Packaging

130 Food Packaging: New Technology

Vanee Komolprasert
Division of Food Processing and Packaging, U.S. Food and Drug Administration

CONTENTS

I. INTRODUCTION

Food packaging is constantly changing to meet new challenges in the market and new needs of the consumer. New technologies continue to emerge with innovations in new packaging materials and packaging techniques that offer new possibilities for manufacturing, packaging, and marketing a wide variety of foods. Today's food package provides not only basic functions (contains and protects) but also offers convenience, facilitates product use, and communicates with intended buyers of the product. The package label informs the consumer of nutrition facts, sells the product through colorful graphics, and addresses environmental concerns such as source-reduction and recycling. Among the innovations and recent developments, major efforts have focused on new barrier materials and technologies for flexible and rigid food containers. Better barrier technology is desirable to enhance quality and safety of food as well as to extend its shelf life. Barrier packaging technology is the main focus in this chapter.

II. EVOLUTION OF PACKAGING

Packaging roles have continuously evolved with social and community development (*1*). Initially bulk packaging was used to deliver goods to retailers where it was received and bagged for merchants. As food processing

technology advanced individual container for consumer products such as canned foods were widely used. By the middle of the 20th century, most consumer goods were individually packed and branded. The small community store that originally sold products manufactured locally evolved into a modern supermarket equipped with refrigeration and accommodated more products. As the number of products increased to hundreds or thousands, the storekeeper could not aid and influence the consumer's purchase. The consumer was left face-to-face with the package. The package had to sell the product as well as to inform the purchaser, calling for the package's motivational and informational roles. To attract the purchaser, package design and graphics needed to be attractive, thus creating a new profession, package design, as well as prompting an evolution in printing and decorating arts.

The post WW II baby boom affected population structure and trends, and subsequently food product and package design. The 1950s marked the emergence of fast food outlets that created a demand for new kinds of packaging, including disposable single-serve packaging and bulk packaging for ready-to-cook food portions. Fast food outlets boomed along with a growing trend toward eating out. This led to formation of the hotel, restaurant, and institutional sector (HRI). The 1960s marked the growth of convenience and prepared food packages, as thermoplastics became available as packaging materials. As use of these plastics increased, the consumer's concern toward environmental problems increased. The 1970s and early 1980s brought changes such as labeling laws, ozone-depleting chlorofluorocarbons (CFCs), standards for the acceptance of new packaging materials, and microwave ovens and microwaveable packaging. Changing demographics of the 1990s were reflected in changes to product packaging. The nutrition labeling law required the package label to include nutrition facts. The aging population became heath conscious and desired food and food products that promote health and living wellness. Families became smaller and the single-person household became common. Married couples have professional careers and higher income levels, calling for "convenient" food products. The food package is required to be environmentally friendly, tamper-proof, and convey detailed information on the nutritional values and ingredients of the food product. Currently, there is a proposed country-of-origin labeling law. Once the law is passed, it will be effective in September 2004 (*2*) and will apply to packaging of meat, seafood and produce, both fresh and frozen. Food packages will continue to evolve in the 21st century.

III. FOOD PACKAGING

Food packaging is the process of wrapping food with a suitable package. The package may be made of one or more materials that provide proper functionalities and properties for holding and protecting the food from the point of production to the consumer, while the quality and safety of the food are maintained. Holding and protecting the food are two major functions for packaging of food. Food is generally sensitive and susceptible to environmental abuse, and deteriorates by chemical, biochemical, and/or microbiological changes that are usually accelerated by environmental factors such as oxygen, water, light, and temperature. With a suitable package, these changes can be prevented or delayed. A suitable package can also prevent contamination by foodborne pathogens, which render the food hazardous and unwholesome for consumption. Food packaging provides wholesome, high-quality, and nutritious food products.

Packaging technology is dynamic as a result of the new challenges and new technologies developed to accommodate new needs in the changing society. Discovery of new packaging materials, new processes, and new techniques have shaped the way we package, deliver, and consume products. The thermoplastics developed in the 1950s have revolutionized the packaging industry. Although many foods are still packaged in traditional glass bottles and tin cans, newer plastic, multilayer, and composite packaging materials are creating opportunities for improved product convenience, presentation, quality, and safety, as well as innovative food product development.

An ideal food package is designed to meet many requirements of the food itself, the processing or preservation methods, distributor and retailer needs, and consumer expectations and acceptance. Modern packaging is driven toward more intensive marketing and globalization. Packaging plays a significant role in motivating purchase. Among competing products that are similar in performance and quality, their packages are different. Package design is then critical in competition, and a new package often helps create uniqueness for its brand.

An increase in market globalization requires a product with an extended shelf life. Better barrier packaging materials and techniques are needed to achieve a desirable shelf life for export. There are two factors influencing the development of food packaging with increased barrier properties. First are the regulatory initiatives that are intended to limit waste generation. Source reduction via downgauging of flexible packaging is one way of reducing plastics' content in solid waste. Second is the improved food preservation that barrier flexible packaging can offer in preventing food losses and spoilage during storage.

IV. RECENT DEVELOPMENTS OF BARRIER PACKAGING SYSTEMS

A barrier can be defined in many ways depending on the desired level of protection from physical damage and chemical and biological changes that affect food quality and safety. Since most food packages are plastics, a barrier

is conceived to be for control of permeation of gases and vapor through the package. Barrier technology has been designed and developed for both flexible and rigid food containers. A desired barrier level can be achieved by using one or more barrier materials for food packages, or by incorporating this barrier material using multi-layer structure, lamination, or coating techniques. Years of research and development have resulted in new barrier technologies for various foods and food products.

V. BARRIER MATERIALS

Although polyethylene terephthalate (PET), high-density polyethylene (HDPE), low-density polyethylene (LDPE), polypropylene, (PP), polyvinyl chloride (PVC), and polystyrene (PS) are widely used plastics for food packaging, they provide inadequate barrier properties. Newer barrier materials were desirable. Several barrier materials of current industry interest include polyvinylidene chloride (PVDC), ethylene vinyl alcohol copolymer (EVOH), nylon (PA), modified nylon (MXD6, Selar PA), liquid crystal polymer (LCP), polyethylene naphthalate (PEN), adhesive barrier materials, nanocomposites, and oxygen scavengers. These materials are high priced, so they are used in as small amounts as possible to give the desired barrier properties. Barrier material can be incorporated into a lower cost material by using lamination for a multilayer structure or coating onto a monolayer material.

PVDC is a favored choice for an improved barrier of a food package. It was usually used in multi-layer films and containers before the arrival of EVOH in the 1970s. PVDC and EVOH could be used in co-extrusion of 5-, 7-, and 9- layer cast barrier sheet structures for shelf-stable and retortable food packaging. The basic 7-layer barrier structure is typically a symmetrical arrangement of polyolefin/ regrind/tie layer/EVOH, PVDC, or PA/regrind/tie layer/ polyolefin. EVOH was used for a ketchup bottle that was developed in 1984, and the first multi-layer packaging for retortable packages and microwaveable soup bowls was commercialized in 1987.

Food packaged in shelf-stable, retortable containers is at least one-third more expensive than similar products in metal cans, mostly due to the price of packaging. Despite high packaging prices, the market for the multi-layer cast barrier sheet for shelf-stable and retortable packaging has continued to grow. The growth is especially high for specialty foods, where the package cost is outweighed by the features and benefits that the products provide and the need they meet (*3*). For example, single-service containers of applesauce offer healthier alternatives to most snack foods consumed at school or work, and microwaveable baby foods offer nutrition and convenience in pre-measured, hot meals. Emerging end uses for the multi-layer barrier containers include aseptic packaging for low acid food with particulates, and modified atmosphere packaging (MAP). MAP of meats is going into supermarket chains. Typical MAP is a foamed PS/ tie layer/EVOH/PE or EVA structure with one regrind layer. Shipping meat from fabricating plants in MAP containers could eliminate the need for butcher shops in supermarkets. The expense of packaging, labor, and freight of MAP could be a slightly lower-cost alternative to the in-store butchers.

In the early 1990s, flexible barrier packaging shifted from metalized films, laminates, and rigid containers to films incorporating barrier resins, especially EVOH, along with films produced by new coating techniques that deposit oxides of silicon or metal to obtain clarity (*4*). EVOH use has grown rapidly as a substitute for PVDC coated films and metalized films that are considered less recyclable. Since its introduction, EVOH grades have been developed to overcome delamination problems when used in multilayer structures. Eval Co. of America (Evalca) developed a third-generation delamination-resistant EVOH barrier resin, Eval grade XEP-567, which has better adhesion to PET without a tie layer than the previous grades, MDX6, and other nylons. The XEP-567 grade offers about 50% lower O_2 permeability and about 40% lower CO_2 permeation than Eval XEP-562, a second generation delamination-resistant resin introduced in 1999 (*5*), and offers carbonated soft drinks a shelf life of 16 weeks.

MXD6 is a modified nylon developed by Mitsubishi Gas Chemical in 1986. Selar PA is modified nylon developed by DuPont. Both are often used in multi-layer structure food packages. MXD6 nylon can provide ca. 19–20 times greater barrier capacity than PET. Since it has similar processing temperature to PET, it can be blended with PET but has a drawback of high haze (*6*). MXD6 and liquid crystal polymer (LCP) blend is then preferred for use in multi-layer PET bottles.

Liquid crystal polymer (LCP) is a barrier material superior to PVDC and EVOH. It functions at one-fifth the thickness of EVOH, resulting in overall material saving (*7*). Superex Polymers Inc. developed counter-rotating die technology for biaxially oriented and extruded LCP (*8*). Packaging applications of LCP include beer bottles and blown films. It has more than 200 times greater O_2 barrier than PET and is not moisture sensitive. A monolayer PET bottle is unsuitable for beer because it is neither an efficient oxygen nor flavor barrier, so product shelf life and taste stability are problems. A thin layer of LCP on the PET eliminates both problems. Since LCP has a high price, its use in packaging is minimal and depends on desired product shelf life. A three-layer structure (PET/tie layer/LCP) less than 0.5 mm thick and containing LCP less than 5% of the bottle weight could provide beer with a one-year shelf life. Less LCP could be used if a 6-month shelf life is acceptable, and thus reduce bottle cost. Biaxially oriented LCP film could be laminated or coextruded to produce a lower cost material for barrier packaging.

PEN, a new polyester that has been blended with PET, improves the CO_2 and O_2 barrier properties of the monolayer PET bottle used for beer. As PEN has a glass transition temperature (T_g) of 122°C, far higher than for PET, PEN blends allow the monolayer to sustain pasteurization temperatures for beer. However, the high price of PEN and PET/PEN blends is a major obstacle preventing its widespread use for single-use containers such as beer bottles. Nevertheless, PEN is cost-competitive with refillable glass bottles and less costly than one-way PET bottles when PEN bottles are refilled at least three to five times (*9*). Monolayer PEN bottles are used for marketing of multi-trip refillable beer and water bottles in countries where refillable bottles are accepted, i.e., European countries, Latin America, South Africa, and China.

Blox is the trade name of a new series of clear, tough, highly adhesive barrier polymers from Dow Plastics. They are poly-amino ethers made by polymerizing liquid epoxy resins with an amine to create solid, low melting thermoplastics (*10*). Blox resins can be extruded into films, injection molded, or blow molded. One series of Blox resins can be co-extruded as a barrier layer of multi-layer bottles for juices, beer, or carbonated soft drinks. Their O_2 and CO_2 barriers are about ten-fold higher than that of PEN and in the range of EVOH or MXD6 nylon, depending on humidity level. The clarity and toughness of Blox materials are higher than those of EVOH and MXD6. Blox resins have better adhesion to PET, permitting design of more complex bottle shapes without the risk of delamination, and no tie layer is required.

Nanocomposites are materials where nanometer particles are dispersed in a polymeric matrix, which can be single or multiple phase. A nanoscale particle is a particle with at least one dimension in the nanometer range. Natural and synthetic clays are mainly used as nanoparticles in plastic composites (*11*). However, mixing plastics and clays is not a simple process because the materials are immiscible and tend to form a very light packing of individual clay layers. As a result, clays must be treated with an organic intercalant to improve interactions between clay platelets as well as dispersion of organoclays. An intercalant is an oligomer or polymer that is sorbed between platelets of the layered material and complexes with the platelet surface to form an intercalate. The original concept for these plastic composites began with the invention of polyamide-clay composites by the Toyota Research Corporation in 1985; these were used to make under the hood heat resistant automotive parts that were lighter than metal. The technology has advanced and can be applied to various plastics including thermoplastic olefin (TPO), thermoplastic elastomer (TPE), PP, PET, and nylon. The nanocomposites offer improved mechanical, electrical, gas, and liquid barrier properties. Nanocomposite technology has been migrating from automotive parts to other applications including rigid and flexible packaging. Nanocomposite plastics are usually enhanced by fillers derived from the industrial clay called bentonite (*12*). The fillers form flat platelets that disperse into a matrix of layers, which force gases to follow a tortuous path through the polymer. By increasing the path of diffusion of gases and other molecules, the clay platelets slow gas transmission and increase the barrier properties of the plastics.

Nylon is a preferred nanocomposite additive for making a barrier layer in multilayer PET containers, which are increasingly used to package oxygen sensitive foods and beverages. Nylon has better inherent adhesion than EVOH (an alternative barrier resin), thus sealants are not needed between the nylon and PET layers. With nanoclay additives, the barrier properties of nylon can be doubled or tripled, making it an alternative barrier material to the superior barrier EVOH resins. However, getting nanoparticles to disperse properly to make the tortuous path principle work is not easy. The most promising way is to introduce the clay additive during polymerization, such as with the Aegis's nanocomposite nylon. Eastman Chemical Co., in cooperation with nanoclay producer Nanocor, has developed a nylon composite barrier material, Imperm (*5*). Imperm was designed for use in multi-layer bottles, providing 50–100 times greater O_2 barrier than PET, compared to 10–20 times barrier improvement of MXD6 nylon over PET. A 20-g three-layer PET/Imperm/PET bottle with 4% Imperm in the bottle wall has a 3–5 times greater O_2 barrier than PET and less than 8% haze. A bottle with 10% Imperm has a 6–11 times greater O_2 barrier and less than 10% haze.

Several oxygen scavenger systems have been developed using either oxidizable metal such as iron, various oxidation promoters, and fillers or metal free absorbent systems such as mixtures of organic compounds including quinines, glycol, and phenolics (*13*). In the early 1990s, Toyo Seikan introduced a non-conventional technology, Oxyguard (iron salt-based), for incorporating a high oxygen barrier into blow molded food containers and other rigid packaging (*14*). Oxyguard is an alternative to the EVOH or PVDC coextrusion of a multi-layer structure, where barrier properties decrease under elevated relative humidity and temperature such as during retorting, and they cannot remove oxygen in the headspace of the bottle between the contents and closure. In contrast, Oxyguard's barrier is claimed to be capable of trapping and holding oxygen coming from the headspace instead of simply blocking it.

Amosorb oxygen scavengers developed by Amoco are available in pellet concentrates of PP, PE, PET, and elastomer resins. The oxygen scavenger resins are designed for either retort and hot-fill food applications or non-retort and refrigerated food and beverage packaging, and can be employed in a wide range of packaging structures including rigid containers, films, and closure liners. They are claimed to be heat stable to 320°C and activated by moisture. Amosorb 3000 copolyester was developed for beer, tomato products, fruit juices, and teas. It is an iron-based system that bonds permanently with oxygen that permeates

the package wall, is present in the internal headspace, or is dissolved in the packaged contents. It is transparent and compatible with other polyesters. A multi-layer package containing one or more core layers of Amosorb 3000 is claimed to offer better protection than glass or metal for even the most oxygen-sensitive products.

Hybrid BA-030 copolyester from Mitsui Chemicals was developed for use in beer bottles as part of a 5-layer structure (PET outer layer/BA-030/O_2 scavenger/UV barrier/PET inner layer). The grade is claimed to reduce acetaldehyde levels to as low as 3 ppm, and match or exceed PEN properties when combined with PET (*15*).

AmberGuard polymer from Eastman Chemical was developed for UV light protection. It can be used in a multi-layer container with Eastman's Imperm nanocomposite polymer to provide UV protection and O_2 and CO_2 barriers.

Oxygen absorbing organic ingredients can be copolymerized with monomers of existing packaging polymers to create inherently absorbent structures. Carnaud Metal Box and Crown Cork & Seal developed Oxbar, which is a non-iron-based system that uses nylon and a cobalt salt formulation incorporated into a polyester base, as a chemical trap (*14)*. It is used in three-layer PET bottles for short term applications e.g., single-serve fruit juice and beer as well as wide mouth containers for tomato-based sauces and condiments (*16*).

Southcorp technology developed $ZERO_2$, which is a non-metallic oxygen scavenger system that is activated by UV light after it is incorporated into packaging structures of materials such as PE, PP, PET, and ethylene vinyl acetate (EVA) (*13*). It is used in conjunction with vacuum packing and barrier films.

VI. BARRIER PET CONTAINERS

Polyethylene terephthalate (PET) is one of the most widely used polymers. It was the first polymer to successfully recycle, generating reclaimed materials for a wide range of non-food and food applications. The recyclability of PET material is a factor promoting its use beyond the carbonated soft drink market to include other foods and beverages. It is replacing glass bottles and some bottles made from other plastics such as HDPE, PP, and PS. PET's success is a result of its better barrier and clarity than the plastics being replaced, as well as technological development of the processes used to convert PET into flexible and rigid packages at high outputs, which is crucial for the minimization of packaging costs. Use of PET resins continues to rise because of new applications, as well as the innovation of barrier technologies that help enhance the barrier properties of PET, and thus making it suitable for other demanding applications including use with oxygen sensitive foods. PET is now a commodity polymer competing directly with polyolefins and styrenics in the markets for food and beverage packaging, as well as for other products.

Monolayer PET packages are generally suitable for many food applications but are not suitable for beverages and food products that require better protection or gas barriers. The ideal approach to improve the gas barrier of PET is to design a monolayer PET structure that will provide package design freedom. This approach requires blending a barrier resin, oxygen scavenger, or both with the PET. The monolayer solutions are less practical mainly because suitable materials are high-priced. However, this approach has been the subject of a recent development by Interbrew in cooperation with M&G Group. Interbrew has launched a single-layer PET barrier bottle, Pivopack, for a Russian beer, Klinskoye brand. Pivopack is claimed to be the first monolayer, barrier-enhanced PET bottle, which uses M&G's new Acti TUF, a PET resin made by a proprietary oxygen-scavenging technology that is triggered to react with oxygen only when a container is filled with beverage (*17*). The monolayer PET provides the advantages of allowing the preforms to be manufactured on standard machines. The pricing of these resins is in a range of Eur330–650/ton above that of standard PET (*18)*.

Two other approaches for improving gas barriers are multi-layer structures and surface coatings. Advancements in multi-layer and surface coating technologies are making PET bottles cost competitive with glass bottles and metal cans for beer, carbonated soft drinks (CSDs), oxygen sensitive juices and hot-filled foods. PET bottles for beer were developed in 1999 with at least nine plastic beer bottle programs underway (*19)*. Bottling beer in plastic is difficult due to beer's extreme sensitivity to light and oxygen. Converting beer bottling from glass to PET requires a barrier against carbon dioxide egress and oxygen ingress, while retaining clarity and strength. Beer in bottles requires 120 days of shelf life with less than 15% loss of CO_2 and no more than 1 ppm gain of O_2 (*20*). A major obstacle is a unit cost that is much higher for barrier PET bottles compared to glass. Shifting to barrier PET bottles requires breweries and blow molders to invest heavily in new development. It is not feasible for brewers to drop PET beer bottles into glass bottle lines capable of a high-speed production at a rate of tens of thousand bottles per hour. Another obstacle is that the PET beer bottles fail when they are exposed to thermal stress and pressure at temperatures beyond 62°C, typically used for tunnel pasteurization by 80% of the world's beer filling operations. One solution is heat setting the PET to increase the crystallinity of the material during blow molding. The process produces heavier preforms and slows the process, but the resultant bottle has a thicker wall that can withstand pasteurization at 65°C. Besides a higher cost than glass and cans, one large hurdle to the growth of PET for beer is consumers' perception that beer tastes better in glass (*21*). As PET beer bottles with multi-layers may disrupt the existing monolayer PET bottle recycling stream because of the layers of nylon and PET, the amber color, aluminum cap, and metalized label, some plastic

beer bottle programs have been discontinued. Although recyclability is technically not a problem because studies demonstrated the multi-layer PET beer bottles could be recycled and reused, most recyclers still cannot economically separate the materials (*22*). Due to these complexities, use of both multi-layer and coated PET beer bottles is currently restricted to low-volume breweries, and to concerts and sporting events where there are public safety issues. The barrier PET beer bottles are not as successful as anticipated, but blow molders remain confident that the PET beer bottle will re-emerge in the future. Blow molders are shifting their efforts toward designing barrier PET bottles for less demanding applications in juices, carbonated soft drinks, and hot-filled products.

VII. MULTI-LAYER STRUCTURES

Multi-layer food packaging structures have been used for many decades. Ethylene vinyl alcohol (EVOH) co-extruded with polypropylene (PP) was commonly used in the 1970s. As demand for bottle transparency increased, co-injection blow molding of polyester (PET) with EVOH was developed during the 1990s. However, clarity improvement of multi-layer PP containers is still emerging. Pechiney Plastic Packaging, Inc. (PPPI) has developed a family of PP barrier containers that are claimed to be as clear as multi-layer PET bottles, and to be a cost-effective alternative to multi-layer PET bottles. The three-layer (PP/EVOH/PP) barrier containers are made using modified reheat stretch-blow mold machines (*23*). Today, PET and PP are competing to determine which of these two base polymers, with other barriers, will dominate the barrier plastic bottle market (*24*).

Multi-layer structures are far more prevalent than coatings and account for about 70% of barrier PET bottles (*25*). The technology has succeeded for a decade in the PET ketchup bottle. It is claimed that the multi-layer PET food bottle is the optimal solution in barrier performance, functionality, and cost. Higher productivity currently favors multi-layer preform co-injection systems over coatings. Multi-layer containers can be engineered to survive pasteurization successfully by new bottle design features, processing techniques, and materials modifications.

In a multi-layer structure, a core layer or layers containing higher priced barrier materials are sandwiched by PET structural layers. There are several five-layer PET bottles designed for beverages. A five-layer PET bottle is used for Reallife® line of new-age beverages, non-carbonated flavors. The bottle incorporates virgin PET, EVOH for barrier properties, and post-consumer recycled (PCR) resin within the five-layer structure (virgin PET/EVOH/PCR-PET/EVOH/virgin PET); no adhesives or tie layers are used. Two thin layers of EVOH provide the necessary barrier (*26*). Instead of EVOH, MXD6 is used in a five-layer structure (virgin PET/MXD6/virgin or PCR-PET/MXD6/virgin PET) for Coca-Cola bottles (*27*). Continental PET Technologies supplies a five-layer structure (PET/O_2 scanvenger/PET/O_2 scavenger/PET) single-serve PET bottle for Miller beer (*28*). Krones has developed a five-layer structure (PET/nylon 6/PET/nylon 6/PET) PET beer bottle for a Swiss brewery, while Bass developed a multi-layer (PET/EVOH/PET) PET bottle for Carlsberg Black Label beer.

A. Sealica

Tetra Pak's patented two-stage process, Sealica, was developed for molding a multi-layer PET preform using a new thermoplastic epoxy barrier resin called Blox from Dow Plastics (*20*). Blox is a resin made by the reaction of resorcinol diglycidyl ether (RDGE), a resorcinol derivative used extensively in high performance composites, with monoethanolamine to yield extreme barrier performance (*29*). The preforms are injection molded using less PET, only 60–70% as thick as normal, and subsequently they are overmolded using a thermoplastic barrier material that fills the remaining 30–40% of the preform cavity. The other half of the mold and its cavities are then injected with PET to complete the molding process. The thickness of the barrier can be adjusted to suit the application.

The multi-layer approach is using promising new barrier materials such as nylon-based nanocomposites and passive-active barrier systems. The latter are dual use of a passive barrier material and an active oxygen scavenger that blocks oxygen entry and absorbs this gas from headspace and content.

B. Nylon-Based Nanocomposites

Nanocor in alliance with Mitsubishi Gas Chemical has melt-compounded its own nanoclay additives with MXD6 nylon for making nanocomposite (M9) for use in barrier PET bottles and films. M9 nanocomposite is claimed to improve the CO_2 and O_2 barrier of standard MXD6 by 50% and 75%, respectively, while retaining high clarity and delamination resistance equal to standard MXD6 (*25*). A three-layer (PET/M9/PET) structure extends the shelf life of beer to 110 days in the US and 180 days in Europe. The structure uses a thinner M9 layer than if plain MDX6 were used; this provides a cost saving for a processor even though M9 costs more than MXD6.

Honeywell developed several nylon 6-based nanocomposites, Aegis products, to cover the full spectrum of high barrier food bottles and film applications. Aegis products are reactor-made or melt-compounded blends of nylon 6 with low levels (2%) of nanoclay platelets (*25*). The platelets act as a tortuous path barrier to CO_2 and O_2 gases. To improve the O_2 barrier to the level of glass, Honeywell uses a proprietary oxygen scavenger that involves a polydiene entity dispersed in the nylon 6 without impairing the matrix properties. Aegis OX is a nanocomposite grade that

contains the O_2 scavenger, offering sufficient passive and active CO_2 and O_2 barriers to protect beer. Aegis CSD and HFX are grades optimized for carbonated soft drinks and hot-filled foods, respectively. Aegis CSD extends the shelf life of carbonated soft drinks in 0.5 L containers from 9 to 14–16 weeks. Aegis HFX is a passive-active system that provides a greater O_2 resistance for foods. Both grades also have improved delamination resistance.

C. Passive-Active Barrier Systems

Use of an oxygen scavenger in multilayer packaging is emerging.

1. SurShield Barrier

Owen Illinois has developed a patented process, SurShot, for co-injection molding a patented five-layer plastic bottle for beer (*30*). The outer, middle, and inner layers of the bottles are made of virgin PET. Sandwiched between them are two layers of proprietary passive-active barrier material, SurShield. This barrier system includes MXD6 nylon and an oxygen scavenger in two super-thin layers sandwiched between outer PET layers and a core layer incorporating up to 35% recyclate (*25*). This structure is claimed to improve the CO_2 barrier up by 40%. The bottles are designed for food applications from ketchup to beer.

2. Oxbar Barrier

Developed by Constar International, this uses a three-layer structure with a barrier layer of MDX6 nylon and O_2 scavenger (*25*). This passive-active barrier system is aimed at juices, flavored alcoholic beverages, hot-filled foods, and beer. The Constar bottles are claimed to survive tunnel pasteurization by using extended necks that expand to relieve pressure and base designs that retain shape and strength.

VIII. SURFACE COATING TECHNOLOGIES

Coating basic plastic structures is not new, but the materials and application methods used to achieve desired properties are. Plastic bottle coating technology is evolving. PVDC coating of polyester bottles exists commercially but its use has been slow because there are too many economic issues and environmental concerns, especially in Europe.

A surface coating can be applied to a PET bottle to improve gas barriers. The coating technologies apply a super thin barrier to one surface of a monolayer PET bottle. Coating systems use monolayer PET bottles for their economies, but require costly equipment for integration into complex, high speed filling-capping-labeling lines. Coatings are less prevalent than multi-layer structures because they offer an intermediate barrier and cannot give the barrier of a multi-layer (*31*). However, coated bottles have advantages. They are less expensive on a per bottle basis than the multi-layer ones. Coatings can be applied by end users. Coated bottles that use only one resin are considered far easier to recycle than multi-layers ones. They are less likely to delaminate during handling, avoiding problems in material handling in retail venues like vending machines. Several barrier-coating technologies are available and differ by the type of coating materials, coating placement (interior or exterior), and application method.

Methods for increasing barrier properties in packaging while reducing material use by applying a microscopic layer of silicon on film emerged in the 1990s (*32*). These methods were achieved by coating or by vacuum or plasma deposition on a substrate, and then sandwiching the silicon for protection in a laminated structure. The silicon layer acts almost as a glass-like barrier. Lawson Mardon Packaging Inc. claimed that silicon monoxide (SiO_x)-coated ceramic films yield substantial reductions in oxygen and water vapor permeation. Because the silicon coating is so thin (400–1000 angstroms), recyclability of the films is not an issue. When used in appropriate laminates, the SiO_x barrier maintains a high degree of flex-crack resistance. Silicon coatings can be applied on PET films for retortable and nonretortable laminates, and on other plastics including PP, PS, and polyamide (PA). Applications for films include pouches for dry foods, and liquid and high-moisture content foods. Another process pioneered by AIRCO and PC Materials, Inc. uses a low temperature (40–50°C) plasma-deposition process that applies silica under a low or soft vacuum (750 milli-torr range). The system is a batch, air-vacuum-air process that produces a coating less than 40 nanometers thick. The low-vacuum nature of the process puts less thermal stress on substrates and reduces wear on the coating chamber. Another silicon-oxide QLF (quartz-like-film) barrier coating for films of PET, oriented PP, LDPE, or biaxially oriented nylon was developed by BOC Coating Technology (*33*). QLF coatings are applied in a low temperature, plasma-enhanced chemical vapor deposition (PECVD) process. The clear, colorless silica coatings are only 20–40 nanometers; it is claimed that they improve the O_2 barrier by 120-fold and the moisture barrier by 45 fold of 12.5 micron PET films. These developments have led to the current technology called plasma-enhanced chemical vapor deposition (PECVD). PECVD is most commonly employed to apply silicon oxide barrier coatings on films, sheets, and bottles. The process applies a microscopically thin (40–60 nanometers thick) layer of silicon oxide on plastic surfaces. Under a low vacuum, a silicon containing chemical such as silane, i.e., hexamethyl disiloxane (HMDSO), is exposed to microwave or radiofrequency energy to convert it to a plasma (*34*). The silicon oxide bonds to the plastic and creates a coating that blocks the permeation of gases, water vapor and flavor. Plasma coating may be applied using carbon or silicon oxide on interior or exterior surfaces of packaging.

A. Interior Coating of PET Bottles

1. Actis (Amorphous Carbon Treatment on Internal Surface)

Sidel developed the Actis cold plasma technology that was originally aimed for beer containers. The process uses acetylene gas as a source of carbon coating. The gas is excited by a microwave-assisted process into plasma, which deposits a layer of hydrogenated amorphous carbon about 100 nanometers thick on the bottle's interior. Actis is claimed to improve the CO_2 barrier seven-fold and the O_2 barrier thirty-fold. It reduces acetaldehyde migration to one-sixth of normal (*19).* The Actis system is a stand-alone rotary-style coating machine and offers an advantage over multi-layer structure machine. Actis Lite is a new Actis system designed for less demanding juice, CSD, and hot-filled applications. Actis-treated bottles have a light amber color, providing some UV protection for beer packaging (*35*). Actis coated bottles cost ca. 20% less than multi-layer PET bottles with comparable barriers. Actis received a letter of non-objection from the FDA for beverage contact and commercial application for Mountain Dew's Code Red product to prolong CO_2 retention.

2. Plasma Nano Shield (PNS)

PNS was formally called Diamond-Like-Coating (DLC), was developed by Kirin/Mitsubishi of Japan. The process uses a radiofrequency source plus internal and external electrodes to ionize the gas to produce a coating 20–40 nanometers thick on the internal surface of PET bottles (*34)*. The coating offers an excellent gas and water vapor barrier. Coated bottles outperform PEN bottles in reduced color and flavor sorption and may be refillable (*15*).

3. Glaskin

Tetra Pak developed Glaskin, a silicon-dioxide plasma-coating system for the interior of PET bottles. The coating is created by reacting hexamethyl disiloxane with oxygen (*34*). Microwave energy is used to excite a gas, depositing a thin (10–20 nanometers), clear layer of silicon oxide, essentially glass, on the bottle's interior wall. It is claimed to deliver CO_2 and O_2 barriers equal to glass. The coating is elastic and ensures barrier integrity with crack resistance despite expansion and contraction during the bottle filling operation. It is designed for beer, juice, carbonated soft drink, and hot-fill applications. It delivers 4–12 months of shelf life for beer and juice (*29*) with excellent flavor retention *(28)*.

4. Plasmax

SIG Corpoplast and Schott HiCotec developed Plasmax, which is another silicone oxide (SiO_x) coating system for the interior of PET bottles. The process is based on the plasma impulse chemical vapor deposition (PICVD) technology of Scott HiCotec (*36*). The technology uses a pulsed, cold plasma process that deposits a thin-layer (0.01–1.0 microns thick) of silicon oxide on the interior of PET bottles. The process occurs in a vacuum chamber, where the bottles are held neck down. The bottles are filled with gaseous hexamethyl disiloxane, and are microwaved to decompose this gaseous precursor to form a deposit of SiO_x on the bottle. Byproducts, CO_2 and water, are removed by the vacuum system. The application process uses a rotary coater that enables the system to be integrated into end users' filling line. A transparent adhesive layer is applied before the coating cycle, allowing for good bonding of the barrier layer to the interior wall of the bottle even in case of asymmetrical or other complex bottles shapes. The process creates a barrier to O_2, CO_2, moisture, and chemicals. The SiO_x layer is claimed to improve the oxygen barrier more than ten-fold, and the CO_2 barrier more than seven-fold.

B. External Coating of PET Bottles

Instead of internal coating, an exterior coating can be applied to the PET bottles.

1. Bairocade

The Bairocade system was developed and is supplied by PPG Industries. It is an epoxy-amine coating applied by electrostatic spray, and cured in an infrared oven to thermoset the material on the exterior of the PET bottles. The cross-linked, 1–6 micron thick coating is glossy, offers excellent O_2 and CO_2 barriers, and survives pasteurization (*25*). It is claimed that the shelf life of certain products can be tripled. The coating's lubricity facilitates the treatment of tens of thousands of bottles per hour in a continuous operation. The coating can be removed by aqueous cleaners commonly used in washing reclaimed PET bottle flake. The system can color the clear coating such as amber for beer. Bairocade bottles are currently used most often in hot-filled applications. The technology allows end users to create the barrier for desired shelf life via coating thickness in a range of 6–8 microns, which will increase by 3–5 times the barrier compared to the untreated PET bottles (*37*). It comes in three formulations: 1) one for carbonated soft drinks that keeps CO_2 inside the bottle, 2) one for juice that keeps O_2 outside the bottle, and 3) one for beer that prevents egress of CO_2 and ingress of O_2. Graham Packaging uses the coating on 12- to 20-oz juice bottles. Pepsi uses the coating on single serve CSD bottles sold in Saudi Arabia.

2. BestPET

The process was co-developed by Krones in cooperation with user Coca-Cola. The system uses an energy-intensive

evaporative process to generate ions of silicone-oxide (glass) that coat the exterior of PET bottles for CSD (*34*). This glass coating is claimed to retain good clarity while improving CO_2 and O_2 barriers. A new BestPET Plus version has a topcoat to protect the outside glass coating, and is used for single serve CSD, juice, beer and hot-fill containers.

3. Combustion Chemical Vapor Deposition (CCVD)

The process was developed by Micro-Coating Technologies. CCVD is a new coating system. It is an open-atmosphere, flame-based system that deposits a thin coating made of several organic or inorganic materials onto the exterior of cans, plastic bottles, or films (*34*). Plastic surfaces do not require pre-treatment to achieve an adhesion that is better than conventional plasma deposition. The process atomizes a low vapor pressure coating solution that contains the precursors into a mist in a flame, where they are combusted to generate the coating material. Heat from the flame provides the energy to evaporate the mists and for the precursors to react and to deposit the vapor on the package material substrate, to dry and simultaneously to cure. Exposure time to the flame is so short that no significant increase of substrate temperature is observed. It is claimed to be simpler to operate, have lower cost per bottle, and be more environmentally friendly than other coating systems. CCVD coatings can be thinner to achieve the same barrier as alternative technologies, and improve CO_2 and O_2 barrier properties without impairing clarity. The company's organic coating is adequately flexible to resist much more physical abuse in packaging and distribution than the conventional silica coating.

Markets for barrier coatings include various types of beverages. Carbonated soft drinks currently using monolayer PET bottles represents one of biggest potential markets for coated PET. Soft drink bottlers have two potential advantages when using coated bottles: increased shelf life and decreased material cost. With coatings, the potential exists for downgauging of monolayer PET. If the total saving from downgauging are more than the cost of coatings, the bottlers will use coatings. Another major market for coated PET bottles is beer. Unlike multi-layer structures, interior coatings provide the protective barrier next to the product. Several European brewers have used barrier coating systems including Actis and Glaskin. The coated PET bottles can also be used with other demanding beverages such as nutraceutical or healthy drinks, which are emerging.

IX. OUTLOOK FOR FOOD PACKAGING

Food packaging technology and food package design have rapidly evolved since the 1950s and 1960s when new container alternatives, including flexible packages and new decorating methods, became part of the packaging choices (*38*). Food package design is becoming a focus for branding, the consumer, and public health. Use of multiple-color printing on all package surfaces has increased to improve a marketer's shelf visibility. The development of healthier foods and nutraceuticals is emerging in response to the consumer demand.

There are several reasons for designing a new package, but the main one is for a new food product. A company uses packaging to introduce new products, as well as to give a new life to the company's existing brand products. Packages are redesigned to meet the changing needs of the target consumer group. Today the number one need driving new designs for food products is convenience, for preparation and consumption either at home and/or at work. Consumers want products that are easy to handle and quick to prepare. Many food packages designed for convenience are using barrier packaging systems (39). Technical aspects of barrier packaging systems are related to the type of processing, including hot filling, retorting, aseptic, and controlled atmosphere package and modified atmosphere package (CAP-MAP). A hot-fillable, heat set PET container is an innovative wide-mouth jar. The jar incorporates an easy-grip pinched-in middle to aid pouring, thus allows the container to withstand the vacuum generated as the hot product cools after filling (*40*). MAP is used with ready-to-eat salad mixtures for the consumer who has neither time nor patience to wash and chop salad ingredients. Borden Foods has launched the first shelf-stable cooked pasta that eliminates the need for refrigeration or freezer storage, and requires minimal preparation and cooking time. The pasta is contained in a rotary thermoformed, polypropylene tray sealed with clear, peelable lidstock that holds pouches of cooked pasta and tomato sauce (*39*). Both pouches use the same clear barrier material. This barrier structure and Borden's proprietary processing techniques yield a nine-month shelf life. For the vending channel, Welch Foods has launched 16-ounce bottles for white grape, grape, and 100% apple juices as the first commercial applications of an epoxy/amide barrier coating (Bairocade), which doubles product shelf life compared to monolayer PET. Del Monte Foods developed shelf-stable, ready-to-eat fruits called Fruit To-Go. The fruit is packaged in a clear, 4-oz. plastic cup that is flushed with a mixture of gases and provides up to an 18-month shelf life when stored at room temperature. The fruit is cold-filled and then retorted in a package made of polypropylene to provide heat resistance during retorting, while ethylene vinyl alcohol in the package acts as an oxygen-barrier layer to help maintain product quality and safety.

