

P. Margarine Mixing, Chilling, and Packaging

Margarine was developed and continues to be a butter substitute. It is a flavored food product containing 80% fat, made by blending selected fats and oils with other ingredients, such as milk, salt, color and fortified with vitamin A, to produce a table, cooking, or baking fat product that serves the purpose of dairy butter but is different in composition and can be varied for different applications. Now, spreads have been developed as margarine substitutes. The major difference between spreads and margarine is that spreads are not required to contain a minimum of 80% fat.

Processing for margarines and spreads begins with the preparation of an emulsion of the ingredients. Emulsions are prepared by adding the oil soluble ingredients to a heated margarine oil formulations in an agitated emulsion tank. Concurrently, a pasteurized aqueous phase is prepared by mixing all of the water soluble ingredients together in another vat. The water phase is then added to oil phase to make the emulsion. The emulsion is rapidly chilled with scraped wall heat exchangers similar to those used for shortening products. The plasticized products are then formed into prints, or filled into the various containers for consumer, restaurant, or food processor use. Most margarine and spread products are stored at refrigerator temperatures immediately after packaging, except for some specialized baking products [4].

The high moisture content with or without milk makes margarine and spreads a good growth media for microorganisms. Bacteria need food, moisture, and heat to grow. They are not mobile and have to be transported from place to place, most often by hands, shoes, and clothes. Therefore, the first preventive measures to practice are the good manufacturing practices or GMPs. The generic first area for any HACCP program for all areas of the plant, but with special attention is the margarine areas, is employee hygiene to prevent the spreading of human bacteria like *E. coli.* The equipment must be kept clean and sanitized to prevent the growth of microorganisms. Normally, margarine processing equipment are cleaned and sanitized with CIP (Clean In Place) systems. In many plants, a highly acidic solution may be held in the equipment and lines during down periods to discourage bacterial growth. Additionally, any suspect ingredient should be pasteurized before use. Many margarine producers will pasteurize the water phase of the margarine or spread emulsions

using continuous in-line HTST (high-temperature-short-time) pasteurization techniques. Formulation-wise, it is desirable to add preservatives to the product, where permitted. After packaging margarine and spread products are stored, shipped, and displayed in the grocery stores under refrigeration.

The product safety preventive measures are followed up with testing for harmful microorganism contamination. The types of bacteria that most margarine manufacturers check for are [4]:

- Coliform — Some members of the coliform group are found in the intestines of all warm blooded animals. They are not generally considered pathogenic or disease producing but rather as "fellow travelers" with intestinal pathogens. Coliforms do not survive pasteurization. When found in pasteurized product, their presence is suggestive of unsanitary conditions or practices during production, packaging, or storage. Coliform testing measures the quality of the sanitation procedures.
- Standard Plate Count — Total plate count is valuable as a sanitation indicator and for quality information. The bacteria that grow at the total plate count incubation temperature are known as mesophiles and include a wide variety of microorganisms. The media used is nutrient-rich and nonselective. Both pathogenic and nonpathogenic organisms may be present.
- Yeast and Mold — Yeast and mold have very similar growth parameters. Both are able to survive extremes in conditions, such as pH, water activity, and high concentrations of sugar, that most bacteria cannot tolerate. Since yeast and mold can survive such conditions, they are important spoilage organisms in margarine and spread products. The presence of yeast and mold in these products indicates poor sanitation practices.
- Thermophile — The term thermophile is used to describe a group of microorganisms that grow in the 131° to 194°F or 55° to 90°C range. These organisms are very heat sensitive and can cause spoilage of product. They will grow into spores if held at elevated temperatures or if the product is improperly cooled.
- Pathogenic Microorganisms — A pathogen is an organism that causes disease. The two types that are of interest for margarine and spread products are infections and intoxications. *Salmonella, E. coliform,* and *Listeria* are infectious organisms that can grow in margarine-type products. These live organisms are poisonous to humans and cause food poisoning when they are ingested. The other organism that pose a problem is *Staphylococcus.* Some strains of *Staph.* produce a toxin that is poisonous to humans when ingested. Pasteurization will kill the organism but once the toxin has been formed, it remains active. This is the reason hand contamination of product after pasteurization can have very critical effects.

Q. Flaking and Spray Chilling

Fat flakes describe the higher melting fat and oil products solidified in a thin flake form for ease of handling, quick remelting, or for a specific function in a food product. Chill rolls and processed oil formulations have been adapted to produce several different flaked products that can provide distinctive performance characteristics in specialty formulated foods. The flaked products, produced almost exclusively the restaurant and food processor consumers, are hardfats or stearines, shortening chips, icing stabilizers, confectioners fats, hard emulsifiers, and other customer specific products.

The flake products are solidified on a chill roll which has been described as an endless moving chilling surface held at a temperature below the crystallization point of the applied fat or oil product to form a congealed film on the outer surface. Specifically, chill rolls are usually 4 foot diameter hollow metal cylinders, in various lengths, with a machined and ground smooth surface, internally refrigerated, that revolve slowly on longitudinal and horizontal axes, with several options for feeding the melted oil onto the surface. After application, a thin film of liquid fat is carried over the roll, and as the revolution of the roll continues, the fat is partially solidified. The solidified fat is scraped from the roll by a doctor blade positioned ahead of the feeding mechanism with all of the chill roll designs. Flakes are packaged in kraft bags, corrugated cartons with vinyl liners or other suitable containers for storage and shipment [3].

Spray chilled or powdered fats are specialized products developed for ease of incorporation, handling, melting efficiency, uniform delivery with addition systems, encapsulation, and other special purpose uses. The spray chilling process consists of atomizing a molten fat in a crystallization zone or tower, maintained under temperature conditions where a very fine mist of the melted fat is contacted with cooled air or gas to cause crystallization without marked supercooling [4].

Flaked products present the most opportunity for product contamination during processing of all the fats and oils products. During chilling the product is exposed to the atmosphere longer than any of the other packaging operations. Most chill rolls are protected from air borne contamination with shields but the chill time and slow packaging rate require constant attention by the packaging

employees. Metal contamination is also a product risk with some of the chill roll arrangements using application rolls or metal doctor blades. Metal detection after packaging and constant visual attention by the packaging employee have effectively identified any problems. Nevertheless, the preventive measures are proper equipment maintenance, proper equipment set-up, and diligent inspection of the equipment.

R. Bulk Fats and Oils Shipments

Food processors that use fats and oils in large quantities many times have the facilities to handle this ingredient liquid in bulk. All of the products packaged for shipment and use can be provided to the customers in tank cars or tank trucks, except margarine and spread mixes which contain milk and salt. The customers for these bulk products must have fats and oils bulk handling systems to receive, store, and handle the liquid products. Impurities and contamination are the two major food safety concerns which are controlled with a through inspection of the cleanliness of the tankers and in-line filtration of the oil during loading. Oil purity is monitored with laboratory filterable impurities evaluations of representative samples obtained from the tanker after loading. An impurity deviation at this point necessitates unloading of the tanker and reprocessing to remove the impurity identified. In addition, it is standard practice for the bulk oil customer to again filter the oil as it is being unloaded into his facility.

ACKNOWLEDGMENT

The information in this chapter has been modified from "Sanitation and Safety for a Fats and Oils Processing Plant," by Richard D. O'Brien, In Eds., Y. H. Hui et al., *Food Plant Sanitation*, Marcel Dekker, New York, 2003.

200 US FDA Guidances for Food Security

Nanna Cross
Chicago, IL

CONTENTS

I. INTRODUCTION

To protect our food supply from terrorist attacks, the U.S. Food and Drug Administration (FDA) has issued a number of guidance documents for the food industry. These documents represent FDA's current thinking on the kinds of measures that food establishments may take to minimize the risk that food under their control will be subject to tampering or other malicious, criminal, or terrorist actions.

This chapter discusses some of these documents. Please note the following premises:

1. The information in each document has been modified to make easy readings. Therefore, the original documents must be consulted for details.
2. Some major abbreviations are:
   FR = U.S. Federal Register.
   CFR = U.S. Code of Federal Regulations.
3. For all documents discussed in this chapter, please note that the Emergency Point of Contact is:
   U.S. Food and Drug Administration
   5600 Fishers Lane, Rockville, MD 20857
4. If a food import establishment operator suspects that any of his/her products that are regulated by the FDA have been subject to tampering, "counterfeiting," or other malicious, criminal, or terrorist action, FDA recommends that he/she notify the FDA 24-hour emergency number at 301-443-1240 or call their local FDA District Office. FDA District Office telephone numbers are listed at http://www.fda.gov/ora/inspect_ref/iom/iomoradir.html. FDA recommends that the operator also notify local law enforcement and public health agencies.
5. Additional Resources:

A process called Operational Risk Management (ORM) may help prioritize the preventive measures that are most likely to have the greatest impact on reducing the risk of tampering or other malicious, criminal, or terrorist actions against food. Information on ORM is available in the Federal Aviation Administration (FAA) System Safety Handbook, U.S. Department of Transportation, FAA, December 30, 2000, Chapter 15, Operational Risk Management. The handbook is available at: http://www.asy.faa.gov/Risk/SSHandbook/Chap15_1200.pdf.

The U.S. Department of Transportation, Research and Special Programs Administration has published an

advisory notice of voluntary measures to enhance the security of hazardous materials shipments. It is available at: http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=2002_register&docid=02-3636-filed.pdf. The notice provides guidance to shippers and carriers on personnel, facility and en route security issues.

The U.S. Postal Service has prepared guidance for identifying and handling suspicious mail. It is available at: http://www.usps.com/news/2001/press/mailsecurity/postcard.htm.

The Federal Anti-Tampering Act (18 USC 1365) makes it a federal crime to tamper with or taint a consumer product; to attempt, threaten, or conspire to tamper with or taint a consumer product; or make a false statement about having tampered with or tainted a consumer product. Conviction can lead to penalties of up to $100,000 in fines and up to life imprisonment. The Act is available at: http://www.fda.gov/opacom/laws/fedatact.htm.

The National Infrastructure Protection Center (NIPC) serves as the federal government's focal point for threat assessment, warning, investigation, and response for threats or attacks against U.S. critical infrastructure. The NIPC has identified the food system as one of the eight critical infrastructures, and has established a public-private partnership with the food industry, called the Food Industry Information Sharing and Analysis Center (Food Industry ISAC). The NIPC provides the Food Industry ISAC with access, information, and analysis, enabling the food industry to report, identify, and reduce its vulnerabilities to malicious attacks, and to recover from such attacks as quickly as possible. In particular, the NIPC identifies credible threats and crafts specific warning messages to the food industry. Further information is available at http://www.nipc.gov/ and http://www.foodisac.org/.

Finally, FDA encourages trade associations to evaluate the preventive measures contained in this guidance document and adapt them to their specific products and operations and to supplement this guidance with additional preventive measures when appropriate. FDA welcomes dialogue on the content of sector specific guidance with appropriate trade associations.

Finally, some trade associations have developed food security guidance that is appropriately focused for that specific industry. For example, the International Dairy Food Association has developed a food security guidance document as an aid to the dairy industry.

FDA encourages other trade associations to evaluate the preventive measures contained in this FDA guidance document and adapt them to their specific products and operations and to supplement this guidance with additional preventive measures when appropriate. FDA welcomes dialogue on the content of sector specific guidance with appropriate trade associations.

- Preparing for the possibility of tampering or other malicious, criminal, or terrorist events
- Assigning responsibility for security to knowledgeable individual(s).

When studying the information, there are many areas of overlap among the different guidance documents. There are guidelines that are the same, whether they are for food producer, food manufacturer, food importer or food transport companies, e.g., a good security record of each employee, suspicious packages in a work area, abnormal looking foods, leaking containers, and so on. Such information is repeated in each of the guidance document for several reasons:

1. To maintain the integrity of each document so that the users will understand the intention and details of each guidance in its entity. It must be emphasized that they are not legal documents.
2. Each guidance document is designed for a specific segment of the food industries. If all documents are combined to avoid over-lapping, then each specific segment of the food industries will be frustrated in the study and dissemination of the information to its intended members. This frustration may potentially lead to ignoring such documents because they are difficult to read.
3. Although the repeated information may take up space and printed pages and be responsible for a minor deviation from full professional English, its benefits to the readers outweigh economical and language considerations.

II. FOOD PRODUCERS, PROCESSORS, AND TRANSPORTERS: FOOD PREVENTIVE MEASURES GUIDANCE

This document was issued by the FDA on March 21, 2003 and covers the following:

A. Goals and Objectives

1. Purpose and Scope

This guidance is designed as an aid to operators of food establishments (firms that produce, process, store, repack, relabel, distribute, or transport food or food ingredients). This is a very diverse set of establishments, which includes both very large and very small entities.

This guidance identifies the kinds of preventive measures operators of food establishments may take to minimize the risk that food under their control will be subject to tampering or other malicious, criminal, or terrorist actions. It is relevant to all sectors of the food system, including farms, aquaculture facilities, fishing vessels, producers, transportation operations, processing facilities, packing facilities, and warehouses. It is not intended as guidance for retail food stores or food service establishments.

Operators of food establishments are encouraged to review their current procedures and controls in light of the potential for tampering or other malicious, criminal, or terrorist actions and make appropriate improvements. FDA recommends that the review include consideration of the role that unit and distribution packaging might have in a food security program. This guidance is designed to focus operator's attention sequentially on each segment of the farm-to-table system that is within their control, to minimize the risk of tampering or other malicious, criminal, or terrorist action at each segment. To be successful, implementing enhanced preventive measures requires the commitment of management and staff. Accordingly, FDA recommends that both management and staff participate in the development and review of such measures.

2. Limitations

Not all of the guidance contained in this document may be appropriate or practical for every food establishment, particularly smaller facilities and distributors. FDA recommends that operators review the guidance in each section that relates to a component of their operation, and assess which preventive measures are suitable. Example approaches are provided for many of the preventive measures listed in this document. These examples should not be regarded as minimum standards, nor should the examples provided be considered an inclusive list of all potential approaches to achieving the goal of the preventive measure. FDA recommends that operators consider the goal of the preventive measure, assess whether the goal is relevant to their operation, and, if it is, design an approach that is both efficient and effective to accomplish the goal under their conditions of operation.

3. Structure

This guidance is divided into five sections that relate to individual components of a food establishment operation: management; human element — staff; human element — public; facility; and operations.

B. Food Establishment Operations

1. Management

FDA recommends that food establishment operators consider:

a. Preparation for the possibility of tampering or other malicious, criminal, or terrorist actions

1. assigning responsibility for security to knowledgeable individual(s)
2. conducting an initial assessment of food security procedures and operations, which we recommend be kept confidential
3. having a security management strategy to prepare for and respond to tampering and other malicious, criminal, or terrorist actions, both threats and actual events, including identifying, segregating and securing affected product
4. planning for emergency evacuation, including preventing security breaches during evacuation
5. maintaining any floor or flow plan in a secure, off-site location
6. becoming familiar with the emergency response system in the community
7. making management aware of 24-hour contact information for local, state, and federal police/fire/rescue/health/homeland security agencies
8. making staff aware of who in management they should alert about potential security problems (24-hour contacts)
9. promoting food security awareness to encourage all staff to be alert to any signs of tampering or other malicious, criminal, or terrorist actions or areas that may be vulnerable to such actions, and reporting any findings to identified management (for example, providing training, instituting a system of rewards, building security into job performance standards)
10. having an internal communication system to inform and update staff about relevant security issues
11. having a strategy for communicating with the public (for example, identifying a media spokesperson, preparing generic press statements and background information, and coordinating press statements with appropriate authorities)

b. Supervision

1. providing an appropriate level of supervision to all staff, including cleaning and maintenance staff, contract workers, data entry and computer support staff, and especially, new staff
2. conducting routine security checks of the premises, including automated manufacturing lines, utilities and critical computer data systems (at a frequency appropriate to the operation) for signs of tampering or malicious, criminal, or terrorist actions or areas that may be vulnerable to such actions

c. Recall strategy

1. identifying the person responsible, and a backup person
2. providing for proper handling and disposition of recalled product
3. identifying customer contacts, addresses and phone numbers
4. investigation of suspicious activity

5. investigating threats or information about signs of tampering or other malicious, criminal, or terrorist actions
6. alerting appropriate law enforcement and public health authorities about any threats of or suspected tampering or other malicious, criminal, or terrorist actions

d. Evaluation program

1. evaluating the lessons learned from past tampering or other malicious, criminal, or terrorist actions and threats
2. reviewing and verifying, at least annually, the effectiveness of the security management program (for example, using knowledgeable in-house or third party staff to conduct tampering or other malicious, criminal, or terrorist action exercises and mock recalls and to challenge computer security systems), revising the program accordingly, and keeping this information confidential
3. performing random food security inspections of all appropriate areas of the facility (including receiving and warehousing, where applicable) using knowledgeable in-house or third party staff, and keeping this information confidential
4. verifying that security contractors are doing an appropriate job, when applicable

2. Human Element — Staff

Under Federal law, food establishment operators are required to verify the employment eligibility of all new hires, in accordance with the requirements of the Immigration and Nationality Act, by completing the INS Employment Eligibility Verification Form (INS Form I-9). Completion of Form I-9 for new hires is required by 8 USC 1324a and nondiscrimination provisions governing the verification process are set forth at 8 USC 1324b.