Innovations in all food package designs must fulfill the basic requirements: to hold the food being contained and provide suitable protection to the food, to offer suitable functional barriers to the permeation of gases and vapors

that cause deterioration of the food, and to be user friendly (ease in opening the package while being tampering-proof). Companies have a significant interest in improving their food products. Like food products themselves, packaging materials are constantly evolving to meet the latest demands of the marketplace. New packaging materials as well as new packaging techniques that offer optimal barrier properties will definitely help the companies meet the challenge of keeping products fresh and extending their shelf life. Trends predict expansion and a promising market for evolving technologies including new barrier resins and oxygen scavengers, low-cost surface coatings, and high-output multilayer PET preforms molding systems (*25*).

131 Food Packaging: Plastics

Susan E.M. Selke
School of Packaging, Michigan State University

CONTENTS

I. INTRODUCTION

Use of plastics as packaging materials has grown rapidly during the last several decades (Figure 131.1) (1). The development of new plastic resins and the combination of resins in multilayer structures has allowed plastics to substitute for glass and metal, in particular, in a variety of applications. Such changes generally result in smaller and lighter packages that take less space and consume less energy in manufacture, storage, and distribution. Plastics have also substituted for paper in a significant number of applications. In other cases, a combination of paper and plastics, sometimes with aluminum foil as well, has replaced glass or metal. The area of flexible packaging has been a major source of growth for the use of plastics. However, plastics are certainly not confined to such uses. Plastic is also used in crates, boxes, and trays where it usually substitutes for corrugated board, and in pallets where it substitutes for wood. Plastic bottles, drums, and other containers are also widely used.

The focus of this chapter is on the use of plastics for food packaging, and our concentration therefore will be on the primary package — the package that directly contacts the food. First, we will discuss the properties and food-related uses of some of the major packaging plastics. Common plastics additives will be covered briefly. The major processing methods for forming plastic resins into food packages will also be described. For many food products, the barrier ability of the package, especially to water and oxygen, is critical, so we will also discuss package permeability and its relationship to product shelf life.

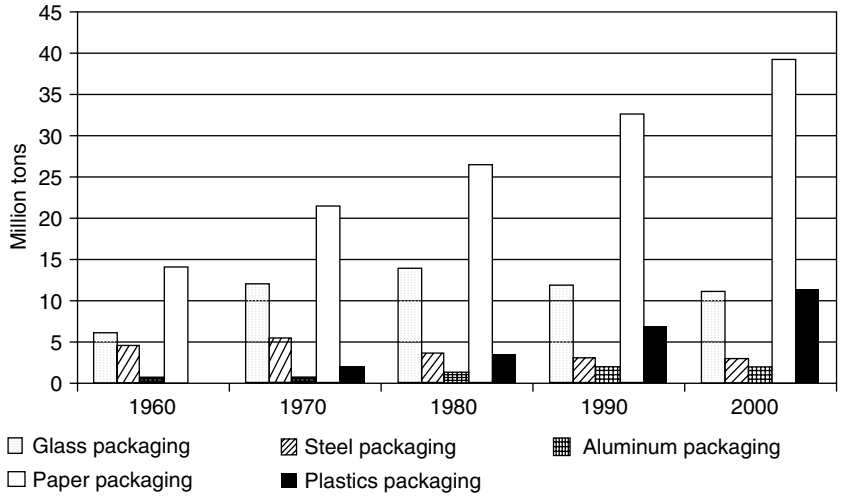

FIGURE 131.1 Packaging material use in the United States (1).

II. BASIC PLASTIC STRUCTURE AND PROPERTIES

Plastics are characterized by being formed by the joining together of small building-block molecules (monomers) into a large chain-like or network structure, in the process known as polymerization. At some point in their manufacture, plastics are capable of being deformed by a combination of heat and pressure. Most of the plastics we use in packaging are thermoplastics, which can be repeatedly softened by the application of heat, and hardened by cooling (think of melting and cooling butter). Most thermoplastics used in packaging are linear, although some branched polymers (low density polyethylene, for example) are very important packaging materials.

A few packaging plastics are thermosets. These plastics undergo a chemical reaction when they are heated, in a process known as curing, which forms them into a network structure, usually three-dimensional, resulting in extremely large molecules, which are no longer capable of flow. These materials cannot be softened and melted once cured (think of cooking an egg). Thermosets are found primarily in can coatings (although some coatings are thermoplastics), and occasionally in rigid closures (although the vast majority of closures are thermoplastics). Because of the preponderant position of thermoplastics in food packaging, we will concentrate on this category of plastics.

Plastics that are formed from only one type of monomer, and hence have a regular repeating unit in their structure, are called homopolymers. Polymers that are formed from more than one type of monomer, so that the units that make up the molecule differ from place to place in the structure, are called copolymers. Copolymerization is used fairly widely as a way to alter the properties of the basic polymer, to fit its performance to application requirements.

Another categorization of plastics is as addition or condensation polymers. In addition (or chain-growth) polymers, generally the whole monomer is added into the polymer structure. The monomers usually have double bonds, and the "opening" of the double bonds allows the monomers to join together in a chain. Condensation (or stepwise-growth) polymers are formed by more "ordinary" chemical reactions such as those between acids and amines, or acids and alcohols, in which a small by-product molecule is eliminated in each step. Despite the definitions of homopolymers and copolymers above, the majority of condensation polymers are made from two different monomers, each containing two identical functional (reactive) groups. Because this results in a polymer with a single repeating unit (formed by the reaction of one type of group with the other and the elimination of the byproduct molecule), these are generally classified as homopolymers. A condensation polymer that is considered a copolymer will be formed from three or more different monomers, so that there are differences between the repeating units.

The processes we use for forming plastics depend, for the most part, on our ability to melt the materials and shape them as desired. An important characteristic of plastics in this regard is their viscoelasticity. Viscoelasticity can be thought of as a plastic's tendency to exhibit viscous flow behavior, characteristic of a liquid, and elasticity, characteristic of a solid, at the same time. In many plastics forming processes, we depend on the ability of a plastic to "hold together" when it flows (melt strength), so that we can shape it in the desired manner while it is in or near a liquid state. At the same time, this flowing plastic has "elastic memory" so that when we remove the deforming force, there is often a response by the plastic to return partially to the shape and dimensions it had before we exerted that force. In the solid state, viscoelasticity is responsible

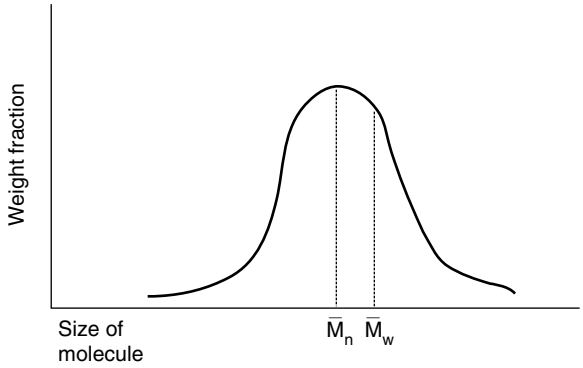

FIGURE 131.2 Example of a molecular weight distribution. $\overline{M}_n$ is the number average molecular weight; $\overline{M}_w$ is the weight average molecular weight.

for our ability to deform the plastic to such an extent that we get limited "flow" of the molecules, resulting in permanent deformation of the plastic, allowing us to modify its shape. Here, too, when the force producing the deformation is removed, we will get an elastic response from the plastic that removes some of the deformation we have imposed. Plastics generally are also characterized by having a viscosity that depends on flow rate, not just on temperature. In other words, they are non-Newtonian fluids. The viscosity of most plastics decreases as the rate of flow (or more accurately of shear) increases.

Another important point about plastics is that many of their properties are influenced by their molecular weight. Unlike materials made up of ordinary small molecules, such as sugar, a plastic resin will contain molecules that differ in size. Whenever we talk about the molecular weight of a polymer, we really mean the average molecular weight. To further complicate matters, these averages can be calculated in different ways, with some being more closely related to certain performance variables than others. Often, we use a viscosity-average molecular weight, $\overline{M}_v$ or $\overline{M}_\eta$, because it is the easiest to determine, and is reasonably closely related to the performance properties of interest for packaging applications. This average is closely related to the weight average molecular weight, $\overline{M}_w$, and is often used to approximate it. In general, when the average molecular weight of a plastic increases, its strength, stiffness, and other mechanical properties improve, while its resistance to flow (its viscosity) increases, as does its cost. Processing is easier for materials with lower viscosity (as long as viscosity is not too low). Therefore, users often must compromise between performance of the finished material and cost and ease of processing.

The behavior of a plastic resin is influenced by its molecular weight distribution, as well as its molecular weight average. Molecular weight distribution (Figure 131.2) refers to the range of sizes of molecules found in the plastic resin. Small molecules contribute to decreased viscosity by, in essence, "lubricating" flow. Large molecules contribute to strength. The proportion of smaller and larger molecules and how much they differ from the average affects performance in much the same ways as does the molecular weight average. Distributions can be characterized as narrow or wide. Polymers with narrow molecular weight distributions tend to have higher strength and other mechanical properties, along with higher viscosity (and cost) compared to polymers with wide distributions. While normally molecular weight distributions approximate the classical normal distribution bell-shaped curve, some polymer resins, typically formed by combining two or more batches of the basic polymer, have bimodal distributions. This is one way to better optimize the mix of mechanical and flow properties of the resin for a particular application.

Plastics can be characterized as crystalline or amorphous. Crystallinity implies the arrangement of molecules (or parts of molecules) in a regular repeating pattern. While materials composed of small molecules such as salt and sugar can be totally crystalline, because of the large size of the molecules in plastics, it is not possible to totally crystallize the material. Thus a crystalline plastic is characterized by crystalline regions linked together by non-crystalline (amorphous) regions. When we refer to a plastic as crystalline, therefore, we mean that it has some significant degree of crystallinity. We classify as amorphous plastics that have no significant crystallinity.

Another difference between plastics and materials composed of small molecules is their melting behavior. While materials such as water melt at a precise temperature, polymers do not. In fact, if a polymer is amorphous, the softening as temperature increases is so gradual that we are unable to clearly distinguish between solid and liquid. Therefore, for amorphous plastics, the melting temperature is not defined. For crystalline plastics, we define the melting temperature as the temperature at which the crystallites (small crystalline regions) break up. Since the size of the crystallites influences how much energy (and therefore what temperature) is required to disrupt the structure, and since the size of the crystallites inside a given plastic resin varies, crystalline plastics melt over a narrow range of temperature, rather than at a precise point. The ability of a polymer to crystallize is determined by its chemical structure. To arrange in a regular repeating order, there has to be a degree of orderliness of the underlying structure. Therefore, some polymers cannot crystallize. If the structure permits crystallization, the way a plastic is processed can have a profound impact on the amount of crystallinity that actually develops. Plastics can crystallize only over a certain temperature range, and the rearrangement of molecules into a crystalline array takes time. If a polymer is cooled rapidly to a temperature below the lower limit for crystallization, it may not develop any significant crystallinity, while the same plastic resin, cooled more slowly, may be highly crystalline. Another factor is that growth of crystals

depends on initiation (nucleation). Think of a supersaturated salt solution that has no crystals. If a seed crystal is dropped into the solution, all at once there can be massive crystallization. Similarly, providing sites that facilitate crystal formation (adding nucleating agents) results in more rapid crystallization.

Another important temperature for understanding polymer behavior is the glass transition temperature, T_g. If a plastic is below its glass transition temperature, it tends to behave like a stiff, brittle material, while above its T_g, it tends to behave like a soft, flexible material. The T_g of a plastic, therefore, serves as a guide to its behavior at any given temperature. All thermoplastics are stiff and brittle if they are cold enough, and soft and flexible if they are warm enough — but the temperatures at which this behavior occurs vary widely.

One important consequence of a change in molecular weight or molecular weight distribution is its effect on melting temperature, and in particular on sealing temperature and sealing temperature range. Polymers with a narrower molecular weight distribution tend to soften and flow (melt) over a narrower range of temperatures. Polymers with a higher average molecular weight tend to soften and flow (melt) at a higher temperature. Since heat sealing fundamentally depends on the flow of molecules, or parts of molecules, from one layer into the adjoining layer, the differences in melting temperature influence the temperature required to produce a seal. At the same time, if the plastic gets too hot, there will be too much flow, resulting in weakening of the material, or even the development of holes. Therefore, if the heat seal range is narrow, greater control over the sealing temperature is required to ensure that it does not deviate too far from the optimum value.

Rather than specifying molecular weight average, molecular weight distribution, or even viscosity, plastic resins are often characterized by their melt index (or melt flow index). The melt index refers to the amount of plastic that will flow through a small orifice of a prescribed size under specified temperature and pressure conditions. Therefore, it is an indirect measure of viscosity; a high viscosity (resistance to flow) means a low melt index, and vice versa. The units normally used for melt index are g/10 min. Plastic resins are often available with a wide variety of melt index. For example, high density polyethylene (HDPE) resins used for milk bottles typically have a melt index of less than one, often in the 0.5 to 0.7 range. HDPE resins are even available that have a melt index of 0 at the usual conditions, so must be subjected to higher pressure to get a measurable value (the result is referred to as a high load melt index). An HDPE resin used for injection-molded margarine tubs, on the other hand, would likely have a melt index of at least 4, and maybe even 90 or so. As would be expected, a high melt index is associated with a wide molecular weight distribution and with a low average molecular weight (low viscosity), and vice versa.

Polyvinyl chloride (PVC)	3	V
Low density polyethylene (LDPE and LLDPE)	4	LDPE
Polypropylene (PP)	5	PP
Polystyrene	6	PS
Other plastics, including multilayer	7	OTHER

III. PLASTICS COMMONLY USED IN FOOD PACKAGING

The most-used packaging plastics, by far, are high density polyethylene (HDPE) and low density polyethylene (LDPE) (Figure 131.3). Polyethylene terephthalate (PET), polypropylene (PP), polystyrene (PS), and polyvinyl chloride (PVC) are considered the other major packaging plastics. A number of other plastics are used in smaller quantities, for specialty applications or as one component in a multi-resin structure. Important examples include ethylene vinyl alcohol (EVOH), polyvinylidene chloride copolymers (PVDC), nylons, polycarbonate, ionomers, and ethylene vinyl acetate (EVA).

In most states, plastic bottles 16 oz. and larger, and other plastic containers 8 oz. and larger, are required to be marked with their resin type, using the Society of the Plastics Industry (SPI) coding symbol. This symbol consists of a triangle formed by three chasing arrows, with a number inside and a letter code below the triangle. Table 131.1 shows the letters and codes used for the various types of resins used for plastic containers.

A. High Density Polyethylene

High density polyethylene (HDPE) is an addition polymer of ethylene, with a predominantly linear structure that can be represented as $-(CH_2-CH_2)_n-$. The few branches that it contains are short, and do not much influence its properties. Polyethylene has a T_g of about $-120°C$ (estimates vary, for reasons too complex to go into here). Therefore, at the vast majority of use temperatures, HDPE is in the soft, flexible range of behavior. The density of HDPE is actually quite low, about 0.94–0.97 g/cm^3, less than water. It is characterized as high density polyethylene only because its density is higher than that of low density polyethylene, which will be discussed next.

The melting temperature, T_m, of HDPE is also relatively low, at about 128–138°C. Therefore, a characteristic of HDPE is that it maintains its flexibility well at cold temperatures, such as those used for frozen food, but it is too soft to be used for hot-filled products. As the existence of a T_m implies, HDPE is a crystalline plastic. It is able to crystallize over a wide range of temperatures, and generally is 65–90% crystalline. The crystallinity and density of polymers are correlated, as crystalline regions pack a larger number of atoms (and therefore higher mass) into a unit volume of space than do amorphous regions, with their greater degree of disorder.

HDPE has excellent chemical and oil resistance. It is a good water vapor barrier, but a poor barrier to gases such as oxygen and carbon dioxide. Its transparency is poor. For the most part, crystalline polymers tend to have inferior transparency to amorphous polymers, as the crystallites tend to scatter light, interfering with its transmission.

The largest use of HDPE is in containers, especially bottles, although it is also used in film. Its single most common use is for plastic milk bottles. The hazy appearance of these bottles is an example of HDPE's natural appearance. For many applications, HDPE is pigmented, making the containers opaque. This can be done to provide protection for the product against light-induced degradation, or for marketing reasons, to make the container, and hence the product, more attractive.

HDPE is produced by polymerization at moderate temperatures and pressures, using a catalyst to facilitate the reaction. The traditional catalyst systems are in the Ziegler-Natta family. In recent years, there has been increasing use of a new catalyst family, metallocenes. These are capable of providing plastic resins with a narrower and more controllable molecular weight distribution, as well as having other desirable attributes.

B. Low Density Polyethylene

Low density polyethylene (LDPE) is also an addition polymer of ethylene (C_2H_4), but it is polymerized at high temperature and pressure, resulting in a polymer with a highly branched structure, containing both long and short branches (Figure 131.4). While its T_g is the same as HDPE, it is softer and more flexible because of its lower crystallinity, 40–60%. This also gives it better transparency, although it still has a significant degree of haze. Like HPDE, it has excellent oil and chemical resistance, and it is a reasonably good water vapor barrier. Its barrier properties are inferior to HDPE, however. Permeation occurs almost exclusively through the amorphous areas in a polymer, as the crystallites do not have wide enough spacing between polymer molecules to allow the passage of the permeant molecules. Therefore, if other factors are the same, plastics with higher crystallinity will be better barriers.

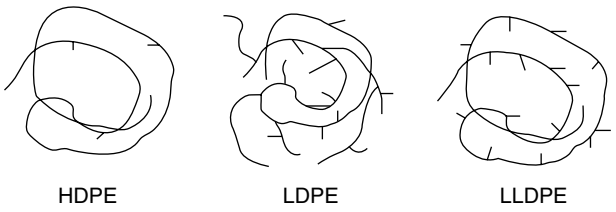

FIGURE 131.4 Illustrations of the structure of HDPE, LDPE, and LLDPE.

LDPE tends to have lower tensile strength than HDPE, but higher impact strength. Tensile strength is increased by HDPE's increased crystallinity, since the crystallites resist both deformation and fracture. On the other hand, impact strength is strongly affected by the ability of the polymer molecules to rearrange without fracture, and in doing so absorb the impact energy. This is facilitated by a greater preponderance of amorphous regions, since the crystallites have very little ability to rearrange without producing fracture.

Applications for LDPE range from stretch wrap for pallet loads of products to bread bags to squeezable drink bottles, but are predominantly in the area of flexible packaging. A common household food bag illustrates the somewhat hazy appearance of LDPE. LDPE is also found in many multimaterial food packages, where it often serves as a heat seal layer. It may also serve as a moisture barrier, or as protection against interaction or chemical attack. For example, in drink box structures, a layer of LDPE on the outside protects the printed paper from exposure to moisture and abrasion, and a layer of LDPE on the inside prevents direct contact of the aluminum foil and the product, as well as providing the ability to form the package by heat sealing. An additional layer of LDPE within the structure serves as an adhesive to bond the foil and paper into a single structure (Figure 131.5).

Discussion of LDPE is complicated somewhat by frequent grouping of the next polymer in our list, linear low density polyethylene (LLDPE), with the type of LDPE we have been discussing, using LDPE to refer to both polymers. The highly branched LDPE described here is produced by

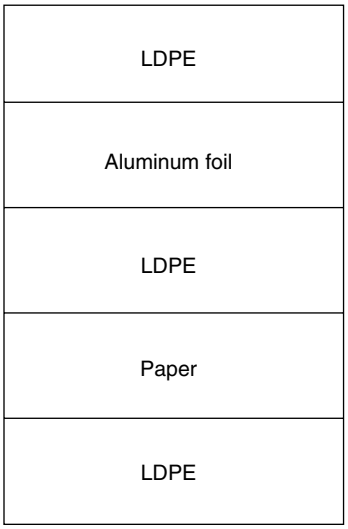

FIGURE 131.5 Structure of a package for aseptic packaging of juice drinks (juice box) (not to scale).

polymerization at high temperature and pressure, and results in the highly branched structure described, having both short and long chain branches.

C. Linear Low Density Polyethylene

Linear low density polyethylene (LLDPE) is a polymer that is formed by a process similar to that used for HDPE, polymerization at moderate temperatures and pressures, with a catalyst, resulting in an essentially linear structure. However, LLDPE has levels of crystallinity, and consequently density, in the same range as LDPE. This is possible because LLDPE is a copolymer. When LLDPE is polymerized, in addition to ethylene, either butene, hexene, or octene are introduced. Where these comonomers are present in the structure, they leave a "tail" hanging off the chain, that looks (and acts) like a short chain branch (see Figure 131.4).

The branches in LDPE cause it to have lower crystallinity than HDPE, because they interfere with the orderly arrangement of the chains — the branches don't fit into the crystal lattice. In just the same way, these side groups in LLDPE interfere with crystallization because they do not fit into the crystal lattice. Therefore, LLDPE is produced with the same range of densities, and the same proportions of crystallinity, as LDPE. The reduction in density depends on both the size and the number of the incorporated comonomer groups. However, because only one type of comonomer is generally used, all the "branches" are identical in size, and their average proportion is readily controlled by varying the amount of comonomer introduced.

The use of moderate temperatures and pressures with a catalyst also permits a greater degree of control over the breadth of the molecular weight distribution. HDPE and LLDPE, in general, have narrower molecular weight distributions than LDPE. This greater degree of uniformity, along with the lack of long chain branches, imparts some significantly different properties to LLDPE than are found in LDPE. Melting temperatures are higher by about 10–15°C, compared to LDPE of the same density. Both tensile strength and impact strength are higher, as well.

Because the comonomers used to produce LLDPE are higher priced than ethylene, LLDPE costs more per pound than LDPE. However, the improvement in performance often means that thinner LLDPE films can be used than would be required to get acceptable performance with LDPE. This downgauging means that fewer pounds of LLDPE are required to package the same amount of goods. The price per unit, as a result, is often less using LLDPE, even though the price per pound is greater. The cost savings that can be gained by using LLDPE have led to it replacing LDPE in a variety of applications.

The primary area where LLDPE is inferior to LDPE is in heat-sealing. The lower melting temperatures of LDPE and broader molecular weight distribution mean heat-sealing temperatures can be lower, and the heat-seal range is wider. Further, entanglement of long-chain branches across the interface between materials occurs faster than entanglement of linear molecules, facilitating the rapid development of sufficient strength in the seal to permit release from the sealing mechanism, and without requiring cooling of the material (hot tack). This combination of improved mechanical properties from LLDPE and better heat seal performance from LDPE has led to these two materials being combined in many applications, either in discrete layers or as blends. Therefore, the term LDPE, as mentioned, sometimes means only the highly branched "true" LDPE, and sometimes means both LDPE and LLDPE, along with materials that are a combination of both resins.

The use of metallocene catalysts, along with other catalysts that are often characterized as "single-site" catalysts, has resulted in the production of a whole new generation of LLDPEs. When Ziegler-Natta catalysts are used, the active sites on the catalyst vary in their reactivity. Some sites produce "average" molecules. Others are not as fast at adding in new monomers to a growing chain, but tend to be relatively better at adding in the larger comonomers, so they produce, on average, smaller molecules with a higher proportion of comonomer groups. Other sites are more efficient at adding in ethylene, but less efficient at adding in comonomers, so they produce, on average, larger molecules with a lower than average proportion of comonomer groups. The "single site" catalysts have active sites that all have identical chemistry and geometry, so they are all equally reactive. Therefore, the polymers produced with these catalysts, although they still vary in molecular weight, etc., are more uniform, both in terms of size and composition, than those produced through typical Ziegler-Natta polymerization.

One other attribute of metallocene catalysts is that they are able to add in monomers that are bigger than octene, which Ziegler-Natta catalysts cannot do. By incorporating larger monomers with a double bond on one end (higher alpha-olefins), it is possible to produce linear polymers with the functional equivalent of long-chain branches. Therefore, better heat-sealing varieties of LLDPE can be produced. Of course, these higher alpha-olefins are also more costly than the smaller ones.

There are also polyethylenes, produced either with Ziegler-Natta or metallocene catalysts, that have a density lower than the range defined as low density polyethylene. These very low density polyethylenes (VLDPEs) incorporate a greater proportion of comonomer, resulting in a lower degree of crystallinity and consequently a lower density. They are used to produce very soft, flexible films, and have so far had only limited applications in food packaging.

D. Polypropylene

Polypropylene (PP) is a close relative of polyethylene, and is a linear addition polymer of propylene. Consequently it has a methyl group attached to every other carbon. While its physical structure is regular, when the molecules are looked at three-dimensionally, three different physical configurations are possible. When the carbons are stretched out in a linear fashion (the fully extended chain conformation), the methyl groups may all be on one side of the chain (isotactic), they may alternate from one side of the chain to the other (syndiotactic), or the side of the chain on which they appear may be random (atactic) (see Figure 131.6).

Although it is not obvious from the two-dimensional view, it is impossible to convert one of these configurations to another without breaking and reforming chemical bonds. If there is no pattern to the placement of the methyl groups, their presence interferes with crystallization in much the same way as does the branching in LDPE. Because the groups appear on every other carbon, this is sufficient to prevent crystallization all together. The result is that atactic PP has very poor performance properties, and is not a desirable packaging material. Fortunately, the Ziegler-Natta catalysts, as well as the metallocenes, tend to add the monomers in a way that results in a preponderantly isotactic configuration (the methyl groups all on the same side of the fully extended chain). Therefore, when we talk about PP for packaging applications (as well as for use in other products), we are almost always talking about isotactic PP, sometimes denoted iso-PP. It used to be very difficult to make syndiotactic PP, and there was little motivation to do so, since for most applications its performance is inferior to the more readily available, and less expensive, iso-PP. With the advent of metallocene catalysts, some interest has emerged in making syndiotactic PP for certain applications. Syndiotactic PP crystallizes less than iso-PP,

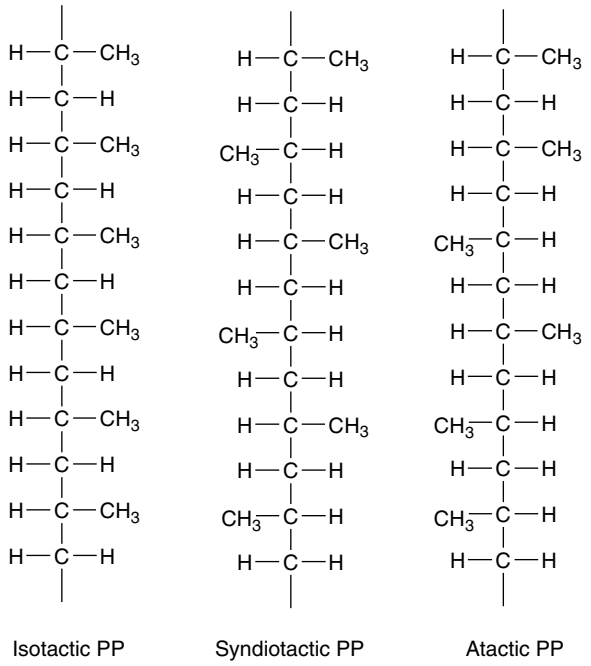

FIGURE 131.6 Illustrations of the structure of isotactic, syndiotactic, and atactic polypropylene.

thereby producing a polymer with increased flexibility and transparency.

Like its cousins in the PE family, PP tends to be chemically inert, have good grease resistance, be a good water vapor barrier, and a poor barrier to gases such as oxygen and carbon dioxide. Its melting point is significantly higher than that of HDPE, about 160–175°C. Its glass transition temperature is much higher than PE, about −10°C. Therefore, PP is significantly stiffer than HDPE. At typical frozen food temperatures, PP is very near its T_g and therefore subject to brittleness which can lead to package failure under impact, such as dropping a frozen microwaveable dinner on the floor. On the other hand, PP can be used at higher temperatures than PE without undergoing excessive deformation. In particular, hot-filling products in PP is possible. The enhanced stiffness of PP also makes it suitable for threaded closures (caps). HDPE cannot be used in such applications because, under load, it will creep too much, causing loosening of the cap and loss of sealing efficacy. PP is much less subject to such deformation, and is by far the most commonly used plastic in closures of all types.

Uses of PP in packaging are divided approximately equally between film, containers, and closures. The stiffness of PP is also an advantage in some film applications. It got its major start replacing cellophane in high-speed packaging lines such as those used for cigarettes. LDPE was too soft for such applications. PP also has better transparency than LDPE; thin PP films generally have excellent transparency.

In thicker gauges, PP often has a somewhat cloudy appearance. This can be modified by blending nucleating

agents into the film. By providing multiple sites for the initiation of crystallite growth, PP with nucleating agents tends to have a larger number of crystallites, but they are smaller, as adjacent crystallites interfere with each other's growth. These small crystallites interfere less with light transmission than larger ones, so the net result is improvement in transparency.

The tendency of PP to be brittle at cold temperatures can be alleviated in two basic ways. One common approach for film is biaxial orientation. Orientation is a process of stretching a plastic film (or container) to partially align the polymer molecules in the direction of the stretch. This tends to enhance mechanical properties and barrier by producing a greater degree of regularity in the structure. Biaxial orientation stretches the plastic in two perpendicular directions, producing alignment in the plane of the stretch. Biaxially oriented PP is called BOPP. Another way to reduce brittleness is to copolymerize propylene with a small amount of ethylene. This introduces ethylene units into the molecule, which bring with them increased flexibility, lowering the T_g of the plastic and reducing its brittleness.

E. Polyethylene Terephthalate

Polyethylene terephthalate (PET) is the plastic that has been growing in use most rapidly. Its largest use remains plastic bottles for carbonated soft drinks, but it is increasingly being used in bottles for a variety of applications, including drinking water, salad dressing, peanut butter, etc. Within the last several years, PET surpassed HDPE as the plastic most often used for bottles. PET also is used in trays, for products varying from croissants to fresh vegetables to meat. PET films and coatings are also used for food packaging applications. One of the earliest uses of PET was as a coating for ovenable paperboard, paperboard trays designed to be useable in both microwave and conventional ovens.

PET is a polyester, and a member of the condensation polymer family, and has the chemical structure shown in Figure 131.7. While there are a large number of different polyesters, products made from PET are often referred to simply as polyester. For example, polyester carpet, polyester clothing, and polyester fiberfill are all made from PET — and often incorporate PET recycled from beverage bottles.

Because condensation polymers have non-carbon atoms (oxygen, in the case of PET) in their main chain, they tend to be more susceptible to chemical reactions leading to rapid decrease in molecular weight than most addition polymers, which generally have only carbon in the main chain. In particular, PET is subject to hydrolysis when exposed to water at high temperature and shear. Therefore, it is important to keep PET dry during processing.

PET is a significantly better oxygen and carbon dioxide barrier than HDPE and PP, but not as effective as a water vapor barrier. The polar bonds in PET result in stronger intermolecular forces, which reduce permeation of non-polar

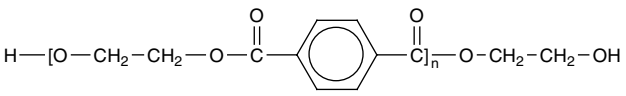

FIGURE 131.7 Polyethylene terephthalate (PET).

substances. However, they also permit greater interaction with water and other polar molecules. Most PET is biaxially oriented for improved performance. As discussed, this orientation improves both strength and barrier properties. Biaxially oriented PET bottles have sufficient CO_2 barrier to provide an adequate shelf life for carbonated soft drinks. While the O_2 barrier of PET is much better than that of HDPE and PP, it is still not sufficient to provide adequate protection for many oxygen-sensitive products, such as ketchup. The most common structure for plastic ketchup bottles, and for plastic containers of other oxygen-sensitive products, combines PET with a barrier resin, usually ethylene vinyl alcohol.

PET has a T_g of 73–80°C. Therefore, at normal use conditions it is on the stiff and brittle side of its behavior. PET is capable of crystallizing, but has a narrow temperature window for crystallization. This permits the degree of crystallinity that develops in PET to be greatly modified by changing the processing conditions. PET films and most PET containers develop only a low degree of crystallinity, with small crystallites that do not interfere substantially with light transmission, resulting in packages with excellent transparency. If increased crystallinity is desired, nucleating agents can be added to facilitate crystallization, resulting in opaque CPET (crystalline PET). Long residence time at temperatures within the crystallization range also produces an opaque white material. Some bottles designed for hot-filling have PET bodies that are transparent, but finishes (the threaded neck area that accepts the closure) that have been crystallized and are opaque white. This results in a bottle neck that is less subject to deformation during the hot-filling process, providing improved sealing.

Because typical hot-fill temperatures are near or even above its T_g, biaxially oriented PET bottles, if unmodified, can undergo a large amount of distortion during hot-filling, as some of the stresses imposed by the orientation are now able to relax. (To see an example, send an empty PET peanut butter jar through a standard dishwasher cycle.) Therefore, containers intended for hot-fill applications have to be stabilized, usually in a process known as heat-setting, where they are subjected to elevated temperature while being held in the desired shape, to allow stress relaxation without permitting deformation.

F. Polystyrene

Polystyrene (PS) is another member of the addition polymer family, with a benzene ring attached to every other carbon (Figure 131.8). Like PP, PS can be either atactic, isotactic,

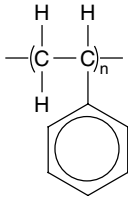

FIGURE 131.8 Polystyrene (PS).

or syndiotactic. The PS used in packaging is atactic. This lack of order in the spatial positioning of the benzene ring means that the PS molecules cannot be packed into an orderly repeating arrangement, so PS is an amorphous polymer. It has a T_g of 74–105°C, so like PET it is stiff and brittle at most use conditions. Since it is amorphous, PS has excellent transparency, but it has poor barrier properties. Transparent grades of PS are often called crystal PS. It should be noted that crystal PS is highly transparent precisely because it is not crystalline!

Despite its high T_g, PS is not suitable for high temperature applications, as it undergoes liquid flow at about 100°C.

The brittleness and low impact strength of PS is a drawback in many food packaging applications, while its relatively low cost and ease of thermoforming are assets. Two distinct approaches are commonly used to modify its brittleness. One of these is foaming. Expanded polystyrene (EPS) uses small bubbles produced by a foaming agent to reduce the density of PS, and also to provide it the ability to better absorb stress without fracture. The low thermal conductivity produced by the bubbles also makes foam PS an excellent insulating material. While the biggest application of foamed PS is as molded or loose-fill cushioning materials, it is also found in such food packaging applications as disposable cups for hot beverages, meat and produce trays, and egg cartons. Since the presence of the bubbles results in light scattering, foamed PS is opaque.

Another way to improve the impact resistance of PS is to modify it with a rubber material that has high impact strength. High impact polystyrene (HIPS) is partially a copolymer and partially a blend of PS with polybutadiene, a synthetic rubber. While HIPS, like PS, is amorphous, the presence of two phases (PS regions and butadiene regions) interferes with light transmission, making HIPS, like foam PS, opaque. Two common applications of HIPS are yogurt containers and disposable cutlery.

G. Polyvinyl Chloride

Unlike most plastic packaging materials, the use of polyvinyl chloride (PVC) in packaging has not been growing. In fact, PVC has lost a number of its packaging markets, mostly to PET. Most of these, however, were in non-food packaging. PVC is FDA-approved only for limited food packaging applications.

PVC is an addition polymer, with a basic structure similar to PP and PS, having, in this case, a chlorine atom attached to every other carbon in the main chain. PVC has a slight tendency to be syndiotactic, but its irregularity is substantial, resulting in a degree of crystallinity so slight that it is often referred to as an amorphous plastic. Because of this low crystallinity, PVC has excellent transparency, with a slight bluish cast. As PVC ages, it tends to yellow, so it is common for PVC containers to have additional blue coloration added, to mask the yellow that will eventually develop.

The T_g of unmodified PVC is 75–105°C, so it is stiff and brittle, and is a reasonably good barrier to oxygen and carbon dioxide. However, PVC used in packaging is generally modified by incorporation of plasticizer. A plasticizer is a component that acts as an internal lubricant in the plastic, getting between the polymer molecules and, by disrupting the attractions between the polymer molecules, increasing their ability to change position, thus lowering the T_g and making the plastic more flexible. PVC, because of its highly polar C-Cl bonds, has a large affinity for plasticizers, so they can be incorporated in substantial amounts. Incorporation of various amounts and types of plasticizer permits the production of a wide variety of PVC resins with significantly differing properties. One of the major uses for PVC in food packaging is in soft, highly flexible stretch films used for meat wrap, etc. In addition to increasing flexibility, incorporation of plasticizer significantly reduces barrier, so these soft PVC films are poor barriers to oxygen, carbon dioxide, etc.

Over the years, PVC has been subject to a number of attacks on environmental and health grounds. The earliest major concern was potential migration of vinyl chloride monomer (the building block for PVC and a carcinogen) into foods or beverages. Changes in production technology greatly reduced the concentration of residual monomer in containers, and hence the potential for migration. The next major concern was the potential for PVC to contribute to formation of dioxins during incineration. This held up the more widespread approval for use in food packaging that was expected following the resolution of the residual monomer problem. Currently, concerns are related primarily to the potentially harmful effects of plasticizers migrating into the package contents. Along the way, the adverse effects on quality of recycled materials from even very slight PVC contamination of recycled PET have also been a concern. Regardless of whether the concerns about PVC are reasonable or not, PVC has suffered from a relatively negative environmental and health image, and PET, with its relatively positive image, has benefited from the comparison.

H. Nylons

Nylons, or polyamides, are a family of condensation polymers made by polymerization of amines and car-

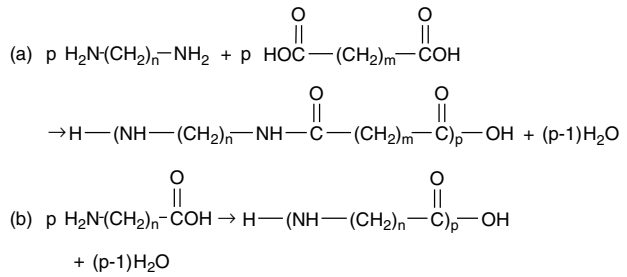

FIGURE 131.9 General scheme for polymerization of nylon: (a) from diamine and dicarboxylic acid, (b) from amino acid. If monomers are linear, structures formed by (a) are named Nylon n, (m + 2), and those formed by (b) are named Nylon (n + 1).

boxylic acids, or by polymerization of amino acids (Figure 131.9). Therefore, they contain nitrogen atoms in the main chain, and attached to the N is a hydrogen atom. This means nylons exhibit hydrogen bonding, resulting in very strong intermolecular attractions, and therefore relatively high T_g and T_m. Nylon 6, for example, has a T_g of 60°C, and a T_m of 210–220°C. The properties of nylons differ, depending on their precise chemical structure. Two of the most common nylons for packaging applications are nylon 6 and nylon 11. Both of these materials are crystalline polymers; as is the case with PET, the amount of crystallinity exhibited is strongly dependent on processing conditions. Some nylon copolymers are amorphous.

Nylons tend to have excellent strength and thermal stability, while maintaining flexibility and strength at low temperatures. They are good gas and oil barriers, and tend to be excellent barriers for odors and flavors. They do tend to be moisture sensitive, however. The combination of low temperature strength and high temperature stability of nylons allows them to be used for applications such as boil-in-bag frozen foods. Nylons are higher in cost than the more common packaging plastics, and therefore are often used in combination with other polymers, in multilayer structures, to reduce overall package cost while still benefiting from nylon's properties.

I. Polycarbonate

Polycarbonate (PC), more properly known as poly(bisphenol-A carbonate) has limited applications in food packaging, primarily due to its high cost. It is a very tough, rigid plastic, which is widely used for 5-gallon refillable water bottles. Recently, however, PET has begun to make inroads into this market. PC has also been used for refillable milk bottles, but this was never a large market and has tended to decrease over time. PC is an amorphous polymer with good impact strength, thermal stability, heat resistance, and good low temperature performance. It is a poor barrier to gases and water vapor, and has relatively poor chemical resistance to alkalis. Like PVC, polycarbonate packaging often incorporates plasticizers, some of which are under attack as hormone mimics or disruptors.

J. Ethylene Vinyl Alcohol

Ethylene vinyl alcohol (EVOH) is another plastic which has grown rapidly in use. It is, in essence, a random copolymer of ethylene and vinyl alcohol, although it is actually made by hydrolysis of ethylene vinyl acetate (EVA), as the vinyl alcohol monomer is unstable. EVOH typically contains 27 to 48 mole % ethylene units.

The O–H groups in the alcohol units of EVOH provide very strong hydrogen bonding between adjacent molecules, and in addition EVOH can crystallize. The –OH and –H groups can both fit the crystal lattice, so the irregularity of the structure does not prevent crystallization in this case. The result is a polymer that is an excellent barrier to gases such as oxygen and carbon dioxide. The most common reason for using EVOH is to take advantage of its excellent oxygen barrier properties. However, the same hydrogen bonding that makes EVOH a good O_2 barrier also makes it highly sensitive to water, and as the polymer absorbs water, its barrier properties decrease. Therefore, EVOH is almost always found in a buried inner layer in a package structure, surrounded by other plastics that can offer protection from exposure to high humidity.

Use of multilayer structures containing EVOH has permitted plastic containers to replace glass and metal in a variety of food packaging applications. The first plastic bottle for ketchup, for example, was a 6-layer structure, PP/regrind/tie/EVOH/tie/PP. The regrind layer is composed of manufacturing scrap from bottle production that is flaked and fed back into the process. The tie layers are a plastic that serves as an adhesive, bonding the EVOH and PP layers together. The current ketchup bottle structure is a 5-layer structure, PET/EVOH/PET/EVOH/PET.

The moisture sensitivity of EVOH is a particular concern for containers that are retorted, as during retorting the package is exposed to the combination of high temperature and high humidity. For such applications, structures have been developed that contain a desiccant in the tie layer, to absorb moisture that gets through the outside package layers and thereby reduce its effect on the EVOH.

K. Polyvinylidene Chloride

The other major oxygen barrier plastic is polyvinylidene chloride (PVDC). The basic structure of PVDC is similar to

PVC, except that instead of a single chlorine on every other carbon, PVDC has two chlorines on every other carbon. One consequence is that PVDC can be highly crystalline. The combination of high crystallinity and strong intermolecular attractions due to the polar C-Cl bonds makes PVDC, like EVOH, an excellent barrier. Since PVDC does not contain hydrogen bonds, however, it is an excellent barrier to water vapor as well as to oxygen, carbon dioxide, odors and flavors, etc. Further, its barrier properties are not much affected by exposure to moisture. A major drawback of PVDC is that its intermolecular forces are so strong that it is very difficult to process. In practice, PVDC must be modified by copolymerization to make it processable; PVDC homopolymers are not used. The degree and type of comonomerization affects PVDC properties, decreasing its barrier. The PVDC polymers with the highest barrier tend to be used as coatings, applied as solutions or emulsions, as they cannot be melt-processed. The melt-processable grades have somewhat poorer barrier properties. Some grades, such as PVDC used for household wrap, have been plasticized, in addition to copolymerization, and consequently their barrier properties are further reduced.

The oxygen barrier of the best PVDC resins is generally inferior to that of the best EVOH resins as long as the EVOH is relatively dry. At very high humidity, PVDC is generally superior in barrier to EVOH. More widespread use of PVDC is limited partially by its cost, and even more by processing difficulties. PVDC copolymers are quite heat sensitive (as is PVC), tending to degrade producing HCl. On the other hand, PVDC coatings on films (or containers) can significantly increase barrier as well as providing heat-sealability.

L. Ionomers

Ionomers are plastics that contain some interchain ionic bonding, most often produced by partially neutralizing ethylene/methacrylic acid or ethylene/acrylic acid copolymers with sodium or zinc bases. The percentage of acid groups is usually between 7 and 30 weight percent, and the amount of neutralization usually is between 15 and 80 percent. The unneutralized acid groups provide hydrogen bonding sites, while the salt ions provide ionic attractions, functioning much like reversible cross-links.

Ionomers, as a result, have increased strength, toughness, tensile modulus, oil resistance, and clarity. Their impact strength and puncture resistance are outstanding. Ionomers excel in difficult heat-seal applications, and are widely used in vacuum packaging of processed meats. Here, their ability to seal through contamination means excellent seals can be obtained even if there is contamination of the seal area with grease. They are also used for packaging of cheese and snack foods. The excellent hot tack of ionomers allows them to be used in form-fill-seal packaging in cases where product is delivered into a pouch before the bottom seal has completely cooled.

M. Other Polymers

Ethylene vinyl acetate is used as an adhesive, as a heat seal layer on other polymers, and as a very flexible but tough cling film. In most food applications, the vinyl acetate content is between 5 and 20 percent. Increasing the vinyl acetate content results in improvement in clarity, increased flexibility, increased impact strength, and increased adhesion.

One of the newest entries in food packaging is polymers based on lactic acid (PLA). PLA plastics tend to have properties somewhat inferior to those of PET, but have the advantage of being biodegradable and compostable. They do not yet have widespread use in food packaging, but this may change in the future.

Polyethylene naphthalate (PEN) is another member of the polyester family. Its properties in general are superior to those of PET, but its cost is much higher, which has greatly limited its use. There is, however, some use of blends and copolymers of PET and PEN, to get some of the advantages of PEN without as much of an increase in cost.

A number of other plastics are used in food packaging applications to a limited extent, because of the properties they can provide.

IV. ADDITIVES

When a plastic resin is formulated, along with the base polymer a number of other components are often added. These additives generally have some potential to migrate to the product, and consequently are regulated by FDA as indirect food additives. It is, therefore, necessary to be sure that food-grade resins are selected for food packaging applications.

A very common class of additives is antioxidants. Some of these are compounds such as BHA and BHT that are also used in food to suppress oxidative deterioration of products. They serve much the same purpose in plastics, usually being targeted primarily at preventing oxidation during processing. These additives can, in some cases, migrate to the product during storage, providing additional product protection. In fact, they have sometimes been added to packaging plastics precisely for this purpose.

Colorants, most often pigments, are used to provide desired colors to plastic packages. For example, certain types of soft drinks are packaged in green PET bottles. Pigments can also be used to prevent transmission of light, or of certain wavelengths of light, in order to minimize light-induced degradation of the product.

Of increasing interest recently are various types of antimicrobial additives, most based on compounds classified as “generally recognized as safe” (GRAS), and intended to inhibit the growth of microorganisms that might otherwise lead to post-processing contamination. Some of these are effective through surface contact, and others act by migrating from the package to the food product. Examples include nisin, potassium sorbate, sorbic acid, natamycin, zeolite-based silver ions, and others.

Other categories of additives include plasticizers, heat stabilizers, UV stabilizers, antiblock agents, slip and anti-slip additives, lubricants, mold release agents, nucleating agents, antifogging agents, antistatic agents, oxygen scavengers, desiccants, etc. Fillers and/or reinforcing materials are also used in some food packaging plastics.

Additives may be mixed uniformly into the resin pellets. Often, however, they are supplied in the form of a "master batch" that has a high concentration of the additive. The amount of master batch added depends on the level of additive desired in the final product. Additives can also be added to the extruder when the plastic is being formed. This is common for fibers and fillers, for example.

V. BASIC PLASTIC FORMING PROCESSES

Most packaging plastics are formed into the desired package shape by melting the plastic and using heat and pressure to shape it as desired. The plastic is generally fed into an extruder in pellet form. The extruder melts and mixes the plastic, so that a uniform stream of melt is available at the desired temperature and pressure for downstream processing. The plastic usually exits through a die, which shapes it to the desired profile.

Plastic film is made in two major ways. For cast film, the melted plastic exits the extruder through a slit die and is brought into contact with a water-cooled chrome roller (or set of rollers). The film may, if desired, then be oriented uniaxially or biaxially. The edges are trimmed off, as relaxation in the plastic makes the edges thicker than the rest of the film. It is then rolled up, and is ready for converting operations, where it may be printed, folded, cut, sealed, etc.

Blown film is made using an annular die, which produces a hollow tube of melted plastic. Increased air pressure inside the tube expands it in diameter, while it is stretched in the lengthwise direction as it is drawn through the machinery. Therefore, blown film is biaxially oriented without requiring an additional orientation step. The tube of plastic may be rolled up as-is, for use in processes such as bag or pouch-making. In this way, it is possible to produce a pouch, for example, that has only top and bottom seams. Often, the tube is instead slit on both edges, producing two rolls of flat film.

Plastic sheet is too thick to be produced by the blown film process, so the cast process is used. For packaging applications, the sheet is usually further modified by thermoforming. In thermoforming, the sheet is reheated and then stretched into or over a mold, using some combination of vacuum and pressure. Foamed plastic sheets, such as polystyrene foam, can be thermoformed, as well as solid plastic sheets. Thermoforming is routinely used for trays, and can also be used for cups and similar shapes. The plastic thins as it is stretched, until it contacts the cool mold and stops stretching. Therefore, the parts of a thermoformed package that have been stretched the most during forming will be the thinnest in the final package. There are a variety of different thermoforming methods; which method is chosen depends on the material used and the package shape being produced. Plug-assist pressure forming, in which a mechanical device (the plug) helps push the plastic into the mold, as well as additional air pressure for forming are used. This facilitates deep draws, can improve the uniformity of wall thickness, and shortens cycle times.

Another way to make plastic containers, closures, etc., is using injection molding. In this process, the plastic is melted in an injection molding machine, which is essentially an extruder, but does not have a die. Instead, the melted plastic is injected into a mold. The mold usually contains multiple cavities, so that several plastic packages or package components (usually identical to each other) are produced in a single step. In injection molding, the plastic fills the entire mold cavity, so there is excellent control over the dimensions of the finished article. Injection molding is limited to shapes that can be removed from the solid core. Therefore shapes such as bottles cannot be made, since there is no practical way to get the solid center out of the molded bottle. For some shapes, innovations such as collapsing cores can be used, where the core is made of multiple pieces that can retract when a center piece is pulled back, allowing their removal. However, this is not practical for bottles. When the plastic flows into the mold block, it passes through a system of runners in order to reach the mold cavities. In packaging applications, these runners are generally heated to keep the plastic inside from solidifying, so that it can be used in the next cycle, rather than needing to be removed and discarded or used as regrind. This process is called hot runner molding. One of the most common applications of injection molding in packaging is in manufacture of threaded plastic closures.

To make containers such as bottles, blow molding is used. There are two major categories of blow molding. In extrusion blow molding, the plastic is extruded as a hollow tube, much like is done for blown film. The tube, or parison, when it is the appropriate length, is cut off and captured in a mold. Air is then blown in to expand the parison into the mold shape. Excess material at the top and bottom of the container is cut off, and generally immediately recycled into the process (this material is known as regrind). Bottles with handles can easily be produced by using a parison that is wide enough to cover both the body and handle area when it is captured in the mold. These handles will be hollow, and have an open connection to the body of the container. The gap between the handle and the body is created by pinching the two plastic layers together during molding, and then cutting out this solid piece of plastic. There is often excess plastic at the sides of the neck of the bottle that must be removed, as well, especially for bottles with handles.

To achieve more uniformity in wall thickness of extrusion blow molded containers, it is common to modify the shape of the die (die shaping) to correct for ovality in the container, and to modify the size of the opening as the parison is produced (parison programming) to control for vertical asymmetry. These techniques can also be used, of course, to produce walls that are thicker at certain points, if this is desired. For example, the thickness in the finish area of the bottle will probably be more than in the body, since greater strength and stiffness are needed there. While these techniques add somewhat to cost, they generally more than make that up by permitting reduced material use.

In injection blow molding, the bottle is produced in two steps. First a parison is produced by injection molding, as was described above. The bottle finish is completely formed in this step. This allows very precise control over finish dimensions. The body of the parison can also be designed to provide varying wall thickness, thus achieving greater wall thickness uniformity in the finished container. In the second step, the parison is placed into the container mold and blown into its final shape, using air pressure. These two steps may be done sequentially in the same machine. In this case, the injection-molded parison is cooled only enough to maintain its shape, with the support of the core rod that shapes the interior of the parison, during the transfer to the blow mold. It is also possible to completely cool the parison and ship it to another location for blow molding at a later time. In that case, of course, the parison must be reheated before it is blown.

It was mentioned earlier that PET soft drink bottles are biaxially oriented. Blow molding naturally produces uniaxial orientation, since the plastic is stretched radially as it is blown. To achieve biaxial orientation, stretching in the vertical direction must be added. This is done by stretch blow molding. While extrusion stretch blow molding does exist, it is rarely used, so we will discuss only injection stretch blow molding. In this process, the parison is produced by injection molding, as already described. However, it is much shorter in length than the height of the final container. The parison is placed in the blow mold with a stretch rod inside. After the parison is carefully reheated to give the desired temperature profile, it is simultaneously blown with air emitted through the stretch rod, and stretched vertically as the stretch rod descends into the cavity, thus producing the desired biaxial orientation.

VI. MULTILAYER PACKAGES

It has become very common to use packages that are made of more than one material. Structures that combine plastic, paper, and/or aluminum and structures that contain more than one type of plastic can efficiently perform functions that cannot be obtained from a single layer structure. There are four basic ways to obtain such multilayer structures.

The first method is coating. We can add a polymer coating to paperboard, for example, to improve its water resistance. We can add a barrier coating to a container to increase the shelf life of an oxygen-sensitive product. When plastic resins are used for coating paper or foil, the most common process used is very similar to that for producing cast film. The plastic is melted in an extruder and then emitted through a slit-shaped die. However, instead of contacting a chrome roller, the plastic goes onto the paper or foil, and adheres to it as the plastic cools. Solvent-based coatings or water emulsions of polymers are sometimes used, instead. The choice depends primarily on the polymer requirements.

The second method is lamination. In this process, two rolls of material (substrates) are joined into a single material by causing them to adhere to each other. Most often the adhesion is achieved by using a third component, an adhesive. The substrates may be plastic, paper, or foil. The choice of the adhesive and how it is applied depends on the requirements of the substrates and the characteristics of the adhesive. If the adhesive is low density polyethylene, for example, it is likely extruded into the gap as the substrates are brought together.

The third method, which has become very common, is coextrusion. In this process, individual plastics are melted, each in their own extruder, and the melt streams are then brought together, either in the die or in a feed block just before the die. The process of bringing the melted plastics together is done very carefully, so that the streams do not mix with each other, but instead flow uniformly in separate layers, each of the desired thickness. Next the multilayer plastic melt is shaped as described already. This can be used to produce multilayer sheet for thermoforming into multilayer structures, multilayer film through either the cast film or blown film process, or multilayer containers through extrusion blow molding.

The fourth method is the newest. Producing multilayer injection-molded objects is more technically challenging than producing multilayer extruded or extrusion-blown objects. Coinjection processes fall into two basic categories. One approach is to use multiple mold cavities and multiple injections, essentially building up the object layer by layer. The more common method, in packaging applications, is to fill the injection mold with a multilayer flow of melted plastic in a single step, again starting with each plastic melted in a separate extruder. Coinjection stretch blow molding, such as is used for PET/EVOH/PET/EVOH/PET ketchup bottles, starts with a coinjection-molded parison, and then uses stretch blow molding to form the final container.

VII. PERMEABILITY AND SHELF LIFE

The length of time a food product remains acceptable once it is packaged is often dependent at least in part on the ability of the package to protect it from external influences

TABLE 131.2
Typical Properties of Plastics Used in Food Packaging

Property	HDPE	LDPE	PP	PET	PS	PVC	Nylon 6	Nylon 11	PC	EVOH	PVDC
T_g (°C)	−120	−120	−10	73–80	74–105	75–105	60		150	48–69	−15 to +2
T_m (°C)	128–138	105–115	160–175	245–265		212	210–220	180–190	265	156–189	160–172
Density (g/cm^3)	0.94–0.965	0.912–0.925	0.89–0.91	1.29–1.40	1.04–1.05	1.35–1.41	1.13–1.16	1.03–1.05	1.2	1.13–1.21	1.60–1.75
Tensile strength (psi)	2500–6500	1200–4550	4500–6000	7000–10500	5200–7500	1490–8020	6000–24000	8000–9500	9100–10500	5400–13600	2800–5000
Tensile modulus (10^3 psi)	89.9–158	24.9–75	165–225	400–600	330–475	600	100–247	185	345		50–80
Elongation at break (%)	10–1200	100–965	100–600	30–3000	1.2–2.5	14–450	300	300–400	110–150	180–330	160–400
WVTR (g mil/100 in^2 d at 100°F, 90% RH)	0.32	0.95–1.3	0.25–0.76	1.0–1.3	4.4–10	1.9–40	9.9–11	2.5–5.1	4.9–5.9	1.40–38.1	0.02–0.61

such as exposure to oxygen or gain of moisture, or from internal changes such as loss of volatile flavor compounds, loss of carbonation, or drying out. In all of these cases, the barrier capability of the plastic, its ability to retard transfer of one or more components through the package wall, is a major factor.

The barrier ability of a plastic is determined by two factors: how soluble the compound in question is in the plastic, and its ability, once in the plastic, to move through it (its diffusivity). Typically, we put these two factors together and evaluate the permeability of the package or package material. A package that is a good barrier has low permeability. As we have seen, plastics can be good barriers for some components of interest, and poor barriers for others. For example, HDPE is a good water vapor barrier but a poor oxygen barrier, while EVOH is a good oxygen barrier but a poor water vapor barrier.

Barrier is enhanced by increasing crystallinity, since crystallites are essentially impervious to permeating molecules. Strong intermolecular forces also increase barrier. Permeation is significantly faster in a polymer above its glass transition temperature than in the same polymer below its glass transition temperature. Above T_g, we have activated diffusion, in which segmental movements of the polymer chain tend to open up pathways for the permeating molecules.

While a thorough discussion of permeability and shelf life is beyond the scope of this chapter, oxygen permeability coefficients for various plastics are presented in Table 131.2. For water vapor, it is traditional in packaging to present water vapor transmission rate (WVTR) coefficients, rather than permeability coefficients. A WVTR is a function of the conditions at which it is measured, so that condition must be taken into account and used to transform the value to a permeability coefficient before it can be used in a shelf life calculation at a differing relative humidity. WVTR values are also listed in Table 131.2. The shelf life of a product depends on how much of the compound of interest can be gained or lost without making it unacceptable, the area available for mass transfer (generally the surface area of the package), its thickness, and the driving force for transfer, in addition to the permeability coefficient. The driving force for transfer is the difference in chemical activity on the two sides of the package (inside and outside), typically expressed as a concentration (partial pressure) difference.

VIII. MIGRATION AND SCALPING

Migration and scalping also involve mass transfer, but instead of transfer between a product and the outside environment, as is the case in permeation, the transfer is between the product and the package itself. By migration, we mean transfer of a component from the package to the product. As mentioned, components that transfer in this way are classified by FDA as indirect food additives. They must either be approved as food additives, have GRAS status, or migrate in such small amounts that they have been determined to pose no real risk. Potential migration of unknown contaminants from a recycled plastic stream is one factor limiting the use of recycled plastics in food packaging. Some recycled resins have been approved for direct food contact, either alone or blended with virgin plastic. Others have been approved provided a "functional barrier" of some minimum thickness of virgin plastic is interposed between the recycled plastic and the food, in a multilayer structure.

Scalping refers to the transfer of a component from the product to the package. Usually, this involves a flavor or odor component, and the transfer is undesirable. Polyethylene, for example, can readily scalp the components that give fruit-flavored cereals their desired smell and taste.

IX. INFORMATION SOURCES

Additional information on plastics used for food packaging, plastic forming processes, additives, mass transfer and shelf life can be found in Refs. 2–4.

132 Paper and Paperboard Packaging

J.M. Park
Paper Technology Information Center, Chungbuk National University

CONTENTS

Various materials, functions, forms, and technologies of food packaging are used to protect and maintain product quality during shipping and storage. Recent concern on food safety, health, and resources conservation are evident ever before. Paper and paperboard are made of fibers from renewable, environmental friendly resources. This chapter describes those characteristics of paper and paperboard most relevant to food packaging applications.

I. INTRODUCTION

Paper and paperboard are made of fibers from easily obtained natural, renewable resources such as wood or vegetable fibers. They are useful for packaging, writing, and a variety of other purposes.

There is no distinct difference between paper and paperboard. Paperboard has characteristics of thick caliper. They are pliable, relatively low cost, easy to convert into various shapes, recyclable, biodegradable, and eco-friendly materials. Depending on purpose of packaging, paper and paperboard can withstand conditions of high and low temperatures which are experienced by sterilized food and frozen or chilled foods. Excellent printability and glueability are required for certain purposes. In spite of various advantages of paper and paperboard, they have certain disadvantages such as easiness to burn, and weakness to water, which can be controlled to a certain extent. Therefore, in order to modify properties of paper and paperboard various additives are added to paper or they are laminated with other materials.

Various materials for packaging are used as the science, technology, and machineries are developed, because the packaging market is changing very rapidly. Convenient, high quality, and safe packaging is sought. Share of paper and paperboard in packaging material consumption is about 40% which is higher than plastic, metal, and glass materials. With growing concerns on environment, recyclablility of paper and paperboard packaging materials appeals to customers.

Properties can be controlled by changing raw materials, adding additives, and modifying papermaking processes, or using converting machines depending on purposes.

II. MANUFACTURING OF PAPER AND PAPERBOARD

Paper is manufactured by Fourdrinier, cylinder, or twin-wire former. Fourdriner former has an endless turning wire to distribute fibers evenly on it. Paper produced by Fourdriner former has different sides because of uneven distribution of fillers and small fibers through thickness of paper structure by downward dewatering only. By rotating a cylinder with a wire rotated partially in a fiber suspension, paper is produced on the outside wire and water is drained inward through the wire. The thickness of paperboard by multiple cylinder formers has no limit by depositing one layer on another layer by additional cylinder formers. One directional dewatering limits the speed of Fourdriner former. By impinging fibers solution between two wires and dewatering from both sides of paper, twin-wire former provides even distribution of fillers and small fibers with high speed. Corrugated medium is produced by corrugator and pasted to linerboard to produce corrugated board.

Manufacturing process of paper is composed of two steps, including adding water to fibers then removing water from the sheet structure. Paper is fibrous material of certain thickness with wide area. In order to distribute fibers uniformly, fibers are dispersed in water at low concentration of 0.3–5.0%. Then diluted fibers solution is spread out through a slot, called "headbox," at high speed (about 100 Km/h for modern machine) across a papermaking machine. Water is removed by gravitation, mechanical pressure, and drying energy. Paperboard is a kind of thick paper with several layers of paper in one structure. It is made by making one layer of sheet first, then adding another layer by another headbox, and so on, to make 3–7 layers of sheet.

A. Raw Materials

Cellulosic fibers are used as raw materials for both paper and paperboard. Fibers can be obtained usually from wood or annual plants, but sometimes from animal, mineral, or synthetic for special paper. The fiber is a tubular or cylindrical element several millimeters long and less than 100 micrometers wide. If you tear a sheet of paper and look under a bright lamp at its edge then you can see individual fiber sticking out from the torn zone.

Fiber properties are quite different depending on source. There are many factors that affect final properties of paper and paperboard, but the most profound effect may come from the fiber resources. It is critical to choose proper fibers for specific characteristics development.

Chemical constituents of wood fibers are cellulose, hemicellulose, lignin, and extractives. Cellulose is beta-glucosidic linked glucose chains. Hemicellulose is various polysaccharides which are associated with cellulose, such as glucose, mannose, galactose, xylose, and arabinose. Lignin is phenyl propane unit with complex structure. Extractives are not a part of cell wall structure, but can be removed by neutral solvent such as ether, benzene, alcohol, and water.

Pulping is a process to prepare fibers from wood or vegetables by using mechanical and/or chemical energy to separate individual fibers, because fibers are assembled with lignin as paste that bind fibers together. Pulp means fibers that are separated through pulping. Mechanical pulping uses a grinder to apply friction force to separate individual fibers. Lignin is still in fibers of mechanical pulp (MP), so fibers are brown in color before bleaching. Chemical pulping uses chemicals to dissolve out lignin which binds fibers together; it gives low yield but fibers are strong. Through bleaching chemical pulp (CP) becomes bright in color. A brown grocery bag, the most common chemical pulp, is strong and made of Kraft pulp (KP). Small pieces of wood (called "chips") and chemicals are mixed in a digester to react at certain temperature for a certain period of time, and the reaction conditions

determine the mechanical, morphological, and chemical properties of fibers.

B. Processes and Equipments

Fibers are supplied in a diluted solution of water after pulping. In order to make fibers suitable for paper properties, fibers are treated by mechanical force to develop microfibrils sticking out of the surface so flexibility of fibers is increased. Fibers are mixed well, pumped, and passed through a "headbox" at a very high speed. Papermaking is basically an efficient process of removing water from the diluted solution of fibers, which involves using gravitational force by putting the fiber solution on the wire, using mechanical squeezing compressional force by passing through two rolls, and evaporization drying by contacting paper on steam heated cylinder can. Continuous paper web is wound by winder. A block diagram of the papermaking process is shown in Figure 132.1.

Various pulps from softwood, hardwood, and annual plants are refined to obtain proper fiber properties. Refining is a mechanical bruising process to develop fibrils on fiber surface and delaminate internal layers to make fibers more flexible to bond easily to improve bonding strength. During refining fibers are hit by mechanical force when they pass through stationary or rotating bars. Refined fibers are diluted in water and ejected at high speed from the headbox on a continuously revolving wire. Fibers are retained on wire and water flows through wire without vacuum or with vacuum to form wet web of fibers. By squeezing wet fibers structure water is removed through porous felt and slit roll at press. After removing a certain amount of water by squeezing, mechanical force cannot remove water any more. Then heat energy at a dryer can be used to remove water by evaporation. For printability smooth surface of paper and paperboard is essential. In order to increase smoothness paper and paperboard pass between several rolls called a calender. In continuous web winder, the web is wound in order to prepare for converting in the next process. Web width is about 2–10 m depending on papermaking machine, and total length of web is about 1–10 km. Sheet cutter makes paper sheets rectangular by using a rotary knife or guillotine. For storage or transportation paper rolls or sheets are wrapped with plastic film or vinyl laminated paper.

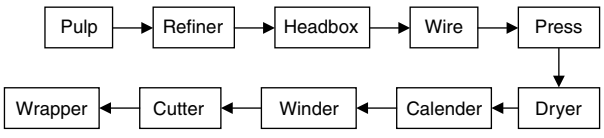

Figure 132.1 Papermaking processes.

III. CONVERTING OF PAPER AND PAPERBOARD

Most papers and paperboards are converted by impregnating, saturating, laminating, embossing, and forming processes to specific shapes and sizes for efficient usage. In food industry, various papers and paperboards are combined with other materials such as aluminum foil, plastic or metallized flexible packaging material, and extruded films.

Representative surface converting processes are coating and laminating. Paper is composed of numerous fibers with many pores in its structure, so its surface is relatively rough. Very fine and white pigment particles are coated on the surface to improve smoothness and brightness of paper. To bind the particles themselves or on the fibers surface, natural or synthetic adhesives are used. Laminating is a combining process of similar or dissimilar webs to impart barrier properties against moisture, oxygen, light, odor and flavor, or to impart special properties.

A. Processes and Equipments

1. Coating

Coating can be divided into aqueous coating and extrusion coating. Aqueous coating, or simply coating, is a process of applying a coating solution on the surfaces of paper and paperboard for enhancing smoothness and printability. Coating is like a makeup on a face for paper. Very fine mineral pigments of 0.1–2 micrometers and adhesives such as natural starch, casein, and synthetic latex are applied on the surface of the paper. To cover coating materials uniformly on paper surface, a very thin knife (called "blade"), an air knife (blowing air), a roll or rod is used to level out across the whole width of paper roll. Extrusion coating is a process that applies high molecular weight polymer on paper by extruder die assembly. It provides heat stability and resistance to water, moisture vapor, some gases, and oil for a paper.

2. Laminating

There are several types of lamination, such as (1) wax and hot melt, (2) wet, (3) dry, and (4) solventless laminations. Critical conditions of lamination are temperatures of web and adhesive, tension of web, humidity of web, and adhesive conditions. Melted wax is supplied from a tank by a geared pump to die or coating station for the wax and hot melt lamination. Wet lamination combines two webs, one of which has wet adhesive on its surface. In dry lamination two webs are combined after drying water or solvent from the adhesives. For solventless lamination, 100% solid adhesives with no volatile components are used and drying is not necessary.

3. Sizing

Pigments or starch solution of low concentration can be applied on paper's surface by passing paper through two or more of rolls (called "size press"). To produce silicone coated baking paper, silicone coating of aqueous emulsion is applied on refined paper fibers at the size press. Silicone coating prohibits sticking of food to the paper during cooking and serving.

Internal sizing is the treatment of fiber slurry. Surface sizing is the addition of starch solution or other materials onto the paper surface.

4. Metallizing

In order to improve appearance and be a barrier to gas and light, a very thin layer of metal (usually aluminum) is deposited on a substrate surface in a vacuum. For satisfactory vacuum-metallized treatment, paper and paperboard should have less than 4% moisture content and be very smooth, and free from pores and voids. The surface of paper is usually treated with polyurethane, acrylic, or polyamide lacquer for proper metallizing.

IV. CLASSIFICATION OF PAPER AND PAPERBOARD

There is no definitive distinction between paper and paperboard, but relatively thick paper is called as a paperboard. Depending on raw materials, converting process, and surface properties, grades of paper and paperboard are classified into various kinds. Usage of paper and paperboard are classified into three categories: packaging, printing and writing, and wiping. In this chapter, packaging grades are discussed.

A. Properties and Test Methods

There are many grades of paper and paperboard depending on purposes. Required properties of paper and paperboard vary depending on production processes, converting processes, and final usage. The moisture content of paper is very important to decide paper quality in many aspects. Therefore properties are measured under standard conditions of temperature and relative humidity since they depend on equilibrium moisture contents.

Properties of paper and paperboard related to food packaging are thickness, grammage, tensile strength, tear strength, impact strength, barrier (vapor or gas barrier), capacity, curl, flexibility, stiffness, static and dynamic friction coefficient, heat sealing, vapor transmission rate, and so on. Chemical properties of food wrapping papers are important, and they must be free of harmful chemicals. Parchment paper for butter should have less than 3 ppm of copper content and 6 ppm of iron content for preventing off-flavor. Properties may be divided into physical, mechanical, strength, chemical, and optical properties.

Physical properties are basis weight, thickness, apparent density, smoothness, porosity, formation, curl, sizing, and printability. Basis weight is a mass of paper per unit area. Thickness of paper is measured as a caliper at the specific pressure as a distance between bottom and top plates where a paper is located. Because detailed contour of paper is not uniform nominal thickness is measured. Apparent density is calculated by basis weight divided by thickness, which is equivalent to mass divided by volume. Smoothness is a measure of how smooth a paper surface is. Smooth surface gives better printability because printing plate contact uniformly on smooth surface. Usually paper has two-sideness which means two sides of paper have different characteristics, because during papermaking process drainage of water occurred in one direction through wire. Top side (felt side) is smoother than bottom side (wire side). Paper structure has a lot of pores in it, and porosity of paper is determined by the degree of fiber refining and filler contents, because filler, small mineral particles, plugs in pores of paper. Porosity may be measured by how fast a specific volume of air can pass through paper structure. Formation is an extent of distribution uniformity of fibers and fillers throughout a paper. Uniformity of paper determines the quality of paper. Paper tends to curl depending on extent of difference in properties of top and bottom side. Paper requires a resistance to ink or liquid. Sizing is an extent of resistance to liquid penetration. Printability may be measured in uniformity of ink density in overall image, sharpness of image, and so on.

Papermaking process is continuous in travel direction that is called machine direction (MD), and perpendicular direction is called cross-machine direction (CD). More fibers tend to align in MD, so paper is stronger in MD and elongates more in CD. The ultimate force a specimen can endure when it is in tension is expressed in tensile strength. Tensile strength may be expressed as the breaking length, which is a length of paper when it is ripped, when a paper roll is unwound to a certain length due to its own weight of paper supported at one end. Burst strength of paper measures the amount of hydrostatic pressure to rupture a piece of paper. Stiffness measures the bending moment of specimen resisting bending. Fold endurance measures number of folding under a specific tensile force before breaking. Tear strength is determined by energy required to tear several sheet of paper at a fixed distance with initial tear.

Chemical contents may be analyzed by various methods of chemical analysis. Optical properties include color, brightness, opacity, and gloss.

For corrugated paperboard, burst strength, edgewise compression strength, flat crush test, pin adhesion, and puncture test are usually performed. For finished

corrugated box, puncture, compression strength, impact resistance, stiffness, and drop test are performed.

Recently the ISO (International Organization for Standardization) issued some global standards for pulp and paper. Each country adopts specific standards to measure the pulp, paper, and paperboard properties. Standard methods such as TAPPI (Technical Association of Pulp and Paper Industry (USA)), SCAN (Scandinavian Pulp, Paper and Board Testing Committee), PAPTAC (Pulp & Paper Technical Association of Canada), PITA (Paper Industry Technical Association), and APPITA (Technical Association of the Australian and New Zealand Pulp & Paper Industry) usually describe the definitions, specimen preparation, conditioning and measuring methods, testing equipment, and reporting method.

B. Functions and Usage of Paper and Paperboard for Food Packaging

Traditional purposes of paper and paperboard were printing and writing. Various packaging and wrapping usage are developed with a variety of characteristics these days. Life cycle of new products (turn-over) becomes shorter than before. There are too much versatile grades to describe here. Only representative paper and paperboard grades are described.

1. Kraft Paper

Bleached or unbleached Kraft pulp (KP), one of the major chemical pulps with high strength, is used in more than 80% for making Kraft paper. Kraft paper is used primarily as a wrapper or packaging material, and its other usage is grocer bags, envelopes, multiwall sacks, butchers wraps, waxed paper, and all types of specialty bags and sacks. Crepe paper is produced by reducing the speed of the press roll to increase elongation rate of 35–200% of its original length. Crepe paper is used for multiwall bags.

2. Greaseproof Paper

By refining chemical pulp severely, fibers bond closely and compactly, and there are few pores in its structure, scattering of light is decreased to have almost transparent appearance. Greaseproof paper is for protective packaging material having a resistance to fat penetration in packaging butter or fatty food with few pores. Greaseproof paper is suitable for lamination and coating with wax or lacquer to improve water resistance. After wax coating, it is used as a wrapping paper of potato chips, dried food, cookies, ice cream, and coffee.

3. Glassine Paper

By very severe calendaring of chemical pulp, paper becomes almost transparent. It has very smooth surface, high density, and low opacity. It also has good grease resistance and gas barrier properties. Transmission of moisture vapor can be enhanced by waxing, lacquering, or laminating the paper. It can be used as a protective wrapper for all kinds of foodstuffs and many purposes where its transparent feature is helpful.

4. Parchment Paper

It is produced by passing paper of cotton fibers or pure chemical pulp through sulfuric acid solution, washing thoroughly, and drying. It is odorless, tasteless, and has good grease resistance and wet strength. It is used for packaging butter, margarine, meat, poultry, and other food products. It can also be used for interleavers for the food (such as meat slice) because of its good releasing property.

5. Waxed Paper

Unsized or sized paper is impregnated or coated with molten wax to make waxed paper. It is used for wrapping or packaging bread and sandwiches, baking cups for cup cakes, and liners for cartons and cracker boxes. To make molten wax, microcrystalline wax and polyethylene are added to paraffin wax.

6. Tissue Paper

Low grammage thin paper is generally called tissue paper. Sometimes it is creped to enhance elongation and softness. It is used as a wrapping tissue, waxing tissue stock, fruit and vegetable wrapping tissue stock, and various specialty purposes. It can be transparent or semi-opaque.

7. Coated Paper

In order to get a high quality printing surface, coating materials such as pigments, adhesives, and additives are used. Clay, calcium carbonate, and titanium dioxide can be used for pigments. Starch, latex, or protein is used for adhesives. Waterproofing agents, plasticizers, rheology control agents, dispersants, defoamers, and dyes can be used as additives to perform specific purposes. Coated paper can be used for labels or bags, and it can be laminated with other material to give special features.