FDA recommends that food establishment operators consider:

a. Screening (pre-hiring, at hiring, post-hiring)

This involves examining the background of all staff (including seasonal, temporary, contract, and volunteer staff, whether hired directly or through a recruitment firm) as appropriate to their position, considering candidates' access to sensitive areas of the facility and the degree to which they will be supervised and other relevant factors (for example, obtaining and verifying work references, addresses, and phone numbers, participating in one of the pilot programs managed by the Immigration and Naturalization Service and the Social Security Administration [These programs provide electronic confirmation of employment eligibility for newly hired employees. For more information call the INS SAVE Program toll free at 1-888-464-4218, fax a request for information to (202) 514-9981, or write to US/INS, SAVE Program, 425 I Street, NW, ULLICO-4th Floor, Washington, DC 20536. These pilot programs may not be available in all states], having a criminal background check performed by local law enforcement or by a contract service provider [Remember to first consult any state or local laws that may apply to the performance of such checks]).

Note: screening procedures should be applied equally to all staff, regardless of race, national origin, religion, and citizenship or immigration status.

b. Daily work assignments

1. knowing who is and who should be on premises, and where they should be located, for each shift
2. keeping information updated

c. Identification

1. establishing a system of positive identification and recognition that is appropriate to the nature of the workforce (for example, issuing uniforms, name tags, or photo identification badges with individual control numbers, color coded by area of authorized access), when appropriate
2. collecting the uniforms, name tag, or identification badge when a staff member is no longer associated with the establishment

d. Restricted access

1. identifying staff that require unlimited access to all areas of the facility
2. reassessing levels of access for all staff periodically
3. limiting access so staff enter only those areas necessary for their job functions and only during appropriate work hours (for example, using key cards or keyed or cipher locks for entry to sensitive areas, color coded uniforms [remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes])
4. changing combinations, rekeying locks and/or collecting the retired key card when a staff member who is in possession of these is no longer associated with the establishment, and additionally as needed to maintain security

e. Personal items

1. restricting the type of personal items allowed in establishment
2. allowing in the establishment only those personal use medicines that are necessary for the health of staff and ensuring that these personal use medicines are properly labeled and stored away from food handling or storage areas
3. preventing staff from bringing personal items (for example, lunch containers, purses) into food handling or storage areas

4. providing for regular inspection of contents of staff lockers (for example, providing metal mesh lockers, company issued locks), bags, packages, and vehicles when on company property (Remember to first consult any federal, state, or local laws that may relate to such inspections)

f. Training in food security procedures

1. incorporating food security awareness, including information on how to prevent, detect, and respond to tampering or other malicious, criminal, or terrorist actions or threats, into training programs for staff, including seasonal, temporary, contract, and volunteer staff
2. providing periodic reminders of the importance of security procedures (for example, scheduling meetings, providing brochures or payroll stuffers)
3. encouraging staff support (for example, involving staff in food security planning and the food security awareness program, demonstrating the importance of security procedures to the staff)

g. Unusual behavior

This involves watching for unusual or suspicious behavior by staff (for example, staff who, without an identifiable purpose, stay unusually late after the end of their shift, arrive unusually early, access files/information/areas of the facility outside of the areas of their responsibility; remove documents from the facility; ask questions on sensitive subjects; bring cameras to work).

h. Staff health

This involves being alert for atypical staff health conditions that staff may voluntarily report and absences that could be an early indicator of tampering or other malicious, criminal, or terrorist actions (for example, an unusual number of staff who work in the same part of the facility reporting similar symptoms within a short time frame), and reporting such conditions to local health authorities.

3. Human Element — Public

FDA recommends that food establishment operators consider visitors (for example, contractors, supplier representatives, delivery drivers, customers, couriers, pest control representatives, third-party auditors, regulators, reporters, tours):

1. inspecting incoming and outgoing vehicles, packages and briefcases for suspicious, inappropriate or unusual items or activity, to the extent practical
2. restricting entry to the establishment (for example, checking visitors in and out at security or reception, requiring proof of identity, issuing visitors badges that are collected upon departure, accompanying visitors)
3. ensuring that there is a valid reason for the visit before providing access to the facility - beware of unsolicited visitors
4. verifying the identity of unknown visitors
5. restricting access to food handling and storage areas (for example, accompanying visitors, unless they are otherwise specifically authorized)
6. restricting access to locker room

4. Facility

FDA recommends that food establishment operators consider:

a. Physical security

1. protecting perimeter access with fencing or other deterrent, when appropriate
2. securing doors (including freight loading doors, when not in use and not being monitored, and emergency exits), windows, roof openings/hatches, vent openings, ventilation systems, utility rooms, ice manufacturing and storage rooms, loft areas, trailer bodies, tanker trucks, railcars, and bulk storage tanks for liquids, solids, and compressed gases, to the extent possible (for example, using locks, "jimmy plates," seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes])
3. using metal or metal-clad exterior doors to the extent possible when the facility is not in operation, except where visibility from public thoroughfares is an intended deterrent (remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes)
4. minimizing the number of entrances to restricted areas (remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes)
5. securing bulk unloading equipment (for example, augers, pipes, conveyor belts, and hoses) when not in use and inspecting the equipment before use
6. accounting for all keys to establishment (for example, assigning responsibility for issuing, tracking, and retrieving keys)
7. monitoring the security of the premises using appropriate methods (for example, using security patrols [uniformed and/or plain-clothed], video surveillance)

8. minimizing, to the extent practical, places that can be used to temporarily hide intentional contaminants (for example, minimizing nooks and crannies, false ceilings)
9. providing adequate interior and exterior lighting, including emergency lighting, where appropriate, to facilitate detection of suspicious or unusual activities
10. implementing a system of controlling vehicles authorized to park on the premises (for example, using placards, decals, key cards, keyed or cipher locks, issuing passes for specific areas and times to visitors' vehicles)
11. keeping parking areas separated from entrances to food storage and processing areas and utilities, where practical

b. Laboratory safety

1. restricting access to the laboratory (for example, using key cards or keyed or cipher locks [remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes])
2. restricting laboratory materials to the laboratory, except as needed for sampling or other appropriate activities
3. restricting access (for example, using locks, seals, alarms, key cards, keyed or cipher locks) to sensitive materials (for example, reagents and bacterial, drug, and toxin positive controls)
4. assigning responsibility for integrity of positive controls to a qualified individual
5. knowing what reagents and positive controls should be on the premises and keeping track of them
6. investigating missing reagents or positive controls or other irregularities outside a normal range of variability immediately, and alerting appropriate law enforcement and public health authorities about unresolved problems, when appropriate
7. disposing of unneeded reagents and positive controls in a manner that minimizes the risk that they can be used as a contaminant

c. Storage and use of poisonous and toxic chemicals (for example, cleaning and sanitizing agents, pesticides)

1. limiting poisonous and toxic chemicals in the establishment to those that are required for the operation and maintenance of the facility and those that are being held for sale
2. storing poisonous and toxic chemicals as far away from food handling and storage areas as practical
3. limiting access to and securing storage areas for poisonous and toxic chemicals that are not being held for sale (for example, using keyed or cipher locks, key cards, seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant federal, state or local fire codes that may apply before making any changes])
4. ensuring that poisonous and toxic chemicals are properly labeled
5. using pesticides in accordance with the Federal Insecticide, Fungicide, and Rodenticide Act (for example, maintaining rodent bait that is in use in covered, tamper-resistant bait stations)
6. knowing what poisonous and toxic chemicals should be on the premises and keeping track of them
7. investigating missing stock or other irregularities outside a normal range of variation and alerting appropriate law enforcement and public health authorities about unresolved problems, when appropriate

5. Operations

FDA recommends that food establishment operators consider:

a. Incoming materials and contract operations

1. using only known, appropriately licensed or permitted (where applicable) contract manufacturing and packaging operators and sources for all incoming materials, including ingredients, compressed gas, packaging, labels, and materials for research and development
2. taking reasonable steps to ensure that suppliers, contract operators and transporters practice appropriate food security measures (for example, auditing, where practical, for compliance with food security measures that are contained in purchase and shipping contracts or letters of credit, or using a vendor approval program)
3. authenticating labeling and packaging configuration and product coding/expiration dating systems (where applicable) for incoming materials in advance of receipt of shipment, especially for new products
4. requesting locked and/or sealed vehicles/containers/railcars, and, if sealed, obtaining the seal number from the supplier and verifying upon receipt, making arrangements to maintain the chain of custody when a seal is broken for inspection by a governmental agency or as a result of multiple deliveries
5. requesting that the transporter have the capability to verify the location of the load at any time, when practical

6. establishing delivery schedules, not accepting unexplained, unscheduled deliveries or drivers, and investigating delayed or missed shipments
7. supervising off-loading of incoming materials, including off hour deliveries
8. reconciling the product and amount received with the product and amount ordered and the product and amount listed on the invoice and shipping documents, taking into account any sampling performed prior to receipt
9. investigating shipping documents with suspicious alterations
10. inspecting incoming materials, including ingredients, compressed gas, packaging, labels, product returns, and materials for research and development, for signs of tampering, contamination or damage (for example, abnormal powders, liquids, stains, or odors, evidence of resealing, compromised tamper-evident packaging) or "counterfeiting" (for example, inappropriate or mismatched product identity, labeling, product lot coding or specifications, absence of tamper-evident packaging when the label contains a tamper-evident notice), when appropriate
11. evaluating the utility of testing incoming ingredients, compressed gas, packaging, labels, product returns, and materials for research and development for detecting tampering or other malicious, criminal, or terrorist action
12. rejecting suspect food
13. alerting appropriate law enforcement and public health authorities about evidence of tampering, "counterfeiting" or other malicious, criminal, or terrorist action

b. Storage

1. having a system for receiving, storing, and handling distressed, damaged, returned, and rework products that minimizes their potential for being compromised or to compromise the security of other products (for example, destroying products that are unfit for human or animal consumption, products with illegible codes, products of questionable origin, and products returned by consumers to retail stores)
2. keeping track of incoming materials and materials in use, including ingredients, compressed gas, packaging, labels, salvage products, rework products, and product returns
3. investigating missing or extra stock or other irregularities outside a normal range of variability and reporting unresolved problems to appropriate law enforcement and public health authorities, when appropriate
4. storing product labels in a secure location and destroying outdated or discarded product labels
5. minimizing reuse of containers, shipping packages, cartons, etc., where practical

c. Security of water and utilities

1. limiting, to the extent practical, access to controls for airflow, water, electricity, and refrigeration
2. securing non-municipal water wells, hydrants, storage, and handling facilities
3. ensuring that water systems and trucks are equipped with backflow prevention
4. chlorinating water systems and monitoring chlorination equipment, where practical, and especially for non-municipal water systems
5. testing non-municipal sources for potability regularly, as well as randomly, and being alert to changes in the profile of the results
6. staying attentive to the potential for media alerts about public water provider problems, when applicable
7. identifying alternate sources of potable water for use during emergency situations where normal water systems have been compromised (for example, trucking from an approved source, treating on-site or maintaining on-site storage)

d. Finished products

1. ensuring that public storage warehousing and shipping operations (vehicles and vessels) practice appropriate security measures (for example, auditing, where practical, for compliance with food security measures that are contained in contracts or letters of guarantee)
2. performing random inspection of storage facilities, vehicles, and vessels
3. evaluating the utility of finished product testing for detecting tampering or other malicious, criminal, or terrorist actions
4. requesting locked and/or sealed vehicles/containers/railcars and providing the seal number to the consignee
5. requesting that the transporter have the capability to verify the location of the load at any time
6. establishing scheduled pickups, and not accepting unexplained, unscheduled pickups
7. keeping track of finished products
8. investigating missing or extra stock or other irregularities outside a normal range of variation and alerting appropriate law enforcement and public health authorities about unresolved problems, when appropriate
9. advising sales staff to be on the lookout for counterfeit products and to alert management if any problems are detected

e. Mail/packages

This involves implementing procedures to ensure the security of incoming mail and packages (for example,

locating the mailroom away from food processing and storage areas, securing mailroom, visual or x-ray mail/package screening, following U.S. Postal Service guidance).

f. Access to computer systems

1. restricting access to computer process control systems and critical data systems to those with appropriate clearance (for example, using passwords, firewalls)
2. eliminating computer access when a staff member is no longer associated with the establishment
3. establishing a system of traceability of computer transactions
4. reviewing the adequacy of virus protection systems and procedures for backing up critical computer based data systems
5. validating the computer security system

If a food establishment operator suspects that any of his/her products that are regulated by the FDA have been subject to tampering, "counterfeiting," or other malicious, criminal, or terrorist action, FDA recommends that he/she notify the FDA 24-hour emergency number at 301-443-1240 or call their local FDA District Office. FDA District Office telephone numbers are listed at: http://www.fda.gov/ora/inspect_ref/iom/iomoradir.html. FDA recommends that the operator also notify appropriate law enforcement and public health authorities.

III. BULK OVER-THE-ROAD FOOD TANKER TRANSPORT SAFETY AND SECURITY GUIDELINES

A. Introduction

On October 2003, the FDA posted this industry information as a service to industry, consumers, the media, and other interested parties. This document was sponsored by the following trade associations:

American Bakers Association
American Frozen Food Institute
Concord Grape Association
Corn Refiners Association
Grocery Manufacturers of America
Institute of Shortening and Edible Oils
International Dairy Foods Association
National Food Processors Association
National Institute of Oilseed Products
National Juice Products Association
National Milk Producers Association
National Tank Truck Carriers
Northwest Food Processors Association
Processed Apples Institute
Snack Food Association
The Vinegar Institute

Information and recommendations contained in this document are intended as voluntary guidelines for the safe and secure transport and handling of over-the-road food tankers. As such, the sponsoring organizations do not guarantee or warrant, expressly or by implication, that compliance with the guidelines will prevent damage, spoilage, accidents, or injuries to persons or property. Any inference of such a guarantee or warranty is expressly and specifically disclaimed.

It is the sole responsibility of any company or person using the guidelines and related information provided in this publication, and not the responsibility of the sponsoring organizations, to ensure that such company or person is proficient in the operations and procedures discussed in this publication. The use of statements, recommendations, or suggestions contained herein creates no responsibility on the part of the sponsoring organizations for damage, spoilage, loss, accident or injury resulting from such use, or irrespective of such use. Moreover, adoption of any of the guidelines or recommendations included in this publication does not assure compliance with legal or regulatory requirements. Those involved with the production, handling and transportation of foods are advised to become familiar with all relevant and applicable local, state and federal regulations and to ensure that they comply with such requirements as appropriate.

A company policy should be established to designate authorized personnel for acceptance of incoming transportation equipment. The policy document should be maintained in company files in accordance with company policy. In addition to these guidelines, a company may provide employees with additional information and forms for use in acceptance of transportation equipment. Consult your legal counsel for guidance on related legal requirements concerning the transportation of foods.

B. Documentation

1. Recommendations

1. The contract and/or verification between a shipper and carrier should include a clause identifying the last three prior cargoes, a copy of the last wash ticket and documentation if the tanker has been converted from non-food to food grade.
2. The carrier should supply documentation to the shipper confirming that all equipment being used is for food grade purposes. This information should be kept on file at the shipper's office.
3. The commodities the carrier may haul in tankers contracted for shipper service are those agreed upon between the parties.

4. A new piece of equipment should have a sanitary cleaning prior to placement in service.
5. Except for dedicated equipment, in-service equipment should have a listing of the last three loads and a copy of the last wash out certificate.
6. If special handling requirements are necessary, they should be specified in the Bill of Lading. Special requirements may include, but are not limited to temperature specifications or restrictions, pumps and nitrogen overlays.