8. Paperboard

Relatively thick paper is called paperboard. Generally it has several layers of paper in whole structure. Properties of each layer of paper determine final properties of paperboard. Various pulps can be used for each layer to save production cost and enhance certain properties. It is classified as containerboard (which is used for corrugated boxes), boxboard (which is used to make cartons), and various paperboards.

9. Corrugated Board

Corrugated board consists of liner board on each side and corrugated medium in between. Various shapes of corrugation determine the compression strength and amount of cushion. Various structures may be produced depending on final usages and required strength. Single wall, double wall, and even triple wall structures may be produced.

V. MANUFACTURING AND USAGE OF PAPER CONTAINERS

A. Paper Bag and Paper Sack

Paper bag is used for packaging dried foods such as sugar or flour is packed in food company and protected during distribution channels of wholesales, and retail stores. Paper bag is also used in grocery stores or retail stores. Recently a high portion of paper bag usage is replaced by plastic bag. Paper sack is made of 2–6 plies of Kraft paper.

B. Paper Box

Paperboard of 0.3–1.1 mm is cut and punctured to produce a paper box. Paper box in folded shape is supplied to a food factory, and final shape of the paper box is produced during the packaging processes. Paper box is used for dried foods such as cookies and snacks in unit packaging. Puncture strength and strength at humid condition are required for frozen food or marine product packaging. Barrier properties and heat sealing properties may be provided by plastic lamination. Paper box is more expensive, but higher in puncture strength, than the corrugated box.

C. Corrugated Box

There are many shapes of corrugated board container. The container may be stored in folded shape for later use, and it is easy to handle for closing and opening. Waterproof properties may be provided for specific end use. This container is used for many purposes including food packaging to protect contained food from impact. Compression strength is required during loading and transportation of box piles. Depending on required burst strength and compression strength, proper shape of container should be provided. Much research is concentrated on reducing raw fibers and use of thinner board for slim packaging in order to reduce the box cost.

D. Liquid Container

For liquid containers, inside or both sides are coated with wax to provide water resistance. Laminated composite paper in pyramid, rectangular hexahedron, or various shapes is used for milk and fruit juice. It is usually used with an aspetic packaging system. PE layer of outside provide protection from water or abrasion. Paper of inside provides strength to support the content.

E. Component Can or Drum

Paper is wound in spiral or normal direction to make a component can or drum that is cheap and easy to discard. It is used to protect salt, pepper, powdered hot pepper, powder, spice, cookies, dried snack, biscuit, doughnut, and so on. Bottom and top are made of metal, plastic, or paperboard. Main body can be also laminated in aluminum foil, plastic film, or high strength paperboard for higher barrier properties and strength. Inside the component can or drum may consist of parchment, waxed paper, aluminum foil, glassine paper, or coated paper to improve protection of contents. Paperboard of 0.25–0.5 mm is used for this purpose.

F. Paper Mould Container

Paper mould is produced in a similar manner as paper. Mechanical pulp, chemical pulp, and recycled pulp are used as raw materials. Screen mould is used to drain water by pressurized extrusion or suction forming method. The container is used for egg tray, shock absorbing packaging, vegetable, and high quality liquor.

VI. NEW TRENDS

Regulations for packaging material are now stricter than ever before. By improving printability for more attractive appearance, increasing strength for better protection and convenient handling, developing efficient recycling method for fewer environmental problems, and reducing raw material for less amount of solid waste, paper and paperboard packaging can be more competent.

CONTENTS

I. FUNCTIONS OF PACKAGING

The basic functions of the package are to contain the food, protect the food, provide convenience, and convey product information. The package protects the food against physical, chemical, and biological damages. It also acts as a physical barrier to moisture, oxygen, volatile compounds, and microorganisms that are detrimental to the food. The package provides the consumer with convenient features such as microwavability, resealability, single serving, and ease of use. The package conveys useful information such as product contents, nutritional values, and preparation instructions. All these functions are applicable to the packaging of frozen foods [1].

The food package can function best when integrated into a food packaging system, which involves certain physical components and operations. The major physical components are the food, the package, and the environment (Figure 133.1). It is useful to divide the environment into internal and external. The internal environment refers

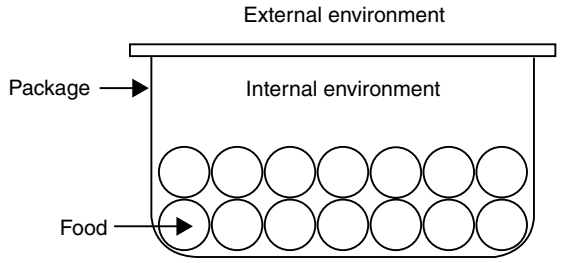

FIGURE 133.1 Physical components of food packaging system.

to the conditions inside the package, which contains the food product and in many cases some air space (also known as headspace). The external environment refers to the conditions outside the package, and it depends on the storage and distribution of the food package. The operations are the manufacturing, distribution, and disposal of the food package. In designing the food packaging system, these physical components and operations must be considered to prevent over-packaging or under-packaging, which results in higher costs, lower quality and in some cases, health risks.

There are several requirements in the selection of packaging materials for frozen foods: temperature stability, barrier properties, thermal insulation properties, consumer appeal, and machine compatibility [2]. Temperature stability is necessary since the packaging materials must be able to withstand the abuses encountered over a broad range of temperatures, including freezer temperatures during transportation and storage as well as high temperatures during the heating of the food package in the microwave or conventional oven. Barrier properties are necessary to minimize deteriorative effects of moisture, oxygen, and light to the food product. Thermal insulation helps maintain low temperatures for frozen foods during distribution, and minimize temperature fluctuations which may cause degradation of the products. Consumer appeal is necessary for successful marketing of the products; the packaging materials should allow high quality printing and graphics. Machine compatibility is necessary to ensure that the packaging materials are compatible with low cost, high speed machineries.

Frozen food packages are typically made using carton machines, form-fill-seal machines, and pouch-forming machines. The constructions and operations of these machines may be obtained from the manufacturers and the literature [3].

II. DETERIORATION MODES OF FROZEN FOODS

In addition to mechanical damages, frozen food products can also fail due to several deterioration modes. The most important deterioration modes of frozen foods are related to the transport of moisture. The water molecules in ice exert a vapor pressure which increases with temperature. Water molecules tend to move from high concentration to low concentration.

Figure 133.2 illustrates the various transport mechanisms of water molecules (small circles in figure) in a frozen food package. Diffusion of water can occur within the food if a concentration gradient exists (in most cases, in the direction from center to surface). Sublimation, evaporation of water from ice to vapor, can occur at the food surface. Precipitation of water vapor as ice crystals can occur on the food surface or on the interior package surface. Permeation is the transport of water vapor across the package

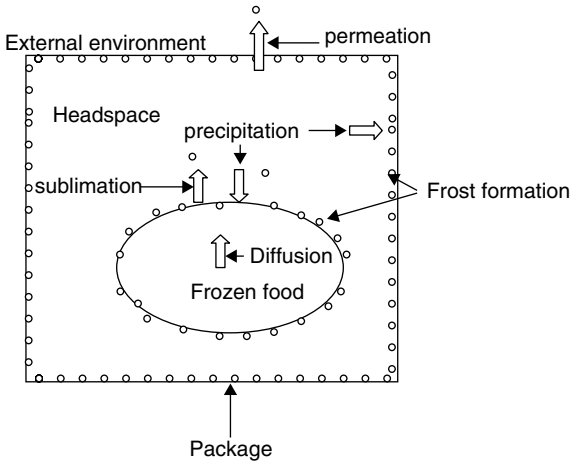

FIGURE 133.2 Transport mechanisms of water molecules.

walls, and the water vapor transmission rate (WVTR) is determined by the permeability of the package. The transport of water molecules can result in dehydration and frost formation, two of the major deterioration modes of frozen foods. In addition to water molecules, the transports of oxygen, flavor, and odor compounds are also important to frozen foods.

Dehydration in frozen foods, also known as freezer burn or desiccation, is the moisture loss at the product surface due to sublimation of ice. The moisture loss results in a drier product surface and a concentration gradient which cause water molecules to diffuse from the food center to its surface. Dehydration is a major deterioration mode in frozen food since it reduces product weight and adversely changes product appearance, texture, and taste. For example, when proteins in meat, poultry, and fish products become irreversibly dehydrated, the tissues become dry and tough. These products frequently contain considerable amount of fats and oils, and dehydration can make these fats and oils more susceptible to oxidation by opening up the tissues and thus making more surface areas available for oxidation.

If the food product is unprotected (i.e., without package), the rate of moisture loss to the external environment is rapid. To retard moisture loss, protecting the product by a good moisture barrier package is necessary. In addition, the package should also have good tensile, tear, and burst strength at low temperatures; otherwise, package damages (such as holes or cuts) can occur and cripple the protective function of the package.

Frost formation is a phenomenon by which water vapor precipitates as frost on the food surface or on the interior surface of the package. Frost formation contributes to the problem of freezer burn since moisture is removed from the product, and it also makes the package less appealing to the consumer. A major factor which affects frost formation is headspace volume: in the

presence of headspace, moisture loss occurs from the food surface to the headspace through sublimation, even when the food is protected by a good moisture barrier package. It is the water vapor in the headspace which is responsible for frost formation. Therefore, an effective packaging technique is to tightly wrap the food product to eliminate the headspace and its water. Another major factor which affects frost formation is temperature fluctuations. Since vapor pressure is temperature dependent, any temperature fluctuations can result in different vapor pressures at different locations, and thus a concentration gradient is created which tends to accelerate the rates of sublimation and precipitation.

Oxidation is another deterioration mode for frozen foods. Although oxidation occurs slowly at freezer temperatures, it remains a problem since frozen foods are often stored for prolonged periods of time and oxygen is more soluble in food at lower temperatures. Oxidative reactions can result in rancidity, off-flavor, and pigment discoloration in frozen meat and seafood products. In general, oxidation reactions accelerate with increasing amounts of oxygen present, but there are exceptions. Different foods have different susceptibility to oxidation; for example, pork and poultry are more susceptible than beef and veal to oxygen. To protect oxygen sensitive frozen foods, the package should have low oxygen permeability.

Flavor loss is also a deterioration mode for frozen foods. Some flavor compounds are volatile and exert considerable vapor pressures even at freezer temperatures. The alternation of flavor profile due to flavor loss may cause the consumer to reject the product. Odor pickup is also a deterioration mode. Trimethylamine, a compound responsible for the objectionable "fishy" flavor, is volatile at temperatures as low as $-23°C$. Therefore, the package should also have low permeability to flavor and odor compounds.

It is clear from the above discussion that packaging is vital for protecting frozen foods. Understanding the deterioration modes can help to develop packaging strategies to extend shelf life of the products.

III. PACKAGING MATERIALS

Packaging materials include paper, plastics, glass, and metal. For packaging frozen foods, paper and plastics are most commonly used, metal is occasionally used (for example, as metal ends in composite cans for frozen concentrated juice), and glass is seldom used. In some package designs, combinations of paper and plastics are used: for example, a frozen meal may be placed inside a plastic tray with a lid, and the tray is placed inside a paperboard carton. The major roles of the package are to protect the products against mechanical damages and deteriorative effects of gas and vapor at low temperatures.

A. Paper and Paperboard

Paper and paperboard are mainly used to provide structural support and protect the frozen food products from mechanical damages. These materials are sometimes used as a light barrier, but their moisture and oxygen barrier properties are poor. These materials are made of wood fibers containing cellulose, hemicellulose, and polymeric residues. They have the advantages of good structural strength, low cost, recyclability, and good printability.

There are several types of paper used for frozen food packaging. Kraft paper is a coarse paper, which may be used in unbleached or bleached form. Greaseproof paper and glassine paper provide good protection against oil and grease. Waxed paper is a good moisture barrier and can serve as a heat-sealable layer. Paper is sometimes used as an insert to separate individual items (such as beef patties) within the same package so that those items do not stick together due to freezing.

Paperboard is commonly used for individual packages and secondary packages (e.g., a box which contains several individual packages). The waxed cartonboard, with a moisture-proof regenerated cellulose film overwrap, was used as earlier packaging for frozen vegetables and fruits [4]. There are two basic folding paperboard designs: skillet and three-flap closed carton [3]. Bleached Kraft carton is often used in packaging for the frozen foods due to its strength and good appearance. To improve moisture and oxygen barrier, paperboard is sometimes coated or laminated with plastics or aluminum. To improve appearance and printing quality, the paperboard is sometimes coated with clay and other minerals. It is quite common that a plastic bag containing a frozen food product is placed inside a paperboard carton. In this case, the plastic bag provides the gas and vapor protection, and the carton provides the structural support and mechanical protection.

B. Plastics

Many frozen food products are packaged in plastics for moisture, oxygen, flavor, and odor protection. Plastics consist mainly of synthetic polymers and small amounts of additives (e.g., antioxidant and pigment) which can be cast, extruded, and molded into various shapes such as films, sheets, and containers. Most polymers used in food-packaging plastics have molecular weight between 50,000 and 150,000. Plastics provide a wide range of properties relating to mechanical strength, gas barrier, printability, heat performance, and machine performance [5].

Plastics have a wide range of gas and vapor barrier properties, which offer many choices for different package requirements. The gas barrier properties of a plastic packaging material are usually quantified in terms of permeability: the lower the permeability, the better the gas barrier. Permeability is a function of the plastic material,

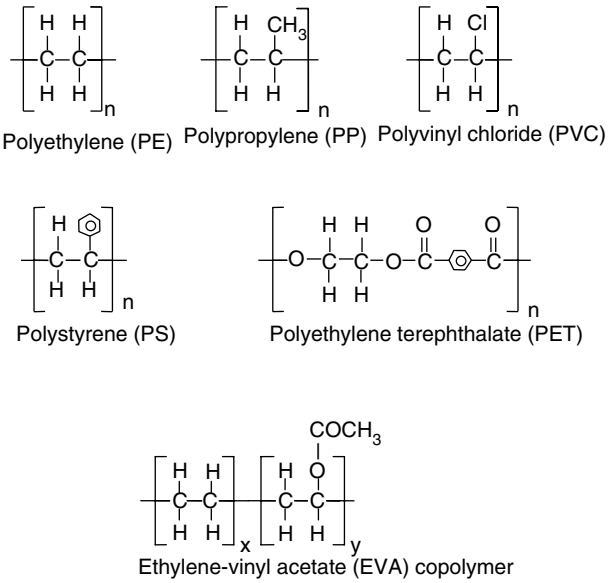

FIGURE 133.3 Chemical structures of some common food-packing polymers.

permeant gas, temperature, and in some cases relative humidity.

In selecting plastic materials for frozen foods, it is necessary to select those which remain flexible at freezer temperatures. Abuse testing (usually includes a combination of shipping, vibration, compression, and drop tests) should be conducted to ensure the package is not brittle and loses its product integrity at low temperatures.

The following is a general discussion of the basic food packaging polymers (Figure 133.3). These polymers are mostly used as bags or pouches for packaging frozen foods. Relatively thick films are used to protect against frozen food products (such as crab legs) which have cutting edges or sharp points. Some packaging films are coextruded or laminated multilayer films consisting of several layers of different polymers. By wisely selecting different polymers, multilayer films can offer the advantages of lower cost and/or better performance.

1. Polyethylene (PE)

PE is a commonly used polymer as plastics bags for individually quick frozen (IQF) foods (e.g., vegetables, fruits, shellfish) [2]. The advantages of PE are low cost, easy processing, and good mechanical and printing properties. PE is usually classified into high-density polyethylene (HDPE), low-density polyethylene (LDPE), and linear low density polyethylene (LLDPE). These classifications differ in density, chain branching, and crystallinity.

HDPE is a linear polymer with relatively few side chains. Its density is typically between 0.94 and 0.97 g/cm^3. It has a higher melting point than LDPE, (135°C versus 110°C typically), and thus it is more suitable for high temperature application such as boil-in-bag applications [2]. HDPE is used in films and containers for frozen foods.

LDPE normally has a density range of 0.91 to 0.93 g/cm^3. It is a branched polymer with many long side chains. LDPE is used mostly as film, an adhesive in multilayer structures, or waterproof and greaseproof coatings for paperboard packaging materials. The film made from LDPE has the advantages of low cost, softness, flexibility, stretchiness, clarity, and heat sealability.

LLDPE is a copolymer with many short side chains. It has LDPE's clarity and heat sealability, as well as HDPE's strength and toughness. Therefore, LLDPE has substituted LDPE in many food-packaging applications.

2. Polypropylene (PP)

PP has the lowest density (~0.9) among all major plastics. It has higher tensile strength, stiffness, and hardness than PE. PP cast film is clearer than PE film and is used in applications where transparency is required.

3. Polyvinyl Chloride (PVC)

PVC is a clear, hard polymer which is often modified with plasticizers (organic liquids of low volatility). Plasticized PVC films are limp, tacky, and stretchable, and the films are commonly used for packaging meat. PVC has better clarity, oil resistance, and barrier properties than those of HDPE.

4. Polystyrene (PS)

PS is a clear, hard, and low impact resistance polymer. High-impact polystyrene (HIPS) is formed by modifying PS with elastomeric molecules such as butadiene. HIPS is more suitable for freezer temperature applications because it has significantly higher impact resistance. Expanded PS (EPS) of various bulk densities are manufactured by adding foaming agents in the extrusion process. Some frozen seafood products (such as lobster tails) are vacuum-skinned down on an EPS tray with a coextruded film.

5. Polyethylene Terephthalate (PET)

PET is the major polyester used in food packaging which can tolerate freezer temperatures and high temperatures. It also provides good resistance to grease and moisture. Biaxial orientation of PET film can improve its clarity and mechanical properties. The crystallized polyethylene terephthalate (CPET) can withstand high temperature up to 220°C, and CPET food trays are suitable for use in microwave and conventional dual ovens.

6. Ethylene-Vinyl Acetate (EVA)

EVA is a copolymer containing 2 to 18% vinyl acetate. It has long chains of ethylene hydrocarbons with acetate

groups randomly throughout the chains. EVA film is tough and tacky, and thus it is often blended with polyethylene to improve sealability, stress resistance, and flex cracking resistance. EVA can be used as bags for frozen foods, and is coextruded with Surlyn ionomer and LDPE for the application in skin packaging.

C. Barrier Properties of Plastics

For foods that are sensitive to moisture or oxygen, gas barrier protection is the major function of the package in providing adequate shelf life, the time period during which the food maintains acceptable quality. Controlling moisture loss is important for frozen foods because moisture loss (sublimation of ice) results in freezer burn and discoloration of the product. Oxidative reaction is also important for some foods even at freezer temperatures.

Transport of gases between the external environment and the headspace through the package can occur by means of leakage and/or permeation. For a properly sealed package in which leakage is not a problem, permeation is the major mechanism of gaseous transport.

Gas permeation is an important consideration in packaging foods with plastics, since food packaging plastics are permeable to moisture, oxygen, carbon dioxide, nitrogen, and other gases (including those that can cause off-odor problems). The gas permeation rate of most interest for frozen foods is water vapor transmission rate (WVTR).

WVTR may be defined as the amount of water vapor transmitted through the package per day [g H_2O/(day(package))] under specific conditions (usually 38°C, 90% relative humidity). WVTR can also be expressed more generally in terms of the amount of water transmitted through 100 in^2 package area per day [g H_2O/(day (100 in^2)] where the package surface area is not specified.

If WVTR is assumed a constant, the shelf life (t_s) can be estimated by

$$t_s = \frac{H_2O,\ max}{WVTR} \tag{133.1}$$

where $H_2O_{,max}$ is maximum allowable water (g H_2O) which can be determined by sensory evaluation. In practice, WVTR is not a constant but decreases with time, because headspace relative humidity decreases and concentration gradient decreases with time. Thus the actual shelf is slightly higher than that predicted by Equation (133.1).

For products that are oxygen sensitive, the oxygen transmission rate (OTR) of a plastic package from the external environment to the headspace can be expressed by

$$OTR = \frac{\bar{P}A}{L}(P_e - P_i) \tag{133.2}$$

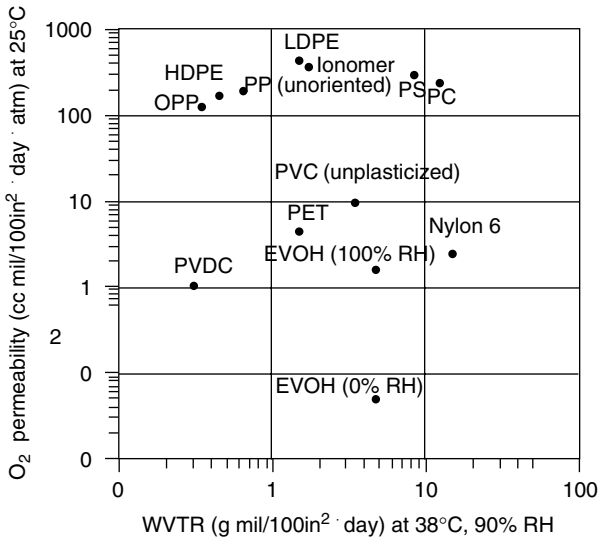

FIGURE 133.4 Gas barrier properties of common food packaging polymers.

where OTR is oxygen transmission rate, cc O_2/day; P is oxygen permeability, cc O_2 (mil)/(100 in^2 (day (atm); A is surface area of package, in^2; L is thickness of package, mil; P_e is oxygen partial pressure in external environment, atm; and P_i is oxygen partial pressure in headspace, atm. The shelf life (t_s) can be calculated using

$$t_s = \frac{O_{2,\ max}}{OTR} \tag{133.3}$$

where t_s is shelf life, day, and $O_{2,max}$ is maximum allowable oxygen, cc O_2. It has assumed in Equations (133.1) and (133.3) that permeation through the package (not the rate of deterioration) is the major factor limiting the shelf life. This is a reasonable assumption when packaging materials of low permeability are used. Combining Equation (133.2) with Equation (133.3) gives

$$t_s = \frac{O_{2,max}\,L}{\bar{P}A\,(P_e - P_i)} \tag{133.4}$$

Equations (133.1) through (133.4) can be used to evaluate many what-if scenarios. For example, according to Equation (133.1), if the thickness of the package is decreased by 20% and the surface area is increased by 20%, then the above equation predicts that the shelf life will be decreased by 33.3%.

An obstacle is that permeability values of packaging polymers are generally not available at freezer temperatures. It is mostly due to the time and cost necessary for measuring permeability at low temperatures. However, literature permeability values are available at higher temperatures, and Figure 133.4 shows the relationship between oxygen permeability and WVTR for some commonly used food packaging plastics [5]. In practice, one can use literature data as

reference when comparing different polymers; better still, one can measure the permeability of interest.

IV. PACKAGING TECHNOLOGIES

A. Vacuum Packaging and Modified Atmosphere Packaging

As mentioned earlier, the headspace is an important factor which affects several deterioration modes of frozen foods. The water vapor in the headspace can cause frost formation, and the oxygen in the headspace can cause oxidation. A technique to control the headspace is vacuum packaging, which simply involves removing air from the headspace. This technique has been shown to help maintain the quality of various frozen products including pizza, seafood, beef, and pork [6]. There are two forms of vacuum packaging depending on rigidity of the package.

The first form of vacuum packaging involves a rigid package (e.g., glass jar) or a semi-rigid package (e.g., plastic container) in which most of the air is evacuated, but a headspace still remains in the package. The removal of air typically reduces the oxygen level in the headspace to as low as 1%, which significantly helps to reduce the problem of oxidation. However, frost formation and freezer burn are still problematic since the headspace exists.

The second form of vacuum packaging involves a flexible package (e.g., a plastic pouch) in which not only the oxygen is removed, but also the headspace is eliminated. Thus both oxidation and frost formation are controlled. This form is also known as vacuum skin packaging, since the food is tightly wrapped by the package. The mechanical stress created by the vacuum also helps to remove air pockets inside the product. This technique has been widely used to package frozen meat and seafood products including meat balls, clam strips, lobster tails, salmon, and farmed rainbow trout [7]. Several types of materials are used for vacuum skin packaging such as a blend of Surlyn ionomer resin with low density polyethylene (LDPE) and ethylene-vinyl acetate (EVA) [8].

Modified atmosphere packaging (MAP) is a technique which involves replacing air (especially its oxygen) in the headspace by other gases such as nitrogen and carbon dioxide. Nitrogen is used as inert gas filler, and carbon dioxide is used because of its ability to inhibit microbial growth. MAP is seldom used for frozen foods because vacuum packaging is often a better alternative in terms of cost (no gas required) and effectiveness (no frost formation). However, MAP is used in some refrigerated and shelf stable food products where the benefit of carbon dioxide is justified or the products cannot withstand the mechanical stress of vacuum packaging.

Both vacuum packaging and MAP requires the use of gas barrier packaging materials; otherwise, the vacuum or the modified atmosphere cannot be maintained for a prolonged period of time. Vacuum equipment or gas flushing equipment is also required.

B. Time-Temperature Indicator (TTI)

It is critical to maintain frozen food products at constant low temperatures. Temperature abuses due to improper handling may result in lower food quality and, even worse, microbial growth if the abuse is severe. Monitoring temperature is a critical control point for frozen foods in designing a HACCP (hazard analysis critical control points) program. While temperature recorders (such as handheld electronic temperature monitoring devices) are often placed in storage rooms and trucks to monitor temperatures, these recorders are not attached directly to the food packages.

A time-temperature indicator (TTI) is a small self-adhesive label that can be attached to a food package for monitoring the package temperatures from the time of production to the time of consumption. The TTI helps to determine whether the product is still fresh at point-of-purchase and at home by providing the consumer with a visual indication.

An important aspect of TTI is the visual indication system which typically involves color change or size change associated with diffusion, chemical reaction, or enzymatic reaction. The visual indication (color change or size change) is correlated to the temperatures or time-temperature history. In order to use the TTI to indicate the shelf life of the product, the kinetics of the TTI and the kinetics of the food must be known, and it is also necessary to match the activation energies of the TTI and food deterioration reaction. The technical details are beyond the scope this chapter but they can be found elsewhere [9].

There are two common types of TTIs. The first type is the temperature limit indicator (or threshold indicator) which triggers an indication when a certain temperature limit is exceeded. For example, if the upper limit is set at $-3°C$, the TTI will trigger a color indication once the temperature limit is exceeded. The second type is the time-temperature integrator which triggers an indication when the time-temperature limit is exceeded. For example, if the indicator is set at 60 days and $-18°C$, the TTI will trigger a color indication once an equivalent of this time-temperature history is exceeded. The equivalent time-temperature history is estimated from the kinetics of the TTI.

Presently several TTIs are available in the market. The LifeLines Fresh-Check® is based on polymerization reaction which responds to cumulative exposure to temperature. The 3M Monitor Mark® is based on dye diffusion which is activated by pulling out an activation strip. Upon exposure to temperatures above the threshold, the activated indicator's window irreversibly turns blue, warning that product quality testing should be performed. The Vitsab® TTI is based on enzymatic color change. More

information about these TTIs can be found on the company websites.

V. CONCLUDING REMARKS

Packaging is essential for protecting frozen foods from mechanical damage, moisture loss, flavor loss, odor pickup, and oxidation. Reducing headspace and air pockets inside of the package by vacuum packaging will help minimize frost formation.

One needs to analyze both the distribution environment and stability of the product in order to formulate the packaging requirements for a specific product. In analysis of food stability, the dominant deterioration modes should be identified. Their kinetics and acceptable limits should also be determined. Once the food stability and required shelf life is known, package requirements for protecting the product from the dominant deterioration modes can be decided.

It is helpful to work with the packaging material supplier and packaging machine manufacturer to design and manufacture the package according to the requirements decided. Other factors including those described earlier in this chapter should also be considered in the package design process.

CONTENTS

I. INTRODUCTION

The term thermal processing has been widely used in food industry to describe the process of heating, holding, and cooling that are required to produce microbiologically safe packaged food products of acceptable quality [1]. Sterilization is a type of thermal processing designed for complete elimination of both spores and vegetable cells. Commercial sterilization does not require complete microbial elimination, but the degree of elimination has to be regulated and optimized under accepted criteria to ensure product safety. Pasteurization eliminates only vegetable cells and thus does not provide shelf-stable food products without other preserving processes such as refrigeration.

A general procedure for evaluating a thermal process of a food package is as follows. First, the heat penetration in the food during the thermal process is determined by measuring the temperature of the food at a specific point (often the slowest heating point) as a function of processing time. Heat penetration parameters such as *f*- and *j*-values may then be determined from this time-temperature profile. Second, a target microorganism is selected based

on the pH, water activity, and other considerations of the food. The thermal destruction properties of the target microorganism including decimal reduction time (D-value) and thermal resistance constant (z-value) may then be obtained from experiments or the literature. Based on these thermal destruction properties and other considerations such as initial microbial load, the minimum heating time (F_r) at a given reference temperature that is required to reduce the target microorganism population to a stated safe standard is determined. Third, the sterilizing value (F-value) of the thermal process is determined. This is the heating time at the reference temperature yielding a microbial lethal effect equivalent to that of the entire actual processing. For commercial thermal processing, the F-value is often set significantly higher than the F_r value to ensure microbiologically stable food products [1].

II. HEAT PENETRATION IN FOOD DURING THERMAL PROCESSING

Figure 134.1 shows typical temperature profiles of heating medium and the slowest heating point of a packaged food during a batch thermal processing. T_{hm} is the holding temperature of heating medium, T_0 is the initial temperature of food, T_1 is the temperature of the slowest heating point at the end of heating phase, and t_{cu} is the come-up time. From these profiles, heat penetration curves of the slowest heating point for the heating and cooling phases may be constructed.

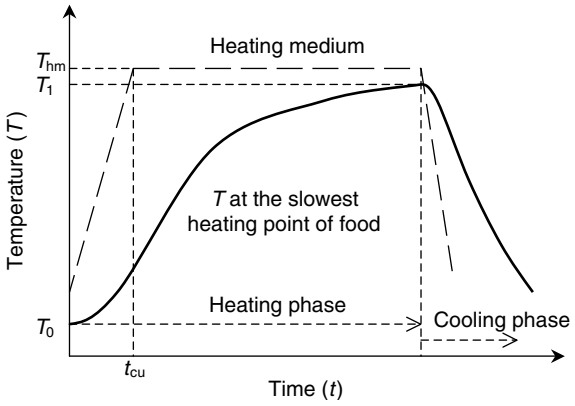

FIGURE 134.1 Typical temperature profiles in a batch thermal processing.

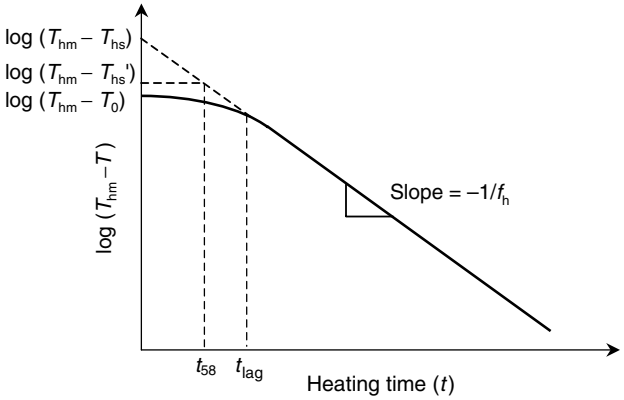

FIGURE 134.2 Heat penetration curve for heating phase.

A. Estimation of Heat Penetration Parameters

For the heating phase, the heat penetration curve is constructed by plotting $\log(T_{hm} - T)$ versus heating time. See Figure 134.2 for the symbols used in the following discussion.

The lag factor for heating phase (j_h) is defined as:

$$j_h = \frac{T_{hm} - T_{hs}}{T_{hm} - T_0} \tag{134.1}$$

where T_{hs} is pseudo-initial temperature obtained by extrapolating the linear line to time zero. The slow come-up of the retort is responsible for part of the lag time (t_{lag}). A widely accepted method to compensate for this come-up effect is to determine a new zero time at 58% of the come-up time (t_{58}) [1, 2]. That is, 42% of the come-up time is added to the process time at T_{hm}. With the new zero time, the j_h-value is redefined as:

$$j_h = \frac{T_{hm} - T_{hs'}}{T_{hm} - T_0} \tag{134.2}$$

where $T_{hs'}$ is pseudo-initial temperature obtained by extrapolating the linear line to time t_{58}. With the j_h-value, the equation for the linear line (for $t > t_{lag}$) can be written as:

$$\log(T_{hm} - T) = -\frac{t}{f_h} + \log[j_h(T_{hm} - T_0)] \tag{134.3}$$

or

$$T_{hm} - T = j_h(T_{hm} - T_0)10^{-\frac{t}{f_h}} \tag{134.4}$$

For cooling phase, plotting $\log(T - T_{cm})$ versus cooling time also yields a negative sloped line with initial curvilinear portion, where T_{cm} is holding temperature of cooling medium. The lag factor for cooling phase (j_c) is defined as:

$$j_c = \frac{T_{cs} - T_{cm}}{T_1 - T_{cm}} \tag{134.5}$$

where T_{cs} is pseudo-end temperature of heating phase obtained by extrapolating the line to the end time of heating phase. The equation for straight line (for $t > t_{lag}$ of cooling phase) can be expressed as:

$$\log(T - T_{cm}) = -\frac{t}{f_c} + \log[j_c(T_1 - T_{cm})] \tag{134.6}$$

or

$$T - T_{cm} = j_c(T_1 - T_{cm})10^{-\frac{t}{f_c}} \tag{134.7}$$

The next section will show that theoretically the *j*-value depends on the location in the food, at which the temperature is measured, when conduction is the main heat transfer mechanism in the food, and the *f*-value depends on the thermal properties and the size of the food.

B. Physical Meanings of f- and j-Values

For a theoretical illustration of the physical meanings of the heat penetration Equations (134.3) and (134.6) as well as the *j*- and *f*-values, two cases of thermal processing are often considered. The first case is when the food is liquid-like and convection is mostly responsible for the heat transfer within the food during thermal processing. The second case is when the food is solid-like and conduction is the main mechanism of heat transfer within the food. The heat transfer resistance due to the packaging material is not taken into account, since the material is assumed to be very thin and have much larger thermal conductivity than that of the food.

1. Convection-Dependent Thermal Processing

If the food being heated or cooled is liquid-like and sufficient convective heat transfer occurs, the temperature gradient within the food may be ignored. Due to the uniform internal temperature, this convection-dependent thermal processing can be analyzed using the lumped capacity method or Newtonian heating or cooling method, which describes the time-temperature history of a solid object when the Biot number (*Bi*) of heat transfer is very small (often less than 0.1) [3]. The mathematical model developed for this method, known as the Schultz-Olson model [1], had been derived by equating the rate of change in internal energy of the food and the rate of heat transfer between the medium and the food. The heat balance equation for heating phase is:

$$\rho V c_p \frac{dT}{dt} = UA(T_{hm} - T) \tag{134.8}$$

where ρ is the density of the liquid food (kg m^{-3}), V is the volume of the food (m^3), c_p is the specific heat of the food at constant pressure (J kg^{-1} K^{-1}), U is the overall heat transfer coefficient at the internal side of the package (W m^{-2} K^{-1}), and A is the internal surface area of the package (m^2). By integrating Equation (134.8) from $t = 0$ to t and $T = T_0$ to T, the Schultz-Olson model for heating phase is obtained:

$$\log(T_{hm} - T) = -\frac{0.434UAt}{\rho V c_p} + \log(T_{hm} - T_0) \tag{134.9}$$

Comparing this model with Equation (134.3), one can obtain theoretical expressions of j_h and f_h for the convection-dependent thermal processing:

$$j_h = 1 \tag{134.10}$$

$$f_h = \frac{2.303\rho V c_p}{UA} \tag{134.11}$$

Equation (134.11) shows that f_h is proportional to the volume and the specific heat of the food but inversely proportional to the overall heat transfer coefficient and the internal surface area of the package. In practice, the value of f_h is smaller than the theoretical value during initial heating, since the initial large temperature difference between the medium and the food yields high U value, and increases gradually to constant theoretical value. Due to the initial small f_h-value, the actual j_h-value is somewhat less than the theoretical value of 1. The meanings of j_c- and f_c-values can be illustrated in a similar manner.

2. Conduction-Dependent Thermal Processing

If a solid food is processed thermally, conduction controls the heat transfer within the food. As an illustration, one may assume a cylindrical food package of radius a and length l, exposed to a constant temperature environment with infinite surface heat transfer coefficient (i.e., infinite *Bi*) and uniform initial temperature. Analytical solution describing the time-temperature history of the cylindrical food during heating phase is found in Cowell and Evans [4] or elsewhere:

$$\frac{T_{hm} - T}{T_{hm} - T_0} = \frac{8}{\pi} \sum_{k=1}^{\infty} \sum_{n=1}^{\infty} \frac{J_0(P_k \rho)}{P_k J_1(P_k)} \times \frac{\sin[(2n-1)\pi\xi]}{2n-1} e^{-AB} \tag{134.12}$$

and

$$\rho = \frac{r}{a}$$

$$\xi = \frac{y}{l}$$

$$A = \left(\frac{P_k}{m}\right)^2 + (2n-1)^2\pi^2, \; m = \frac{a}{l}$$

$$B = \frac{\alpha t}{l^2}$$

where J_0 and J_1 are Bessel functions of the first kind of order zero and one, respectively; P_k is the root of Bessel

functions; r and y are the coordinates of radial direction and length-direction, respectively; and α is the thermal diffusivity of the food. For a large value of B, the first-term approximation of Equation (134.12) may be used:

$$\frac{T_{hm} - T}{T_{hm} - T_0} = \frac{8}{\pi} \frac{J_0(P_1\rho)}{P_1 J_1(P_1)} \sin(\pi\xi) e^{-A_{11}B} \qquad (134.13)$$

where

$$A_{11} = \left(\frac{P_1}{m}\right)^2 + \pi^2 \quad \text{and} \quad P_1 = 2.4048$$

Comparing Equation (134.13) to Equation (134.3), theoretical expressions of j_h and f_h for the conduction-dependent thermal processing can be obtained:

$$j_h = \frac{8}{\pi} \frac{J_0(P_1\rho)}{P_1 J_1(P_1)} \sin(\pi\xi) \qquad (134.14)$$

$$f_h = \frac{2.303}{\alpha\left[\left(\frac{P_1}{a}\right)^2 + \left(\frac{\pi}{l}\right)^2\right]} \qquad (134.15)$$

Equation (134.14) shows that j_h depends on the position in the food, at which the temperature is measured, regardless of the size and the type of the food. At center, the theoretical value of j_h is 2.0397 since $\rho = 0$ and $\xi = 0.5$. Equation (134.15) shows that f_h depends on the thermal diffusivity and the size of the food, but it is the same at any location in the food. The meanings of j_c- and f_c-values can be also illustrated in a similar manner.