C. Receipt and Inspection of Empty Tanker

1. Receipt

1. Plant personnel should take all reasonable measures and precautions to assure that plant operators conform to the requirements in 21 CFR 110 (Current Good Manufacturing Practices (CGMPs) and 9 CFR Part 417 (Hazard Analysis Critical Control Point (HACCP) Systems). The loading and unloading areas should be designed and maintained in accordance with Good Manufacturing Practices or appropriate regulations in order to reduce the potential for contamination of the inbound product.
2. The tanker should be identified for use if there are specific regulation requirements — juice, seafood, meat and poultry, etc., and/or if there are specific customer requirements.
3. Confirm that access points were sealed at the wash station with numbered, tamper-evident seals to guard against subsequent contamination of the cleaned trailer before delivery. This should include at least all major points of entry and discharge. Sealing points may include the dome cover, tank outlet, vent cap, pump inlet, pump outlet, and hose tube covers.
4. In the event that transfer hoses and/or the shipper or consignee supplies piping, seals need not be applied to hose tubes mounted on the cargo tank. If seals are present and are broken or tampered with by enforcement personnel, documentation must be produced by enforcement personnel to verify such action. Tank wash facilities, shippers and consignees should be authorized to remove and replace seals.
5. Confirm that hoses and pump outlets were capped and sealed at the wash station after cleaning. Trailers hauling food grade commodities should be washed on a regular schedule regardless of whether or not they have hauled food, the interval for which will be determined under the terms of the contract.
6. All documentation, including wash certificates or tags and bills of lading, should be reviewed and seal identification checked and verified.
7. Seal numbers should be recorded on the wash ticket, or a suitable document designed for that purpose, and verified by the receiver when inspecting the vehicle. Any discrepancy should be reported to management immediately. If the driver indicates that it has been necessary to transfer the lading from one tank to another after washing, contact appropriate plant management.
8. Obtain appropriate documentation from the trucker or the truck company concerning the previous cargo(es). The prior load should be accurately documented and documentation available to assure that the tank has been in acceptable transportation service. Additionally, the trucking company should be able to present independent documentation (e.g., shipper bills of lading) of the last three prior load commodities (by fax or e-mail), upon request.
9. The cleaning certificate issued by the wash station should contain the name of the product last hauled determined via the last shipping documents and should be reviewed and copied for filing. If no cleaning certificate is presented, management should be consulted.
10. If washing is required, a copy of the wash ticket, noting the prior commodity, should be presented to the outbound truck operator. The carrier should also provide wash schedules/wash histories for a specific cargo tank upon request.
11. The prior load records should be verified as designated in the documentation section of this guideline. If the prior cargo was not an acceptable material, do not accept the load and contact appropriate plant management immediately.

2. Visual Inspection

1. The interior of the tank should be inspected visually. The interior of the tank should be clean and free of cracks and corrosion, which can harbor contaminants. If condensate is present or the interior is otherwise unacceptable, check with your supervisor prior to loading. Internal damage or corrosion, foreign objects, incompatible product residue, mold, and moisture are potential causes for rejection.
2. The presence of off-odors or of any residual material when opening the dome cover should be reported to appropriate plant management immediately.
3. Inspect the inside of the tank for evidence of residue of prior cargoes or flaking, which

indicates inadequate cleaning/rinsing of the tank or unacceptable prior cargoes. Be especially alert to those areas hard to inspect visually, such as the top inner portion of the tank.

4. It is recommended that the shippers/receivers use their own pumps and hoses. If the tanker or tractor pump and hoses are used, they should meet all applicable tanker guidelines. If the truck's pumping system is to be used for loading, all hoses and pumps should be visually inspected. Special attention should be paid to pumps located on the tractor, as the tractor unit may not be dedicated to food service use and may not have been cleaned when the trailer was cleaned. If pumps and/or hoses carried on the tractor are to be used, they should be indicated as having been cleaned on the wash station certificate. Tractor mounted blowers, used for the transfer of dry commodities should not be cleaned, but move only air.
5. Inspect all seals, gaskets, pumps, valves, hoses, and hose tubing for cleanliness, integrity, and proper capping. Cracked, corroded, or improperly protected equipment can trap [residual material] and serve as a source of contamination or create an environment conducive to bacterial growth with the potential for contaminating product coming in contact with the surface.
6. The company should have a visual inspection form for plant employees to check off during the tanker inspection. The form should have an accept/reject notation and a space for the employee and/or appropriate signature(s). (Refer to Appendix "C" for an example of an empty tanker inspection form.)
7. A clear company policy should be established to designate authorized personnel for acceptance of incoming transportation equipment. The policy document should be maintained in company files in accordance with company policy. In addition to these guidelines, a company may provide employees with additional information and forms for use in acceptance of transportation equipment. Consult your legal counsel for guidance on related legal requirements concerning the transportation of foods.

D. Tank Truck Loading

1. Recommendations

1. If the tanker is deemed acceptable for loading, sufficient care should be exercised during loading to ensure that the integrity of the product and the tanker vessel are maintained.
2. Product loading and unloading facilities should be designed and maintained in accordance with Good Manufacturing Practices 21 CFR, part 110.
3. After loading, the tanker should be closed and tamper-evident security seals affixed to any access ports, which were unsealed during inspection to preclude tampering with or adulteration of the product during shipment.
4. Seal numbers should be recorded on the bill of lading or other appropriate document.
5. The cargo should be identified on the bill of lading by the common or usual name of the food or food ingredient or as identified by DOT regulations. If the product is classified as a "hazardous material" by DOT regulation, the shipper must supply appropriate product hazard information (e.g., Material Safety Data Sheet (MSDS), vehicle placards and shipping documents.) Product hazard information will also assist carriers and wash rack personnel to determine proper cleaning and passivation procedures, thus preserving the integrity of the cargo tank for food grade service.
6. A copy of the incoming wash certificate with information about the previous cargo should be provided to the outbound truck operator if the tanker has been cleaned prior to loading.
7. Food ingredients such as food-grade chemicals should be identified by the proper shipping name (FDA or DOT regulations).
8. Shippers should ensure that they have provided the trucker with any emergency action information required. Identification will assist the receiver and those responsible for wash station operations in determining the clean-up procedure and assure that tankers dedicated to food shipments remain available.
9. When all information is recorded, sign the bill of lading indicating the shipment may proceed.
10. A clear company policy should be established to designate authorized personnel for certifying proper loading of outbound transportation equipment.

E. Loaded Tanker

1. Receipt

1. When receiving a loaded tanker, obtain a copy of the bill of lading and confirm the cargo and security seal numbers. (If seal numbers do not match or the seals appear to have been tampered with, notify appropriate management immediately. Do not open the tanker or begin unloading.)

2. Review the information provided in the wash ticket copy, and evaluate the prior load information to insure that proper food, food-grade commodities, or acceptable non-food products have been previously carried in the tank. If the prior cargo was not acceptable material, contact appropriate plant management.
3. If all documents and seals are in order, begin your inspection of the tanker and all attendant equipment, including pumps and hoses, for cleanliness and state of repair. (See Appendix "B" for an example of an appropriate checklist.)

F. Minimum Cleaning Requirements for Non-Dairy Food, Food Grade, Liquid Cargo Tanks

1. "Food to Food"

Acceptable media (depending on the prior load, and which may be applied alone or in combination) include:

1. Steam;
2. Hot or cold water;
3. Detergent, where appropriate, according to customer's specifications and the product hauled, observing manufacturer's and chemical suppliers recommendations on pH;
4. Caustic, according to customer's specifications observing manufacturer's recommendation on pH; and
5. Air drying — using an appropriate filter.

Overall criteria to be applied as appropriate to the media used:

1. When used alone or as part of another media, the term "hot water" should mean that water (and cleaning agents applied to product contact surfaces) should be appropriate to clean and sanitize internal surfaces;
2. The term "water" means potable water;
3. Only cleaning compounds as covered by appropriate food additive regulations as established by FDA (or USDA-approved cleaning substances) should be used in any cleaning media (or combinations thereof); and
4. At a minimum, the following accessories and components should be removed (and disassembled) from the unit for cleaning — gaskets, external valves, vents and caps as applicable.

Seals should be applied to all cargo tank access points after cleaning and prior to shipment of the tank to the facility for product loading.

2. "Food to Food" — Dry Bulk

Product wash cycles should follow defined industry standards, or as specified by carriers and shippers. In terms of solutions, the same basic processes used in the cleaning of liquid trailers would be, as appropriate, applicable to the cleaning of dry bulk units. In addition:

1. All lines should be disassembled and cleaned separately; note that standard washes, used routinely between compatible commodities, do not require disassembly of the product line, and conversion washes, used between incompatible commodities, do require disassembly of the product line.
2. Remove, inspect, clean and/or replace aeration pads and dust collectors. Gaskets should be removed and cleaned on all washes. If the prior load involved approved non-food products, all gaskets should be removed and replaced.
3. The internal loading tube and product piping should receive separate cleaning;
4. All fumigants, chemicals and/or detergents must be covered by and used in accordance with appropriate regulations;
5. The drying phase should utilize filtered air; and
6. Seals and tags as appropriate should be applied at the cleaning facility.

3. Additional Criteria Applicable to Both "Food to Food" and "Approved Non-Food to Food" Interior Cleaning

1. Nothing herein should be construed to prohibit internal visual inspections of the trailer, including tank entry to perform such inspection prior to the final hot water rinse.
2. If the use of seals is required, such should be applied by the tank wash facility to all external openings (manways, caps, vents, valves, inlet and outlet side of the pump, etc.) prior to the vessel's return to service.
3. In addition to the above, and whether or not seals are required, the tank wash facility should (prior to the vessel's return to service) supply appropriate documentation noting at a minimum:
   - The name, address, phone and fax numbers of the cleaning facility;
   - The certification number of the facility if Federal, state or local authorities require such information:
   - The date of interior cleaning;
   - The prior load:

- The temperature of water applied for cleaning purposes;
- The cleaning agents applied; and
- If seals are utilized, the seal numbers should be recorded.

4. In some cases, it may be necessary for a given trailer to be subjected to two (or more) cleaning processes, which may involve the use of materials not specified in this standard. Nothing herein should be construed to prohibit this practice, except that the methods, specified herein, should always be the final step in a multi-stage cleaning process.
5. All tank wash facilities performing specified tank wash services for the food industry should receive "third party" inspection and certification. If appropriate, the tank wash facility should be inspected and certified by Federal, state and/or local authorities and/or representatives of shippers, carriers and consignees. Such inspection and/or certification should verify that the facility:
   - Has the equipment and personnel to meet the standards (including document preparation and retention);
   - Has piping (integral to any wash rack mechanism) after a pre-determined filtered control point used to conduct steam, hot and cold water, and cleaning solutions involved in the cleaning of food-grade equipment that is constructed of stainless steel alloys;
   - Has safeguards to preclude the commingling of steam, water, and cleaning solutions used in the interior cleaning of food-grade cargo tanks with steam, water, and cleaning solutions used in the cleaning of non-food grade cargo tanks;
   - Possesses sufficient insurance, or otherwise evidence of financial responsibility, at levels equivalent to those for motor carriers for public liability, property damage, and environmental restoration;
   - If hot washing tankers, has a boiler capable of providing hot water on a continuous basis for a minimum needed to ensure the tanker is clean;
   - Avoids direct contact of steam with food contact surfaces. If steam injection is used to heat water, only food grade boiler treatment additives are used;
   - Utilizes appropriate sanitary wash equipment designed to ensure that all interior surfaces are cleaned and sanitized; and
   - Where appropriate, has a permanently mounted thermometer capable of monitoring and recording water temperature at the discharge valve.

G. Conversion of Trailers from "Non-Approved, Non-Food Service" to "Approved Non-Food to Food" and "Food to Food" Service

(Note: There should be clear, legally binding agreement between carriers, shippers and consignees concerning the use of converted tankers. All conversion steps should be documented.)

1. Minimum Tank Conversion Steps

1. The tank should be appropriately cleaned of prior product;
2. An internal inspection should include determination evaluation and/or removal of:
   - Finish (parent metal and welds);
   - Evidence of pitting;
   - Corrosion;
   - Weld and parent material discoloration; and
   - Odors.
3. Remove, clean, pacify and/or replace:
   - Internal and external vents, valves and caps, discs, and piping;
   - Manifolds;
   - All gaskets (including those on accessories); and
   - Tank interior metal surfaces.
4. A final wash should be performed before applying a seal.
5. Apply a "Food Grade" decal, cleaning tag, and seals (if required).

H. Tank Requirements

1. Non-Dairy Liquid Food Grade Products

1. The shell, heads, and appliances with product contact surfaces should be a minimum alloy #304 SS, low carbon;
2. Weld finish should be W-3;
3. All parent metal finish on product contact surfaces should be 2B;
4. The entire tank surface should be clean-bore (no baffles);
5. If compartments are permitted they should be equipped with double bulkheads with evacuated airspace between bulkheads;
6. With the exception of center-discharge (belly drop) tanks, all tanks should have a positive drain (minimum 4 inch slope from front to back of tankers).

2. Accessories and Fittings on Non-Dairy Liquid Tanks

1. All internal accessories should be capable of being disassembled to clean product-contact surfaces.
2. Internal valves should be acceptable (note: internal valves are mandatory if food-grade product is flammable or corrosive liquid).
3. Clean-out openings should be appropriate.
4. Gaskets should be removable and non-porous.
5. Manways, fittings, and connections should be a minimum alloy #304 SS, low carbon.
6. Vehicle-mounted product transfer equipment if used, should meet the requirements established for the tanker. Product transfer equipment (vehicle-mounted versus facility-supplied) is a matter of choice involving the shipper, carrier and consignee. If "vehicle-mounted" product transfer equipment is used, such equipment should meet the requirements established for the cargo tank.
7. If the use of seals is required by the shipper (at loading) such should be provided and affixed by shipper representatives and should be "cable type" or equivalent "tamper evident." The shipper should provide authorized seals to carriers loading from remote rail facilities where the carrier or a third party acts as the "shipper representative."

3. Dry-Bulk Food Grade Cargo Tanks

1. The use of aluminum alloys in the construction of shell, heads, and accessory equipment is appropriate.
2. Clean-out openings are appropriate.
3. All gaskets should be removable and non-porous.
4. Product transfer equipment - vehicle mounted equipment to accomplish pressure unloading is appropriate.

I. Security

1. Trucking Company

In the interest of safety and security, shippers should maintain and regularly update records of:

1. Carrier contacts (to include names, phone and fax numbers and (if applicable) e-mail contacts;
2. The carrier's "U.S. DOT Safety Rating" available via the Internet;
3. The carrier's compliance with U.S. DOT insurance regulations (available via the internet); and
4. Verification that the carrier has resources (in-house or contractual) to respond to a product spill.

2. Driver

Each cargo tank driver, entering a shipper, wash station, carrier terminal or consignee facility should produce:

1. His/her Commercial Drivers License (with photo); and
2. In light of security concerns, many trucking companies have established methods and procedures whereby parties to the transportation transaction can verify employment status of an individual driver. Shippers and consignees should consult with individual trucking companies for more details.

3. Cleaning Facilities

Shippers, carriers and consignees should maintain and update:

1. Facility contacts (to include names, phone and fax numbers, and if applicable e-mail contacts; and
2. All appropriate certificates (if required by Federal, state and local authorities and/or by carriers, shippers and consignees).

4. Receiving Facility

Follow appropriate instructions discussed in this section and include:

1. That access points are sealed and match appropriate paperwork;
2. That paperwork is verified including previous washing record, investigate and verify suspicious alterations;
3. Verification of the driver; if the driver has changed, do not unload (or load) until his/her credentials are confirmed;
4. If delivery schedule has been changed the receiver should be notified in advance, if not, confirm the reasons for the change before unloading or loading;
5. Where scales are used, reconciliation before unloading, where appropriate, of differences between the amount of product shipped and that received; and
6. Limited access of drivers to the facility.

5. General

In addition to the above, shippers and consignees should assure themselves that trucking companies and/or cleaning facilities have the resources for:

1. Collecting, maintaining and reproducing relevant documents including but not limited to;

shipping papers, records of prior hauls (on a vehicle-by-vehicle basis), cleaning certificate, inspection reports and exception reports; and
2. A written procedure regarding the use of cargo tank access seals (including "what to do" in the event that a seal is broken or shows evidence of tampering.)

Food facilities should consider:

1. Using only known, pre-approved and appropriately licensed or permitted (where appropriate) carriers and wash stations;
2. Establishing agreed upon security measures with shippers;
3. Taking reasonable steps, such as auditing, to ensure that carriers are in compliance with the company's food security measures;
4. Establishing and adhering to regular delivery schedules where feasible;
5. Exercising strict control including scheduling, egress to the facility, unloading and supervision of unloading of "hazardous" materials; and
6. Establishing a formal review process for evaluating shippers, and where appropriate, wash stations.