III. EVALUATION OF THERMAL PROCESSING

A thermal process should be carefully evaluated to ensure microbiologically safe food products. In most cases, the evaluation requires either of the followings: (1) determination of process sterilizing value (F-value) for a given processing time and a heat penetration curve, or (2) determination of a proper processing time required for a target F-value [1, 5].

A. Sterilizing Value

The F-value is defined as the heating time at a reference temperature, which can yield the lethal effect equivalent to that of the actual process at a critical location, often the slowest heating point. For example, if the reference temperature is 121.1°C and the determined F-value is 3 min for a thermal process, then this means that the process can inactivate the target microorganism as much as the 3 min-heating at 121.1°C at the location. By determining the F-value, different thermal processes can be compared for their lethality.

To determine the F-value, the lethal rate (L) needs to be defined:

$$L = \frac{F_r}{F_T} = \frac{D_r}{D_T} = 10^{\left(\frac{T - T_r}{z}\right)} \qquad (134.16)$$

where F_r and F_T are minimum heating times required for reducing the population of target microorganism at the critical location to a stated safe standard value at a reference temperature T_r and at a certain temperature T, respectively. And D_r and D_T are D-values for the target microorganism at T_r and T, respectively. The fundamental equation for determining F-values is given by:

$$F = \sum_i \left(\frac{F_r}{F_T}\right)_i t_i = \int_0^t L\,dt = \int_0^t 10^{\left(\frac{T - T_r}{z}\right)} dt \qquad (134.17)$$

where t_i is the actual heating time at a certain temperature T, and t is the total processing time. Various methods developed for integrating Equation (134.17) is discussed in Section IV.

The reference temperature T_r is decided depending on the purpose of thermal processing. For sterilization, the value of T_r is in the range 115–130°C. For example, in canning industry, 121.1°C (250°F) is often used. For pasteurization, the range of T_r is 60–100°C. For example, 60°C and 72°C are suggested for beer and milk industries, respectively [2, 6].

B. Guide to Sterilizing Value

Viability of microorganisms depends on various factors such as the type of microorganism, initial microbial load, the pattern and the stage of cell growth, processing conditions, operating procedure, physicochemical properties of food, etc. While F-value should be determined and validated for each food process, some useful guides are available. Holdsworth [1] provides general principles for selecting F-values and summarizes the recommended F-values for meat, vegetable, fish, poultry, and other food products based on various sources including Alstrand and Ecklund [7], Townsend et al. [8], NFPA [9, 10], Hersom and Hulland [11], Codex Alimentarius Commission [12], and reports from UK.

C. Mass Average Sterilizing Value

The concept of mass average sterilizing value (F_s-value) or integrated F-value was introduced by Stumbo [13, 14] for evaluating the lethality of entire food, not just at the slowest heating point. The F_s-value is useful when the location at which the temperature is measured, mostly the geometrical center of the food, is not the slowest heating point. According to Holdsworth [1], the phenomenon is not observed for the domestic sizes of cans, but for large cans the slowest heating location could be a toroidal ring around the center. However, using the F_s-value is not quite

appropriate in evaluating the lethal effect of a thermal processing, since the microbial safety of a food product always depends on the population of a target microorganism at the slowest heating point. A more useful application of the F_s-value can be the quality optimization of thermally processed foods [1, 15–18]. The thermal degradation of heat-sensitive food components, which are distributed throughout the food product, can be evaluated using the F_s-value.

IV. METHODS FOR DETERMINING STERILIZING VALUE

A. General Method

Once the time-temperature profile of the slowest heating point is obtained experimentally or theoretically, the lethal rate (L) at the location can be calculated using Equation (134.16) and plotted with respect to the processing time (Figure 134.3). From the definition (Equation 134.17), the F-value can be determined by calculating the area under the lethal rate curve.

Various methods are available for the area calculation. The simplest method is to count squares or use a planimeter [1]. Another well-known method involves the construction of lethal rate paper [19–22]. Numerical calculations have also been used using trapezoidal rule [23], Simpson's rule [24, 25], or Gaussian integration formula [20].

B. Analytical Method

Analytical solutions of Equation (134.17) could be obtained if the time-temperature profile follows analytical heat penetration equations based on heat transfer theory, such as Equations (134.9) and (134.12). Examples of the solutions were discussed by Holdsworth [1], Hicks [26], and Hurwicz and Tischer [27]. An advantage of the analytical method is that the meanings of the F-value and various processing factors can be better understood and, therefore, it can provide theoretical basis for other F-value determination methods. However, the analytical solutions of Equation (134.17) are not always available, and the assumptions needed for the derivations sometimes greatly reduce the accuracy of the method.

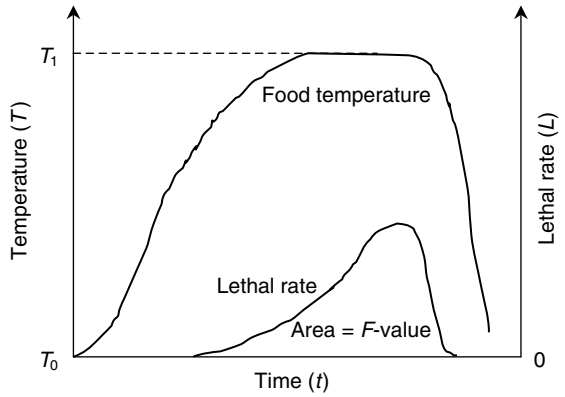

FIGURE 134.3 Typical profiles of temperature and lethal rate at slowest heating point.

C. Formula Method

In the formula method, empirical heat penetration equations such as Equations (134.4) and (134.7) are obtained experimentally and substituted into Equation (134.17) to yield the F-value. The method was first proposed by Ball [28] and further developed by a number of researchers, including Ball and Olson [2], Stumbo [14], Gillespy [29], Jakobsen [30], and Hayakawa [5, 31]. In the following sections, the Ball's method and the Hayakawa's method are discussed.

1. Ball's Method

In the Ball's original method [28], Equations (134.4) and (134.7), which are linear on the semi-logarithmic heat penetration curve (see Figure 134.2), are substituted to Equation (134.17) and integrated to determine the F-value (F_h) for heating phase and the F-value (F_{cl}) for cooling phase, respectively. The F-value (F_{cc}) for the curvilinear portion of the heat penetration curve, observed at the beginning of cooling phase, is also considered.

Therefore, the F-value for the entire thermal process is calculated as:

$$F = F_h + F_{cc} + F_{cl} \tag{134.18}$$

By the substitution and integration, the F_h-value for heating phase is given by:

$$F_h = \frac{f_h}{\ln 10} \cdot 10^{\frac{T_{hm}-T_r}{z}} \left[E_1\left\{ \ln 10 \cdot \left(\frac{T_{hm} - T_1}{z} \right) \right\} - E_1\left\{ \ln 10 \cdot \left(\frac{j_h (T_{hm} - T_0)}{z} \right) \right\} \right] \tag{134.19}$$

where $$E_1(x) = \int_x^\infty \frac{e^{-p}}{p}\, dp \tag{134.20}$$

or $$E_1(x) = -\gamma - \ln x - \sum_{n=1}^{\infty} \frac{(-1)^n x^n}{n \cdot n!} \tag{134.21}$$

Equation (134.20) is useful when $x > 0.01$, because its solution tables are available. Equation (134.21) is used when $x < 0.01$ and γ is Euler's constant (0.577215665). Temperatures are expressed in degree Fahrenheit. For a broken heating curve, the F_h-value is given by:

$$F_h = \frac{1}{\ln 10} \cdot 10^{\frac{T_{hm}-T_r}{z}} \left[f_{h1} \left[E_1\left\{ \ln 10 \cdot \left(\frac{T_{hm} - T_1^*}{z} \right) \right\} - E_1\left\{ \ln 10 \cdot \left(\frac{j_h (T_{hm} - T_0)}{z} \right) \right\} \right] \right.$$

$$+ f_{h2}\left[E_1\left\{\ln 10 \cdot \left(\frac{T_{hm} - T_1}{z}\right)\right\} - E_1\left\{\ln 10 \cdot \left(\frac{(T_{hm} - T_1^*)}{z}\right)\right\}\right]\Bigg] \quad (134.22)$$

where f_{h1} and f_{h2} are f_h-values before and after breaking point, respectively, and T_1^* is the food temperature at breaking point.

For cooling phase, $j_c = 1.41$ is assumed. The F_{cc}-value for the initial curvilinear portion of the semi-logarithmic heat penetration curve is calculated using the following equation:

$$F_{cc} = f_c \cdot 10^{\frac{T_1 - T_r}{z}}\left[0.1435 \cdot e^{-\frac{0.789m}{z}} + 0.1096 \cdot \frac{E}{m} \cdot e^{\frac{0.692m}{z}}\right] \quad (134.23)$$

where

$$E = (2.303n)^2 \int_1^{2.14} e^{-2.303nx}\sqrt{x^2 - 1}\, dx$$

$$m = T_1 - T_{cm}$$

$$n = \frac{0.3m}{z}$$

And the F_{cl}-value for the linear portion is given by:

$$F_{cl} = \frac{f_c}{\ln 10} \cdot 10^{\frac{T_{cm} - T_r}{z}}\left[E_i\left\{\ln 10 \cdot \left(\frac{0.657m}{z}\right)\right\} - E_i\left\{\ln 10 \cdot \left(\frac{m + g - 80}{z}\right)\right\}\right] \quad (134.24)$$

where $g = T_{hm} - T_1$ and

$$E_i(x) = \int_{-\infty}^{x} \frac{e^p}{p} dp \quad (134.25)$$

Tables for Equation (134.25) are also available elsewhere. Ball's original method was further modified by Ball and Olson [2], Hicks [32], Pflug [33], and many other researchers.

2. Hayakawa's Method

Hayakawa [5] introduced the special sterilizing value (U) for determining the F-value. According to his two theorems, the F-value can be calculated using the following equation.

$$F = (U_h + U_c) \cdot 10^{\left(\frac{T_{hm} - T_r}{K_s z_a}\right)} \quad (134.26)$$

The relative z-value, K_s, is defined as:

$$K_s = \frac{z_b}{z_a} \quad (134.27)$$

where z_a is a reference z-value and z_b is any z-value of interest. With Equation (134.27), the F-value can be determined for any z-value. The U-value for heating phase (U_h) and the value for cooling phases (U_h) are given by:

$$U_h = \int_0^{t_h} 10^{-\frac{(T_{hm} - T)}{K_s z_a}}\, dt \quad (134.28)$$

$$U_c = 10^{-\frac{(T_{hm} - T_1)}{K_s z_a}} \cdot \int_0^{t_c} 10^{-\frac{(T_1 - T)}{K_s z_a}}\, dt = 10^{-\frac{(T_{hm} - T_1)}{K_s z_a}} \cdot U_{gc} \quad (134.29)$$

where t_h and t_c are heating and cooling times, respectively. The values of U_h and U_c can be conveniently obtained from the universal tables of U_h/f_h and U_{gc}/f_c, respectively.

The tables were prepared based on the following two observations: (1) the U_h/f_h-values are independent of f_h-values when the j_h- and g ($= T_{hm} - T_1$)-values are fixed, (2) the U_{gc}/f_c-values are independent of f_c-values when values for j_c and for $T_1 - T_{cm}$ are fixed. In the calculations for table preparation, Equations (134.4) and (134.7) were used for the linear portions of heating and cooling curves, respectively. The curvilinear portions of heating and cooling curves were evaluated using the following empirical circular formulas.

a. *Formulas for the curvilinear portion of heating curve*

(i) $0.4 \leqslant j_h < 1.0$:

$$T_{hm} - T = (T_{hm} - T_0)^{\cot(Bt + \pi/4)} \text{ for } 0 \leqslant t \leqslant t_{lag} \quad (134.30)$$

where

$$B = \frac{1}{t_{lag}}\left\{\arctan\left[\frac{\log(T_{hm} - T_0)}{\log\{j_h(T_{hm} - T_0)\} - t_{lag}/f_h}\right] - \frac{\pi}{4}\right\}$$

$$t_{lag} = 0.9 \cdot f_h\,(1 - j_h)$$

(ii) $1.0 < j_h \leqslant 3.0$:

$$T_{hm} - T = (T_{hm} - T_0)^{\cot Bt} \quad \text{for } 0 \leqslant t \leqslant t_{lag} \quad (134.31)$$

where

$$B = \frac{1}{t_{lag}} \cdot \arccos\left[\frac{\log\{j_h(T_{hm} - T_0)\} - t_{lag}/f_h}{\log(T_{hm} - T_0)}\right]$$

$$t_{lag} = 0.7 \cdot f_h\,(j_h - 1)$$

b. *Formulas for the curvilinear portion of cooling curve*

The curvilinear formulas for the cooling curve can be obtained by replacing some symbols in the above formulas in the following ways.

$$f_h \Rightarrow f_c$$

$$\begin{gathered} j_h \Rightarrow j_c \\ T_{hm} - T \Rightarrow T - T_{cm} \\ T_{hm} - T_0 \Rightarrow T_1 - T_{cm} \\ t_{lag} \text{ for heating} \Rightarrow t_{lag} \text{ for cooling} \end{gathered} \tag{134.32}$$

The Hayakawa method is considered as one of the most versatile and reliable techniques [1, 34, 35].

V. FACTORS AFFECTING THERMAL PROCESSING

The severity of a thermal processing, that is, the required F-value, is affected by a number of factors originated from the complexity of food nature and the variety of processing methods and packages. An outline of such factors is well presented in Holdsworth [1].

A. Food Factors

1. The phase and the rheological behavior of the food, the packing of food components in the package determines if the main mechanism of internal heat transfer is conduction, convection, or both, as well as the rate of heat transfer [36].
2. As the initial temperature of the product increases, the processing time and the f_h-value decrease, and the j_h-value increases. The initial temperature is more important in the conduction-dependent thermal processing. Also, the initial temperature distribution in the product affects the j_h-value [37, 38].
3. Initial load of target microorganisms and their z- and D-values are important to determine the process severity.
4. The thermal diffusivity and specific heat of the food, affected by the food composition and the consistency of food components, greatly influences the f-value (Equations (134.11) and (134.15)). Therefore, the change of thermal diffusivity or specific heat with temperature may not be negligible.
5. The pH of the product determines the process severity. The products with lower pH may require lighter thermal processing.
6. Certain additives such as nitrite, salt, sugar, and including various antimicrobial agents can reduce the process severity.

B. Processing Factors

1. As the temperature of heating medium increases, the processing time and the f_h-value decrease, and the j_h-value increases.
2. The rotation of product in the retort can enhance the internal heat transfer to reduce the f_h-value.
3. The longer the processing time, the greater the heat penetration.
4. As the surface heat transfer coefficient between the package and the heating medium increases, the f_h-value decreases and the j_h-value increases [2, 39].

C. Package Factors

1. The thermal conductivity of the packaging material determines the rate of heat penetration.
2. The shape and dimension of the package are important. The f- and j-values depend on the package shape [37]. Equations (134.11) and (134.15) show that the f_h-value depends on the size of the packaged food. The heat penetration into the package is greater for the package of larger surface area and the smaller thickness.
3. The amount of headspace is important for agitation and rotation, which can enhance the internal heat transfer.
4. The position of packages inside the retort and the type of stacking can affect the heat transfer to individual packages.

VI. RETORTS AND HEAT TRANSFER MEDIA

A. Retorts

Currently, a large number of different types of retort are available. In general, the type of retort may be classified into five groups depending on the mode of operation: (1) batch-static (e.g., conventional vertical or horizontal batch retorts without rotation), (2) batch-rotary (e.g., batch retorts with internal rotation of packages), (3) continuous-static (e.g., hydrostatic cookers without rotation), (4) continuous-rotary (e.g., hydrostatic cookers with rotating carrier bars, reel and spiral cookers), and (5) semi-continuous (e.g., Crateless retorts) [1]. Selecting a proper retort requires careful considerations on the three types of factors mentioned in Section V. The pressure balance between the inside and outside of the package is another important factor to be considered, especially for rigid and plastic packages prone to distortion at high temperatures and at high rates of cooling. Beyond the scientific evaluation of the factors, the economic factors such as available area, factory layout, the number of operator, production yield, the cost of installation, operation, and maintenance should be also considered. More detailed considerations on retort systems are presented by Holdsworth [1], Lopez [40], Rees and Bettison [41], and Footitt and Lewis [42].

B. Heat Transfer Media

For heating media, saturated steam, steam-air mixture, hot water, and gas flame, and for cooling media, chilled water, are available. For a proper selection of heat transfer media, the factors presented in Section V, especially surface heat transfer coefficients and packaging materials, as well as various economical, environmental factors must be carefully taken into account.

The heat transfer coefficient at the surface of the package in contact with the heat transfer media is one of the critical parameters to determine the efficiency of heat penetration. Its values for saturated steam, vigorously boiling water, and gas flame are very high and thus the heat transfer resistance at the package surface is often negligible, that is, the Biot number can be assumed infinite. Due to their rapid heat transferring ability, those heat transfer media are suitable for HTST (high-temperature short-time) processes. Other media have much lower values of surface heat transfer coefficient, and therefore, the resistance at the surface is necessary to be considered in the process evaluation. The ranges of the surface heat transfer coefficient (or overall heat transfer coefficient) of the media are well reviewed in Holdsworth [1].

The type of packaging materials is also an important factor to be considered in the media selection. For heating metallic packages, all the existing media are usable. The air heating and cooling of canned products have been also developed, however, their commercial applications have not been appeared yet [1]. For heating retortable laminated pouches or plastic packages, hot water [43] or steam-air mixture [44] can be used. For glass packages, saturated steam, steam-air mixture, and hot water are suitable heating media.

The cooling stage generally uses chilled water of about 10°C, and is slower than the heating stage due to the lower surface heat transfer coefficients. Relatively few studies have been reported on the cooling media and their surface heat transfer coefficients [1].

VII. RETORTABLE PACKAGES

A. Metal and Glass Packages

Metal cans and glass jars have been widely used in thermal processing due to their mechanical strength and thermal stability under high temperature and pressure conditions. The excellent closure integrity of these packages is especially advantageous for protecting high water activity, low acid, meat-based foods against microbial contamination. Metal cans may be two- or three-piece cans made of tin-plated steel, lacquered tin-free steel, or aluminum [1, 45]. An advantage of using glass jars is the visibility of the contents; however, careful operation and handling are required to prevent shock breakage [1].

B. Plastic Packages

Plastic packages are sometimes used for thermal processing of foods, especially ready-to-eat military rations. These packages are usually in the form of pouches or containers. A typical retortable pouch for military rations is made of a foil layer sandwiched between two layers of plastics such as polypropylene. A typical retortable plastic container is made of an oxygen barrier layer such as EVOH sandwiched between two polypropylene layers.

There are several advantages of using plastic packages for thermal processed foods [46]: (1) high surface-to-volume ratio that allows rapid heat transfer under mild thermal conditions, (2) convenience due to light weight, easy opening, easy handling, and microwavability, (3) large surface area for printing, and (4) flexibility in package design. However, plastic packages are not as reliable as metal or glass packages due to the following limitations [46]: (1) lower tolerance to heat and pressure, (2) relatively poor oxygen barrier, (3) heat seal of plastic packages is not as reliable as double seam of metal cans, and (4) seal inspection is more difficult.

135 Edible Films and Coatings

S.-Y. Lee and V.C.H. Wan
Food Science and Human Nutrition Department, University of Illinois

CONTENTS

I. HISTORY OF EDIBLE FILMS AND COATINGS

The properties and applications of edible films and coatings (EFC) have been studied extensively during the past few decades. It has been demonstrated that EFC can extend shelf life and maintain quality of various food products.

In fact, applying EFC to a food product is not a new concept. Waxing on fruits to reduce water loss and to provide attractive gloss has been used for thousands of years (1). In the sixteenth century, Englishmen wrapped foods with fat, a process called "larding," to prevent water loss (2). Furthermore, sausage casings made with collagen, which is mainly used for containment of meat batter, is one of the earliest forms of food processing.

II. DEFINITION

Edible films and coatings are classified differently by definition. Edible films are defined as a pre-formed edible layer which can be placed on or between food components. Edible coatings are defined as a thin layer of edible material formed as an integrated coating on food surfaces (3).

III. FUNCTIONS OF EDIBLE FILMS AND COATINGS

A. Retard Moisture Migration

Maintaining an appropriate range of moisture level is crucial for the quality and shelf life of food products. Physical structure of bakery products would collapse if moisture is absorbed. Sensory properties such as texture and flavor are also significantly affected by the changes in moisture content. Furthermore, water loss of food products such as fruits and vegetables, decreases shelf life.

One of the functions of edible coatings is to retard moisture migration. Studies have shown that some EFC are efficient moisture barriers (4). Lipid edible films and bilayer films made with lipid and protein or polysaccharide are generally better moisture barriers than protein and polysaccharide films due to higher level of hydrophobicity. Waxes have the lowest water vapor permeability (WVP) among edible film-forming materials. They have 25 times less WVP compared to common oil films and 100–200 times less WVP than for protein films (5). Raisins pretreated with starch and coated with beeswax had less moisture loss than untreated raisins after five weeks of storage (6). Chocolate brownies coated with beeswax and methylcellulose (MC) had significantly less moisture gain than uncoated brownies. This study also showed that moisture barrier property of MC coating alone is poor, since there is no difference in moisture gain between MC coated and uncoated brownies (7). Besides coating products, edible films can be placed on or between layers of food product to retard moisture migration from a higher moisture level component to a lower moisture level component. Kamper and Fennema (8) developed an edible bilayer consisting of stearic-palmitic acid and hydroxypropyl methylcellulose (HPMC), and placed it between tomato paste and crackers. It significantly delayed water transfer from tomato paste to crackers. Conventionally, waxes are applied to fruits and vegetable surfaces to reduce shrinkage due to water loss (1).

B. Retard Gas Transfer

The levels of carbon dioxide and oxygen that come in contact with a product have to be taken into consideration in order to retain quality of the product and consequently lengthen shelf life (9). The primary deterioration that is involved with gases is rancidity, developed by oxidation of lipids, which results in off-flavors. Products with high content of fat such as nuts and potato chips are susceptible to rancidity (10). Protein and polysaccharide coatings which are highly impermeable to fat, oil, and oxygen are effective in preventing lipid oxidation (11). Wu, Rhim, Weller, Hamouz, Cuppett, and Schnepf (12) reported that wheat gluten, soy protein, chitosan, and carrageenan coatings effectively controlled lipid oxidation of precooked beef patties. Lee, Trezza, Guinard, and Krochta (13) showed that rancidity of whey-protein-coated peanuts was significantly lower than uncoated peanuts. It is desirable to regulate gas transfers during storage of fruits and vegetables, since respiration of fruits and vegetables depletes oxygen and increases carbon dioxide level. If the level of oxygen is too low, anaerobic respiration will occur and lead to abnormal ripening, development of off-flavors, and spoilage. In the presence of oxygen, production of ethylene increases and promotes ripening and senescence, which results in shorter shelf life (14). Internal modified atmosphere can be achieved by applying edible coatings made with materials that have low permeability to gases. Protein and polysaccharide coatings are generally good barriers to gases. Lee, Park, Lee, and Choi (15) reported lower initial respiration rate of apples coated with carrageenan or whey protein than uncoated apples.

Enzymatic oxidative browning is another deterioration that can be prevented by minimizing the uptake of oxygen. When oxygen, polyphenol oxidase, and copper ion are present, enzymatic oxidative browning occurs, which turns phenol, a colorless substance, into a brown substance, melanoidins. This could, thus, lead to the decrease in acceptance of the product. Delayed browning of apple and potato slices coated with calcium caseinate or whey protein solutions were observed by Le Tien, Vachon, Mateescu, and Lacroix (16).

C. Retard Aroma Loss/Gain

Aroma, along with other attributes, such as appearance, taste, and texture is important to the quality of food products. Aroma is perceived when volatile compounds are dissolved in the nasal cavity and perceived by the olfactory system. Volatile compounds that are lost to or picked up from the storage environment could be regulated with edible coatings (11). Debeaufort and Voilley (17) showed that wheat gluten film is an effective barrier for 1-octen-3-ol, which represents a smell of mushrooms. They suggested that it can be used for wrapping cheeses to prevent aroma gain of 1-octen-3-ol from the refrigerator. Oranges coated with cellulose-based coating or commercial shellac coating had retained higher concentration of volatile compounds after storage up to 55 days than uncoated oranges (18). Shellac-coated apples had higher concentrations of fruit-like and apple-like volatiles than uncoated apples, which was due to the reduction in evaporation rate of these volatile

compounds (19). Nisperos-Carriedo, Shaw, and Baldwin (20) also stated that fruits coated with beeswax emulsion and TAL Pro-Long (commercial coating composed of different fatty acids and carboxymethyl cellulose (CMC) sodium salt) effectively retained and increased volatile compounds that were considered important to fresh orange flavor.

D. Retard Lipid Migration

Lipid migration is a major problem in confectionary products. Liquidly lipid such as fatty acid tends to migrate to the surface of chocolate coatings, which results in soft and sticky surface (21,22). Chocolate "bloom" is a result of migration of cocoa butter from chocolate to the surface. Nelson and Fennema (21) investigated lipid barriers of five hydrocolloid films — MC, hydroxypropylmethyl cellulose (HPMC), CMC, carrageenan, and polyethylene glycol alginate (PGA) — and reported that they all were effective barriers to lipid migration.

Methods of reducing fat intake during deep-frying have been investigated extensively due to the rising health concerns of consumers. Studies have shown that edible coatings that had good lipid barrier property could significantly trim down fat intake of fried products. Soy protein isolate (SPI), whey protein isolate (WPI), and MC coatings were listed as the best film-forming materials to be used to reduce fat absorption of fried dough (23,24). Rayner, Ciolfi, Maves, Stedman, and Mittal (25) reported that doughnut mix and potato fries that were coated with soy protein film had considerable fat reduction. They also showed that consumers preferred the coated fries over the uncoated. Balasubramaniam, Chinnan, Mallikarjunan, and Phillips (26) explained that the layer of thermal gel formed by HPMC film controlled the transfer of fat between the meatball and the oil medium, and consequently reduced fat intake.

E. Improve Mechanical Properties

Mechanical strength of products can be improved by EFC. The structure of extruded or molded products can be protected by coating with EFC (9). Waxing of fruits and vegetables minimizes surface abrasion during handling of these products (27). Xie, Hettiarachchy, Ju, Meullenet, Wang, Slavik, and Janes (28) investigated puncture strength of eggshell coated with SPI, WPI, CMC or WG. They showed that eggshell coated with SPI and WPI had the greatest puncture strength, which implied that the SPI and WPI EFC could minimize breakages of eggs during processing, handling, and storage. Guilbert, Gontard, and Gorris (4) stated that food filling coated with edible coating could reinforce the structure and protect the filling. In addition to improving mechanical strength of products, EFC such as mineral oil (29) and hydrocolloid coatings such as pectinates, alginates, and starch (10) were used to minimize stickiness of food products. Improving the mechanical and handling properties can lead to a smoother process operation and reduction in product loss.

F. Carrier of Additives

EFC can provide a cohesive surface structure for additives such as anitmicrobial agents and antioxidants. Antimicrobials are substances that are added to EFC to improve quality and shelf life of products by retarding growth of yeast, molds, and bacteria during storage and distribution. Examples of food grade antimicrobial agents are organic acids and their salts such as benzoic acid, sodium benzoate, sorbic acid (SA), potassium sorbate, propionic acid, lactic acid, and acetic acid (30,31). Cagri, Ustunol, Osburn, and Ryser (32) investigated the effect of adding antimicrobial, p-aminobenzoic acid (PABA) and/or SA into WPI coating for bologna, summer sausage and hot dogs. Zein film coatings with nisin were shown to effectively prevent growth of *L. monocytogenes* on ready-to-eat chicken (33).

Antioxidants may be added to EFC to protect products from oxidation which results in oxidative rancidity, degradation of nutrients, and discoloration. Tocopherols, carotenoids, acids (as well as their salts and esters), and phenolic compounds such as butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) are some examples of food grade antioxidants. Antioxidants such as ascorbic acid and citric acid were added to MC edible films, which were applied to mushrooms and cauliflower. It was found that the coatings significantly decreased oxygen permeability of the vegetables and thus slowed the browning reactions (34). Lee, Park, Lee, and Choi (15) also reported that adding these two antioxidants along with oxalic acid to whey protein or carrageenan coatings helped maintain the color of minimally processed apple slices.

Calcium chloride, known to be a firming agent, was incorporated into EFC to inhibit softening of fruits and vegetables. Lee, Park, Lee, and Choi (15) reported that addition of calcium chloride to whey protein or carrageenan coatings in acidic condition could minimize softening of apple slices. Firmness of kiwifruit slices were also maintained during storage by adding calcium chloride to coating (35).

EFC could also serve as adherence surfaces for seasonings and flavor enhancers (10). Salt and flavorings were added to wheat gluten and dextrin coatings and modified food starches and gum Arabic coatings (36).

IV. COMPONENTS OF EDIBLE FILMS/COATINGS

EFC are made with a high molecular weight molecule as the backbone, a plasticizer, and a surfactant if needed. In this section, macromolecules including protein, polysaccharide,

and lipid that are used to make EFC will be discussed. They are listed in Table 135.1 along with the solvent they are dissolved in to make the film-forming solution.

A. Film Forming Agents

Film forming capability of macromolecules largely depends on their polymer backbone (37). Chain length, number of functional groups, and structure of macromolecules influence the functionality of EFC. For example, wheat gluten film is hydrophobic in nature because it has a large number of non-polar amino acids (38).

Polysaccharides and proteins are hydrophilic in nature, while lipids are hydrophobic. Therefore, EFC made with polysaccharides or proteins have limited water vapor barrier properties while EFC made with lipids have good water vapor barrier properties. Table 135.2 summarizes some of the WVP values of protein and polysaccharides that are investigated in the literature.

Oxygen permeability (OP), in contrast, is high in lipid films while low in polysaccharide and protein films. Krochta (42) summarized that protein EFC such as corn zein and wheat gluten films are better oxygen barriers than polysaccharide films. In general, as the hydrophobicity of the film increases, OP decreases.

TABLE 135.1
Film Preparation for Different Macromolecules

Macromolecule	Solvent
Protein	
Soy protein	Water
Corn zein	95% ethanol
Wheat gluten	Water-95% ethanol
Whey protein	Water
Polysaccharides	
Methyl cellulose	Water-95% ethanol
Hydroxypropylmethyl cellulose	Water-95% ethanol
Hydroxypropyl cellulose	Water-95% ethanol
Lipids	
Beeswax	Melt
Shellac	95% ethanol

TABLE 135.2
Water Vapor Permeability Values of Different Edible Films

Reference	Composition	Thickness[a]	Condition	WVP[b]
105	SPI[c]/GLY[d] (5:3)	0.000254	25°C, 50%RH	2.54
106	WG[e]/GLY (15:6)	0.087	25°C, 50%RH	1.41
69	WPI[f]/GLY (1.6:1)	0.121	25°C, 65%RH	1.39
78	CZ[g]/GLY	—	25°C, 50%RH	0.59
62	MC[h]/PG[i]	0.025	25°C, 52%RH	1.00
107	HPC[j]	0.05	21°C, 85%RH	0.11
39	HPC/SA[k] (1.1:1)	0.019	27°C, 97%RH	0.0005

[a] Thickness in mm, [b] WVP in $\times 10^{-9}\,gm^{-1}\,s^{-1}\,Pa^{-1}$, [c] soy protein isolate, [d] glycerol, [e] wheat gluten, [f] whey protein isolate, [g] corn zein, [h] methyl cellulose, [i] propylene glycol, [j] hydryoxypropylcellulose, [k] stearic acid.

1. Proteins

Proteins can be classified into water-soluble and water-insoluble proteins. Soy proteins and whey proteins are examples of water-soluble proteins, while wheat gluten and corn zein are water insoluble proteins.

a. Soy proteins

Soybean, in the family of Leguminosae, is believed to be originated in Eastern Asia (43). The whole soybean, with 40% protein, 21% fat, and 34% carbohydrate, has much higher protein content than other grains which usually have 8–15% protein (44). Globulin is the major protein group of soy proteins. Soy proteins are further fractionated according to the molecular weight of the protein by ultracentrifugation. The four most widely known soy protein fractions are 2S, 7S (conglycinin), 11S (glycinin), and 15S. Conglycinin and glycinin make up approximately 60–70% of the soybean globulins (45).

Many researches have been conducted to determine the mechanism of soy protein film formation. Okamoto (46) suggested that heat-denatured proteins, which are partially unfolded and more hydrophobic, move to the surface of the film solution, and as water evaporates, protein molecules interact to form film structure. Rangavajhyala, Ghorpade, and Hanna (47) found that aggregation of proteins under heat treatment is through hydrogen bonds and intermolecular disulfide bonds. Kinsella (45) stated that under alkali condition, glycinin breaks down to subunits and unfolds due to disulfide bond cleavage, which is followed by gelation of the protein solution. He also suggested that 11S fraction dissociates into subunits and aggregates under heat treatment.

b. Whey proteins

Whey is a by-product of cheese production. There are five main components in whey proteins: α-lactalbumin, β-lactoglobulin, bovine serum albumin, immunoglobulins, and proteosepeptones. Different components can be fractionated by differential solubility, electrophoretic, and chromatographic methods. Researchers have shown that EFC can be made with β-lactoglobulin and bovine serum albumin alone (48), as well with WPI and whey protein concentrate (WPC).

Denatured whey protein films are water insoluble due to the intermolecular disulfide bonds induced by thiol-disulfide interchange and thiol oxidation reactions which are promoted by heat treatment (3).

c. Wheat gluten

Wheat gluten is the protein of wheat kernels which accounts for 8–15% of the dry weight (49). Most of the protein

consists of gliadins and glutenins which are only soluble in alcohol. Therefore, wheat gluten films are prepared by dispersing wheat gluten in a mixture of ethanol and water. The pH of wheat gluten film solutions have to be adjusted to the range of 2 to 4 or 9 to 13 to avoid extreme acidic or alkaline conditions, and to avoid isoelectric point (pI) of wheat gluten at which proteins coagulate. Gontard, Guilbert, and Cuq (50) reported that wheat gluten films made in acidic conditions (pH $\approx$ 2 to 6) have better sensory and visual properties than films made in alkaline conditions. However, Gennadios, Brandenburg, Weller, and Testin (51) reported that wheat gluten films made in alkaline conditions have higher tensile strength.

Wheat gluten films are cohesive and elastic (51). Due to the high glutamine content of wheat gluten, highly cooperative protein-protein interactions occur, which contribute to the cohesiveness of the film (52). Hydrogen bonds between hydrated gluten are responsible for film's elasticity (53). Wheat gluten films are very effective oxygen barriers (54). Like other protein-based EFC, wheat gluten films have poor water barrier properties because of the hydrophilic nature of the proteins (42).

d. Corn zein

Corn zein, which is the prolamine fraction of corn proteins, account for about 45–50% of corn proteins (55). It has large amounts of non-polar amino acids, which contribute to the hydrophobic nature of zein (56). The low polar amino acid content and high nonpolar amino acid content also contribute to the insolubility of corn zein in water (57). Therefore, corn zein is generally solubilized in a mixture of water and alcohol (ethanol).

Shukla and Cheryan (55) concluded that corn zein films are glossy, tough, hydrophobic, and good lipid barriers. Tomatoes coated with corn zein had delayed ripening and color development, due to low permeability of oxygen of corn zein EFC, when compared to tomatoes coated with typical shrink wrap films. However, tomatoes coated with corn zein EFC exhibited higher weight loss than the ones coated with typical shrink wrap films, due to high WVP of the zein films (58). They also compared corn zein–coated tomatoes with uncoated tomatoes. Again, they showed that corn zein EFC significantly delayed color development of tomatoes. In this case, corn zein–coated tomatoes reduced softening and weight loss over a period of 8 days comparing to the uncoated tomatoes (59).

2. Polysaccharides

Polysaccharides such as cellulose and its derivatives, starches and its derivatives, pectins, seaweed extracts, and gums are used to form EFC.

Cellulose is a rigid material composed of plant cell walls. It is insoluble in water due to high amount of intramolecular hydrogen bonding in the cellulose polymer (60). Therefore, cellulose is generally dispersed in water and ethanol. MC, hydryoxypropylcellulose (HPC), and HPMC are examples of water-soluble cellulose ethers that are modified by etherification. MC is the least hydrophilic among the soluble cellulose ethers (9,60). It is shown to have better moisture barrier property than other cellulose ether (24,61). Mechanical and barrier properties of MC films with different plasticizers were investigated (62).

Cellulose edible films are tough and flexible (60). They are resistant to oxygen and lipid migration. Cellulose-based films exhibited lower OP than synthetic films, such as low density polyethylene film (LDPE) (40). MC, HPMC, and HPC coatings applied to fried pastry mix and fried potato ball reduced fat uptake (23,24,61). Williams and Mittal (61) showed that HPC and MC films reduced water loss of fried pastry mix. Cellulose-based EFC, like protein-based EFC, are hydrophilic. Therefore, they generally have poor water barrier properties. Park and Chinnan (40) reported that WVP of cellulose films were 100 times greater than LDPE. Cellulose-based films were supplemented with a layer of shellac to form an edible film layer to separate one food phase from another phase (63).

3. Lipid

Lipids that are generally used for making EFC are waxes (i.e., paraffin and carnauba wax), mineral oil, fatty acids, monoglycerides, resins (i.e., shellac), and rosins. EFC made with lipid are cohesive and flexible (64). These characteristics are dependent on molecular weight of both hydrophilic and hydrophobic phases, branching, and polarity of lipid. As hydrophobicity of the film increases, OP decreases. Films that are made with resins such as shellac have lower permeability to oxygen and carbon dioxide than films that are made with waxes. On the other hand, waxes are more resistant to water vapor than other lipid film, due to the tight orthorhombic arrangement of the crystals. Lipid films, in general, are good water vapor barriers due to their hydrophobic nature.

Some example applications of wax and oil coatings are on fruits and vegetables to prevent moisture loss (14), on raisins to prevent moisture migration from the raisin to dry cereal (10), and on confectioneries to provide gloss (64).