B. Inspection Report Form [Incoming Tanker (Loaded)]

1. Vehicle Identification

Tractor Identification_____ Tanker Identification_____ Date Inspected_____
Name of Carrier_____ Name of Inspector_____ Cargo_____
Shipper_____ Drivers_____
Bill of Lading_____ Identification:_____ Cargo Verified_____

1. Is the outside of the carrier clean? Yes____ No____If no, describe_____
2. Is there written documentation or prior loads? Yes____ No___ If no, notify appropriate management immediately.
3. Source of prior load written documentation: driver_____ truck company_____ broker_____ shipper_____ other_____
4. Are all major points of entry and discharge sealed? Yes____ No____
5. Are seals numbered and recorded on the wash ticket/bill of lading? Yes___ No___
6. Do seal numbers correspond to the numbers on the wash ticket/bill of lading? Yes___ No___
7. Are seals intact with no evidence of tampering? Yes____ No____

If no to #'s 3, 4, 5, 6, or 7, Notify Appropriate Management Immediately.

8. As you open the tanker lid, do you smell off-odors? Yes___ No___. If yes, identify if possible: Describe_____
9. Appearance of the product: Does the product appear normal (color, consistency)? _____ Do you observe evidence of foreign material (identify if possible)?
   - Surface_____
   - Particles_____
10. Samples taken for testing: Yes___ No___
11. Is the following auxiliary equipment clean and in good repair?
    - Hoses: Yes___ No___ Gaskets and seals: Yes___ No___
    - Pump(s): Yes___ No___ Fittings: Yes___ No___
12. Add any other comments or remarks that you may wish regarding what you observed during the inspection:__ _____

Recommendation: Accept ___ Reject___ tanker. Inspector:_____

C. Inspection Report Form [Incoming Tanker (Empty)]

1. Vehicle Identification

Tractor Identification_____ Tanker Identification_____ Date Inspected_____
Name of Carrier_____ Name of Inspector_____
Cargo_____ Shipper_____ Drivers_____

1. Is the outside of the carrier clean? If no, describe:_____
2. Is there written documentation on prior loads? Yes___ no___ If no, notify appropriate management immediately.

Prior Loads:
a.
b.
c.

3. Source of your load written documentation:

trucker____ truck company____ broker___ other ___

4. Is there a valid wash ticket provided with the tanker? Yes___ no___ If no to #4, notify your supervisor immediately.
5. Wash Station_____ Date of Wash_____
6. Are all major points of entry and discharge sealed? Yes___ No___
7. Are seals numbered and recorded on the wash ticket? Yes___ No___
8. Do seal numbers correspond to the numbers on the wash ticket? Yes____ No____
9. Are seals intact with no evidence of tampering? Yes___ No___

If No to #'s 6, 7, 8, or 9, Notify Your Supervisor Immediately.

10. As you open the tanker lid:

    Does it smell clean Yes___ No___ Do you smell off-odors Yes___ No___

11. Condition of Inside of Tanker: Describe as appropriate_____

* Remember, this surface will come in contact with your product, and any residue could contaminate the shipment.

- Clean and in good shape?_____
- Dirty(describe)?_____
- Damaged (describe)?_____

12. Is the following auxiliary equipment clean and in good repair?

Hoses: Yes___ No___ Gaskets and seals: Yes___ No___
Pump(s): Yes___ No___ Fittings: Yes___ No___
Vents: Yes____ No____

Add any other comments or remarks that you may wish regarding what you observed during the inspection:_____
Recommendation: Accept____ Reject____ tanker. Inspector:_____

D. Food Grade Tanker Wash Facility Audit Form

1. General Information

Company:_____
Street Address:_____
City, State, Zip:_____
Phone(s):_____ Fax:_____
Mailing Address:_____
City, State, Zip:_____
Directions from nearest Interstate: _____
Hours of Operation: Monday–Friday _____ Saturday _____ Sunday_____
Contact Person:_____
Product Limitations:_____
Does this facility offer cleaning services outside of normal business hours?
[ ] Yes [ ] No If Yes, please note contact person

- Name:_____
- Phone:_____Fax:_____

Service Capabilities
(i). Check all offered at this facility:

[ ] Caustic	[ ] Exterior wash
[ ] Detergent	[ ] Drying
[ ] Steam	[ ] IBC cleaning
[ ] Hot/Cold water	[ ] ISO container cleaning
[ ] Kosher wash	[ ] Dry bulk container cleaning

(if Kosher box checked, attach copy of Kosher certificate)
If other, please note:_____
[ ] Yes [ ] No Does this facility have insurance?

- If yes, who is insurance carrier?_____
- What are the aggregate amounts?_____

[ ] Yes [ ] No Does this facility routinely check the Bills of Lading from the previous load?

(ii). Chemicals
[ ] Yes [ ] No Does this facility have a chemical use training program for its employees?
[ ] Yes [ ] No Are Material Safety Data Sheets (MSDS) for products handled and used at the facility readily accessible?
[ ] Yes [ ] No Are chemicals used to clean food contact surfaces FDA or USDA approved?
[ ] Yes [ ] No Are the boiler treatment chemicals of food grade?
[ ] Yes [ ] No Are chemicals stored in a locked cage or other restricted area?

(iii). Facilities and Equipment
[ ] Yes [ ] No Does this facility have a covered roof to prevent contamination by dirt and other residues?
[ ] Yes [ ] No Is this facility's housekeeping adequate to prevent contamination by dirt, filth, trash, and other residues?
[ ] Yes [ ] No Does this facility have a boiler capable of providing 180° F water for a minimum of 15 minutes?
[ ] Yes [ ] No Does this facility utilize a sanitary power wash spinner operated to manufacturer's recommended operating conditions?
[ ] Yes [ ] No Does this facility have a permanently mounted thermometer capable of monitoring and recording water temperature at the discharge valve?
[ ] Yes [ ] No Is the piping involved in the cleaning of food grade equipment constructed of stainless steel alloys?
[ ] Yes [ ] No Are safeguards in place to prevent co-mingling of steam, water, and cleaning solutions between food grade and non-food grade systems?

(iv). Water/Wastewater
Please describe water source and any pretreatment systems:_____
Is water source hard? If so, is it softened? Is it filtered? How?_____
[ ] Yes [ ] No Does the facility have a written waste-management program?
What is the disposal method for waste from food grade tank washes?_____
Name and address of the waste water receiving service:_____
Receiving disposal facility's EPA identification number:_____

(v). Audit Recommendations
[ ] Qualified [ ] Not Qualified
If not qualified, list recommendations for qualification:_____
Signed_____Title _____ Date_____
Company_____

V. DAIRY FARMS, BULK MILK TRANSPORTERS, BULK MILK TRANSFER STATIONS AND FLUID MILK PROCESSORS FOOD SECURITY PREVENTIVE MEASURES GUIDANCE

This guidance (July 2003) presents FDA's current thinking on the kinds of measures that operators of dairy farms, bulk milk transportation operations, bulk milk transfer stations, and fluid milk processing facilities may take to minimize the risk that fluid milk under their control will be subject to tampering or other malicious, criminal, or terrorist actions. It does not create or confer any rights for or on any person and does not operate to bind FDA or the public. If you want to discuss an alternative approach, contact the FDA staff responsible for implementing this guidance. If you cannot identify the appropriate FDA staff, call the telephone number listed on the title page of this guidance.

A. Purpose, Scope and Limitations

This guidance is designed as an aid to operators of dairy farms, bulk milk transportation operations, bulk milk transfer stations and fluid milk processing facilities. It identifies the kinds of preventive measures operators of these establishments may take to minimize the risk that fluid milk under their control will be subject to tampering or other malicious, criminal, or terrorist actions. Operators of these establishments are encouraged to review their current procedures and controls in light of the potential for tampering or other malicious, criminal, or terrorist actions and make appropriate improvements.

FDA's guidance documents, including this guidance, do not establish legally enforceable responsibilities. Instead guidances describe the Agency's current thinking on a topic and should be viewed only as recommendations, unless specific regulatory or statutory requirements are cited. The use of the word *should* in Agency guidances means that something is suggested or recommended, but not required.

Not all of the guidance contained in this document may be appropriate or practical for every dairy farm, bulk milk transportation operation, bulk milk transfer station, or fluid milk processing facility. FDA recommends that operators of these establishments review the guidance in each section that relates to a component of their operation, and assess which preventive measures are suitable. FDA further recommends that operators consider the goal of the preventive measure, assess whether the goal is relevant to their operation, and, if it is, design an approach that is both efficient and effective to accomplish the goal under their conditions of operation.

B. Management

FDA recommends that operators of dairy farms, bulk milk transportation operations, bulk milk transfer stations and fluid milk processing facilities consider:

1. Conducting an initial assessment of the adequacy of food security procedures and operations, which we recommend be kept confidential.
2. Developing a security management strategy to prepare for and respond to tampering and other malicious, criminal or terrorist actions, both threats and actual events, including identifying, segregating and securing affected product.
3. Developing a product recall strategy
4. Providing training in food security awareness to encourage all staff to be alert to any signs of tampering or other malicious, criminal or terrorist actions or areas that may be vulnerable to such actions, and report any findings to management. The training may also encourage staff to be alert to the presence of unidentified or unknown individuals or individuals that are in areas to which they are not designated access, and to directly question such individuals or report them to management
5. Providing appropriate supervision to all staff with access to raw and pasteurized milk storage, vitamin supplement receiving and storage,

and milk processing and packaging areas of the facility, including cleaning, maintenance and quality control staff, seasonal, temporary, contract, and volunteer staff, and especially, new staff. The supervision may include watching for unusual or suspicious behavior by staff (e.g., staff who, without an identifiable purpose, stay unusually late after the end of their shift, arrive unusually early, access files/information/areas of the facility outside of the areas of their responsibility; remove documents from the facility; ask questions on sensitive subjects; bring cameras to work)
6. Conducting routine security checks of the raw and pasteurized milk storage, vitamin supplement receiving and storage, and milk processing and packaging areas of the facility, for signs of tampering or malicious, criminal or terrorist actions or areas that may be vulnerable to such actions.
7. Alerting appropriate law enforcement and public health authorities about any threats of or suspected tampering or other malicious, criminal or terrorist actions. FDA may be contacted through its 24-hour emergency number, 301-443-1240, or through a local FDA District Office. FDA District Office telephone numbers are listed at: http://www.fda.gov/ora/inspect_ref/iom/iomoradir.html.
8. Reviewing, at least annually, the effectiveness of the food security plan, using knowledgeable in-house or third party staff, and revising the program accordingly, which we recommend be kept confidential.

C. Human Element

FDA recommends that operators of dairy farms, bulk milk transportation operations, bulk milk transfer stations and fluid milk processing facilities consider:

1. Obtaining and verifying work references, addresses and phone numbers of all staff with access to raw and pasteurized milk storage, vitamin supplement receiving and storage, and milk processing and packaging areas of the facility, including cleaning, maintenance and quality control staff, seasonal, temporary, contract, and volunteer staff.
2. Having a criminal background check performed by local law enforcement or by a contract service provider for the above listed staff, except if such staff are under direct supervision when they access the above listed areas.
3. Limiting access to raw and pasteurized milk storage, vitamin supplement receiving and storage, and milk processing and packaging areas of the facility to those staff that need to enter because of their job functions and only during appropriate work hours.
4. Preventing staff from bringing personal items (e.g., lunch containers, purses) into raw and pasteurized milk storage, vitamin supplement receiving and storage, and milk processing and packaging areas of the facility.
5. Being alert for atypical staff health conditions that staff may voluntarily report and absences that could be an early indicator of tampering or other malicious, criminal or terrorist actions (e.g., an unusual number of staff who work in the same part of the facility reporting similar symptoms within a short time frame), and reporting such conditions to local health authorities
6. Accompanying all visitors.

D. Facility

FDA recommends that operators of dairy farms, bulk milk transportation operations, bulk milk transfer stations and fluid milk processing facilities consider:

1. Securing doors (including freight loading doors, when not in use and not being monitored, and emergency exits), windows, roof openings/hatches, vent openings, ventilation systems, utility rooms, loft areas, trailer bodies, tanker trucks, and bulk storage tanks, to the extent possible.
2. Inspecting bulk unloading equipment and pumps in the receiving area before use.
3. Monitoring the security of the premises.

FDA further recommends that operators of dairy farms consider:

Locking or sealing, with serially numbered seals, all entrances to the milk house or all entry ports on the bulk milk tank from the time the bulk milk tank is washed until the time it is emptied, except when it is under direct, visual supervision (Remember to first make arrangements with the State regulatory agency that will ensure that the regulatory agency, rating agency and FDA continue to have ready access to the milk house and milking operation for routine inspections, Grade "A" IMS ratings and FDA check ratings, when applicable).

E. Operations

Vitamin supplements and laboratory supplies

FDA recommends that operators of fluid milk processing facilities consider:

1. Using only known, appropriately licensed or permitted (where applicable) sources for vitamin supplements.

2. Establishing delivery schedules for vitamin supplements, not accepting unexplained, unscheduled deliveries or drivers, and investigating delayed or missed shipments.
3. Supervising off-loading of incoming vitamin supplements, laboratory reagents and positive controls, including off-hour deliveries.
4. Reconciling the product and amount received with the product and amount ordered and the product and amount listed on the invoice and shipping documents.
5. Investigating shipping documents with suspicious alterations.
6. Inspecting incoming vitamin supplements for signs of tampering, contamination or damage (e.g., abnormal powders, liquids, stains, or odors, evidence of resealing) or "counterfeiting" (e.g., inappropriate or mismatched product identity, labeling, product lot coding or specifications).
7. Storing vitamin supplements, laboratory reagents, and positive controls in a secure location.
8. Keep track of vitamin supplements, laboratory reagents and positive controls and investigating any missing or extra stock outside a predetermined normal range of variability.

F. Labeling

FDA recommends that operators of fluid milk processing facilities consider:

1. Storing product labels in a secure location and destroying outdated or discarded labels

G. Raw Milk

FDA recommends that operators of bulk milk transfer stations and fluid milk processing facilities consider:

1. Accepting only those incoming tanker loads of raw milk for which all openings were either locked or sealed, with a serially numbered seal, from the time the tanker was last washed until the load is delivered. Exception may be provided for incoming loads for which a thorough investigation demonstrates that there is a verified, reasonable explanation for a deviation. Seals or locks need not be in place during those times that the tanker was under the direct, visual supervision of the driver.
2. Using only known, reputable transportation companies
3. Establishing delivery schedules for raw milk, not accepting unexplained, unscheduled deliveries or drivers, and investigating delayed or missed shipments. We recommend that driver identification include the name of the transportation company.
4. Supervising off-loading of incoming milk.
5. Reconciling the amount received with the amount listed on the shipping documents.
6. Verifying that operators of bulk milk transfer stations that supply raw milk adhere to the preventive measures listed in this guidance.

FDA recommends that operators of bulk milk transportation operations consider:

Locking or sealing, with a serially numbered seals, every tanker from the time it is last washed until the time the load of milk is delivered to the bulk milk transfer station or fluid milk processing facility. Seals or locks need not be in place during those times that the tanker is under the direct, visual supervision of the driver.

VI. IMPORTERS AND FILERS: FOOD SECURITY PREVENTIVE MEASURES GUIDANCE

This guidance (March 21, 2003) represents the Agency's current thinking on the kinds of measures that food importers and filers may take to minimize the risk that food under their control will be subject to tampering or other malicious, criminal, or terrorist actions. It does not create or confer any rights for or on any person and does not operate to bind FDA or the public.

A. Purpose and Scope

This guidance is designed as an aid to operators of food importing establishments, storage warehouses, and filers. It identifies the kinds of preventive measures that they may take to minimize the risk that food under their control will be subject to tampering or other malicious, criminal, or terrorist actions. Operators of food importing establishments are encouraged to review their current procedures and controls in light of the potential for tampering or other malicious, criminal, or terrorist actions and make appropriate improvements.

This guidance is designed to focus operator's attention sequentially on each segment of the food delivery system that is within their control, to minimize the risk of tampering or other malicious, criminal, or terrorist action at each segment. To be successful, implementing enhanced preventive measures requires the commitment of management and staff. Accordingly, FDA recommends that both management and staff participate in the development and review of such measures.

B. Limitations

Not all of the guidance contained in this document may be appropriate or practical for every food importing establishment, particularly small facilities. FDA recommends that operators review the guidance in each section that

relates to a component of their operation, and assess which preventive measures are suitable. Example approaches are provided for many of the preventive measures listed in this document. These examples should not be regarded as minimum standards. Nor should the examples provided be considered an inclusive list of all potential approaches to achieving the goal of the preventive measure. FDA recommends that operators consider the goal of the preventive measure, assess whether the goal is relevant to their operation, and, if it is, design an approach that is both efficient and effective to accomplish the goal under their conditions of operation.

C. Structure

This guidance is divided into five sections that relate to individual components of food importing operations and practices: Management; Human Element — Staff; Human Element — Public; Facility; and Operations.

D. Food Importing Operations

1. Management

FDA recommends that operators of food importing establishments consider:

1. Preparing for the possibility of tampering or other malicious, criminal, or terrorist actions.
2. Assigning responsibility for security to knowledgeable individual(s)
3. Conducting an initial assessment of food security procedures and operations, which we recommend be kept confidential
4. Having a crisis management strategy to prepare for and respond to tampering and other malicious, criminal, or terrorist actions, both threats and actual events, including identifying, segregating and securing affected product
5. Planning for emergency evacuation, including preventing security breaches during evacuation
6. Becoming familiar with the emergency response system in the community
7. Making management aware of 24-hour contact information for local, state, and federal police/-fire/rescue/health/homeland security agencies
8. Making staff aware of who in management they should alert about potential security problems (24-hour contacts)
9. Maintaining any floor and food flow plan in a secure, off-site location
10. Promoting food security awareness to encourage all staff to be alert to any signs of tampering or malicious, criminal, or terrorist actions or areas that may be vulnerable to such actions, and to report any findings to identified management (for example, providing training, instituting a system of rewards, building security into job performance standards)
11. Having an internal communication system to inform and update staff about relevant security issues
12. Having a strategy for communicating with the public (for example, identifying a media spokesperson, preparing generic press statements and background information, and coordinating press statements with appropriate authorities)

2. Supervision

1. Providing an appropriate level of supervision to all staff, including cleaning and maintenance staff, contract workers, data entry and computer support staff, and especially, new staff (for example, supervisor on duty, daily visits by supervisor, two staff on duty at all times, monitored video cameras, one way and two way windows)
2. Conducting routine security checks of the premises and critical computer data systems (at a frequency appropriate to the operation) for signs of tampering or malicious, criminal, or terrorist actions, or areas that may be vulnerable to such actions

3. Recall Strategy

1. Identifying the person responsible, and a backup person
2. Providing for proper handling and disposition of recalled product
3. Identifying customer contacts, addresses, and phone numbers

4. Investigation of Suspicious Activity

1. Investigating threats or information about signs of tampering or other malicious, criminal, or terrorist actions
2. Alerting appropriate law enforcement and public health authorities about any threats of or suspected tampering or other malicious, criminal, or terrorist actions

5. Evaluation Program

1. Evaluating the lessons learned from past tampering or other malicious, criminal, or terrorist actions and threats
2. Reviewing and verifying, at least annually, the effectiveness of the security management program (for example, using knowledgeable

in-house or third party staff to conduct tampering or other malicious, criminal, or terrorist action exercises and mock recalls and to challenge computer security systems), revising the program accordingly, and keeping this information confidential
3. Performing random food security inspections of all appropriate areas of the facility (including receiving and storage, where applicable) using knowledgeable in-house or third party staff, and keeping this information confidential
4. Verifying that security contractors are doing an appropriate job, when applicable

E. Human Element — Staff

Under Federal law, operators of food importing establishments are required to verify the employment eligibility of all new hires in accordance with the requirements of the Immigration and Nationality Act, by completing the INS Employment Eligibility Verification Form (INS Form I-9). Completion of Form I-9 for new hires is required by 8 USC 1324a and nondiscrimination provisions governing the verification process are set forth at 8 USC 1324b.

FDA recommends that operators of food importing establishments consider:

1. Screening (pre-hiring, at hiring, post-hiring)
2. Examining the background of all staff (including seasonal, temporary, contract, and volunteer staff, whether hired directly or through a recruitment firm) as appropriate to their position, considering candidates' access to sensitive areas of the facility and the degree to which they will be supervised and other relevant factors (for example, obtaining and verifying work references, addresses, and phone numbers, participating in one of the pilot programs managed by the Immigration and Naturalization Service and the Social Security Administration [These programs provide electronic confirmation of employment eligibility for newly hired employees. For more information call the INS SAVE Program toll free at 1-888-464-4218, fax a request for information to (202) 514-9981, or write to US/INS, SAVE Program, 425 I Street, NW, ULLICO-4th Floor, Washington, DC 20536. These pilot programs may not be available in all states], having a criminal background check performed by local law enforcement or by a contract service provider [Remember to first consult any state or local laws that may apply to the performance of such checks])

Note: screening procedures should be applied equally to all employees, regardless of race, national origin, religion, and citizenship or immigration status.

1. Daily Work Assignments

1. Knowing who is and who should be on premises, and where they should be located, for each shift
2. Keeping assignment information updated

2. Identification

1. Establishing a system of positive identification and recognition that is appropriate to the nature of the workforce (for example, issuing uniforms, name tags, or photo identification badges, with individual control numbers, color coded by area of authorized access), when appropriate
2. Collecting the uniforms, name tag, or identification badge when a staff member is no longer associated with the establishment

3. Restricted Access

1. Identifying staff that require unlimited access to all areas of the facility
2. Reassessing levels of access for all staff periodically
3. Limiting access so staff enter only those areas or have access to only those segments of the operation necessary for their job functions and only during appropriate work hours, including access to data operating systems for purchasing, storing and distributing imported foods (for example, using key card or keyed or cipher locks for entry to sensitive areas, color coded uniforms [remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes])
4. Changing combinations, rekeying locks and/or collecting the retired key card when a staff member who is in possession of these is no longer associated with the establishment, and additionally as needed to maintain security

4. Personal Items

1. Restricting the type of personal items allowed in non-public areas of the establishment
2. Allowing in the establishment only those personal use medicines that are necessary for the health of staff and ensuring that these personal use medicines are properly labeled and stored away from food handling or storage areas

3. Preventing staff from bringing personal items (for example, lunch containers, purses) into food preparation or storage areas
4. Providing for regular inspection of contents of staff lockers (for example, providing metal mesh lockers, company issued locks), bags, packages, and vehicles when on company property (Remember to first consult and federal, state, or local laws that may related to such inspections)

5. Training in Food Security Procedures

1. Incorporating food security awareness, including information on how to prevent, detect, and respond to tampering or other malicious, criminal, or terrorist actions or threats, into training programs for staff, including seasonal, temporary, contract, and volunteer staff providing periodic reminders of the importance of security procedures (for example, scheduled meetings, providing brochures, payroll stuffers)
2. Providing periodic reminders of the importance of security procedures (for example, scheduled meetings, providing brochures, payroll stuffers)
3. Encouraging staff support (for example, involving staff in food security planning and the food security awareness program, demonstrating the importance of security procedures to the staff)

6. Unusual Behavior

Watching for unusual or suspicious behavior by staff (for example, staff who, without an identifiable purpose, stay unusually late after the end of their shift, arrive unusually early, access files/information/areas of the facility outside of the areas of their responsibility; remove documents from the facility; ask questions on sensitive subjects; bring cameras to work).

7. Staff Health

Being alert for atypical staff health conditions that staff may voluntarily report and absences that could be an early indicator of tampering or other malicious, criminal, or terrorist actions (for example, an unusual number of staff who work in the same part of the facility reporting similar symptoms within a short time frame), and reporting such conditions to local health authorities.

F. Human Element — Public

FDA recommends that operators of food importing establishments consider:

1. Visitors (for example, contractors, supplier representatives, delivery drivers, customers, couriers, pest control representatives, third-party auditors, regulators, reporters, tours)
2. Inspecting incoming and outgoing vehicles, packages and briefcases for suspicious, inappropriate or unusual items or activity, to the extent practical
3. Restricting entry to the establishment (for example, checking visitors in and out at security or reception, requiring proof of identity, issuing visitors badges that are collected upon departure, accompanying visitors)
4. Ensuring that there is a valid reason for the visit before providing access to the facility - beware of unsolicited visitors
5. Verifying the identity of unknown visitors
6. Restricting access to food handling and storage areas (for example, accompanying visitors, unless they are otherwise specifically authorized)
7. Restricting access to locker rooms

G. Facility

FDA recommends that operators of food importing establishments consider:

1. Physical Security

1. Protecting perimeter access with fencing or other deterrent, when appropriate
2. Securing doors (including freight loading doors when not in use and not being monitored, and emergency exits), windows, roof openings/hatches, vent openings and trailer bodies, to the extent possible (for example, using locks, "jimmy plates," seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes])
3. Using metal or metal-clad exterior doors to the extent possible when the facility is not in operation, except where visibility from public thoroughfares is an intended deterrent (remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes)
4. Securing bulk unloading equipment (for example, augers, pipes, conveyor belts, and hoses) when not in use and inspecting the equipment before use
5. Minimizing the number of entrances to restricted areas (remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes)

6. Accounting for all keys to establishment (for example, assigning responsibility for issuing, tracking and retrieving keys)
7. Monitoring the security of the premises using appropriate methods (for example, using security patrols [uniformed and/or plain-clothed] and video surveillance)
8. Minimizing to the extent practical, places that can be used to temporarily hide intentional contaminants (for example, minimizing nooks and crannies, false ceilings)
9. Providing adequate interior and exterior lighting, including emergency lighting, where appropriate, to facilitate detection of suspicious or unusual activity
10. Implementing a system of controlling vehicles authorized to park on the premises (for example, using placards, decals, key cards, keyed or cipher locks, issuing passes for specific areas and times to visitors' vehicles)
11. Keeping parking areas separated from entrances to food storage and processing areas and utilities, where practical

2. Storage and Use of Poisonous and Toxic Chemicals (for Example, Cleaning and Sanitizing Agents, Pesticides)

1. Limiting poisonous and toxic chemicals in the establishment to those that are required for the operation and maintenance of the facility and those that are being held for sale
2. Storing poisonous and toxic chemicals as far away from food handling and storage areas as practical
3. Limiting access to and securing storage areas for poisonous and toxic chemicals that are not being held for sale (for example, using keyed or cipher locks, keycards, seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant state or local fire codes before making any changes])
4. Ensuring that poisonous and toxic chemicals are properly labeled
5. Using pesticides in accordance with the Federal Insecticide, Fungicide, and Rodenticide Act (for example, maintaining rodent bait that is in use in covered, tamper-resistant bait stations)
6. Knowing what poisonous and toxic chemicals should be on the premises and keeping track of them
7. Investigating missing stock or other irregularities outside a normal range of variation and alerting appropriate law enforcement and public health authorities about unresolved problems, when appropriate

H. Operations

FDA recommends that operators of food importing establishments consider:

1. Incoming Products

1. Using only known and appropriately licensed or permitted (where applicable) sources for all products
2. Taking reasonable steps to encourage suppliers, distributors and transporters to practice appropriate food security measures (for example, auditing, where practical, for compliance with food security measures that are contained in purchase and shipping contracts or letters of credit or using a vendor approval program.)
3. Authenticating labeling, packaging configuration, tamper-evident packaging and product coding/expiration dating systems (where applicable) in advance of receipt of shipment, especially for new products
4. Requesting locked and/or sealed vehicles/containers/railcars, and, if sealed, obtaining the seal number from the supplier, and verifying upon receipt, making arrangements to maintain the chain of custody when a seal is broken for inspection by a governmental agency or as a result of multiple deliveries
5. Requesting that transporters have the capability to verify the location of the load at any time, when practical
6. Establishing delivery schedules, not accepting unexplained, unscheduled deliveries or drivers, and investigating delayed or missed shipments
7. Supervising off-loading of incoming materials, including off hour deliveries
8. Reconciling the product and amount received with the product and amount ordered and the product and amount listed on the invoice and shipping documents, taking into account any sampling performed prior to receipt
9. Investigating shipping documents with suspicious alterations
10. Inspecting incoming products and product returns for signs of tampering, contamination or damage (for example, abnormal powders, liquids, stains, or odors, evidence of resealing, compromised tamper-evident packaging) or "counterfeiting" (inappropriate or mismatched product identity, labeling, product lot coding or specifications, absence of tamper-evident

packaging when the label contains a tamper-evident notice), when appropriate
11. Inspecting incoming products for authenticity, packaging/product integrity, and evidence of unauthorized relabeling/repackaging (for example, shipping cases and described contents not consistent with actual contents) and verifying batch/lot/container codes
12. Verifying conformance with FDA requirements for product safety, quality, effectiveness, and labeling (may require contact with and verification from the foreign manufacturer/processor)
13. Evaluating the utility of testing incoming products and product returns for detecting tampering or other malicious, criminal, or terrorist action
14. Developing and implementing procedures for inspecting shipping containers, vehicles
15. Investigating damage and loss and alerting appropriate authority of discrepancies
16. Rejecting suspect food
17. Alerting appropriate law enforcement and food public health authorities about evidence of tampering, "counterfeiting" or other malicious, criminal, or terrorist action

2. Storage

1. Having a system for receiving, storing and handling distressed, damaged, returned, and reworked products that minimizes their potential for being compromised or to compromise the security of other products (for example, destroying products that are unfit for human or animal consumption, products with illegible codes, products or questionable origin, and products returned by consumers to retail stores)
2. Keeping track of incoming products, salvage products, and returned products
3. Minimizing reuse of containers, shipping packages, cartons, etc., where practical
4. Investigating missing or extra stock or other irregularities outside a normal range of variability and reporting unresolved problems to appropriate law enforcement and public health agencies, when appropriate

3. Outgoing Products

1. Ensuring that public storage warehousing and shipping (vehicles and vessels) practice appropriate security measures (for example, auditing for compliance with food security measures that are contained in contracts or letters of guarantee
2. Performing random inspection of storage facilities, vehicles, and vessels
3. Requesting locked and/or sealed vehicles/containers/railcars and providing the seal number to the consignee (remember to consult any relevant federal, state or local fire or occupational safety codes before making any changes)
4. Establishing scheduled pickups and not accepting unexplained, unscheduled pickups
5. Restricting access to distribution process to employees with appropriate clearance
6. Requesting that the transporter have the capability to verify the location of the load at any time
7. Advising sales staff to be on the lookout for counterfeit products during visits to customers and notify management if any problems are detected
8. Investigating missing or extra stock or other irregularities outside a normal range of variation and alerting appropriate law enforcement and public health authorities about unresolved problems, when appropriate

4. Security of Water and Utilities

1. Limiting, to the extent practical, access to controls for airflow, water, electricity, and refrigeration securing non-municipal water wells, hydrants, storage, and handling facilities
2. Ensuring that water systems and trucks are equipped with backflow prevention
3. Chlorinating water systems and monitoring chlorination equipment, where practical, and especially for non-municipal water systems
4. Testing non-municipal sources for potability regularly, as well as randomly, and being alert to changes in the profile of the results
5. Staying attentive to the potential for media alerts about public water provider problems, when applicable
6. Identifying alternate sources of potable water for use during emergency situations where normal water systems have been compromised (for example, bottled water, trucking from an approved source, treating on-site or maintaining on-site storage)

5. Security of Ventilation System (where Applicable)

1. Securing access to air intake points for the facility, to the extent possible (for example, using fences, sensors, guards, video surveillance)
2. Examining air intake points for physical integrity routinely

6. Mail/Packages

Implementing procedures to ensure the security of incoming mail and packages (for example, following U.S. Postal

Service guidance, locating the mailroom away from food handling and storage areas, securing mailroom visual or x-ray mail/package screening).

7. Access to Computer Systems

1. Restricting access to critical computer data systems to those with appropriate clearance (for example, using passwords, firewalls)
2. Eliminating computer access when a staff member is no longer associated with the establishment
3. Establishing a system of traceability of computer transactions
4. Reviewing the adequacy of virus protection systems and procedures for backing up critical computer based data systems
5. Validating and periodically challenging the computer security system and procedures

VII. FIELD INSTRUCTIONS FOOD FEDERAL FOOD INSPECTORS REGARDING "FOOD PRODUCERS, PROCESSORS AND TRANSPORTERS: FOOD SECURITY PREVENTIVE MEASURES GUIDANCE" AND "IMPORTERS AND FILERS: FOOD SECURITY PREVENTIVE MEASURES GUIDANCE"

The above named guidance documents were published in the Federal Register on 3/19/03, and are designed primarily as aids for operators of food establishments (i.e., firms that produce, process, store, repack, relabel, distribute, or transport food or food ingredients) and food importers, warehouses, and filers. This guidance is voluntary and is not tied to existing regulations. The guidance documents identify preventive measures that these kinds of establishments can take to minimize the risk that food under their control will be subject to tampering or other malicious, criminal or terrorist actions. The documents set out goals in this regard and provide example strategies for achieving those goals.

You should not perform a comprehensive food security audit of the establishment, nor should you conduct an extensive interview in an attempt to determine the level of adoption of preventive measures listed in the guidance. The goal is to facilitate an exchange of information to heighten awareness of food security. Management of the establishment should be encouraged to voluntarily implement those preventive measures that are appropriate for their operations. Not all of the guidance contained in this document is appropriate or practical for every food establishment, food importer, warehouse, or filer, particularly smaller entities.