4. Composite or Bilayer Film

Fats, fatty acids, and waxes can be added to polysaccharide or protein films to improve water barrier properties (38). There are three main types of composite films: lipid bilayer films, emulsion films, and composite films made of polysaccharide and protein. Bilayer films composed of HPMC and solid lipids such as beeswax (2), and corn zein with a layer of oil or waxes (65) had significantly lower WVP than protein or polysaccharide films alone. Emulsion films developed with whey proteins, beeswax, and glycerin showed

reduction in WVP by 50% compared to films made of whey proteins alone (41). Krochta (42) stated that emulsion films had even lower WVP than bilayer films due to the optimum orientation of fatty acids in emulsion films. SPI and wheat gluten composite film was made by mixing the macromolecules with the plasticizer and solvent to form the film-forming solution. The film was shown to have lower WVP and improved TS than film made with SPI alone (38).

B. Plasticizer

1. Definition and Functions

Plasticizer is defined as "a substantially nonvolatile, high boiling, nonseparating substance, which when added to another material changes the physical and/or mechanical properties of that material" (37). Plasticizers induce flexibility of films by reducing the degree of hydrogen bonding and increasing intermolecular spacing of the polymers (66).

2. Selection of Plasticizers

Selection of plasticizers is based on compatibility of the plasticizer and the substance which they plasticize. For example, water-soluble substance should be plasticized with compound(s) containing hydroxyls (37). The number and position of hydroxyl groups and the number of hydrogen bonds capable of forming with the macromolecule affect the efficiency of plasticization (67). Cho and Rhee (68) stated that hydrophilicity and concentration of plasticizers affect moisture sorption of SPI films. SPI films plasticized with glycerol, which is more hydrophilic than sorbitol, absorbed more moisture than sorbitol-plasticized films. Plasticizer concentration also affected plasticizing effect of whey protein films (69). Addition of plasticizer increases permeability of the film due to the increase in free volume (66). Studies showed that plasticizers increased oxygen and/or water vapor permeability of MC films (62), gellan films (70), whey protein films (71), and gelatin films (72). Increased concentration of plasticizer further increased permeability of edible films (73,74).

Water and polyols such as glycerol, propylene glycol (PG), polyethylene glycol (PEG), and sorbitol are commonly used plasticizers. Glycerol is the most widely used plasticizer, probably because it has small molecule weight, which enables it to incorporate into polymer matrix very easily. Studies have been conducted to investigate the effect of incorporating different plasticizers into polymers on mechanical and permeability properties of edible films. McHugh and Krochta (71) reported that sorbitol-plasticized whey protein film has lower OP than glycerol-plasticized film. Sucrose-plasticized β-lactoglobulin film showed the lowest OP, followed by sorbitol and glycerol, while PEG 200- and 400-plasticized films exhibited the poorest oxygen barrier property (48). Glycerol-plasticized β-lactoglobulin film had higher tensile strength (TS) and percent elongation than sorbitol-, PEG 200-, PEG 400-, and sucrose-plasticized films at equivalent amount of plasticizers (48). Chick and Ustunol (75) reported that sorbitol-plasticized lactic acid casein films were more effective in oxygen and water barrier properties than glycerol-plasticized film.

Addition of plasticizers often decreases TS and increases elongation-at-break of caseinate films (76), MC films (62), peanut films (77), SPI films (68), gellan films (70), and whey protein films (69,71). Effects of using mixture of plasticizers on mechanical and WVP properties were investigated. Park, Bunn, Weller, Bergano, and Testin (78) reported that as the ratio of glycerol to PEG decreased, TS of wheat gluten film increased, while elongation and WVP decreased. A 50:50 mixture of PEG and glycerin plasticizers for protein edible films exhibited the highest TS (78). Environmental factors such as relative humidity and temperature of the room where films are made also affect the plasticizing effect of plasticizers. Gontard, Guilbert, and Cuq (52) reported that the plasticizing effect of water for wheat gluten film is highly temperature dependent.

C. Surfactant

Surfactants are surface-active compounds that have the ability to reduce the interfacial tension between two interfaces since they have both hydrophilic and hydrophobic ends. They are usually incorporated into emulsion systems. Surfactants are chosen according to hydrophilic-lipophilic balance (HLB) and phase inversion temperature (PIT). HLB is a system of values of 1 to 40 according to the hydrophobic and hydrophilic portion of the surfactant. Surfactants with low HLB are used in water-in-oil (w/o) emulsification and surfactants with high HLB values were used in oil-in-water (o/w) emulsification. PIT is the value where emulsions reverse from o/w to w/o depending on the temperature. It is believed that o/w interfacial tension is the smallest at PIT. Naturally occurring emulsifiers, phospholipids, monoglycerides, soy lecithin, sodium stearoyl lactylate, sodium lauryl sulfate, propylene glycol alginate, and paraffin wax are some examples of food grade emulsifiers.

V. METHOD OF MAKING EFC

Two broad categories of manufacturing EFC are: wet processing technologies (i.e., casting) and low-moisture processing technologies (i.e., compression molding and extrusion) (80).

A. Casting

Casting is one of the most common methods to make stand-alone films, which can be used to evaluate physical

and chemical properties of films. Proteins or polysaccharides, in concentrated or naturally occurring form, are dispersed in a mixture of water (with addition of solvent for water insoluble proteins and polysaccharides) and plasticizer(s). After thoroughly mixing the components, pH of the film forming solution is adjusted to the desired range by titrating with acidic or basic solution. Subsequently, the film forming solution may undergo heat treatment for a period of time. Then a controlled amount of solution is filtered and poured into a casting plate. Then this film forming solution is allowed to dry to a stand-alone film at a specific condition (temperature and relative humidity) and for a specific time period (~12 to 24 hr). Finally, the dried film is peeled from the plate and evaluated for various basic film properties. Example of the casting procedure of making soy protein isolate film is showed in Figure 135.1.

Drying temperature of the film should be taken into account since studies have shown that it had an effect on film properties. Thickness of wheat gluten films (81), and whey protein films (82) decreased by increasing the drying temperature. As temperature increases from 70°C to 80°C and 90°C, TS and elongation of peanut film increased while WVP and OP decreased. At 90°C, peanut films had the lowest WVP and OP and the highest TS (77). TS of wheat gluten film investigated by Kayserilioglu, Bakir, Yilmaz, and Akkas (81), on the other hand, decreased as drying temperature increased. Perez-Gago and Krochta (83) explained that WVP of an emulsion film of WPI-beeswax decreased as drying temperature increased, probably due to change in the lipid crystalline morphology and/or lipid distribution within the matrix.

B. Compression Molding

Compression molding is one form of low-moisture processing method used to make EFC. Thermoplastic material, which softens when it is heated, is placed on one half of a mold. Heat and pressure are applied to the mold once it is closed. Film material then fills the mold cavity and polymerization occurs. The film is, then, obtained by cooling the mold. One of the differences between compression molding and extrusion is that flowability of the film-forming material for compression molding can be low, while for extrusion, the material needs to have high flowability. Because compression molding has very limited production amount, it is economical for small production.

Compression molding was used recently as one of the methods to make EFC. Foulk and Bunn (84) showed that SPI films could be produced by compression molding. Films were made according to the method developed by Poly-Med Inc. (84). Mechanical and barrier properties of the SPI films that have various solubility were significantly different. They concluded that compression molded acetylated SPI film could be used as commercial thermoplastic. Slightly yellow and transparent SPI films plasticized with ethylene glycol (EG) formed by compression molding under a pressure of 15 MPa at 150°C was developed by Wu and Zhang (85). Due to the physical cross-linking between protein chains induced by EG, water adsorption of SPI films was reduced. SPI films made by compression molding had improved TS, breaking elongation, water resistance and thermostability, and therefore, they suggested that the thermoplastic materials from SPI could be used commercially for food packaging. Other proteins such as whey proteins (86) and cottonseed proteins (80) were also used to successfully produce compression-molded films.

C. Extrusion

Low-moisture process technologies take less energy and time. One of the advantages of extrusion is that it could be a continuous process in-line and could obtain larger

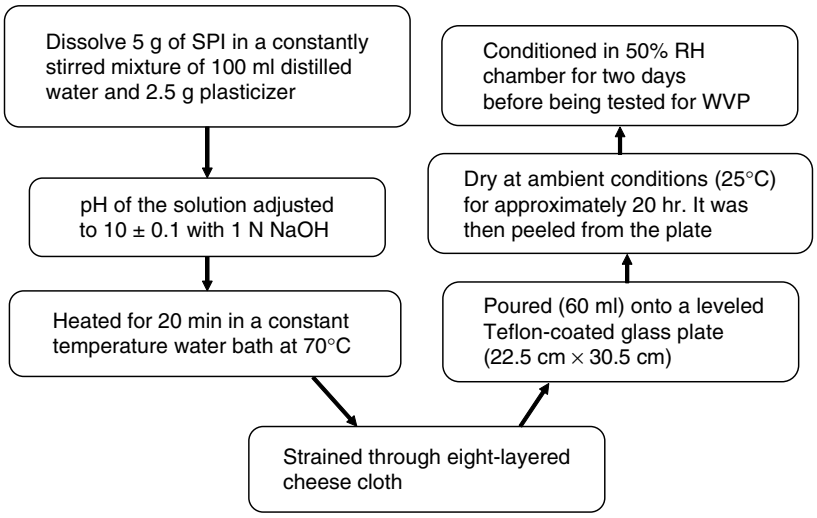

FIGURE 135.1 Flowchart for making soy protein isolate film.

production volume. Extrusion has been used to manufacture industrial polymers such as LDPE (87). A blend of polypropylene and thermotropic liquid crystalline polymer (TLCP), Rodrun LC5000, was fed to a twin-screw extruder and polymerized through a mini-extruder to form a film (88). Biodegradable films manufactured by melt blow extrusion were developed with polyvinyl alcohol (PVA) and collagen hydrolysate (CH) (89). A patent of a soy protein thermoplastic composition containing soy protein, carbohydrate filler, a reducing agent, a plasticizer, and water manufactured by extrusion was granted to Jane and Wang (90). They showed that this soy protein blend has the desirable flowability for processing by extrusion. Feasibility of using other edible film materials such as wheat gluten (91) and corn zein (92) in extrusion was also investigated. Redl, Morel, Bonicel, Vergnes, and Guilbert (93) suggested that extrusion of wheat gluten with plasticizers is feasible under steady-state conditions. Koh and Lim (94) concluded that protein cross-linking is an important characteristic of the leathery structure of extruded wheat gluten. They reported that extruded wheat gluten had higher water absorption capacity and lower protein solubility than unextruded wheat gluten.

Plasticizers were also added to the polymer matrix to improve flexibility of the film for extrusion. Water and glycerol were added to extruded corn gluten meal (92) and extruded soy protein (90).

VI. FACTORS AFFECTING FILM FUNCTIONALITIES

A. pH

Formation of edible films only occurs at a certain pH range (46,95). In general, pH of the film solution should be away from the isoelectric point (pI) of the protein used as the film-forming macromolecule. SPI films formed well at pH range of 7.5 to11, while no films were formed at pH range of 3.5 to 5.5 due to coagulation of soy protein (95). When the pH of the film-forming solution of WPI-beeswax emulsion film was adjusted away from the pI of whey proteins, films had lower WVP (96).

Also, if protein is one of the components of the film forming solution, the pH should be adjusted not to be extremely acidic or extremely alkaline, since intramolecular protein repulsive force develops under extremely acidic and alkaline conditions. Therefore, films formed in these conditions will be less dense and more permeable (51). Film opacity, solubility, WVP, and mechanical properties of wheat gluten films were affected by pH (52). They reported that the films made at pH 5 were the strongest, while films made at pH 6 had the lowest WVP. Jangchud and Chinnan (77) also found that as pH of the peanut film-forming solution increased, protein solubility increased, and the film was darker and more yellow.

Sian and Ishak (95) investigated the effect of pH on the composition of soybean protein-lipid films. They reported that films prepared at higher pH (pH $>$ 7.5) had higher protein proportion and lower fat proportion than films that were prepared at lower pH.

B. Heat Treatment and Irradiation

Heat treatment breaks intramolecular disulfide bonds in proteins and allows the proteins to unfold. Then the unfolded bonds interact and form intermolecular disulfide and hydrophobic bonds, which reduce mobility of protein solution. As temperature of the heat treatment is increased, solubility of SPI films decreased (47). Minimum requirement of heat treatment is different for various macromolecules. Whey protein films need to be heated at 75°C for 30 min in order to form intact water-insoluble films (69). Heat treatment also influences appearance. Heated films are smoother and more transparent than unheated films (97). Cuq, Boutrot, Redl, and Lullien-Pellerin (98) stated that thermal treatment induces inter- and intramolcular cross-linking of proteins which improve mechanical strength. Wheat gluten films developed by Micard, Belamri, Morel, and Guilbert (99) which underwent heat treatment (above 110°C for 15 min and above 90°C) were stronger and more flexible.

When WPI-calcium caseinate and SPI-WPI films underwent γ-irradiation (100), puncture strength and water resistance significantly increased. It is due to protein cross-linkage which contributed to a more ordered and stable structure. Ouattara, Canh, Vachon, Mateescu, and Lacroix (101) also reported that covalent bonds formed between protein molecules under irradiation decreased WVP of caseinate-whey protein films.

C. Concentration and Molecular Weight of Macromolecule

An intact film cannot be obtained if the concentration of the film-forming macromolecule is too high or too low. If the concentration of macromolecules is too high, the film-forming solution will form a gel. If the concentration of macromolecules is too low, film will not form due to the lack of intermolecular interactions (71).

Molecular weight (MW) of cellulose also had influence on film properties. As molecular weight of HPMC increased from 22,000 to 26,000 and 86,000, WVP of film decreased. This suggested that it may be due to decreased mobility of the molecules as MW increased (102).

VII. FUTURE RESEARCH DIRECTION

Basic mechanical and barrier properties of stand-alone edible films have been extensively investigated. Various EFCs have shown high potential to be used commercially.

Composite and bilayer films, especially, received a lot of attention because of the improvement of water barrier property that they offer. Continuous research on understanding and modifying properties of composite/bilayer films are to be expected.

Besides studying the basic properties of EFC alone, the latest interest of EFC research is to investigate the feasibility of applying EFC onto different food products. Physical structure, chemical reaction between the EFC and the product, and sensory properties (103,104) of the product should further be investigated.

Ingredients Technology

136 Seasonings and Spices

Zhang Lin
International Flavors & Fragrances (China) LTD

CONTENTS

I. SEASONINGS

[1]*Seasonings are compounds, containing one or more spices, or spice extractives, and other flavour ingredients such as salt, sugar, dairy products and flavour enhancers, which when added to a food, either during its manufacture or in its preparation, before it is served, enhances the natural flavour of the food and thereby increases it acceptance by the consumer.*

The compounding of seasoning is considered a specialised, skilful art. The proper blending of such dissimilar components as spice extracts, essential oils, spices, salt, sugars, monosodium glutamate, ribotides, dairy products, and the many other components that enter into complex seasoning mixtures require:

- a high level of technical expertise and a long period of practical experience
- a list of government regulations and restrictions
- a sense of economics in the selection of the ingredients with the optimum use to which they can be used

A seasoning must be compounded in such a way that it increases the natural flavour of the product to be seasoned.

It should not overpower or diminish the product's flavour but add a balanced interest with an odour identity, a smoothly blended, rounded flavour with no perceptible undesirable aftertaste. In general the weaker the flavour of the product to be seasoned the lower the level of added seasoning required to achieve a satisfactory balance of flavour in the finished product.

A. Basic Groups of Ingredients

- Salt
- Sugar/dextrose
- Food acids — citric/sodium diacetate/lactic/malic/tartaric
- Flavour enhancers — MSG/I&G
- Herbs and spices
- Spice extracts
- Vegetable powders — tomato/onion/garlic
- Savoury — HVP/yeast extracts/reaction flavors
- Cheese/dairy powders
- Flavour top notes
- Colours
- Carriers — flour/starch/maltodextrin/lactose etc.
- Free flow agents

1. Salt

Salt is an indispensable flavouring for all snacks, sweet or savoury. In many varieties of foods it is the predominant flavour note. Hundreds of chemical compounds are classified as salts, and most of the water-soluble ones exhibit what we recognise as a salty taste, but only pure sodium chloride gives this flavour in a form not modified by sour, bitter, or sweet tastes.

In addition to having a pronounced and generally agreeable taste of its own, sodium chloride will modify other flavours. In most test situations, it has been found to enhance the sweetness of sugars and decrease the sourness of acids. In some liquid products the addition of small quantities of salt, even below the threshold level, will increase the apparent sweetness of dissolved sucrose.

Wherever practical, salt should be applied to snacks as a topping. This ensures a quickly sensed saltiness which is a primary determinant of consumer acceptability. A sufficient level (super-threshold) should be applied to yield a distinct salty flavour, but gross overstating should be avoided because it can mask or depress desirable flavour notes such as the mild sweetness of potatoes, or accentuate undesirable flavours.

2. Acid

The considerations which govern the choice of acid type and use concentration are extremely complicated. It has been demonstrated that tartness or sour taste of the common food acidulants is directly related to the molar concentration of undissociated acid.

Tartness values for various acids, as reported in the literature, vary considerably, probably reflecting differences in testing conditions. Citric acid and malic acid are quite close in organoleptic tartness value whereas tartaric acid is more tart. One part of citric or malic acid is reported to be equivalent to 0.8–0.7 parts of tartaric acid.

The acids are reported to differ somewhat in their tartness character. Tartaric is slightly bitter, citric acid gives a sharper tartness peak than malic, which gives a smooth and long lasting tartness. Some general observations on the effect of organic food acidulants:

- High viscosity reduces the organoleptic tartness.
- Organoleptic tartness drops when the free acid/sugar ratio is reduced.
- Organoleptic tartness is reduced by higher flavour level.

3. Flavour Enhancers

Savoury or Umami is the descriptive term given to the glutamate found naturally in foods or as added monosodium glutamate. It is also used to describe combinations of glutamate and nucleotides. It usually works as a flavour enhancer, that is, bringing out the flavour of the food itself.

Naturally occurring glutamate is found in foods as diverse as cheese such as parmesan, kelp, tomatoes, anchovies, and potatoes. Naturally occurring nucleotides — the main two being disodium-5′-guanylate (GMP) and disodium-5′-inosinate (IMP) — are mainly found in tuna fish, sardines, bonito, beef, prawns, chicken, and shitake mushrooms.

Nowadays, monosodium glutamate is manufactured by fermentation commercially from molasses. Nucleotides are commercially produced by the natural fermentation of tapioca starch. Commercially, MSG is the more widely used — in various food products. More recently nucleotides have started to be used either in combination with naturally occurring glutamates, or with MSG. The three most common forms of nucleotides used are:

IMP — Disodium inosinate
GMP — Disodium guanylate
Disodium ribotide (I + G) — which is IMP + GMP in a 50:50 mixture

As mentioned before, glutamates can be used alone to impart the Umami flavour whereas nucleotides require a source of glutamate to function as a flavour enhancer. Nucleotides have a very marked synergistic effect with glutamate. The glutamate can be present naturally in the food product or can be added to the food. Even though

foods naturally contain nucleotides and glutamate, they are still used in seasoning as you would use salt. Very small amounts of nucleotides are added to replace some of the MSG to give a magnification of the flavour enhancement effect.

Glutamates and nucleotides are completely water-soluble at use levels. IMP has a low moisture absorption which may be an important point when being used in dry mix products and favours. GMP has the strongest flavour enhancement and both nucleotides have high heat stability and tolerate a wide range of pH without large levels of decomposition.

Nucleotides enable the manufacturer to control excessive saltiness in snack foods such as potato crisps and other snack items. MSG can be used to reduce salt levels and give the same amount of perceived saltiness to a product by bringing out the flavour.

4. Savoury

We have many materials available to use which will enhance and/or add a savoury meaty flavour to seasonings. These products can be derived from yeasts and yeast autolysates, hydrolysed plant proteins, or meat products. Some materials add a savoury meaty flavour with no definite profile, some are specifically tailored to a profile (i.e., Chicken HVP, Beef yeast autolysate, and chicken processed flavours, etc).

Available to us also are vegetable flavoured yeast autolysates, vegetable powders, many different sugars, starches, acids, and an entire range of natural identical flavours.

II. SPICES & HERBS

[1]*Spices and herbs are aromatic natural products that are used to flavor food. Spices are the dried seeds, buds, fruit or flower parts, bark, or roots of plants, usually of tropical origin. Herbs are the leaves and sometimes the flowers of plants, usually grown in a climate similar to the Mediterranean.*

A. Classification of Spices by Sensory Characteristics

Flavour Characteristics	Spices
Alliaceous	Onion, chives, shallots, garlic
Bitter	Celery seed, curry powder, fenugreek, hops, mace, marjoram, nutmeg, oregano, rosemary, saffron, savory, turmeric
Fragrant & delicate	Bail, chives, shallots
Herbaceous	Dillweed, parsley, rosemary, saffron, sage, thyme
Pungent & hot	Capsicum, ginger, horseradish, mustard, black and white pepper
Pungent & sweet	Cassia, cloves, cinnamon
Sour, astringent	Capers
Sweet	Anise, cardamom, fenugreek, star anise
Sulfurous	Garlic, onion
Warm, fruity	Anise, bayleaf, caraway, cardamom, cumin, fennel, rosemary, savory
Warm fragrant & cooling	Basil, oregano, peppermint, spearmint
Warm heavy & aromatic	Cumin
Warm spicy and aromatic	Allspice, basil, caraway, cardamom, cassia, celery, chervil, chilli, cinnamon, cloves, coriander, dillweed, ginger, mace, marjoram, nutmeg, pickling spice, sage, tarragon, thyme, saffron
Woody	Cassia, cinnamon, cloves

B. Main Spices in Asia[1] [2]

1. Cinnamon

Cinnamon is the dried inner bark of various evergreen trees belonging to the genus Cinnamomum. At harvest, the bark is stripped off and put in the sun, where it curls into the familiar form called "quills."

Cinnamon in the ground form is used in baked dishes, with fruits, and in confections. Cassia is predominant in the spice blends of East and Southeast Asia. Cinnamon is used in moles, garam masala, and berbere.

2. Clove

Cloves are the dried, unopened, nail-shaped flower buds of the evergreen Syzygium aromaticum. They are reddish-brown in color and have a strong aroma.

Cloves are an important ingredient in the spice blends of Sri Lanka and North India. They are used in garam masala, biryanis, and pickles. In the U.S., cloves are used in meats, salad dressings, and desserts. Clove is a key flavour contributor to ketchup and Worchestershire sauce seasoning blends. Chinese and German seasonings also depend on cloves to flavour meats and cookies.

3. Cumin

Cumin is the dried seed of the herb *Cuminum cyminum*, a member of the parsley family. The cumin plant grows to about 1 to 2 feet tall and is harvested by hand. Cumin is a key component in both chili powder and curry powder.

The flavor of cumin plays a major role in Mexican, Thai, Vietnamese, and Indian cuisines. Cumin is a critical ingredient of chili powder, and is found in achiote blends, adobos, garam masala, curry powder, and baharat.

4. Fennel

Fennel is the dried, ripe fruit of the perennial *Foeniculum vulgare*. Tall and hardy, this plant has finely divided, feathery, green foliage and golden yellow flowers. Oval seeds form in clusters after the flowers have died and are harvested when they harden.

Fennel seeds are an important ingredient in seasoning blends of the Mediterranean, Italy, China, and Scandinavia. Fennel seeds may be roasted prior to incorporation into seasoning blends to intensify their flavor. Fennel is used in curry blends, Chinese five spice, mirepoix, and herbes de Provence. Fennel is also used to flavor fish, sausages, baked goods, and liquors.

5. Ginger

Ginger is the dried knobby shaped root of the perennial herb *Zingiber officinale*. The plant grows two to three feet tall. Once the leaves of the plant die, the thick roots, about 6 inches long, are dug up. Crystallized ginger is fresh gingerroot cooked in syrup and dried.

Ginger is used in Indian curries, and Chinese, Japanese, and European spice blends.

6. Red Pepper

Red pepper is the dried, ripened fruit pod of *Capsicum frutescens*, one of the most pungent capsicums. It is sometimes referred to as cayenne red pepper, having been named after the high heat chilies grown in the vicinity of the Cayenne River in French Guiana.

Red pepper adds heat and bite to seasoning blends, meats, pickles, seafood, Italian, Indian, Mexican, and Caribbean cuisines. Red pepper is used in seasoned salt, chili powder, jerk, mole negro, and berbere seasoning blends.

7. Black Pepper

Black and white pepper are both obtained from the small dried berry of the vine *Piper nigrum*. For black pepper, the berries are picked while still green, allowed to ferment, and are then sun-dried until they shrivel and turn a brownish-black color. They have a hot, piney taste.

Black pepper adds flavor to almost every food of every nation in the world. It is used in rubs, spice blends, salad dressings, and peppercorn blends.

8. White Pepper

Black and white pepper are both obtained from the small dried berry of the vine *Piper nigrum*. For white pepper, the berry is picked when fully ripe. The outer layer of shunken

skin is removed, leaving the dried, grayish-white kernel. It has a milder, more delicate flavor than black pepper.

White pepper is used whole in pickling spices and marinades. Ground white pepper is used in light colored foods such as sauces and soups. It is especially popular in European cuisine.

9. Bay Leaves

Bay leaves or laurel, are the dried leaves of the evergreen tree, *Laurus nobilis*. The elliptically shaped leaves are light green in color and brittle when dried. They have a distinctively strong, aromatic, spicy flavor. Bay leaves is the approved term for this spice, but the name "laurel" is still seen frequently.

It is used in soups, stews, stocks, pickles, marinades, tomato dishes, and meats. Mediterranean, French, Moroccan, and Turkish cuisines use bay leaves in spice blends such as bouquet garni and curry blends.

10. Chives

Chives, *Allium schoenoprasum*, are the reed-like stems of a perennial, bulbous plant of the lily family. The name "chives" is derived from the Latin *cepa*, meaning onion. Chives are a member of the onion family.

It is used in cold soups, stir-fried items, cheese and cream sauces, dips, potatoes, and as a garnish. Chives are popular in European and Chinese cuisines and in seasoning blend fines herbes.

11. Cilantro

Cilantro is the dried leaves of the herb, *Coriandrum sativum*, an annual herb of the parsley family. Also known as Chinese parsley, cilantro has a distinctive green, waxy flavor. Cilantro is the usual name for the leaf of the plant that is otherwise identified as coriander, and from which coriander seed is obtained.

Cilantro is used in salsas, chutneys, salads, dips, beans, and soups. Cilantro is used in Asian, Mexican, Indian, Tex Mex, Caribbean, and North African cuisines, and is used in seasoning blends such as masala, curry, salsa, and recados.

12. Coriander

Coriander is the dried, ripe fruit of the herb *Coriandum sativum*. The tannish brown seeds have a sweetly aromatic flavor which is slightly lemony. A zesty combination of sage and citrus, coriander is actually thought to increase the appetite.

Coriander is used in lentils, beans, onions, potatoes, hotdogs, chili, sausages, stews, and pastries. It is used in the cooking of North American, Mediterranean, North African, Mexican, Indian, and Southeast Asian cuisines, as well as spice blends, including curry powders, chili powders, garam masala, and berbere.

13. Mint

Mint leaves are dried spearmint leaves of the species *Mentha spicata*. The dark green leaves have a pleasant warm, fresh, aromatic, sweet flavor with a cool aftertaste.

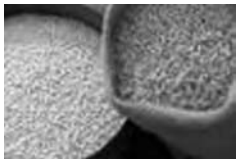
Mint leaves are use in teas, beverages, jellies, syrups, ice creams, confections, and lamb dishes. Mint is used in Afghanistani, Egyptian, Indian, and Mid-Eastern cuisines and spice blends such as chat masola, mint sauce, and green Thai curry.

14. Paprika

Paprika is the dried, ground pods of *Capsicum annum*, a sweet red pepper. It is mildly flavored and prized for its brilliant red color.

Paprika is used in seasoning blends for barbeque, snack foods, goulash, chili, and the cuisines of India, Morocco, Europe, and the Middle East.

15. Sesame Seed



Sesame is the dried, oval-shaped seed of the herb *Sesamum indicum*. Sesame seed is harvested by hand. The seeds have a rich nut-like flavor when toasted. Sesame seed contains 25 percent protein.

Sesame seeds are used to add texture and flavor to a variety of breads, rolls, crackers, and salad dressings. Middle Eastern, Muslim, and Asian seasoning blends use crushed, whole, and toasted sesame seeds for flavour and texture.

16. Turmeric

Turmeric is the dried root of the plant *Curcuma longa*. Noted for its bright yellow colour, it is related to and similar in size to ginger. Turmeric's flavor resembles a combination of ginger and pepper.

Turmeric is a powerful colouring agent. It is used to colour and flavour prepared mustard, pickles, relish, chutneys, and rice dishes as well as butter and cheese. It is also used in spice blends in the Caribbean, India, North Africa, the Middle East, and Indonesia such as curry powder and rendangs.

137 Sweet Flavor Application

Yuanchao Fang, Hangyu Jiang and Ming Cai
International Flavors & Fragrances (China) LTD

CONTENTS

Flavors are generally divided into two categories according to their end uses: sweet flavors and savory flavors. Sweet flavors include cola, orange, lemon, apple, strawberry flavors, etc. which are generally applied to sweet foods like beverage, dairy products, bakery products and confectionery. In some multinational companies, oral care flavors like peppermint and spearmint flavors are also divided into sweet flavors. Savory flavors include meat flavors, seafood flavors, mushroom, cheese flavors and so on, which are mainly used in savory foods such as spices, meat products, snack, seasoning, soup, etc.

I. SWEET FLAVOR CLASSIFICATION

Sweet flavors can be divided into four categories according to their existence status:

A. Water-Soluble Flavors

Ethyl alcohol, propyl glycol and water are generally used as solvents for water-soluble flavors. Solvents account for 40%～99% of the composition in the formulae. These flavors are clear and have good topnote, but they are sensitive to heat. Water-soluble flavors are wildly used in beverage, ice cream, water ice, dairy products, pectin jelly, jam, etc.

B. Oil-Soluble Flavors

Corn oil, triacetin and octyl and decyl glycerate (ODO) are used as solvent in this kind of flavors. This kind of flavor has higher concentration of chemicals, longer aroma retention ability and better stability against heating,

but they are water-insoluble. Oil-soluble flavors are generally used in biscuit, confectionery, chocolate, chewing gum, etc.

C. Emulsion Flavors

This kind of flavor is oil-in-water (o/w) flavor which contains two phases: water phase and oil phase. The oil phase is composed of flavor oils, weighting agents, vegetable oils, emulsifiers and antioxidants. The commonly used weighting agents include sucrose acetate isobutyrate (SAIB), ester gum, brominated vegetable oil (BVO), darmmar gum and elemi gum. There is strict legislation restrictions in different countries for each weighting agent. Because the specific gravity of flavor oils are generally between 0.84 and 0.87, and the specific gravity of beverage is above 1.00, weighting agents must be added to increase the specific gravity of oil phase. The specific gravity of several weighting agents is as follows:

SAIB: 1.146
Ester gum: 1.085
BVO: 1.333
Darmmar gum: 1.065
Elemi gum: 1.03

The water phase consists of water, emulsifier (e.g. arabic gum), acid, preservative, thickening agent and antioxidant.

Stokes' Law plays an important part in the formulation of emulsion flavor. The law can be expressed with the equation as follows [1]:

$$V = -\frac{2}{9} \times \frac{gr^2(d_2 - d_1)}{\eta}$$

Where:

V: the velocity of creaming or sedimentation
g: acceleration due to gravity
r: the radius of the droplet
d_2: the density of the dispersed phase
d_1: the density of the continuous phase
η: the viscosity of the continuous phase

According to Stokes' Law, the following measures can be taken to decrease the velocity of creaming or sedimentation of droplets in the finished drinks:

1. Decrease the particle size at the premise of not influencing cloudiness
2. Decrease the difference of specific gravity between the two phases
3. Increase the viscosity of the continuous phase

Emulsion flavors are wildly used in carbonated drinks, juice drinks and sports/isotonic drinks. It also can be used in ice cream, water ice, dairy products and bakery foods.

D. Powdered Flavors

This kind of flavor can be mainly divided into two categories. One is absorptive powdered flavor which is made by absorbing flavor base on carriers like maltose or maltodextrin. The other is encapsulation powdered flavor which is made by emulsifying and spray-drying the flavor base. This kind of flavor is mainly used in powder drinks.

II. FLAVOR DESCRIPTION

It's very important for food developers to give correct and precise description on flavor, which is the basic skills for food developer to create new food products. In flavor houses, primary, secondary and tertiary words are used to describe each flavor. For example, juicy, sweet, peely and other adjective words are used to describe orange flavor, so the primary word is orange, while juicy, sweet, peely and other adjective words are secondary words. If one orange flavor is very sweet with a little juicy note, it can be described as follows:

Orange (Primary)
Sweet (Secondary)
Juicy (Tertiary)

Generally, one can make the correct description on a variety of flavors after receiving at least one year' training on description.

In Table 137.1, a series of secondary/tertiary descriptive words are listed for commonly used flavors.

TABLE 137.1
Descriptive Words for Commonly Used Flavors

Primary Words	Secondary/Tertiary Words
Orange	Sweet, Juicy, Peely, Fresh, Oxidized, Aldehydic, Tangerine, Mandarin, Oily, Candy
Lemon	Juicy, Fresh, Peely, Oxidized, Oily, Candy
Coffee	Roasted, Brewed, Expresso, Sweet, Vanilla-like, Bitter, Fresh, Instant
Cola	Spicy, Citrus, Woody, Oxidized, Vanilla-like
Apple	Red, Green, Peely, Juicy, Delicious, Fresh, Ripe
Vanilla	Vanillin, Hay-like, Creamy, French, Extracted
Banana	Ripe, Green, Candy, Cooked, Spicy
Blueberry	Juicy, Perfumed, Candy, Cooked, Ripe
Grapefruit	Juicy, Sweet, Bitter, Peely
Grape	Concord, Muscat
Honey	Floral, Herbal, Perfumed, Caramellized
Mango	Juicy, Ripe, Green, Floral, Skinny
Lime	Juicy, Peely, Oily, Candy, Fresh, Soapy
Peach	Ripe, Skinny, White, Candy, Canned
Pineapple	Juicy, Ripe, Canned, Candy

III. FOOD FLAVOR, TASTE AND MOUTHFEELING DESCRIPTION AND ANALYSIS

In most cases, food developers tend to describe and analyze their competitors' successful market sample. They are interested in the following information involved in the market sample:

1. Which kind of flavor is used in the product: orange, apple or lemon if the market sample contains only one type of flavor?
2. How many types of flavors are used in this product if the product contains several types of flavor: orange + mango, orange + lemon or orange + mango + peach?
3. Once the developer confirms that the product contains certain flavor (e.g. orange), he wants to know the flavor directions (e.g. juicy, sweet or sweet plus juicy).
4. Flavor solubility. For example, juice manufacturers add orange extracted flavors in juice product, but they may add orange topnote flavor or orange oil to improve the topnote of the juice product. The beverage developer has to gauge from his experience whether it contains orange topnote flavor or orange oil.
5. Food taste, mouthfeeling and texture. Flavors play an important part in food taste and mouthfeeling. Other factors affecting taste and mouthfeeling include sweeteners, acids, emulsifiers, thickening agents, mineral elements, vitamins, etc. The food developers must judge or guess from experience which specific function in the food product is caused by which specific kind of ingredient.

Table 137.2 shows an example that describes a market coffee milk sample.

TABLE 137.2
Flavor, Taste and Mouthfeeling Description of Market Coffee Milk Drink

		Primary*	Secondary*	Tertiary*
Coffee Milk Drink	Flavor	Coffee Milk Vanilla	Roasted Powdered Creamy, extracted	Burnt
	Taste	Very sweet (judge from experience that sugar content is about 8%)		
	Mouthfeeling	Creamy, smooth, flavor lasting		

* Only suitable for flavor description.

IV. FLAVOR SELECTION

Flavor selection is the critical step for a food developer to create high-quality, popular and quality-consistent food. Much attention should be paid to the following factors during the selection of flavors:

1. Flavor supplier.
2. Legal status of flavors in different countries: natural, natural identical, artificial; Kosher or Halal; Does the flavor contain any chemical which is not allowed in the local country?
3. Flavor solubility: water-soluble or oil-soluble?
4. Flavor existence status: liquid, powder or emulsion?
5. Flavor flashpoint. Flavors with the flashpoint below 61°C are classified as dangerous goods, which are easy to fire or explode. These flavors should receive special care during the transportation, storage and usage.
6. Flavor price.
7. Flavor stability against heating, oxygen, light and storage.
8. Flavor dosage and specifications like specific gravity, refractive index, odor, color, etc.
9. Flavor combination.

A food developer generally uses two or more flavors while creating a new food, especially matching a successful food sold well in the market. He has to use another flavor to complement the note which one flavor lacks; or use oil-soluble flavor to produce topnote in juice products although water-soluble flavor has been used. Flavor combination also causes the greatest difficulties for the competitors to match the market successful product.

V. SWEET FLAVOR APPLICATION

In this chapter, we will concentrate on the application of sweet flavors to beverages, dairy products (e.g. yogurt, yogurt drinks, ice cream, water ice) and confectionery.

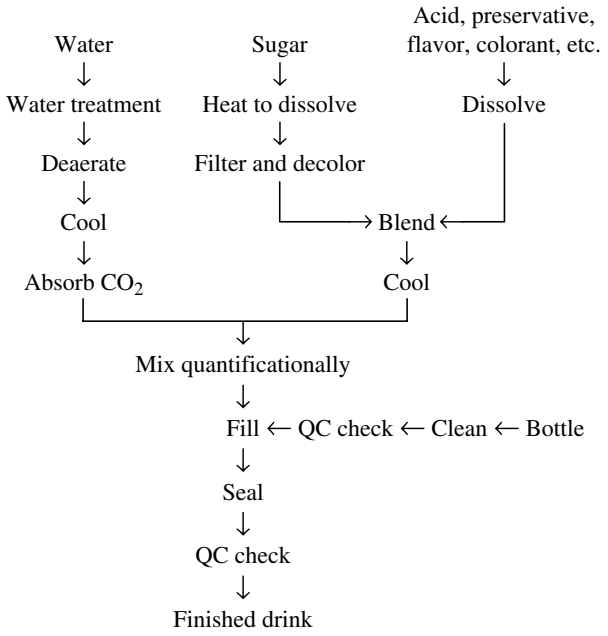
A. In Beverages

The ingredients of beverage consist of water, sweetener, acidulant, colorant, flavor, stabilizer, thickener, antioxidant, concentrated juice, mineral element, preservative, etc. Flavors for beverage must be water-soluble. Generally, the ratio of flavor in the finished drink is between 0.01%~0.3%, but the needed dosage will depend on flavor category, beverage category and other factors. Although flavor only occupies a small ratio in the finished drink, it plays a critical role in the beverage flavor and acceptability.