Food regulatory officials should cover the preventive measures during regular inspections or audits of food establishments, food importers, warehouses, and evaluation of filers. Based on conditions observed during the normal course of the inspection/audit, the appropriate material in the guidance documents should be discussed with management of the establishment and a copy of the guidance should be provided during the close-out meeting. Additionally, any opportunities for improvement or enhancement of the establishment's preventive measures that were identified during the inspection/audit should be discussed with management, but should not be listed as violations (e.g., on FDA's form FDA-483 Inspectional Observations) unless they likewise constitute deviations from Current Good Manufacturing Practice.

The fact that the discussion took place and that a copy of the guidance document was provided should be recorded in the inspection report (e.g. FDA's Establishment Inspection Report [EIR]) or evaluation report, but the details of the inspectional findings in this regard should not be recorded. For example, under a section heading titled, "Food Security," the regulator should only state, "A copy of the Food Security Guidance Document was provided to and food security issues were discussed with (name of food establishment official)." Additionally, you should minimize the quantity and detail of notes taken relative to the establishment's food security program, taking only those needed to serve as a "memory jog" during the discussion with management.

If management of the establishment has suggestions for improvement of the referenced guidance he/she should be encouraged to provide comments to the Agency via Docket # 01D-0583 (see Federal Register Notice of Availability dated January 9, 2002).

VIII. RETAIL FOOD STORES AND FOOD SERVICE ESTABLISHMENTS: FOOD SECURITY PREVENTIVE MEASURES GUIDANCE

On November 2003, the FDA issed the above guidance document. A brief discussion follows.

A. Purpose and Scope

This guidance is designed as an aid to operators of retail food stores and food service establishments (for example, bakeries, bars, bed-and-breakfast operations, cafeterias, camps, child and adult day care providers, church kitchens, commissaries, community fund raisers, convenience stores, fairs, food banks, grocery stores, interstate conveyances, meal services for home-bound persons, mobile food carts, restaurants, and vending machine operators). This is a very diverse set of establishments, which includes both very large and very small entities.

This guidance identifies the kinds of preventive measures they may take to minimize the risk that food under their control will be subject to tampering or other

malicious, criminal, or terrorist actions. Operators of food retail food stores and food service establishments are encouraged to review their current procedures and controls in light of the potential for tampering or other malicious, criminal, or terrorist actions and make appropriate improvements.

This guidance is designed to focus operators' attention sequentially on each segment of the food delivery system that is within their control, to minimize the risk of tampering or other malicious, criminal, or terrorist action at each segment. To be successful, implementing enhanced preventive measures requires the commitment of management and staff. Accordingly, FDA recommends that both management and staff participate in the development and review of such measures.

FDA's guidance documents, including this guidance, do not establish legally enforceable responsibilities. Instead, guidances describe the Agency's current thinking on a topic and should be viewed only as recommendations, unless specific regulatory or statutory requirements are cited. The use of the word *should* in Agency guidances means that something is suggested or recommended, but not required.

B. Limitations

Not all of the guidance contained in this document may be appropriate or practical for every retail food store or food service establishment, particularly smaller facilities. FDA recommends that operators review the guidance in each section that relates to a component of their operation, and assess which preventive measures are suitable. Example approaches are provided for many of the preventive measures listed in this document. These examples should not be regarded as minimum standards. Nor should the examples provided be considered an inclusive list of all potential approaches to achieving the goal of the preventive measure. FDA recommends that operators consider the goal of the preventive measure, assess whether the goal is relevant to their operation, and, if it is, design an approach that is both efficient and effective to accomplish the goal under their conditions of operation.

1. Structure

This guidance is divided into five sections that relate to individual components of a retail food store or food service establishment operation: management, human element-staff, human element-public, facility, and operations.

Related Guidance:

C. Management

FDA recommends that retail food store and food service establishment operators consider:

Preparing for the possibility of tampering or other malicious, criminal, or terrorist events

1. assigning responsibility for security to knowledgeable individual(s)
2. conducting an initial assessment of food security procedures and operations, which we recommend be kept confidential
3. having a crisis management strategy to prepare for and respond to tampering and other malicious, criminal, or terrorist actions, both threats and actual events, including identifying, segregating, and securing affected products
4. planning for emergency evacuation, including preventing security breaches during evacuation
5. becoming familiar with the emergency response system in the community
6. making management aware of 24-hour contact information for local, state, and federal police/fire/rescue/health/homeland security agencies
7. making staff aware of who in management they should alert about potential security problems (24-hour contacts)
8. promoting food security awareness to encourage all staff to be alert to any signs of tampering or malicious, criminal, or terrorist actions or areas that may be vulnerable to such actions, and to report any findings to identified management (for example, providing training, instituting a system of rewards, building security into job performance standards)
9. having an internal communication system to inform and update staff about relevant security issues
10. having a strategy for communicating with the public (for example, identifying a media spokesperson, preparing generic press statements and background information, and coordinating press statements with appropriate authorities)

1. Supervision

1. providing an appropriate level of supervision to all staff, including cleaning and maintenance staff, contract workers, data entry and computer support staff, and especially, new staff (for example, supervisor on duty, periodic unannounced visits by supervisor, daily visits by supervisor, two staff on duty at same time, monitored video cameras, off-line review of video tapes, one-way and two-way windows, customer feedback to supervisor of unusual or suspicious behavior by staff)

2. conducting routine security checks of the premises, including utilities and critical computer data systems (at a frequency appropriate to the operation) for signs of tampering or malicious, criminal, or terrorist actions, or areas that may be vulnerable to such actions

2. Investigation of Suspicious Activity

1. investigating threats or information about signs of tampering or other malicious, criminal, or terrorist actions
2. alerting appropriate law enforcement and public health authorities about any threats of or suspected tampering or other malicious, criminal, or terrorist actions

3. Evaluation Program

1. evaluating the lessons learned from past tampering or other malicious, criminal, or terrorist actions and threats
2. reviewing and verifying, at least annually, the effectiveness of the security management program (for example, using knowledgeable in-house or third-party staff to conduct tampering or other malicious, criminal, or terrorist action exercises and to challenge computer security systems), revising accordingly (using third-party or in-house security expert, where possible), revising the program accordingly, and keeping this information confidential
3. performing random food security inspections of all appropriate areas of the facility (including receiving and storage areas, where applicable) using knowledgeable in-house or third-party staff, and keeping this information confidential
4. verifying that security contractors are doing an appropriate job, when applicable

D. Human Element-staff

Under Federal law, retail food store and food service establishment operators are required to verify the employment eligibility of all new hires, in accordance with the requirements of the Immigration and Nationality Act, by completing the INS Employment Eligibility Verification Form (INS Form I-9). Completion of Form I-9 for new hires is required by 8 USC 1324a and nondiscrimination provisions governing the verification process are set forth at 1324b.

FDA recommends that retail food store and food service establishment operators consider:

1. Screening (Pre-Hiring, at Hiring, Post-Hiring)

This involves examining the background of all staff (including seasonal, temporary, contract, and volunteer staff, whether hired directly or through a recruitment firm) as appropriate to their position, considering candidates' access to sensitive areas of the facility and the degree to which they will be supervised and other relevant factors (for example, obtaining and verifying work references, addresses, and phone numbers, participating in one of the pilot programs managed by the Immigration and Naturalization Service and the Social Security Administration [These programs provide electronic confirmation of employment eligibility for newly hired employees. For more information call the INS SAVE Program toll free at 1-888-464-4218, fax a request for information to (202) 514-9981, or write to US/INS, SAVE Program, 425 I Street, NW, ULLICO-4th Floor, Washington, DC 20536. These pilot programs may not be available in all states], having a criminal background check performed by local law enforcement or by a contract service provider [Remember to first consult any state or local laws that may apply to the performance of such checks]).

Note: screening procedures should be applied equally to all staff, regardless of race, national origin, religion, and citizenship or immigration status.

2. Daily Work Assignments

1. knowing who is and who should be on premises, and where they should be located, for each shift
2. keeping information updated

3. Identification

1. establishing a system of positive identification and recognition (for example, issuing uniforms, name tags, or photo identification badges with individual control numbers, color coded by area of authorized access), when appropriate
2. collecting the uniforms, name tag, or identification badge when a staff member is no longer associated with the establishment

4. Restricted Access

1. identifying staff that require unlimited access to all areas of the facility
2. reassessing levels of access for all staff periodically
3. limiting staff access to non-public areas so staff enter only those areas necessary for their job functions and only during appropriate work

hours (for example, using key cards or keyed or cipher locks for entry to sensitive areas, color coded uniforms [remember to consult any relevant federal, state, or local fire or occupational safety codes before making any changes])
4. changing combinations, rekeying locks, and/or collecting the retired key card when a staff member who is in possession of these is no longer associated with the establishment, and additionally as needed to maintain security

5. Personal Items

1. restricting the type of personal items allowed in non-public areas of the establishment
2. allowing in the non-public areas of the establishment only those personal use medicines that are necessary for the health of staff (other than those being stored or displayed for retail sale) and ensuring that these personal use medicines are properly labeled and stored away from stored food and food preparation areas
3. preventing staff from bringing personal items (for example, lunch containers, purses) into nonpublic food preparation or storage areas
4. providing for regular inspection of contents of staff lockers (for example, providing metal mesh lockers, company issued locks), bags, packages, and vehicles when on company property (Remember to first consult any federal, state, or local laws that may relate to such inspections)

6. Training in Food Security Procedures

1. incorporating food security awareness, including information on how to prevent, detect, and respond to tampering or other malicious, criminal, or terrorist actions or threats, into training programs for staff, including seasonal, temporary, contract, and volunteer staff
2. providing periodic reminders of the importance of security procedures (for example, scheduling meetings, providing brochures, payroll stuffers)
3. encouraging staff support (for example, involving staff in food security planning and the food security awareness program, demonstrating the importance of security procedures to the staff)
4. encouraging staff support (for example, involving staff in food security planning and the food security awareness program, demonstrating the importance of security procedures to the staff)

7. Unusual Behavior

This involves watching for unusual or suspicious behavior by staff (for example, staff who, without an identifiable purpose, stay unusually late after the end of their shift, arrive unusually early, access files/information/areas of the facility outside of the areas of their responsibility; remove documents from the facility; ask questions on sensitive subjects; bring cameras to work).

8. Staff Health

This involves being alert for atypical staff health conditions that staff may voluntarily report and absences that could be an early indicator of tampering or other malicious, criminal, or terrorist actions (for example, an unusual number of staff who work in the same part of the facility reporting similar symptoms within a short time frame), and reporting such conditions to local health authorities.

E. Human Element — Public

FDA recommends that retail food store and food service establishment operators consider:

1. Customers

1. preventing access to food preparation and storage and dishwashing areas in the non-public areas of the establishment, including loading docks
2. monitoring public areas, including entrances to public restrooms (for example, using security guards, monitored video cameras, one-way and two-way windows, placement of employee workstations for optimum visibility) for unusual or suspicious activity (for example, a customer returning a product to the shelf that he/she brought into the store, spending an unusual amount of time in one area of the store)
3. monitoring the serving or display of foods in self-service areas (for example, salad bars, condiments, open bulk containers, produce display areas, doughnut/bagel cases)

2. Other Visitors (for Example, Contractors, Sales Representatives, Delivery Drivers, Couriers, Pest Control Representatives, Third-Party Auditors, Regulators, Reporters, Tours)

1. restricting entry to the non-public areas of the establishment (for example, checking visitors in and out before entering the non-public areas, requiring proof of identity, issuing visitors

badges that are collected upon departure, accompanying visitors)
2. ensuring that there is a valid reason for all visits to the non-public areas of the establishment before providing access to the facility - beware of unsolicited visitors
3. verifying the identity of unknown visitors to the non-public areas of the establishment
4. inspecting incoming and outgoing packages and briefcases in the non-public areas of the establishment for suspicious, inappropriate or unusual items, to the extent practical

F. Facility

FDA recommends that retail food store and food service establishment operators consider:

1. Physical Security

1. protecting non-public perimeter access with fencing or other deterrent, when appropriate
2. securing doors (including freight loading doors, when not in use and not being monitored, and emergency exits), windows, roof openings/hatches, vent openings, ventilation systems, utility rooms, ice manufacturing and storage rooms, loft areas and trailer bodies, and bulk storage tanks for liquids, solids and compressed gases to the extent possible (for example, using locks, "jimmy plates," seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant federal, state, or local fire or occupational safety codes before making any changes])
3. using metal or metal-clad exterior doors to the extent possible when the facility is not in operation, except where visibility from public thoroughfares is an intended deterrent (remember to consult any relevant federal, state, or local fire or occupational safety codes before making any changes)
4. minimizing the number of entrances to non-public areas (remember to consult any relevant federal, state, or local fire or occupational safety codes before making any changes)
5. accounting for all keys to establishment (for example, assigning responsibility for issuing, tracking, and retrieving keys)
6. monitoring the security of the premises using appropriate methods (for example, using security patrols [uniformed and/or plain-clothed], monitored video surveillance)
7. minimizing, to the extent practical, places in public areas that an intruder could remain unseen after work hours
8. minimizing, to the extent practical, places in non-public areas that can be used to temporarily hide intentional contaminants (for example, minimizing nooks and crannies, false ceilings)
9. providing adequate interior and exterior lighting, including emergency lighting, where appropriate, to facilitate detection of suspicious or unusual activity
10. implementing a system of controlling vehicles authorized to park in the non-public parking areas (for example, using placards, decals, key cards, keyed or cipher locks, issuing passes for specific areas and times to visitors' vehicles)
11. keeping customer, employee, and visitor parking areas separated from entrances to non-public areas, where practical

2. Storage and Use of Poisonous and Toxic Chemicals (for Example, Cleaning and Sanitizing Agents, Pesticides) in Non-Public Areas

1. limiting poisonous and toxic chemicals in the establishment to those that are required for the operation and maintenance of the facility and those that are being stored or displayed for retail sale
2. storing poisonous and toxic chemicals as far away from food handling and food storage areas as practical
3. limiting access to and securing storage areas for poisonous or toxic chemicals that are not being held for retail sale (for example, using keyed or cipher locks, key cards, seals, alarms, intrusion detection sensors, guards, monitored video surveillance [remember to consult any relevant federal, state, or local fire codes before making any changes])
4. ensuring that poisonous and toxic chemicals are properly labeled
5. using pesticides in accordance with the Federal Insecticide, Fungicide, and Rodenticide Act (for example, maintaining rodent bait that is in use in covered, tamper-resistant bait stations)
6. knowing what poisonous and toxic chemicals should be on the premises and keeping track of them
7. investigating missing stock or other irregularities outside a normal range of variation and alerting local enforcement and public health agencies about unresolved problems, when appropriate

G. Operations

FDA recommends that retail food store and food service establishment operators consider:

1. Incoming Products

1. using only known and appropriately licensed or permitted (where applicable) sources for all incoming products
2. informing suppliers, distributors, and transporters about FDA's food security guidance, "Food Producers, Processors, and Transporters: Food Security Preventive Measures Guidance" and "Importers and Filers: Food Security Preventive Measures Guidance," available at: http://www.cfsan.fda.gov/~dms/guidance.html.
3. taking steps to ensure that delivery vehicles are appropriately secured
4. requesting that transporters have the capability to verify the location of the load at any time, when practical
5. establishing delivery schedules, not accepting unexplained, unscheduled deliveries or drivers, and investigating delayed or missed shipments
6. supervising off-loading of incoming materials, including off hour deliveries
7. reconciling the product and amount received with the product and amount ordered and the product and amount listed on the invoice and shipping documents, taking into account any sampling performed prior to receipt
8. investigating shipping documents with suspicious alterations
9. inspecting incoming products and product returns for signs of tampering, contamination, or damage (for example, abnormal powders, liquids, stains, or odors, evidence of resealing, compromised tamper-evident packaging) or "counterfeiting" (for example, inappropriate or mismatched product identity, labeling, product lot coding or specifications, absence of tamper-evident packaging when the label contains a tamper-evident notice), when appropriate
10. rejecting suspect food
11. alerting appropriate law enforcement and public health authorities about evidence of tampering, "counterfeiting," or other malicious, criminal, or terrorist action

2. Storage

1. having a system for receiving, storing, and handling distressed, damaged, and returned products, and products left at checkout counters, that minimizes their potential for being compromised (for example, obtaining the reason for return and requiring proof of identity of the individual returning the product, examining returned or abandoned items for signs of tampering, not reselling returned or abandoned products)
2. keeping track of incoming products, materials in use, salvage products, and returned products
3. investigating missing or extra stock or other irregularities outside a normal range of variability and reporting unresolved problems to appropriate law enforcement and public health authorities, when appropriate
4. minimizing reuse of containers, shipping packages, cartons, etc., where practical

3. Food Service and Retail Display

1. displaying poisonous and toxic chemicals for retail sale in a location where they can be easily monitored (for example, visible by staff at their work stations, windows, video monitoring)
2. periodically checking products displayed for retail sale for evidence of tampering or other malicious, criminal, or terrorist action (for example, checking for off-condition appearance [for example, stained, leaking, damaged packages, missing or mismatched labels], proper stock rotation, evidence of resealing, condition of tamper-evident packaging, where applicable, presence of empty food packaging or other debris on the shelving), to the extent practical
3. monitoring self-service areas (for example, salad bars, condiments, open bulk containers, produce display areas, doughnut/bagel cases) for evidence of tampering or other malicious, criminal, or terrorist action

4. Security of Water and Utilities

1. limiting, to the extent practical, access to controls for airflow, water, electricity, and refrigeration
2. securing non-municipal water wells, hydrants, storage, and handling facilities
3. ensuring that water systems and trucks are equipped with backflow prevention
4. chlorinating non-municipal water systems and monitoring chlorination equipment and chlorine levels
5. testing non-municipal sources for potability regularly, as well as randomly, and being alert to changes in the profile of the results
6. staying attentive to the potential for media alerts about public water provider problems, when applicable

7. identifying alternate sources of potable water for use during emergency situations where normal water systems have been compromised (for example, bottled water, trucking from an approved source, treating onsite or maintaining onsite storage)

5. Mail/Packages

This involves implementing procedures to ensure the security of incoming mail and packages

6. Access to Computer Systems

1. restricting access to critical computer data systems to those with appropriate clearance (for example, using passwords, firewalls)
2. eliminating computer access when a staff member is no longer associated with the establishment
3. establishing a system of traceability of computer transactions
4. reviewing the adequacy of virus protection systems and procedures for backing up critical computer-based data systems
5. validating the computer security system

If a retail food store or food service establishment operator suspects that any of his/her products that are regulated by the FDA have been subject to tampering, "counterfeiting," or other malicious, criminal, or terrorist action, FDA recommends that he/she notify the FDA 24-hour emergency number at 301-443-1240 or call their local FDA District Office. FDA recommends that the operator also notify local law enforcement and public health authorities.

FDA District Office telephone numbers are listed at: http://www.fda.gov/ora/inspect_ref/iom/iomoradir.html.

201 USDA Safety and Security Guidelines for the Transportation and Distribution of Meat, Poultry, and Egg Products

Nanna Cross
Chicago, IL

CONTENTS

I. INTRODUCTION

In May 2002, FSIS issued the FSIS Security Guidelines for Food Processors to assist Federal- and State-inspected meat, poultry, and egg product plants in identifying ways to strengthen their food security protection. The FSIS made the following statement:

"At the time the FSIS noted its commitment to providing continued guidance to businesses engaged in the production and distribution of USDA-regulated foods. We have worked with the Food and Drug Administration (FDA) and other agencies to now provide guidance for those handling food products during transportation and storage.

The FSIS Food Safety and Security Guidelines for the Transportation and Distribution of Meat, Poultry, and Egg Products are designed to assist small facilities and shippers handling these products. The guidelines provide a list of safety and security measures that may be taken to prevent contamination of meat, poultry, and egg products during loading and unloading, transportation, and in-transit storage. In these voluntary guidelines, we strongly encourage shippers and receivers, as well as transporters of these products, to develop controls for ensuring the condition of the products through all phases of distribution. Such controls are necessary to protect the products from intentional, as well as unintentional, contamination. We recognize that not all of these measures will be appropriate or practical for every facility."

Meat, poultry, and egg products are transported by air, sea, and land. Hazards may be present at any point during transportation and distribution, but are most likely at changes between transportation modes and during loading and unloading. Meat, poultry, and egg products frequently are transported multiple times on their way to the consumer and may be exposed to hazards at each step. For example, a product might be transported from a slaughter establishment to a raw-product processing establishment, next to a further processing plant, and then onto distribution sites and retail markets.

The first section of these guidelines provides food safety measures to help prevent the physical, chemical, radiological, or microbiological contamination of meat, poultry, and egg products during transportation and storage. The second section of the guidelines deals specifically with security measures intended to prevent the same forms of contamination due to criminal or terrorist acts. Both sections apply to all points of shipment from the processor to their delivery at the retail store, restaurant, or other facility serving consumers of the products. These guidelines can be applied whether the potential contamination occurs due to an intentional or unintentional act.

Protecting our Nation's food distribution network is essential to the Nation's homeland security. These guidelines are intended to assist the food industry, as well as Federal, State, and local authorities, in that effort.

II. FOOD SAFETY DURING TRANSPORTATION AND DISTRIBUTION OF MEAT, POULTRY, AND EGG PRODUCTS

Meat, poultry, and egg products are susceptible to contamination from a wide variety of physical, microbial, chemical, and radiological agents. These products are particularly vulnerable to microbiological hazards because their moisture, pH levels, and high protein content provide ideal environments for the growth of bacteria. Because of these characteristics, the products must be carefully monitored to prevent their exposure.

Food safety protection can be improved by the control of hazards through the use of preventive methods including good sanitation, manufacturing practices, and the Hazard Analysis and Critical Control Point (HACCP) system throughout the food production and distribution chain. Meat, poultry, and egg products must be refrigerated or frozen after processing and before shipment to inhibit spoilage and growth of pathogens. During transportation and storage, the challenge is to maintain proper refrigeration

temperatures and to keep the "cold-chain" from breaking during steps such as palletization, staging, loading and unloading of containers, and in storage.

A. General Guidance

In the United States, most food is transported by truck. However, meat, poultry, and egg products may be transferred to and from other modes of transportation during shipment and held at intermediate warehouses as well as at transfer or handling facilities, such as airports, break-bulk terminals, and rail sidings. Because transportation and storage are vital links in the farm-to-table food chain, effective control measures are essential at each point in the food distribution chain to prevent unintentional contamination.

The following general guidelines address food safety measures that should be taken by shippers from the point of food production through delivery. The guidelines do not cover breeding, feedlot, or any other pre-slaughter live-animal operations or pre-shipment operations at egg-laying farms.

B. Transportation Safety Plan

1. Identify Vulnerable Points and Develop a Comprehensive Transportation Sanitation and Safety Plan

1. Processors and distributors shipping products should assess and implement measures that will ensure the sanitation and safety of products from initial shipment through delivery to other destinations. A flow diagram from the point-of-origin to final destination, including all shipping modes/routes, can be a helpful assessment tool.
2. Identify all points of vulnerability where there is potential for adulteration or contamination to occur:

2. Identify Potential Hazards

1. If control points are identified, then determine the method, frequency, and limit that must be met.
2. Identify if control is possible at the point(s) of hazard and what is the most effective point to exert control.
3. This will determine where and how often monitoring and verification of the limits set should occur and what, if any, corrective and preventive actions should be taken.
4. Define what controls should be put in place to prevent product adulteration or contamination during the transportation and storage process.
5. As an additional check on product condition during and after transportation and storage, processors may want to include special arrangements with receivers to sample and conduct microbiological or other tests on products. The results could be compared with pre-shipment results to determine whether adjustments are needed in transport methods or procedures.
6. Verify that contracted transporters (e.g. air, ground, maritime, rail) and storage/warehouse facilities have a food safety program in effect. Consider including specific security measures in contracts and verify that measures are being met.
7. Include procedures for the immediate recall of adulterated products from trade and consumer channels (this applies to processors, transporters, and wholesale and retail distributors).
8. Have a system in place to track your products, including salvage, reworked, and returned products.

C. Train Personnel

1. Train managers and supervisors involved in the transportation, handling, and storage of food products in food hygiene and sanitation. They should be able to judge potential risks, take appropriate preventive and corrective actions, and ensure effective monitoring and supervision to prevent intentional and unintentional contamination from occurring.
2. Train personnel involved in all phases of transport, handling and storage in personal hygiene, vehicle inspection procedures, and transportation procedures that will ensure the safety of meat, poultry, and egg products.

D. Storage Food Safety System

1. Design and maintain a storage and warehousing food safety system.
2. The facility should permit easy access to all areas for cleaning.
3. Adequately insulate the facility and have an adequate temperature control capacity.
4. Prevent access by unauthorized persons through the use of locks and fences, etc.
5. Have an effective, systematic program for preventing environmental contamination and infestation by insects, vermin, etc.

E. Vehicles used to Transport Meat, Poultry, and Egg Products

1. Design and Construct Vehicles to Protect Product

1. Vehicles should be designed and built to make locking and sealing easy, protect the cargo against extremes of heat and cold, and prevent infestation by pests.

2. Vehicle design should permit effective inspection, cleaning, disinfection, and temperature control.
3. Interior surfaces should be made of materials that are suitable for direct food contact. For example, the surfaces may be made with stainless steel or be coated with food-grade epoxy resins.

2. Sanitize and Properly Maintain Vehicles

1. Meat, poultry, and egg product transportation vehicles, accessories, and connections should be kept clean and free from dirt, debris, and any other substance or odor that may contaminate the product. They should be disinfected as needed. Cleaning and sanitation procedures should be specified in writing.
2. Different cleaning procedures may be necessary for the different types of meat, poultry, or egg products that are to be transported. The type of product transported and the cleaning procedure used should be recorded. Generally, wash water should be at least 180°F (82°C) and an approved sanitizer may be used to reduce the number of microorganisms and dissolve any fat particles adhering to interior surfaces.
3. Cargo pallets, load securing devices, and loading equipment should be kept clean and free of potential food contaminants and be regularly washed and sanitized.
4. Equipment used in transferring meat, poultry, and egg products, such as hand trucks, conveyors, and forklifts, should be well maintained and kept in a sanitary condition.
5. Secure transport vehicles to prevent tampering when not in use.

3. Use Dedicated Transport Vehicles

1. Transport vehicles, containers, and conveyances should be designated and marked "for food use only," and be used only for transporting foods. If feasible, they should be restricted to a single commodity. This reduces the risk of cross contamination from previous cargoes.

F. Pre-Loading

1. General Guidelines

1. Loading and unloading areas should be configured, cleaned, disinfected (where appropriate), and properly maintained to prevent product contamination.
2. Loading or unloading facilities should be designed to permit easy access to all areas for cleaning.
3. Facilities should be adequately insulated and have an adequate temperature control capacity.
4. Facilities should have an effective, systematic program for preventing environmental contamination and infestation by insects, vermin, etc.

2. Examine Vehicles before Loading

1. Trailer or truck body should be sufficiently insulated and be in good repair with no holes in the body that might allow heat, dust, or other adulterants to enter the cargo area.
2. Check for residues of previous cargoes.
3. Check for residues from cleaning and sanitizing compounds.
4. The cooling unit must be in good repair and operating. Both truck drivers and plant personnel should check the functioning of the trailer refrigeration unit.
5. Trailers and trucks should be pre-cooled for at least 1 hour before loading to remove residual heat from the insulation and inner lining of the trailer as well as from the air of the trailer. For pre-cooling, the doors should be closed and the temperature setting of the unit should be no higher than 26°F. (Note, however, that poultry products labeled "fresh" must be shipped at temperatures higher than 26°F, usually between 26°F and 32°F.)
6. Inspect trailers prior to loading to determine that the air chutes, if used, are properly in place and that the ribbed floors are unclogged so that adequate air circulation can occur.
7. Examine trailer doors and seals to ensure that they can be secured and that there will be no air leaks.
8. When shipping a mixed load of products, such as both frozen and refrigerated products, it may be necessary to use a trailer with compartments that accommodate different temperature or other handling requirements.

3. Stage Loads to Facilitate Proper Stowage and Minimize Exposure during Loading and Unloading

1. Proper staging of loads is especially important when there are loads of products with different temperature requirements, or different delivery destinations.
2. Dock foremen should document that all freight is 40°F or lower before loading. Freight should not be allowed to remain on the loading dock in warm weather in order to prevent the product temperature from rising above 40°F.

3. *Note*: Federal regulations require processed poultry to be packaged and shipped at a temperature no higher than 40°F.

G. Loading

1. General Guidelines

1. Protect products from exposure to environmental contaminants such as microbes, dust, moisture, or other physical contamination.
2. Maintain the "cold chain" to ensure meat, poultry, and egg products are kept at appropriate temperatures continuously throughout all phases of transport.
3. Meat, poultry, and egg products must be kept refrigerated and protected from temperature changes. All persons involved in the transportation, storage, and handling of these products are responsible for keeping them at appropriate temperatures and preventing any break in the cold chain.
4. Maintain the appropriate temperature of the pre-cooled product by minimizing the time of loading or unloading, conducting the loading and unloading in an appropriately chilled environment, and reducing the amount of surface contact of the product with floors and walls of the storage areas or loading equipment.
5. Appropriately packaged meat, poultry, or pasteurized egg products can be stacked, provided that air circulation is sufficient to maintain the temperature of the products during shipment.
6. Product should be at the desired transit temperature before loading. The boxes and pallets should be secured within the vehicle and pallets should be center-loaded off the walls of the vehicle.
7. Seal vehicles shipping egg products from one official plant to another for pasteurization, repasteurization, or heat treatment. (A certificate stating that the products are not pasteurized or that they have tested positive for *Salmonella* should accompany applicable shipments.)

2. Use Appropriate Loading Procedures and Equipment

1. Use spacers on sidewalls and at the ends of trailers as well as pallets on the floor so that proper air circulation can be main tained.
2. Keep loading time as short as possible to prevent temperature changes (increases or decreases) that could threaten the safety or quality of food products.
3. Close doors immediately after the truck/trailer has pulled away from dock.

3. Use Special Care with Mixed or Partial Loads

1. Partial and mixed loads increase the frequency and duration of open doors, leading to a greater possibility of temperature fluctuations and exposure to tampering.
2. Other factors affecting temperature include the time of loading and unloading, the number of stops, the total length of the haul from origin to destination, and the outside temperature.
3. During periods of warm weather, loading or unloading should be done in the evening or early morning to minimize the likelihood of products warming.

H. In-Transit

1. General Guidelines

1. Establish procedures to periodically check integrity of the load during transit.
2. Check for leakage of heating or cooling fluid onto food products.
3. Monitor the temperature and function of the refrigeration unit at least every 4 hours. If there is a unit malfunction, the problem should be corrected by an authorized refrigeration mechanic before the temperature of the load rises.
4. Check for breakdown of temperature control.
5. Use time-temperature recording, indicator, or integrator devices, if they are available, to monitor the condition of cargo. Check the devices every 4 hours.

2. Establish Procedures to Ensure Product Safety during Interim Storage

1. Maintain logbook documenting product condition upon arrival and during storage.
2. Ensure proper temperatures are maintained during storage of meat, poultry, and egg products.

I. Unloading

1. Carefully Examine Incoming Products

1. Product should be inspected and sorted before being accepted at any point during transportation.
2. Develop and implement methods to check and document condition of product and packaging upon receipt at destination. Examine checks of time-temperature recording, indicating or integrator devices or, by prior arrangement with the

shipper, test to determine if bacterial growth has occurred after the product was packaged and shipped.
3. Include procedures for the safe handling and disposal of contaminated products. Identify where and how to separate contaminated products.
4. Establish policy and procedures for rejection of packages and products that are not acceptable, can't be verified against the delivery roster, or contain unacceptable changes to shipping documents. Have a monitoring plan and record-keeping system in place to document steps taken.
5. Do not accept products known to be, or suspected of being, adulterated.
6. Move product from the loading dock into cold storage immediately to minimize product exposure to heat and contaminants.

III. FOOD SECURITY DURING TRANSPORTATION AND DISTRIBUTION OF MEAT, POULTRY, AND EGG PRODUCTS

The tragic events of September 11, 2001, forever changed our world. They proved to us that the unthinkable could become reality, and that threats to our Nation's food supply are very plausible from those who want to harm us through any possible means. Since the terrorist attacks on America, security — including food security — has been the highest priority at both the Federal and State levels.

Ensuring safe food within the processing plant, during transportation, in storage, and at retail is a vital function to protect public health. We must now look at all possible threats, examine the risks, and take action to prevent any intentional attack on the food supply.

A. General Guidance

Meat, poultry, and egg products are susceptible to intentional contamination from a wide variety of physical, chemical, biological, and radiological agents. Everyone in the food distribution system is responsible for ensuring that these products are safe, wholesome, and unadulterated. Therefore, as part of this system, those responsible for transportation and delivery should implement every possible security measure to ensure the integrity of the products throughout the supply chain.

There are many potential benefits of having an effective security plan in place such as:

1. protects public health and assets;
2. increases public and customer confidence, including trading partners;
3. provides value-added component to product;
4. deters theft and tampering;
5. creates production and distribution efficiencies;
6. maintains greater control over product through supply chain; and
7. possibly reduces insurance premiums and freight rates.