1. In Carbonated Drinks

a. Process flowchart of carbonated drinks

There are two kinds of process for carbonated drinks: one time filling and two times filling. One time filling is much more popular than two times filling due to its consistent quality of the finished drink. Two times filling has been phased out by most beverage companies because the quality of the finished drink is inconsistent. The process flowchart of one time filling is as follows [2]:



b. Formula examples

Example I: Carbonated cola drink

The syrup:	
Sugar	650.0 g
Phosphoric acid 85%	3.60 g
Caffeine	0.60 g
Color	to suit
Cola flavor	as needed
Water to make	1000 ml
Throw: 1 + 5	

The syrup: brix = 53°
The finished drink: brix = 10.6°; volume of CO_2 = 4.

Example II: Carbonated orange flavored drink

The syrup:	
Sugar	778.0 g
Sodium benzoate	1.50 g
Citric acid	9.00 g
Sunset yellow	0.175 g
Tartarine	0.040 g
Orange emulsion	~1.5 g
Water to make	1000 ml
Throw: 1 + 5	

The syrup: brix = 63.4°; acid% = 0.90%;
The finished drink: brix = 13.1°; acid% = 0.15%.

Two kinds of orange flavors can be used in carbonated drink: orange emulsion and water-soluble orange flavor, but the latter generally can't be used solely in carbonated orange drink because it is a washed flavor and has relative weak flavor profile. The latter is generally used to improve body and bottom note. Orange emulsion can be solely used or combined with water-soluble orange flavor.

2. In Juice Drink

a. Process flowchart of juice drink

Treated water and sugar, acid, juice concentrate, etc. → Deaerate → Homogenize(170/40 bar) → Sterilize (105°C, 15S) → Fill (88°C) → Seal → Cool → QC check → Finished drink.

b. Formula example: 10% orange juice drink

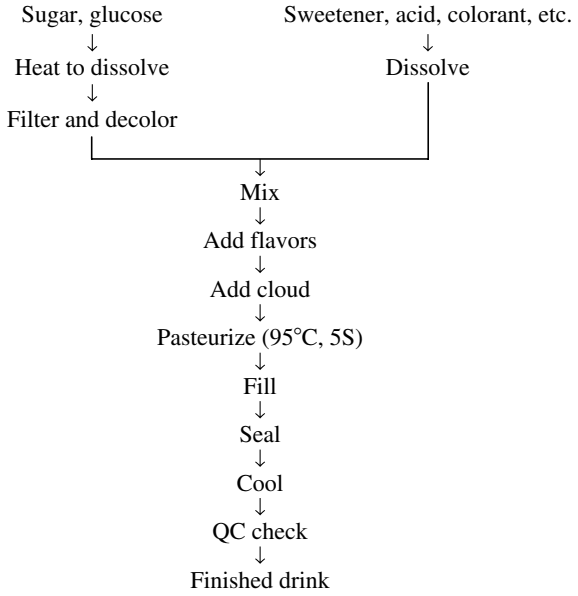
Sugar	90.28 g
Citric acid	1.63 g
Orange juice concentrate (8X)	12.5 ml
CMC(FH9, acid-proof)	1.0 g
β-Carotene emulsion (1%)	to suit
Orange emulsion	~1.0 g
Orange topnote	~0.2 g
Water to make	1000 ml

The finished drink: brix = 9.50°; juice content (%) = 10%.

Three kinds of orange flavors can be used in orange juice drink: orange emulsion, orange topnote flavor and washed orange flavor. Orange topnote flavor is used to improve the topnote, which dosage in the juice drink is 0.01%~0.02%; orange extract flavor improves body and bottom note, which dosage is 0.02%~0.08%.

3. In Sports Drink and Isotonic Drink

a. Process flowchart of sports drink and isotonic drink



b. Formula example: lemon flavored sports drink

Sugar	50.0 g
Glucose	15.0 g
Acesulfame potassium	0.14 g
Potassium citrate	0.30 g
Sodium citrate	0.30 g
Citric acid	1.60 g
Malic acid	0.80 g
Lemon washed flavor	~1.00 g
Cloud	~1.00 g
Water to make	1000 ml

The finished drink: brix = 6.8°; total acid % = 0.24%.

4. In Coffee Mix Drink

a. Process flowchart of coffee mix drink

Sugar and emulsifier → Premix → Dissolve in hot water → Dissolve milk powder and starch → Add coffee extract → Dissolve sodium citrate, etc. → Add flavor → To make 1000 ml → homogenize @170/40 bar → Fill → Sterilize @121°C, 20 min → Cool → QC check → Finished drink.

b. Formula example

Sugar	75.0 g
Whole milk powder	18.0 g
Coffee extract (brix = 51°)	14.0 ml
Sugar ester P1670	0.40 g
Sodium citrate	0.30 g
Sodium ascorbate	0.30 g
Instant textra (Nation starch)	2.0 g
Vanilla flavor	0.40 g
Milk flavor	0.33 g
Coffee flavor	0.85 g
Water to make	1000 ml

The finished drink: pH = 6.6; brix = 11.0°.

5. In Powder Drink

a. Process flowchart of powder drink

Sugar, acid, colorant, anti-caking agent, powder flavor, etc. → Blend → Sieve → Package → QC check → Finished powder drink.

b. Example formula: mango flavored powder drink

Sugar	90.0 g
Citric acid	2.40 g
Ascorbic acid	0.30 g
Lake color #5	0.004 g
Lake color #6	0.006 g
Sodium citrate	0.30 g
Anti-caking agent	0.40 g
Malto dextrin	30.5 g
Powdered cloud	~0.30 g
Powdered mango flavor	~1.0 g
Total	125.0 g

Use: 125 g dilute to 1000 ml for drink.

B. In Dairy Products

Yogurt, yogurt drinks, acidified milk drinks, ice cream and sherbets are classified as dairy products. Raw materials used in dairy products include the following:

Fat: milk fat, cream, butter, butter oil, vegetable oil (sunflower oil, soybean oil, rapseed oil, etc.)
Nonfat milk solids (NMS): proteins, lactose, mineral salts.
Sweeteners: sucrose, glucose, HFCS, etc.
Stabilizers: gelatin, pectin, xantham, carrageenan, agar-agar, CMC, guar, locust bean, sodium alginate, karaya, etc.
Emulsifiers: monoglycerides, diglycerides, etc.
Flavors: commonly used flavors in dairy products include coffee, milk, vanilla, nutty flavors (i.e. hazelnut), fruit flavors (i.e. orange, pineapple, strawberry), chocolate, cream, bean (i.e. green bean, red bean), ube yam, melon, etc.
Water and air
Juice preparations: orange, apple, strawberry, pineapple, banana, etc.
Yogurt cultures
Acids: citric acid, lactic acid, etc.
Colorants
Others

1. In Yogurt Drink

a. Process flowchart of yogurt drink

Skimmed milk
↓
Pasteurize (e.g. 90~95°C for 3~5 minutes)
↓
Culturing to pH 3.8~4.2
↓
Cool to about 20°C
↓
Slowly agitate for minimum 15 minutes
↓
Control pH 3.8~4.2
↓
Pasteurize at 90~95°C for 10~15 seconds
↓
Homogenize at 150~200 kg/cm^2
↓
Cool to filling temperature
↓
Aseptic filling

← Fruit juice, Pectin dispersion, Sugar, flavor, etc.

b. Formula example: strawberry yogurt drink

Skimmed milk yogurt	843 g
Fruit juice (50% sugar)	120 g
Pectin dispersion*	35 g
Strawberry flavor	~1.0 g
Yogurt flavor	~1.0 g
Total	1000 g

*Pectin dispersion: 3.5 g pectin is dispersed in 31.5 g 65% sugar solution at high mixing speed.

The finished yogurt drink:
Fat: 7.6%;
NMS: 8.0%;
Sugar: 0.35%;
Total solids: 15.95%.

2. In Ice Cream

a. Process flowchart of ice cream

Mix at 50~60°C
↓
Pasteurize (e.g. 80~85°C for 20~25 seconds)
↓
Homogenize (e.g. 140/40 bar at 75~80°C)
↓
Cool to 4°C
↓
Age below the temperature 4°C
| ← Add flavor, color, etc.
Freeze (e.g. 5.55°C at the outlet from the freezer)
| ← Incorporation of fruit, nut, cookie solids, ripple, etc.
Harden to −30 ~ −35°C
↓
Store below the temperature −17°C

b. Formula examples

Table 137.3 displays typical formulas for ice cream in different regions.

C. In Confectionery

Market confectionery products can be mainly sorted as: hardboiled candy, chewy sweets (soft candy), gummy candy, pectin jellies, chewy and bubble gums, chocolate, pressed tablet candies, jellies and marshmallows.

Raw materials used in confectionery products involve:

Sweetener: castor sugar, glucose syrup, invert syrup, synthetic and natural sweeteners
Fat: butter, hydrogenated vegetable oil, cocoa butter
Dairy products: fresh milk, butter cream, milk powder, condensed milk
Gelling agents: starch, agar, gelatin, pectin, etc.
Emulsifiers: lecithin, glycerol mono stearate, sucrose esters of fatty acids, span, tween, etc.
Acid: citric acid
Flavors: orange, lemon, strawberry, mint, blueberry, nutty flavors, etc.
Nuts and fruits products
Colorants
Others

TABLE 137.3
Typical Formulas of Ice Cream in Different Regions [5]

Ingredients	U.S.A	Europe	Asia
Milk fat	10.0%	8.0%	6.0%
NMS	10.5%	10.5%	7.0%
Sucrose	12.0%	12.0%	14.0%
Glucose solids (36DE)	6.0%	—	5.0%
Glucose solids (42DE)	—	3.0%	—
Stabilizer/emulsifier	0.4%	0.5%	0.4%
Flavor	~0.1%	~0.1%	~0.1%
Total solids	38.9%	34.0%	32.4%
Overrun	80–100%	100–130%	70–90%

1. In Hard Candy

a. Process flowchart of hard candy

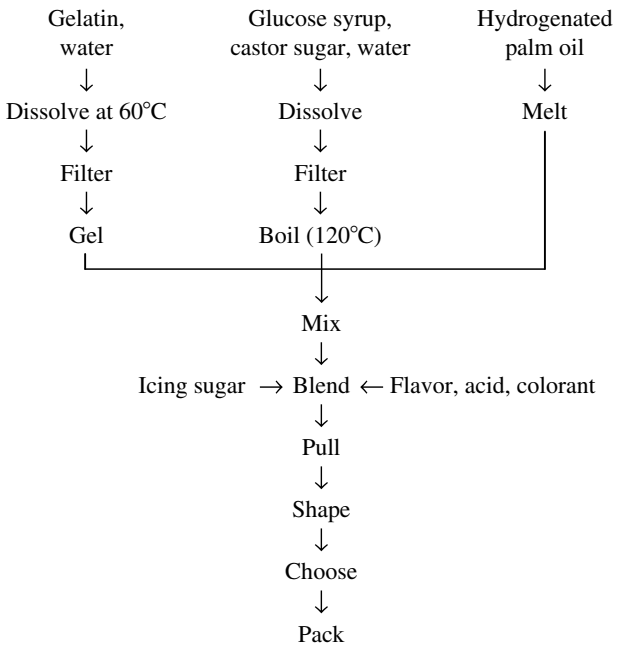
Castor sugar, glucose syrup, water → Dissolve → Filter → Boil → Cool → Add flavor, acid and color → Blend → Cool → Desposit → Cool → Select → Pack

b. Formula example: orange flavored hard candy

Castor sugar	57.0%
Glucose syrup	29.7%
Water	13.1%
Orange flavor	~0.3%
Color	to suit
Total	100%

2. In Chewy Sweets

a. Process flowchart of chewy sweets



b. Formula example: peppermint flavored chewy sweets

Castor sugar	34.36%
Water	18.38%
Glucose syrup	43.23%
Hydrogenated palm oil	3.06%
Emulsifier	0.55%
Gelatin 150 bloom	0.22%
Color	to suit
Peppermint flavor	~0.2%
Total	100%

3. In Chewing/Bubble Gum

a. Process flowchart of chewing/bubble gum

Gum base → Intenerate → Mix → Roll → Shape → Pack
↑
Icing sugar, flavors, other ingredients

b. Formula example: blueberry flavored chewing/bubble gum

Gum base	19.7%
Icing sugar	59.7%
Glucose syrup	19.8%
Glycerin	0.5%
Blueberry flavor	~0.3%
Total	100%

Gorton's Technology and Innovation Center

CONTENTS

Only the simplest foods are present as one continuous phase. In practice, much of the texture and other complex behavior of food systems arises from phase heterogeneity. A common and relatively simple form of heterogeneity is when the food is present as a dispersed system — small particles of one material (or phase) in a second continuous phase [1]. We are concerned with that subset of dispersed systems where one of the phases is lipid and the other aqueous, i.e., emulsions. Some examples of water-in-oil food emulsions include milk, ice cream mix, mayonnaise, salad dressings, soups, beverage emulsions, and flavor emulsions. The classic definition of an emulsion requires both phases to be liquid but in foods this definition is frequently expanded to include systems where one or more phases are solid. It is possible to make an emulsion with either a lipid or an aqueous dispersed phase and this distinction largely governs the overall properties of the emulsions (e.g., a lipid-continuous system will disperse poorly in water, and have a low conductivity and a greasy mouthfeel). However, in this work we will focus on aqueous-continuous emulsions.

We will describe the structure of food emulsions and the effect this structure has on the properties of the food. We will consider the mechanisms of emulsion (de)stabilization and finally the effects of food processing on emulsion structure. Our goal in this work is to provide an accessible introduction to the main issues essential to the engineering of food emulsions, but clearly such a brief treatment cannot be comprehensive. In Table 138.1 we provide a selected bibliography of sources that may be helpful for further exploration of the subject.

I. EMULSION STRUCTURE

Figure 138.1 shows an optical micrograph of a coarse food emulsion. The oil is present in spherical droplets in a continuous aqueous phase. The interfacial layer, although insignificant volumetrically, is essential to governing the

"Colloids in Food" [54]	Although somewhat dated, the treatment of the fundamentals underlying the chemistry of food colloids remains unrivalled.
"An Introduction to Food Colloids" [55]	A simplified text covering many of the topics from #1.
"Foundations of Colloid Science" [27]	Highly technical and comprehensive on the fundamentals of dispersion technology. Particularly useful discussion of surfactants and self-assembled colloids.
"The Colloidal Domain" [16]	A good general reference particularly in the fields of the properties of surfaces and surfactants.
"Advances in Food Colloids" [56]	A useful update to #1.
"Food Emulsions: Principles, Practice and Techniques" [24]	Particularly strong in the application of colloidal force arguments to food systems and analytical methods.
"Physical Chemistry of Foods" [57]	Comprehensive treatment of all of the main aspects of food physical chemistry. Especially relevant are chapters 9–13 on aspects of dispersed systems.

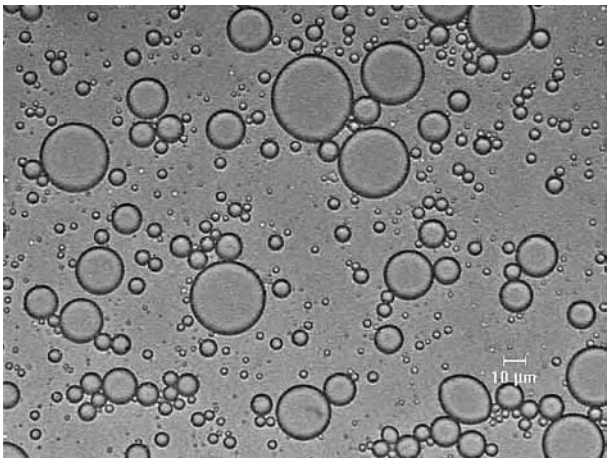

FIGURE 138.1 Optical micrograph of a coarse food emulsion. The oil is present in spherical droplets several 10 s of micrometers in diameter (most food emulsions would be an order of scale finer) surrounded by an aqueous phase. The interfacial layer is seen as a thick line here, but that is an optical artifact. In reality the interfacial region discussed in the text would only be a few nanometers thick.

overall properties of the system. Although all emulsions must have an aqueous and a lipid phase and an interface between them, they may vary widely, and it is useful to develop a vocabulary to describe their microstructure.

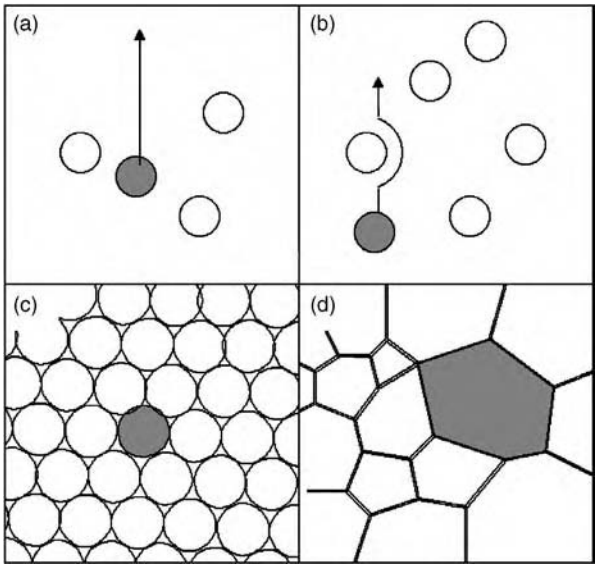

FIGURE 138.2 Schematic diagram showing the effect of volume fraction on the structure and dynamics of an emulsion. (a) A dilute emulsion, the movement of the highlighted particle is not affected by other particles. This would be realistic up to a few percent volume fraction. (b) In a more concentrated emulsion ($\phi \sim 10\%$) the movement of the highlighted droplet would be slowed by interactions with other droplets and the system would be more viscous and slower creaming than predicted from an extrapolation of the properties of the dilute system. (c) An ideally close packed emulsion where the particles are packed into a hexagonal array. The indicated droplet cannot readily move relative to the other droplets and the bulk material may develop elastic properties. Further concentration yields (d), a fluid foam where the droplets are distended into polyhedral shapes separated by narrow lamellae. Note ideal compression of (c) would yield a regular hexagonal structure but the polydisperse structure shown in (d) suggests some of the lamellae have ruptured to allow some coalescence.

First the amount of dispersed phase is typically expressed as a mass or volume fraction:

$$\phi_m = \frac{m_o}{m_o + m_a} \qquad \phi_v = \frac{v_o}{v_o + v_a} \tag{138.1}$$

where ϕ_v and ϕ_m are the volume and mass fraction of dispersed phase and v and m are the volume and mass of the oil (subscript o) and aqueous (subscript a) phases. Mass and volume fractions are readily interconvertable knowing the density (ρ) of each phase. Droplet volume fraction can vary from zero to approaching 100% (Figure 138.2). As the volume fraction increases, the particles increasingly interact with one another until they are close packed (as shown in Figure 138.2). The maximum theoretical close packing of identical spheres is 0.7405, but in reality this type of highly organized structure does not occur and random close packing occurs at much lower volume fractions ($\sim$0.64). Given an appropriate droplet size distribution (including particles approaching zero diameter) it would

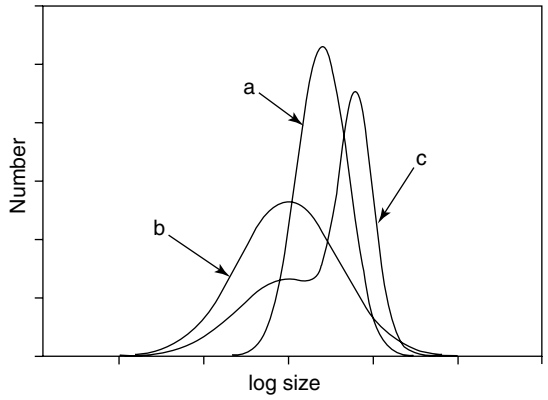

FIGURE 138.3 Typical particle size distributions seen in emulsions. (a) has a larger median diameter than (b) but (b) is more polydisperse and so has more larger particles and may be less stable than (a). (c) is bimodal, very often the larger population of droplets is formed due to the flocculation of smaller droplets.

be possible to achieve a much higher volume fraction but Princen [2] points out that in practice most real polydisperse distributions do not exceed the perfect close packing of homogeneous spheres. Droplet volume fractions beyond close packing are only attainable by deforming the spherical droplets.

Emulsion droplets are spherical (under all but the most extreme conditions) so can be characterized with a single length dimension. Real emulsions are polydisperse, i.e., contain droplets of varying sizes, and thus it may be more useful to represent their size as a distribution or in terms of a mean and polydispersity. For example a typical log-normal size distribution is shown in Figure 138.3a. Figure 138.3b has a lower median diameter, but as it has a broader distribution. It has more large droplets and may be effectively less stable. Figure 138.3c shows a bimodal distribution formed from the overlap of two polydisperse emulsions. Distributions such as Figure 138.3c are often seen in partly aggregated emulsions. Most stable emulsions have average diameters less than a few micrometers, and few are smaller than 100 nm.

A. Lipid Phase

The lipid phase is largely a mix of triacyglycerol molecules of animal or plant origin along with (typically) minor constituents of the lipids including free fatty acids and mono- and di-glycerides. Food lipids typically crystallize over the range of temperatures found in food processing and storage so we may also be concerned with semi-crystalline droplets. In general the melting point of a fat decreases with decreasing chain length and increasing unsaturation. Fats cooled below their melting point may crystallize, but the crystallization process is often very slow. Fat crystallization is further complicated by the fact that there are often several stable solid forms under given conditions and their rate of formation and interconversion may vary widely [3]. In the emulsified state the situation is further complicated as the fat is isolated into many self-contained droplets. In bulk fat it would require in principle only one nucleation event to crystallize all of the fat present but in the emulsified state each droplet must nucleate independently. In the most extreme case, each droplet is effectively pure and nucleation must occur homogeneously in the droplet [4]. Homogeneous nucleation is typically very slow and very large supercooling can occur when the number of droplets is much larger than the number of effective nucleating impurities. More commonly in foods there are sufficient impurities to allow most droplets to nucleate heterogeneously but this often still requires significant supercooling. Moreover, Walstra [5] pointed out that many real food emulsions contain several fat crystals, which implies multiple nucleation events per droplets. He argued this most likely occurs by secondary nucleation, the detachment of nuclei from the surface of a growing crystal.

The pressure of the oil droplet surface also affects the development of crystal structures within the droplet. Lopez and co-workers [6, 7] showed that crystals are more disordered in the emulsion droplets than in bulk, presumably due to the physical constraints of the surface. The effect of the droplets was most strongly seen in the less stable crystal forms. These and other workers have also seen an emulsified fat crystallizes into an α-form more readily than the same fat in bulk [6–8].

A second major reaction we may be concerned with in emulsion lipids is oxidation [9]. Lipid oxidation can lead to rancid off-flavors and -odors that can spoil food when present at very low levels. Further oxidation can lead to the formation of potentially toxic compounds and can also degrade the nutritional value of foods. In general oxidation proceeds through a radical reaction between an unsaturated lipid and oxygen. Radicals are generated by interactions of metals, the action of light, or enzymatic activity and the reactivity of lipids increases greatly with the number of double bonds present. The reactivity of emulsified lipids is notably different from the bulk properties of the same lipid and offers new ways to control the reaction [10]. While oxygen is usually present in significant quantities in both the lipid and aqueous phases, some of the important oxidation catalysts are concentrated in one or either phase. Notable here are aqueous metal ions which are only effective catalysts of lipid oxidation when they can approach the lipid droplets. Consequently emulsion droplets with negatively charged surfaces (e.g., proteins pH $>$ pI, sodium dodecyl sulfate) were much more prone to catalysis by iron cations than positively charged droplets. The actions of antioxidants are also different in dispersed systems. Frankel noted the "polar paradox" in which oil-soluble surfactants are more effective in stabilizing dispersed lipids while water-soluble surfactants are more effective in bulk [11]. He argued that in both cases

the antioxidant concentrates in the portion of the system most prone to oxidation (i.e., the emulsion droplets or the surface of the bulk respectively) where they can be most effective.

B. Aqueous Phase

The aqueous phase contains the water-soluble food ingredients including simple sugars and salts. Other ingredients may be largely water or oil soluble but partition to some extent between the two phases according to their partition coefficients: the ratio of the activity of the solutes in lipid and in water. Very often we are concerned with highly dilute additives such as flavors and antioxidants and it is reasonable to express a partition coefficient in terms of a ratio of concentrations. Lipids and sugars have partition coefficients close to infinity and zero, respectively but many other food ingredients have some solubility in either phase and while their equilibrium concentrations remain constant, individual molecules move dynamically between phases.

The properties of the aqueous phase can also affect the interactions between the emulsion droplets. For example, the change on an ionizable group is a function of pH and so the amount of charge carried on a protein-stabilized emulsion droplets will decrease from a positive to a negative plateau value as the pH is increased (Figure 138.4). The ionic strength ($=\frac{1}{2}\Sigma cz^2$, where c is the concentration of an ion of valence z) decreases the range of effective electrostatic interactions so they will be less important in salty systems. Some other components, particularly sugars, can act as co-solutes and stabilize proteins against thermal denaturation [12]. They achieve this by structuring the water around the hydrophobic groups on the protein and the same effect can reduce the hydrophobic drive to aggregation amongst denatured proteins.

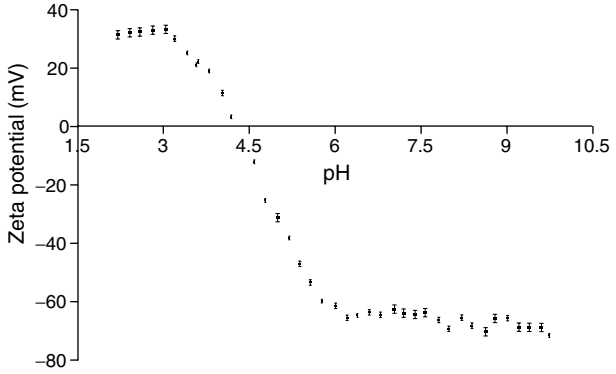

FIGURE 138.4 Effective surface charge (ζ-potential) on fine hexadecane emulsion droplets stabilized with whey protein as a function of pH. The charge on the droplets is governed by the charge on the protein molecules and follows a typical sigmoidal shape with pH.

C. Interface

The fact that oil and water are immiscible and have a clear interface (Figure 138.1) stems from the strong water-water attractive force. A water molecule is so strongly attracted to its peers that it will overcome the entropic drive for mixing with oil and remain as an isolated phase [13]. (In reality there is some small solubility of oil in water and although at the bulk scale an interface is a clear line separating the two phases, at the molecular level there is local mixing and an interfacial region where the concentration of both phases changes from its bulk value to its solubility in the second phase. It is possible to draw a Gibbs interface in this region so that the excess concentration on one side of the interface is equal to the deficit concentration on the other). The tendency of water and oil to demix also leads to a tendency to minimize the interfacial area because each surface water molecule is more exposed to the unfavorable oil phase than a corresponding molecule in bulk water [14]. The energy cost to increase the surface area of a system is manifested in the surface tension, a force opposing surface expansion:

$$\gamma = \frac{dG}{dA} \tag{138.2}$$

where γ is the interfacial tension, G is the surface excess free energy, and A is the surface area. The role of interfacial tension pushing against surface expansion also means droplet interiors are somewhat compressed (i.e., the Laplace pressure). Increased pressure can increase the solubility of lipid components and helps maintain the droplet's spherical shape against applied forces.

The unique molecular environment of a surface allows the accumulation of surface-active ingredients. Surface-active molecules have part of their structure water soluble and part oil soluble. Important examples in food emulsions are predominantly proteins [15] and to a lesser extent small molecule surfactants [16] and some hydrocolloids [17]. If a surface-active molecule is added to a two-phase system it can either remain free in one or both phases (enthalpic disadvantageous) or adsorb to the interface (entropically disadvantageous) [14]. The competition between terms means the amount of adsorbed surfactant will increase non-linearly with added concentration. The maximum amount of sorbed surfactant is defined by packing concerns at the surface but typically for food proteins is in the order of a few $mg\,m^{-2}$. Adsorbed surfactant shields the immiscible water and oil phases from one another and so decreases the interfacial tension from about $30\,mN\,m^{-1}$ for a clean oil-water surface to a surfactant-dependent minimum at surface saturation [1]. The most important functional roles of the interfacial layer in controlling emulsion functionality are to: (i) lower the interfacial tension to ease the formation of the emulsions, (ii) self-repair incipient holes in the lamella separating two approaching droplets via the

Gibbs-Marangoni effect, and (iii) provide a basis for repulsive colloidal forces between droplets. This final point is crucial in limiting destabilization by aggregation (see below).

Surface binding is not instantaneous. The potentially surface active molecule must first diffuse to the surface then "react" and bind. Diffusion is faster for smaller molecules so small molecules will usually develop an interfacial layer in a few seconds while a protein layer would take several minutes for the process to complete [14]. Although the binding of a single hydrophobic group to a surface is a spontaneously reversible event, the multiple binding of several sites on a polymer means that proteins will not typically spontaneously desorb from a surface. However if a more surface active material is added (i.e., small molecule surfactants) it may displace the protein from the interface by a competitive adsorption process. The surface protein concentration is not affected by small amounts of added surfactant, but will be completely desorbed following a small further increase [18]. Gunning and co-workers used atomic force microscopy to image protein displacement from a mica surface and saw that the initial portion of desorption the surfactant accumulated at the surface and pushed the protein into an increasingly thick and dense network surrounding the droplets [19]. At a critical level the surface protein network ruptured and detached from the surface. These workers termed this orogenic process as an analogy to the process of the formation of continents from tectonic plate activity. Oil soluble surfactants are less effective than aqueous surfactants at displacing proteins [20].

When globular proteins bind to a surface they often slightly rearrange their structures to better configure to the interfacial environment and as a result are often denatured. The interfacial protein concentration is relatively high even if the bulk concentration is relatively low and the properties of a concentrated protein solution are seen in two dimensions at the interface [21]. The proteins can cross react and form a viscoelastic two-dimensional gel that can improve the stability to coalescence. The same types of interprotein bonds responsible for bulk protein gelation (e.g., disulfide, hydrophobic) have been identified in the two dimensional surface analogue. Mixed protein films can phase separate in two dimensions just as a thermodynamically incompatible polymer mixture can in bulk [22, 23].

D. Formation of Emulsions

Emulsions can only be formed from bulk oil and aqueous phases through the application of amounts of energy. Some of the energy is used to create oil-water surface free energy but the bulk is "wasted" as heat losses in turbulent flow. Typically a coarse emulsion premix is made by blending or shaking the ingredients together. The particle size of the premix is very large, typically several (1–100) micrometers, and so they have a very short shelf life. However, the goal here is to produce a transiently homogeneous mixture that can be fed through a higher-energy secondary homogenization step for further particle size reduction to the desired final goal [24]. The second stage of homogenization can be achieved by a variety of technologies, e.g., colloid mill, ultrasonication, high pressure valve homogenizer, or microfluidizer, each of which enjoy various advantages and disadvantages but all serve to apply a critical mechanical stress to the droplets.

As noted previously, emulsion droplets are spherical to minimize their surface area and are somewhat pressurized. To disrupt a droplet it must be stretched and eventually fractured and to achieve this the forces input from the homogenizer via the continuous phase must exceed the cohesive forces of the droplets (Figure 138.5) [25]. The cohesive strength of a droplet increases with surface tension and decreasing particle size so one of the main roles of a surfactant in facilitating homogenization is to reduce interfacial tension. The relationship between the applied forces and the operating conditions of the homogenizer depend on the type of flow occurring (i.e., laminar or turbulent) but generally particle diameter is believed to be inversely proportional to either shear rate in laminar flow or (power density) in turbulent flow [24]. It is possible for the homogenizer to very effectively fragment particles but there may be little or no net effect on the particle size because the newly formed droplets take a finite time to become coated in surfactant and may recoalesce before this can happen. Thus the second role of surfactant in homogenization is to rapidly diffuse to and adsorb to newly created

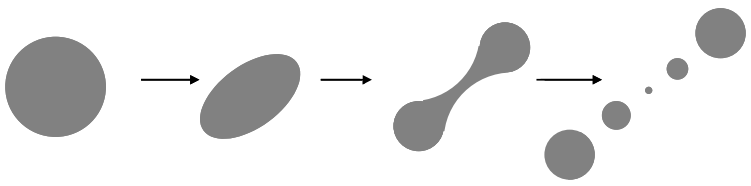

FIGURE 138.5 Schematic diagram showing the effect of applied force on a droplet. Initially the droplet is spherical but deforms into a spheroid under the applied force. Eventually a neck forms in the shape and fractures to form many smaller droplets. The small droplets formed can quickly recoalesce if they are not protected by surfactant or protein diffusion to the interface.

surfaces to protect them before any droplet-droplet collisions occur.

II. PROPERTIES OF FOOD EMULSIONS

We are rarely interested in food microstructure for its own sake but rather as a way to understand the sources of food quality [26]. So for food emulsions we are most concerned with how they affect perceived food texture, color, and flavor.

A. Texture

A dispersed system is always more viscous than the pure continuous phase due to the increased friction between the particle and the liquid layers causing greater energy dissipation. In a highly dilute, uncharged suspension containing non-interacting solid particles (volume fraction ϕ) the relative viscosity (η', i.e., apparent viscosity normalized to that of the dispersed phase) is given by the Einstein relationship (Figure 138.6):

$$\eta' = 1 + 2.5\phi \tag{138.3}$$

The "hard-sphere" assumption may be acceptably valid when a thick surfactant layer limits the transmission of flow from the continuous to dispersed (liquid) flow but in most real foods there are significant particle-particle interactions that will further increase the effective viscosity (Figure 138.2b). Extensions to the Einstein equation are available to account for paired and multi-body interactions.

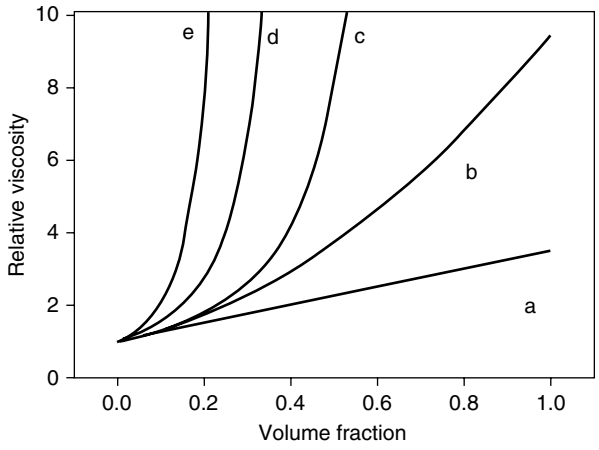

FIGURE 138.6 Theoretical relative (i.e., normalized to the continuous phase) viscosity of an emulsion as predicted by (a) the Einstein equation, (b) a modified version of the Einstein equation including a second order term in volume fraction, and (c) the Krieger-Dougherty relation. (d) and (e) were calculated assuming the emulsion was flocculated. (e) and (f) were calculated assuming the emulsion was flocculated into flocs 10 times the primary particle radius with fractal dimensions 2.8 and 2.6 respectively.

$$\eta' = \sum_{i=0} k_i \phi^i \tag{138.4}$$

where k_i are constants (1, 2.5, ~6, …). Using the first two powers Equation 138.4 reduces to Equation 138.3 and even using the third power it is only useful up to about 15 vol% [24]. At higher concentrations it is common to resort to empirical and semi-empirical expressions such as the Krieger-Dougherty relation:

$$\eta' = \left(1 - \frac{\phi}{\phi_{\max}}\right)^{-2.5\phi_{\max}} \tag{138.5}$$

where ϕ_{max} is a volume fraction approximating (0.6–0.7, Figure 138.2c) close-packing [27]. The ϕ_{max} parameter can be allowed to relax between a high and low shear value to account for non-Newtonian behavior. The Krieger-Dougherty relation tends towards infinity at $\phi = \phi_{max}$ and gives no meaningful solution beyond that point. However highly concentrated emulsions have a real viscosity and also develop significant elastic properties (e.g., mayonnaise). In order to maintain the very high levels of dispersed phase (often >80%) the droplets are distended and the microstructure approaches that of a foam with many polyhedral droplets in very close association (Figure 138.2d) [2].

B. Flavor

Our perception of food flavor comes largely from volatiles released into the headspace in the mouth and detected by nerves at the back of the nose. As well as being volatile, many food flavors have a significant solubility in oil and aqueous phases so the presence of emulsified lipid can affect the kinetics and thermodynamics of their release and therefore our overall flavor perception. Considering the partitioning of a volatile between the oil, water, and headspace in a food emulsion we can quickly see the effects of fat content on the perceived flavor of foods (here presumed to be related to the absolute headspace concentration). Using the subscripts o, w, e, and g to refer to the oil, aqueous, overall emulsion, and headspace gas phases respectively we can define an effective partition coefficient between the emulsion and the headspace) [28].

$$K_{ge} = \frac{K_{gw}}{1 + (K_{ow} - 1)\phi} \tag{138.6}$$

Figure 138.7a shows the effect of oil concentration on the headspace concentration of a number of different flavors with different partition coefficients (partition coefficient data from [24, 28]). The partitioning of the non-polar flavors (octanal, heptan-2-one) between the headspace and the emulsion decreases with oil concentration, the partition coefficient of the more volatile flavor (ethanol) increases. This is logical as oil provides a better reservoir for the non-polar flavors than the polar flavors. While volatile concentration does not necessarily correlate with sensory appreciation of flavor [29], this simple calculation shows the

magnitude of the changes that can be caused by changing the emulsion structure. For example, van Ruth and Roozen [30] studied the headspace concentration of volatiles above an oxidized sunflower oil in water emulsion and noted that while more volatiles partitioned into the headspace above the emulsion than the corresponding bulk fat, the relative change was different for different aromas. In another example fat content was shown to increase the amount of a non-polar flavor (linalool) released more than the polar flavor (diacetyl) [29].