The guidelines below provide a list of security measures to be considered by processing plants, shipping companies, and warehouse facilities to minimize the risk of tampering or other criminal action for each segment of the food-delivery system.

B. Security Plan

1. Assess Vulnerabilities

Identify a food protection management team and assign a leader to verify required actions are implemented and effective.

Develop a comprehensive transportation security plan and assess vulnerabilities using a recognized threat/risk/vulnerability model such as Operation Risk Management (ORM) and Systematic Assessment of Facility Risk (SAFR). A flow diagram from your point-of-origin to final destination, including all shipping modes/routes, can be a helpful tool in your assessment.

In your security plan, identify all points of vulnerability where there is the potential for intentional adulteration or contamination to occur during the transportation and distribution process:

1. identify potential biological, chemical, and physical hazards.
2. identify if control is possible at the point(s) of hazard and what is the most effective point to exert control.
3. if control points are identified, then determine the method, frequency, and limit that must be met.
4. this will determine where and how often monitoring and verification of the established limits should occur and what, if any, corrective and preventive actions should be taken.

2. Develop and Implement Procedures

1. Implement identified security measures at each point to ensure the protection of products from the time of shipment through delivery to each destination.
2. The plan should include a system to identify and track your product at any time during transportation and distribution such as the use of tamper-resistant seals corresponding to specific shipments and their documentation.

3. Verify that contracted transporters (e.g. air, ground, maritime, rail) and storage/warehouse facilities have a security program in effect. Consider including specific security measures in contracts and verify that measures are being met.
4. Include procedures for the immediate recall of adulterated products from trade and consumer channels.
5. Have a system in place to track salvaged, reworked, and returned products.
6. Include procedures for handling threats to and actual cases of product tampering.
7. Establish an evacuation plan for the facility.
8. Include procedures for the safe handling and disposal of contaminated products. Identify where and how to separate suspected products.
9. Develop and implement methods to check and document condition of product and packaging upon receipt at destination.
10. Establish policy and procedures for rejection of packages and products that are not acceptable, can't be verified against the delivery roster, or contain unacceptable changes to shipping documents. Have a monitoring strategy and record keeping system in place to document steps taken.
11. Establish policy and procedures for allowing rail crew, truckers, etc., to enter the facility and monitor their activities while on the property.
12. Food security plans should be kept in a secure location and shared on a "need-to-know" basis.

3. Emergency Operations

1. Regularly update a list of local, State, and Federal emergency contacts, local Homeland Security contacts, and local public health official contacts.
2. Develop procedures for notification of appropriate authorities if an event occurs.
3. Identify all entry and exit points available to emergency personnel in the plan.
4. Develop a strategy for communicating with the media, including identifying a spokesperson, drafting press statement templates, or referring media to trade association or corporate headquarters.

4. Train and Test

1. Train each team member in all provisions of the plan.
2. Conduct drills regularly to test and verify the effectiveness of the plan. Continually review policies and procedures in the plan. The food-protection management team leader should coordinate these activities.

5. Screen and Educate Employees

1. Screen all potential employees, to the extent possible, by conducting background and criminal checks appropriate to their positions, and verifying references (including contract, temporary, custodial, seasonal, and security personnel). When this is not practical, such personnel should be under constant supervision and their access to sensitive areas of the facility restricted.
2. Consider participating in the Immigration and Naturalization Service (INS) pilot program for screening (888-464-4218).
3. All employees should be trained on how to prevent, detect, and respond to threats or terrorist actions so they can recognize threats to security and respond if necessary.
4. Promote ongoing security consciousness and the importance of security procedures.
5. Personnel involved in the transport, handling, and storage of meat, poultry, and egg products should be trained in procedures that will ensure the security of these products (e.g., train dock and security personnel on documentation requirements for incoming and outgoing shipments).
6. Train appropriate personnel in security procedures for incoming mail, supplies, and equipment deliveries. Mail handlers should be trained to recognize and handle suspicious mail using U.S Postal Service guidelines.
7. Ensure employees know emergency procedures and contact information.
8. Encourage employees to report any suspicious activities such as signs of possible product tampering or break in the food security system. Have a tracking system in place for these reports and follow-up activities.

C. Secure the Facility

1. Access

1. Maintain a positive ID system for employees. Require identification and escort visitors at all times in your facility.
2. Collect company-issued IDs, keys and change lock combinations when a staff member is no longer employed by the company.
3. Ensure clear identification of personnel to their specific functions (e.g. colored hats or aprons, ID cards).
4. Restrict types of personal items allowed in the establishment, especially firearms or other weapons.

5. Secure and restrict access to facilities, transportation trucks, trailers, or containers, locker rooms, and all storage areas with alarms, cameras, locks and fences or other appropriate measures, to prevent access by unauthorized persons.
6. All visitors should be escorted while on the premises. Establish procedures for handling unauthorized persons in a restricted access area.
7. Control access to food products by unauthorized persons by limiting access to food delivery, storage, food ingredient, and chemical storage areas.
8. Restrict access to computer data systems. Protect them using firewalls, virus detection systems and secure passwords, changing them routinely.
9. Restrict access to outside water tanks, water supplies, ice machines, and conveying water pipes.
10. Restrict access to central controls for heating, ventilation, and air conditioning (HVAC), electricity, gas, and steam systems to prevent contamination from entering the air distribution systems.

2. Shipping/Receiving

1. Consider developing a checklist for shipping and receiving procedures (this can also help identify anomalies).
2. Loading docks should be secured to prevent unauthorized deliveries.
3. All deliveries should be scheduled and truck drivers should show proper identification upon arrival.
4. Shipping documents should contain product information, name of carrier(s), driver information, and seal numbers.
5. Establishments should require that incoming shipments be sealed with tamper-proof, numbered seals, and that the seal numbers are shown on the shipping documents for verification prior to entry to the facility.
6. Shipping documents with suspicious alterations should be thoroughly investigated. Product should be held and segregated during investigation process.
7. Properly secure transportation trucks, trailers, or containers:
8. Doors should not be left open when picking up a load from a warehouse.
9. Ensure shipping trucks, trailers, and containers are secured after loading is complete.
10. Lock transportation trucks, trailers, and containers when not in use, during meal breaks and at night.
11. Apply seals to all containers being shipped and maintain a seal log. Have a system in place to verify seal numbers and the integrity of the seals throughout the distribution process.
12. Ensure security procedures are in effect for interim storage at in-transit warehouses.

3. Facility

1. Designate limited and specific entry and exit points for people and trucks.
2. Secure all access and exit doors, vent openings, windows, outside refrigeration and storage units, trailer bodies and bulk storage tanks.
3. Ensure adequate interior and exterior lighting at the facility.
4. Parking areas for visitors should be situated away from the main facility, if practical. Vehicles of employees and visitors should be clearly marked (e.g., placards, decals). This is intended to identify vehicles authorized to be on the premises and deter bombing attempts.
5. Hazardous chemical storage areas or rooms should be secured and located away from food preparation and storage areas. In addition, they should be constructed and safely vented in accordance with national or local building codes.
6. Incoming mail should be handled in an area of the facility separate from food handling, storage, or preparation areas.
7. Install backflow devices on all water supply equipment.

D. Monitor Operations

1. Employees

1. Maintain a daily shift roster to easily identify persons who are/should be on the premises and indicate that they are in their appropriate location.
2. Provide appropriate level of supervision to all staff, including food handlers, cleaning and maintenance staff, and computer support staff.
3. Monitor employees for unusual behavior (e.g., staying unusually late, arriving unusually early, taking pictures of the establishment, or removing company documents from the facility).

2. Shipping/Receiving

1. Purchase all food ingredients, food products, and packaging materials only from known, reputable suppliers. Require Letters of Guaranty, if possible.
2. Require locked or sealed trucks, trailers, or containers for deliveries. Maintain an inbound load verification logbook. Verify inbound

trucks for seal numbers and integrity and load manifest. Document seal numbers and the truck or trailer number.
3. Hold unscheduled deliveries outside the premises pending verification of shipper and cargo. Do not accept deliveries from, or release product to, unknown shippers using only cell phone numbers or known shippers with unknown phone/fax numbers or e-mail addresses.
4. Supervise off-loading of incoming products, ingredients, packaging, labels, and product returns. Only a supervisor or other agent of the owner should break seals and sign off in the trucker's logbook.
5. Have system in place to ensure integrity of product when seal will need to be broken prior to delivery due to multiple deliveries or for inspection by government officials.
6. Verification of the last company seal put on a truck should be available throughout the delivery chain.
7. Examine incoming products and their containers for evidence of tampering or adulteration:
   a. Determine a random or other sound plan for checking incoming product;
   b. The warehouse supervisor should note on the bill of lading any problems with the condition of the product, packaging, labels, and seals;
   c. Do not accept products known or suspected of being adulterated; and
   d. Check food for unusual odor or appearance.
8. Processors may want to arrange with receivers to sample and conduct microbiological or other tests on products.
   a. This would require an in-house testing plan prior to shipment.
   b. The results should be compared with preshipment results to determine whether adjustments are needed in transport methods or procedures.
   c. Establish chain-of-command procedures providing for the proper handling of samples.
   d. Samples should be clearly marked and kept in a secure area.
   e. Ensure all trucks leaving the facility are sealed.
   f. Maintain a logbook of seal assignments.

3. Storage/Water

1. Maintain an accurate inventory of food and chemical products and check daily to allow detection of unexplained additions to, or withdrawals from, existing stocks. Include information about the sources and date of shipment. All discrepancies should be investigated immediately.
2. Perform random inspection of storage facilities (including temporary storage trailers or containers), trucks, trailers, containers, and vessels regularly. Keep a log of results. Designate an individual to conduct the inspection and have a record-keeping system in place.
3. Regularly test water and ice supply to ensure it is safe to use.
4. Inspect water storage and conveying lines inside and outside of the facility regularly for tampering or irregularities.

4. Respond

1. Be aware of and report any suspicious activity to appropriate authorities (e.g., unscheduled maintenance, deliveries, or visitors should be considered suspicious).
2. Processors, transportation managers, and wholesale and retail distributors should ensure traceability and recall of products.
3. Ensure procedures are in place to accomplish a complete, rapid recall, and removal from the market of any shipment of meat, poultry, and egg products in the event products are found to present a hazard to public health.
4. Keep detailed production records, including packaging lot or code numbers and where finished product was stored or served.
5. Trace Forward – Shippers (including operators of federally inspected meat, poultry, and egg processing establishments) and carriers should have systems in place for quickly and effectively locating products that have been distributed to wholesalers and retailers.
6. Trace Backward – Retailers, wholesalers, carriers and others who have received products from federally inspected meat, poultry, or egg processing establishments should be able to identify the source of the products quickly and efficiently.
7. Investigate threats or reports of suspicious activity swiftly and aggressively.
8. In the event of a food security emergency, first contact your local law-enforcement authority.

E. Additional Guidance for Specific Modes of Transportation

Of the approximately 200.5 billion metric tons of food shipped internationally each year, 60 percent goes by sea, 35 percent by land, and 5 percent by air. Domestically, most food products move via ground transportation (truck and rail). Thus, it is critical that everyone involved in the food

delivery system understands his or her role and responsibility to ensure the security of meat, poultry, and egg products to the end point or consignee. Recognizing the inter-modal nature of this system, a multi-layered approach to protecting food is essential.

F. General Guidance for All Modes

Make certain that contracted shippers and consignees have security measures in place to ensure product integrity and traceability and verify that they are meeting contractual security obligations. Security measures should include:

1. Physical boundaries of the facility/terminal are secure;
2. Background checks are conducted for all potential employees by shipping, trucking, and drayage companies;
3. A positive identification system is in place for all employees. (Recommend requiring participation in the Transportation Worker Identification Card (TWIC) program which is coordinated by the Transportation Security Administration);
4. A security training and awareness program for all employees on how to prevent, detect, and report suspicious activity is conducted;
5. A system is in place to track movement of products and truck, trailer, and containers/vessels (e.g., Global Positioning System);
6. Maintains record-keeping system to document chain-of-custody, which will aid in tracing product;
7. Uses a system (e.g., x-ray scanners) to detect tampering and radiological, biological, and chemical agents in shipping containers;
8. Policies and procedures are in place for the handling of suspicious product; and
9. Ensures all containers are properly secured at all times when held in storage yards.

1. Aviation

Although fewer meat, poultry, and egg products are transported by air than by other modes, it is still critical to ensure the security of these products when this mode of transport is utilized.

1. Check all trucks entering a terminal facility.
2. Trucks carrying meat, poultry, and egg products should have seal logbooks and the seals should be examined and numbers verified.
3. Inspect containers arriving at a terminal for loading before admitting them to the terminal.
4. Immediately report suspicious or inconsistent servicing of a container to terminal security.
5. Design internal and external packaging so customers will be able to determine if the product was tampered with and can immediately notify you. Provide instructions and contact information with shipment.

2. Truck

Approximately 21 million trucks transport products across the United States every day. Keeping containers secure is a huge undertaking as there can be many opportunities for tampering.

1. Develop and implement procedures for drivers to ensure security of the truck, trailer, or container when stopping for meals, gas, and repairs.
2. Transportation trucks, trailers, and containers should be designed and built to make locking and sealing easy and should permit effective inspection.
3. Examine trailer doors and seals to ensure that the trailer can be secured.
4. Keep empty trailers locked at all times.
5. Check product load periodically during transit to ensure its integrity has not been compromised (e.g., use weigh station stops as an opportunity to check condition of products).
6. Processors, distributors, and transporters should have action plans for emergencies, such as breakdowns or reporting criminal activity. The plans should include notification of the relevant Federal, State, and local authorities.
7. Drivers should be trained to take appropriate precautions while en route (e.g., do not pick up hitchhikers, do not discuss the nature of cargo at stops, be aware of surroundings, lock truck, trailer, or container when unattended and avoid low-lit areas).
8. Prevent unauthorized access to delivery truck, trailer, or containers. Require drivers to secure truck, trailer, or containers while en route, including while on break, at restaurants, at overnight stays, etc.
9. Drivers should report unusual circumstances, such as being followed, to appropriate authorities.
10. Develop procedures to be followed when reefer boxes or trailers are found unlocked.
11. Deter diversion or hijacking of cargo by keeping track of trucks. Ensure time logs for trips are maintained and provide trucks with communication and tracking equipment.
12. Hold drivers accountable for ensuring security measures are taken to prevent contamination of

meat, poultry, and egg products while under their control.

3. Maritime

Ports are vulnerable due to their size, accessibility by water and land, location in metropolitan areas, and the quantity of products moving through them. Approximately 80% of U.S. imports arrive via American seaports, yet U.S. Customs physically inspects only a fraction of all containers; the remainder are electronically screened. Therefore, enhanced security measures are necessary for products shipped by sea.

1. Check all trucks entering a terminal facility. Trucks carrying meat, poultry, and egg products should be sealed, drivers should have seal logbooks, and the seals should be verified.
2. Seals should be removed in the presence of terminal personnel so they can verify the seal number and its integrity.
3. Immediately report suspicious or inconsistent servicing of a container to terminal security.
4. Supervise opening of ship hatches.
5. When unloading product from sea-going vessels, inspect seals for evidence of tampering. Have documentation system in place.
6. Document cutting of seals (e.g., when seal is cut for inspection by government official).
7. Shipping line agents should provide importers and customs brokers with a record of vessel discharge and checks at discharge and in transit.
8. Establish policy and procedures to download reefer electronic information during inspection (this will also allow identification of anomalies);
9. Have reporting system in place when the discharging of any product looks suspicious or the product shows evidence of tampering.
10. The terminal facility should be locked during meal breaks and at night.
11. Facility doors should be closed immediately after the truck/trailer has pulled away from dock.

*Importers and Exporters may want to consider participation in government initiatives pertaining to maritime shipment of products such as:

1. Customs-Trade Partners Against Terrorism (C-TPAT)
2. Operation Safe Commerce
3. Container Security Initiative
4. Sea Carrier Initiative Agreement

4. Rail

Rail transportation is an integral part of the domestic food distribution system, therefore, it is important to recognize that unsecured containers can be easy targets for tampering and address this vulnerability.

1. Use boxcars dedicated for food products.
2. Employ measures to secure loaded and empty containers from tampering when being stored at the train yard for any length of time.
3. Locks/seals on boxcars should be inspected at pull and place.
4. Review shipping documents upon arrival at the trainyard and before the train engineer leaves.
5. Inspect integrity of seals upon arrival and before departure of the load.

IV. RESOURCES

If you have questions or need clarification about the guidelines, contact the FSIS Technical Service Center at: 1-800-233-3935.

Obtain additional copies of the guidelines at: http://www.fsis.usda.gov or call 202-720-9113.