Partition coefficients are thermodynamic constants but very often we are concerned with the dynamics of flavor release. Harrison and co-workers [28] proposed a mathematical model for the release kinetics of flavor from an emulsion. They assumed that as the droplets are relatively small, diffusion in the droplets and hence partitioning between oil and water occurs relatively fast, leaving the transport across the emulsion-headspace barrier as the rate-limiting step. Assuming the emulsion is well mixed they showed the concentration of gaseous volatile (c_g) is given as:

$$\frac{c_g(t)}{c_g(\infty)} = 1 - \exp\left\{-\left(1 + \frac{v_e}{K_{ge}v_g}\right)\frac{h_D A_{ge}}{v_g}t\right\} \quad (138.7)$$

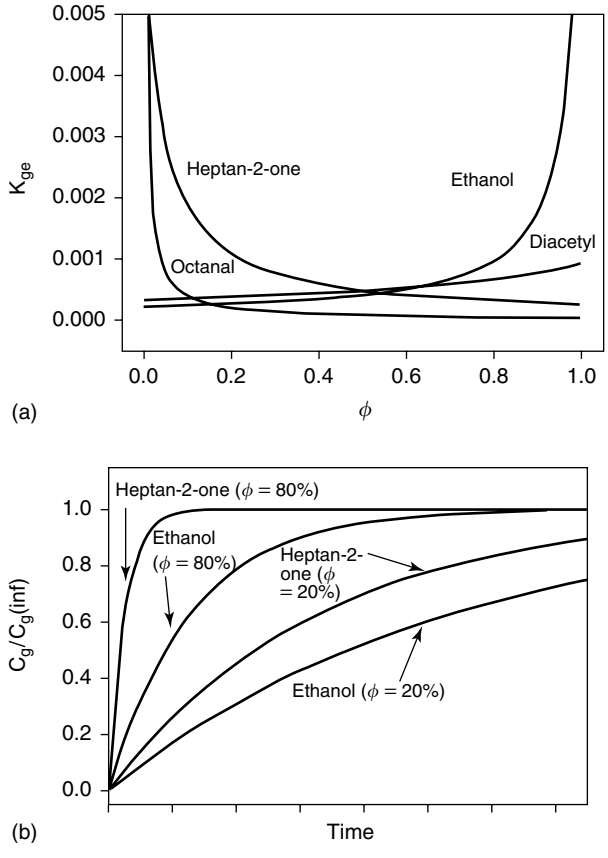

FIGURE 138.7 Calculated (a) partition coefficients and (b) flavor release kinetics for four volatiles as a function of emulsion volume fraction.

where v is the phase volume, K is the partition coefficient, t is time, h_D is the mass transfer coefficient in the emulsion, and A is the interfacial area of the emulsion surface (not the surface of the individual droplets). Emulsion particle size and volume fraction only entered into their formulation as terms controlling the viscosity of the emulsion (and hence h_D). Neglecting this effect, this approach clearly shows the effect of K_{ge} and hence oil content on the release kinetics. Some calculated rates of release of the aroma with partition coefficients calculated are shown in Figure 138.7b. While heptan-2-one is released more rapidly than ethanol in the higher water system ($\phi = 20\%$) the converse is true in the concentrated emulsion ($\phi = 80\%$).

Harrison and co-workers obtained reasonable agreement with their model in a study of the release kinetics of diacetyl and heptan-2-one [28]. However other workers have challenged their assumptions and investigated the effect of particle size and interfacial barrier effects [31]. For example Miettinen and others [29] showed that decreasing droplet size had no affect on the amount of diacetyl flavor (i.e., polar) but increased the release of linalool (i.e., nonpolar) and the effects of surfactant type were quite minor (sucrose stearate vs. modified starch).

The sensory perception of creaminess is associated with food emulsions and while it is related to the flavor present, rheology and particle size also play a complex role and vary by product [32].

C. Color

Fine emulsion droplets have diameters approaching the wavelength of light and therefore scatter light efficiently. Consequently, emulsions containing oil concentrations above a few percent appear turbid and white. Finer emulsions scatter short wavelength light more strongly and therefore take on a bluish tinge. Theory has been developed to calculate the perceived color of an emulsion from droplet size and concentration. First the scattering effects of the droplets are calculated and from this reflectance spectrum and hence the tristimulus values [33].

III. EMULSION STABILITY

Emulsion destabilization is driven by the tendency to minimize interfacial area by lipid droplet coalescence, and by phase separation (under gravity) by creaming. These are both thermodynamic effects and so emulsions will inevitably break down eventually. The goal therefore is not absolute but adequate stability, i.e., we are as much concerned with kinetics as we are with thermodynamics. The product must last as long as expected for that type of food, be it seconds for vinaigrette dressing, days for a dairy product, or years for a beverage emulsion. Some of the main mechanisms are illustrated in Figure 138.8 and discussed further below.

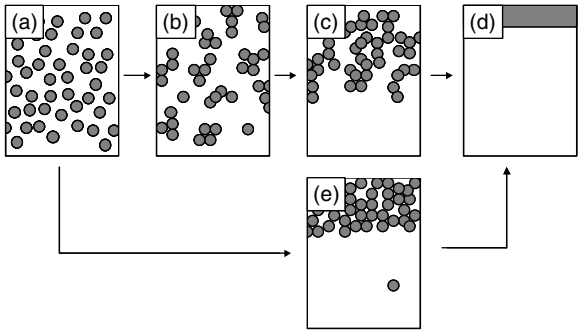

FIGURE 138.8 Schematic diagram illustrating the mechanisms of emulsion destabilization. The primary particles (a) flocculate (b) and rapidly cream (c) into a concentrated layer. The droplets may maintain their individual integrity in this state for a considerable period of time before (d) coalescing into a single phase. This is not the inevitable pathway, in some cases creaming (e) may occur without extensive flocculation. Note the two different creams shown (c and e) have different volumes. This is not the only route to destabilization.

A. Creaming

Oil is usually less dense than the aqueous phase of an emulsion, so it will tend to float to the surface in response to gravity or other applied forces. The movement of oil particles is impeded by viscous drag of the continuous phase and the net rate of particle movement (v_s) can be approximated from a balance of these forces in Stokes' equation:

$$v_s = \frac{d^2(\rho_{water} - \rho_{oil})g}{18\eta_c} \tag{138.8}$$

where d is oil droplet diameter, ρ_{oil} and ρ_{water} are the densities of the respective phases, g is acceleration due to gravity, and η_c is the viscosity of the continuous phase. Equation 138.8 is based on a series of assumptions largely violated in real food emulsions, i.e., the droplets are isolated spheres moving in a Newtonian fluid (Figure 138.2a) but it provides some qualitative guidelines to limit creaming (e.g., minimize particle size, density difference, or increase the viscosity of the continuous phase to reduce the rate of creaming). For example homogenization reduces the size of milk fat droplets approximately tenfold so we would expect homogenized milk to be stable against creaming approximately 100 times longer. As the droplet volume fraction increases, particle-particle interactions become more important (Figure 138.2b), the rate of creaming slows and Equation 138.8 becomes less reliable. An analytical solution is available for moderate concentrations of spherical particles and in principle better fits could be achieved by incorporating higher powers of volume fraction.

$$v = v_s(1 - 6.5\phi) \tag{138.9}$$

However a better description of the effect of volume fraction is achieved by assuming the effective viscosity (in Equation 138.8) experienced by a creaming droplet in a concentrated emulsion is the viscosity of the emulsion (rather than the continuous phase) and calculating that using a Krieger-Dougherty type relation. In this formulation, the emulsion achieved solid-like character as the volume fraction approaches close packing and at this point creaming effectively stops (Figure 138.2c and d, [27]).

Creaming can be readily and temporarily undone by gently shaking an emulsion. It can be measured by visually identifying the junction between a fat rich and fat poor region of a tube of emulsion, but only after creaming is well advanced. Earlier detection is possible using devices that can measure oil concentration as a function of position (e.g., ultrasonic velocity or optical reflectance), but it is often possible to identify systems likely to cream upon long term storage from particle size measurements or by using centrifugation to accelerate the process.

In the remainder of this section we will discuss the aggregation mechanisms responsible for emulsion breakdown. We will first consider the kinetics of aggregation, the various types of aggregation and finally the effects of aggregation on emulsion properties.

B. Aggregation Kinetics

Droplets in an emulsion move either by Brownian motion or under gravitational or other applied forces. The moving droplets collide and may (i) bounce off one another causing no change in the properties of the system, (ii) merge (coalesce) to form a single larger droplet, or (iii) stick together but maintain the shape of two conjoined droplets (i.e., flocculation). Either of the latter two cases will reduce the number of particles in the system and be a step towards destabilization. The rate of aggregation is given by the product of the rate of droplet-droplet collision (β) and the proportion of those collisions leading to reaction (α). Relatively simple terms for collision rates under static (i.e., perikinetic) and sheared (i.e., orthokinetic) conditions were derived by Smoluchowski and are given in Equations 138.10 and 138.11 respectively [34].

$$\beta_{perikinetic} = \left(\frac{2kT}{3\eta}\right) \tag{138.10}$$

$$\beta_{orthokinetic} = \frac{4G}{3}d^3 \tag{138.11}$$

where k is the Boltzmann constant, T is the temperature, η is the viscosity of the continuous phase, d is the droplet diameter, and G is the velocity gradient in the fluid. Smolokowski made several assumptions to derive these expression: (1) particles remain spherical after collision, i.e., complete coalescence, (2) no interparticle forces, (3) no particle or aggregate fracture, (3) fluid motion is exclusively either diffusional or laminar shear, (4) particles are of identical size, and (5) only two-body collisions occur. These

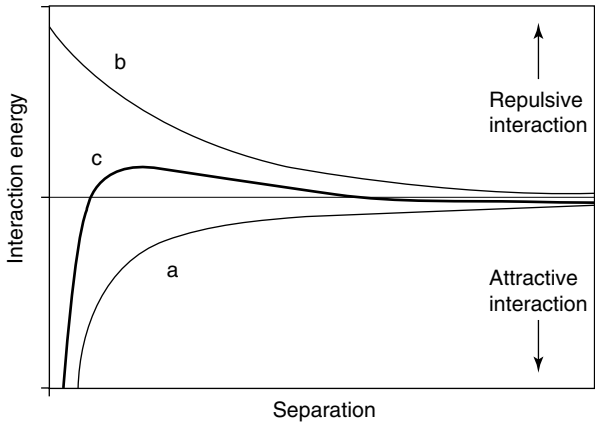

FIGURE 138.9 Schematic illustration of some typical interaction potentials. (a) is attractive at all separation, (b) is repulsive, and (c) shows a barrier to droplet aggregation at intermediate separations.

are clearly violated in real systems so again the full analytical solution can only be used to (at best) give some qualitative guidance. More complete analytical and empirical solutions are available to deal with some of these but the simple equations are still widely used [34].

The collision efficiency parameter α is often used as a fitting parameter to describe flocculation kinetics, but should in principle be relatable to the interdroplet forces acting on the system. If two droplets approaching one another have a significant repulsive force between them they may not collide, whereas if the force is attractive they may veer towards one another and collide even if their original, unmodified trajectories would have caused them to miss. The collision efficiency parameter α would be respectively less than or greater than one in these cases. The interaction forces between droplets vary with range and tend towards zero at long separations. They can also be expressed as interaction potentials — the energy cost of bringing one particle to a given separation from a second particle. Some sample interaction potentials are given in Figure 138.9. The potential is negative at all separations for Figure 138.9a so an approaching particle will tend to be attracted to the second. At very low separations the potential becomes increasingly negative so it will be difficult for the reverse process to occur and the particles will irreversibly coalesce. Figure 138.9b is positive at all separations so the droplets will tend to be repelled from one another. Figure 138.9c is negative or zero at large separations so the particles may approach one another. There is then a positive barrier which can slow the aggregation of particles (if $>kT$) but any particles which have sufficient potential energy to surmount the barrier will permanently coalesce into the potential energy pit at small separations. Interaction potentials can be measured directly or calculated as a sum of attractive and repulsive contributions from the physicochemical properties of the system [24, 35]. The physical bases for a few of the more important interactions are described below:

- **Electrostatic Repulsion.** Most food emulsions are protein-stabilized and under most conditions those proteins have a significant net charge. Consequently protein-stabilized oil droplets act as charged particles. The magnitude of their charge depends on the pH (Figure 138.4) and the amount and type of interfacial protein. However in a given emulsion each droplet is likely to have a similar net charge and thus repel the other droplets. The magnitude of the electrostatic potential force is proportional to the square of surface potential and decreases exponentially moving away from the droplet. The exponential decay is faster in high ionic strength systems so the stability of charged emulsion often decreases in the presence of salt. (Note the ionic strength effect is theoretically independent of ion type. Some specific protein-ion interactions (notable casein and calcium) can also lead to strong droplet aggregation [36].) Demetriades and others [37, 38] studied the effect of salt and pH on the stability of thermally treated whey protein stabilized emulsions. They noted the emulsions thickened and creamed at pH $\sim$ pI and particularly at high salt concentrations. Presumably away from the isoelectric point the electrostatic repulsion was capable of preventing droplet aggregation.
- **Van der Waals Attraction.** Transient dipoles in the bonds within matter lead to a weak colloidal attractive force. The force is relatively long-range, decaying with the reciprocal of distance, and is dependent on the dielectric properties of the component phases.
- **Hydrophobic Attraction.** There is an energetic advantage to moving hydrophobic materials out of an aqueous environment. This is manifested in a strong attractive force between hydrophobic surfaces, which decays exponentially over quite long distances. While this force can be readily measured, until recently there has been relatively poor understanding of the physical basis of the relatively long range of the attraction [35]. However, Pashley [39] recently noted that oil was soluble (as a turbid dispersion) in water if the water was first rigorously degassed by freeze-thaw under vacuum. He proposed that the dissolved gasses were the cause of the long-range hydrophobic effect and once they were removed oil became effectively water-soluble. Emulsion droplets not adequately protected

with surface active material have significant oil-water contact and will quickly aggregate as a result of the attractive hydrophobic forces. Surface protein usually shields the oil from the water and diminishes the hydrophobic attraction but surface denaturation can unfold the proteins and allow some protein-protein hydrophobic attraction to draw the droplets together. For example, Demetriades and others showed that thermally treating whey protein stabilized emulsions led to extensive aggregation [37, 38].

- **Steric Repulsion.** Adsorbed material acts as a barrier to coalescence at very short range (i.e., when the surface layers begin to overlap). The two main contributions to this mechanism are compression (volume exclusion) and mixing (osmotic) effects. Compression is always strongly repulsive but mixing can be attractive at slightly longer range depending on the solvent-polymer interactions [24]. Strong steric repulsion due to the protein layer at very short range is often responsible for the predominance of flocculation over coalescence in many food emulsions.
- **Depletion Interactions**. Non-adsorbing particles are excluded from a region close to a surface equivalent to their hydrodynamic radius. In an emulsion, this sets up an osmotic pressure gradient between particle-rich and particle-free regions of the continuous phase that favors droplet aggregation to reduce the volume of this region. Depletion attraction is particularly important when a non-adsorbing polymer is added to a food emulsion (e.g., xanthan gum, protein aggregates) and can lead to extensive flocculation and creaming [40–42].
- **Hydrodynamic Repulsion.** In sheared systems we can add hydrodynamic interactions to this list. Hydrodynamic forces represent the energy required to make the fluid between the approaching droplets "get out of the way" and so produces a repulsive force. The relative movement of the fluid will also tend to cause approaching particles to rotate and take on a curved trajectory and miss one another. Consequently the presence of hydrodynamic forces will always reduce the collision frequency, sometimes by up to 5 orders of magnitude, compared to rectilinear trajectories [34].

C. Types of Aggregation

Flocculation is the aggregation of oil droplets without mixing of their contents whereas during coalescence the membrane separating the approaching droplets is breached and allows the dispersed phases of the droplet to mix. Once oil is allowed to flow between droplets they quickly revert to a (larger) spherical shape. Coalescence can take place either following droplet collision (see above) or after periods of prolonged storage in a concentrated emulsion (often in a cream layer). The resistance of the interdroplet membrane to rupture depends on the strength of the protein films and the ability of the interdroplet repulsive forces to maintain a thick aqueous layer between the droplets. Surfactant layers can also favor film rupture if their optimal surface curvature favors hole formation [43] and oppose it through the Gibbs-Marangoni effect [44]. Extensive coalescence increases the particle size and therefore the tendency of an emulsion to cream.

In practice, coalescence is rarely the initial cause of food emulsion failure. More common is flocculation whereby droplets collide and stick together but the membrane separating them does not rupture. There is no mixing of oil so the individual droplets retain their spherical shape and a large, porous, and frequently fractal floc develops. A floc immobilizes a mixture of dispersed and continuous phase so the effective volume fraction of a flocculated emulsion, and hence the viscosity (Equation 138.3) is much greater than the corresponding unflocculated emulsion. Coalescence decreases the number of droplets but causes no change in the volume fraction of the emulsion and hence no change in product rheology. Both flocculated and coalesced droplets have larger particle sizes so often cream more readily than the primary emulsion.

Flocs can be characterized in terms of a size and density (fraction of the floc taken up by particles) but in many cases it is possible to ascribe a fractal dimension to the flocculated structure. A fractal object shows some level of self-similarity over several orders of scale. All objects show some relation between length and mass, for Euclidean solids, planes, and lines it is cubic, quadratic, or linear respectively, but for fractal objects it is non-integer. To describe a fractal floc the closer fractal dimension of the floc to three, the more the particles pack together to form a "perfect" Euclidean 3D object, i.e., complete coalescence. The lower the fractal dimension, the more open the structure. Fractal dimension can be used to calculate an effective volume fraction ϕ_{eff}:

$$\phi_{eff} = \phi\left(\frac{R}{r}\right)^{3-D} \tag{138.12}$$

where R is the floc radius, r is the primary particle radius, ϕ is the particle volume fraction, and D is the fractal dimension (= 1–3). The effective volume fraction can be used in the Krieger-Dougherty type relation to link microstructure and viscosity. Plots of viscosity as a function of volume fraction are shown in Figure 138.6d and e for R/r = 10 and D = 2.8 and 2.6 respectively. The looser floc (Figure 138.6e) reaches a critical volume fraction at

lower concentrations. Fully coalesced droplets (D = 3) behave the same as unflocculated emulsion (Figure 138.6c).

Emulsions may flocculate when too little protein is used in their formation. In this case a single protein strand may encompass several droplets and cause them to stick together). Factors which increase attractive colloidal forces or decrease repulsive forces (see above) such as adjusting pH to pI or thermal denaturation of the protein layer will also tend to induce flocculation. This can also be seen as factors that make the aqueous phase a poorer solvent for the protein will tend to favor protein precipitation and hence emulsion destabilization [45].

Related to both flocculation and coalescence is partial coalescence which is a novel mechanism of emulsion destabilization which can occur when the droplets are semi-crystalline (especially in sheared, refrigerated dairy products [44]). The fat crystals penetrate the aqueous layer separating the colliding droplets and then liquid oil flows out to wet the crystal surface and to reinforce the link between the droplets. The solid fat network in each droplet provides a skeleton to prevent the oil flowing completely between droplets and thus prevents full coalescence and maintains the characteristic shape of individual droplets. However if a partially coalesced emulsion is heated so the fat crystals melt they will merge and can lead to significant oiling off. Partially coalesced fat droplets play a role in supporting the foam of whipped cream and ice cream [46].

In conclusion, the typical mode of emulsion destabilization in real food emulsions is flocculation with associated increases in viscosity and often complete or partial phase separation. Later the membranes separating the flocculated droplets may break allowing coalescence and eventual oiling off. (When semi-crystalline droplets are sheared partial coalescence with associated formation of visible clumps or even phase-inversion may dominate.) It is notable that the distinct mechanisms of emulsion destabilization introduced above do not in practice occur in isolation but instead catalyze one another.

IV. EFFECT OF PROCESS CONDITIONS

Foods are processed to improve their safety and quality and sometimes these affect the colloidal forces responsible for the stabilization of emulsions.

Thermal Treatments. Most cooking operations involve some thermal denaturation of proteins. The extent of denaturation depends on the type of protein present at the surface, the temperature and time to which it is exposed, and to a lesser extent the pH and other co-solutes present. Thermal denaturation leads to some protein unfolding and the increased exposure of hydrophobic amino acids to the aqueous phase. The increased hydrophobicity leads to protein aggregation between the surface proteins and either (i) unadsorbed protein, or (ii) adsorbed protein on the same droplets (intradroplet bonding), or (iii) adsorbed protein on other droplets (interdroplet bonding). Of these, (iii) is the most significant as it leads to droplet flocculation and consequent changes in emulsion properties. The prevalence of each case depends on the relative concentration of oil droplets and non-adsorbed protein, and the inter-particle forces acting.

Chilling is important as it induces oil crystallization within the droplets. Droplet oil tends to crystallize more slowly than bulk oil due to the isolation of active catalysts but once there are crystals present there is an increased likelihood of partial coalescence and the formation of visible clumps in the product [44]. Freezing can quickly destabilize many emulsions via a variety of mechanisms. Firstly droplets are forced into very high concentrations in the unfrozen channels between the ice crystals [47]. This can first lead to the conventional forms of droplet aggregation found in concentrated unfrozen emulsions [48], in particular partial coalescence [49]. In addition the dehydrating effect of freezing on the surfactant head groups can alter spontaneous curvature and favor the formation of pores between droplets and eventual full coalescence [47]. In some emulsions the freezing will induce polymer-polymer interactions and droplet flocculation and the formation of a cryo-gel [50, 51].

Other Operations. High pressure treatment can have a denaturing effect on proteins and thereby affect the functional properties of emulsions [52]. The effect of the pressure treatment depends on the nature of the protein and on the solvent conditions, for example, 700 kPa had no effects on the surface pressure of casein but significant effects on whey.

Pulsed electric fields have an antimicrobial effect often exploited to reduce the microbial loads on minimally processed foods but have little effect on the properties of food emulsions, for example, disrupting flocs and rupturing larger droplets [53].

Irradiation inactivates food spoilage organisms by damaging their nuclear material. Extremely high levels of irradiation could in principle trigger more rapid lipid oxidation or damage other ingredients present but it is unlikely the levels used in food processing would have any detectable effect on the physical microstructure.

ACKNOWLEDGEMENTS

We are grateful to Dr. Julian McClements for generously providing a pre-print of parts of the forthcoming second edition of his book and to Ms. Andrea Docking for providing Figure 138.1.

CONTENTS

I. HYDROCOLLOIDS: OVERVIEW OF CHEMISTRY AND FUNCTIONALITY

Hydrocolloids, commonly known as water-soluble gums, are high molecular weight plant polysaccharides, usually with some inorganic or mineral content and low levels of protein. Gums are naturally occurring, water-soluble polymers with thickening, film-forming, and/or gelling properties based on their chemical nature, given specific conditions. Gums as complex carbohydrates exhibit properties that are affected by many factors including the following: active functional groups as substituents, molecular size, orientation, molecular association, water-binding and swelling, concentration, particle size, degree of dispersion, temperature, pH, processing conditions, etc. (1, 2, 3).

Soluble dietary fiber is defined as being resistant to degradation by human digestive enzymes and can help decrease high serum cholesterol levels. Water-soluble gums are good sources of soluble dietary fiber (about 85% on a dry basis) when used as an ingredient in processed foods. Low viscosity gums, such as gum acacia, inulin, hydrolyzed guar, and polydextrose, may be used as fiber source at higher levels in nutraceutical products. Gums can also be used as one of the ingredients in fat mimetic systems due to their ability to bind as much as 100-fold their weight of water. This chapter aims to highlight the functional properties of various commercially available hydrocolloids for applications in food and beverage products. A list of the various categories, examples, and botanical sources of naturally occurring hydrocolloids is shown in Table 139.1A. Examples of the most important chemically modified gums are shown in Table 139.1B.

TABLE 139.1A
Types of Natural Hydrocolloids

Type (Function)	Examples	Botanical Source
Plant Exudates (Emulsifying & Film-Forming Agents)	Gum Arabic Karaya Tragacanth	Acacia sp. Sterculia sp. Astragalus sp.
Seed Gums (Thickeners & Water Binders)	Guar Locust Bean	Cyamopsis tetragonolobus Ceratonia siliqua
Seaweed Extracts (Gelling Agents & Film Formers)	Carrageenan Agar Alginate	Chondrus, Eucheuma spp. Gracilaria, Gelidium spp. Laminaria, Macrocystis spp.
Microbial Gums (Thickener/Gelling)	Xanthan Gum Gellan Gum	Xanthomonas campestris Pseudomonas elodea
Plant Extracts (Gelling/Thickener)	Pectins Inulin Konjac Flour	Apple & citrus fruits Chicory & Artichokes Amorphophallus sp.

TABLE 139.1B
Types of Chemically-Modified Water-Soluble Gums

Type	Examples	Synonym
Cellulose Derivatives (Thickening & Suspending Agents)	Cellulose Gum	Sodium carboxymethyl cellulose
	Methyl Cellulose	Cellulose ether
	Cellulose Gel	Microcrystalline cellulose
	HPMC	Hydroxypropylmethyl cellulose
	EHEC	Ethylhydroxyethyl cellulose
Modified Gums (Emulsifying Agents)	Modified Gum Acacia	Esterified Gum Acacia

A. Hydration Rate, Functional and Rheological Properties

Gums are highly functional ingredients in beverages, salad dressings and sauces, snack foods, cereal products, and other food systems (1, 2, 3). In food applications, they function in a variety of ways (Tables 139.2A and 139.2B), an attribute that may be related to their viscosity characteristics or to their water binding, gelling, and other specific properties. These characteristics ensure the production of high quality food products with extended shelf life. As is evident from Table 139.3, viscosity ranges of the various hydrocolloids can vary greatly due to their chemical nature and degrees of branching and polymerization.

Depending on their chemical nature, type of branching, molecular weight, residual ionic charge, and ability to undergo intermolecular or intermolecular associations, the gums exhibit a variety of rheological properties. Shear-thinning behavior or pseudoplascticity is shown by xanthan gum while gum acacia, a branched, globular arabinogalactan is Newtonian (i.e., does not decrease in viscosity with increasing shear rate) up to 40% concentration. Thixotropic behavior has been observed in some cellulose gum solutions, depending on degree and uniformity of substitution.

To optimize the functional properties of gums, it is essential that the product is completely dispersed and fully

TABLE 139.2A
Functions of Gums in Food Products (1)

Function	Application
Adhesive	Glazes & cereal clusters
Binding agent	Granola bars & sausages
Bulking agent	Sugar-free foods
Clouding agent	Fruit beverages
Crystallization inhibitor	Ice cream, syrup, & candy
Coating agent	Confectionary
Emulsifier	Beverage emulsions & salad dressings
Encapsulating agent	Spray-dried flavors
Fat mimetic	Low-fat cookies & dressings
Film former	Edible films & coatings

Xanthan	1,000–2,000
Carrageenan*	100–1,500
Karaya	300–1,000
Tragacanth	500–750
Sodium Alginate	200–400
Gum Acacia	2–10

[a] Centipoise (cP) after 24 hours at 25°C (77°F) with 1% gum solns. (Brookfield Viscometer), RV4 at 20 rpm, except for gum acacia, LV2 at 60 rpm.
* Requires heating to 180°F to hydrate completely.

hydrated. Factors affecting hydration rate and functionality include the following: (a) chemical nature of the hydrocolloid, (b) particle size distribution, (c) method of incorporation of ingredients, (d) temperature, (e) pH and the presence of other ionic salts, (f) shear rate, (g) duration of mixing, (h) synergy between gums, (i) potential incompatibility between food components, (j) factors required for gel formation including cations and percent solids, and (k) processing conditions and equipment design.

TABLE 139.4
Proximate % Composition of Selected Gums

Gum	Complex Carbohydrates[a]	Protein	Ash	Others[b]	Sodium mg/100 g
Agar	85.0	<1	6.5	8.5	<10
Arabic	85.0	2–3	3.8	9.3	100
Carrageenan	60.0	<1	35.0	5.0	3,000
Guar	85.0	3–6	1.5	9.9	250
Locust Bean	80.0	6.0	1.2	12.8	<10
Tragacanth	80.0	2.5	3.0	14.5	10
Xanthan	85.0	0–2	10.0	5.0	5,000

[a] Soluble dietary fiber.
[b] Primarily moisture.

B. Proximate Composition: High Soluble Dietary Fiber Content

As mentioned earlier, gums have minute quantities of lipids and contain low levels of protein, depending on their source. They consist primarily of complex carbohydrates derived from plants or from the biosynthesis of end products by pure microorganisms (e.g., xanthan gum and gellan gum). They act as soluble dietary fiber (Table 139.4), which has been reported to lower serum cholesterol and improve gastro-intestinal function as well as improve glucose tolerance. Seaweed extracts also contain an appreciable level of ash, which may naturally occur with the gum or may be the consequence of manufacturing conditions.

C. Plant Exudates as Emulsifying Agents

1. Gum Acacia or Gum Arabic

Gum arabic is derived from the plant exudate of *Acacia senegal* or related Acacia species grown mainly in African regions. The general properties of this plant exudate are affected by the age of the tree, the amount of rainfall, type of storage conditions, and other factors. Salts and other electrolytes as well as temperature can affect the viscosity of acacia, which is typically not more than 300 cps at 30% gum level. The highly branched, compact structure may account for its low viscosity. The emulsifying properties are attributed to the protein moieties covalently linked to the polysaccharide (2).

Gum arabic is an anionic heteropolysaccharide consisting of an arabinogalactan complex (about 88%), an arabinogalactan-protein complex (10.4%), and a glycoprotein fraction (about 1.2%). It consists of rhamnose and glucuronic acid, in addition to arabinose and galactose (Figure 139.1). Gum arabic exhibits emulsifying properties and may be used at high concentrations up to 30% in spray dried flavors, due to its unusually low viscosity. When the protein moiety in gum acacia is damaged by high temperature and other specific processing parameters, the emulsifying capacity of the gum may be adversely

affected. Gum arabic is widely used in the food industry due to its emulsifying properties, low viscosity, high fiber content, water-binding capacity, and adhesive and film-forming properties (4).

Gum arabic is reported to be incompatible with vanillin, pyrogallol, vanillin, phenol, thymol, cresols, tannin, etc. However, it is compatible with most other plant hydrocolloids, proteins, carbohydrates, and starches.

2. Modified Gum Acacia: New Emulsifying Systems

The emulsifying properties of gum acacia are significantly enhanced by introducing a covalently linked lipophilic group through reaction with compounds such as octenylsuccinic anhydride (5). Modified gum acacia may be used to replace gum tragacanth and emulsifying starches used in bakery emulsions. Modified guar gum has also been used as a replacement for propylene glycol alginate in emulsion stability studies (5). These new products are members of the series of modified, emulsifying hydrocolloids covered by U.S. Patent No. 6,455,512 (6). A petition for GRAS certification has been approved after a thorough review by a panel of experts. The new products are available for initial evaluation in various formulations including beverage emulsions, cosmetics, and salad dressings.

D. Seed Polysaccharides

1. Guar Specialty Products: Deodorized and Hydrolyzed Guar Gums

Guar gum is a non-ionic galactomannan isolated from the seeds of the shrub that belongs to the species *Cyamopsis tetragonolobus*, Fam. *Leguminoseae*. It is grown in Pakistan and India and may also be cultivated in Texas, Arizona, and other arid regions of the U.S. The structural building blocks of guar are the sugars mannose and galactose at a ratio of 2:1 (Figure 139.2). The protein content ranges from 3 to 6% but the Food Chemicals Codex allows a maximum limit of 10%. It swells in cold water and is one of the highly efficient water thickening agents used in the food industry.

Solutions of guar are non-Newtonian and pseudoplastic or shear-thinning in nature (Figure 139.3). More recent specialty guar types have been developed to reduce the grassy odor and flavor, using a proprietary manufacturing process (7). Reduced odor guar gum is recommended for various food and beverage products with delicate flavor and odor. Hydrolyzed guar gum with lower viscosity (60 to 150 cps at 2%) may also be used to increase the fiber content of the finished product.

The viscosities of two special types of deodorized guar as a function of concentration after hydration for 2 and 24 hours are shown in Figure 139.4. Viscosity loss is reversible when heat is applied and subsequently removed. Guar gum can vary in its viscosity, rate of hydration, and dispersion properties depending on the conditions under which it is manufactured. Being the same as other gums, it has a high dietary fiber content of 80 to 85%.

2. Locust Bean (Carob) Gum

Locust bean gum is a non-ionic polysaccharide obtained from *Ceratonia siliqua*, a tree that belongs to the Family Leguminoseae, and consists of mannose and galactose sugar units in a ratio of 4:1 (Figure 139.5). Unlike guar gum, which hydrates rapidly in cold water, locust bean gum has to be heated to 80°C (176°F) for full hydration. The distribution

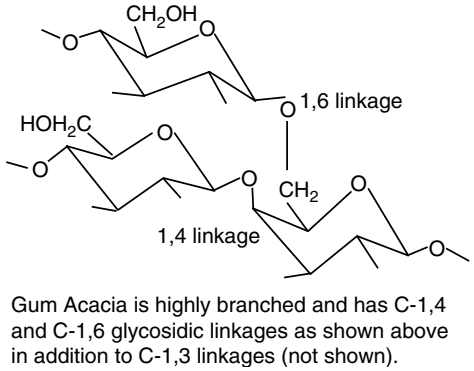

FIGURE 139.1 Glycosidic linkages in disaccharide repeating units in gum acacia.

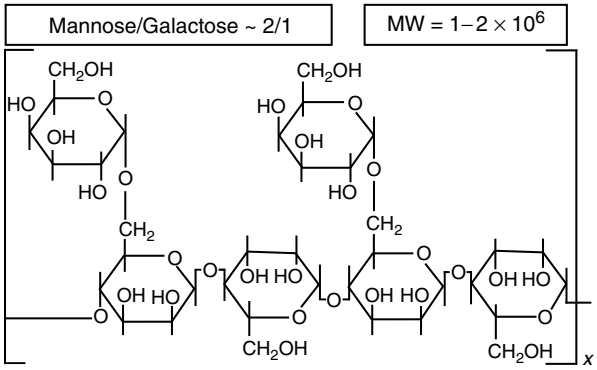

FIGURE 139.2 Structure of guar gum.

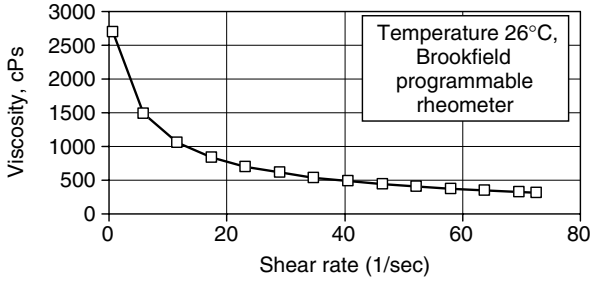

FIGURE 139.3 1% Deodorized guar: shear rate vs. viscosity.

of D-galactosyl groups in guar and locust bean gum has been described by Baker and Whistler (8). Food grade locust bean gum should have a protein content not exceeding 8% as specified in the Code of Federal Regulations.

Solutions of locust bean gum are non-Newtonian with zero yield value and, thus, flow as soon as slight shear is applied. When combined with xanthan, locust bean gum yields heat-reversible, pliable gels. It also acts synergistically with kappa carrageenan to form strong, somewhat elastic gels. Locust bean gum is classified as a direct food additive under FDA regulations. Dilute solution properties of guar and locust bean gum in sucrose have been characterized by Richardson et al. (9).

E. Seaweed Polysaccharides

Some seaweed extracts from the Family *Rhodophyceae* (agar), *Phaeophyceae* (algin), and *Gigartinaceae* (carrageenan) are used as gelling and stabilizing agents in various food products and beverages, based on the optimum gum levels and conditions required for functionality. The seaweeds are typically dried by sun-drying or mechanical means, washed to remove sand, salt, and other debris, mixed with water, and treated with alkali to facilitate the extraction of the polysaccharide. Alcohol is sometimes used to precipitate the concentrated extract. The general principles involved in the purification and isolation of these gums from the seaweeds are essentially similar, but the specific procedures are proprietary in nature and differ slightly for each manufacturer. The structure of the repeating unit of the gelling components from agar and carrageenan are shown in Figures 139.6 and 139.7, illustrating the presence of the ester sulfate groups that account for the anionic character of agar and carrageenan.

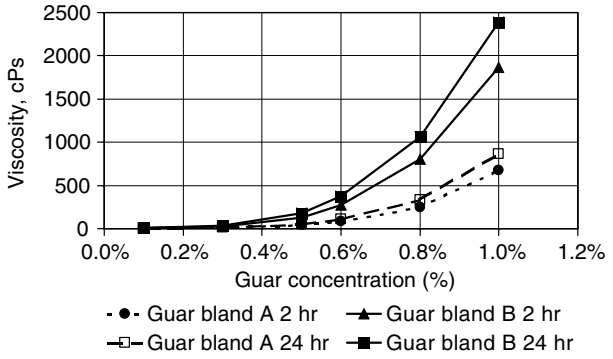

FIGURE 139.4 Deodorized guar levels vs. viscosity.

1. Agar and Agaroid Series as Gelling Agents

Agar and its agarose constituents have been characterized by Armisen (10). Agar consists of a repeating unit of beta-D-galactose attached to 3,6-anhydro-alpha-L-galactose. It is isolated from seaweeds that mainly belong to the *Gelidium*, *Gelidiella*, or *Gracilaria* species. Traditional agar can bind about 100 times its weight of water, and, when boiled to 212°F and cooled, forms a strong gel. It is one of the most potent gel-forming gums known and, unlike most other gelling gums, has a gelation temperature that is far below the gel-melting temperature. A solution of agar (1.5%) congeals in the range of 32 to 39°C (89.6 to 102.2°F) but does not melt below 85°C (185°F). This property is important in many of its applications in the food industry.

A more recently developed type of agar (Agar RS-100) from TIC Gums, Inc. does not require boiling as does the traditional agar (11). The seaweed sources are subjected to a series of manufacturing procedures that yield a product that may be hydrated at 170 to 180°F instead of 212°F. This is a desirable feature, considering the expense involved in boiler operations in the industry.

A series of synergistic systems, the Agaroid Series, that make use of non-boiling agar and other hydrocolloids

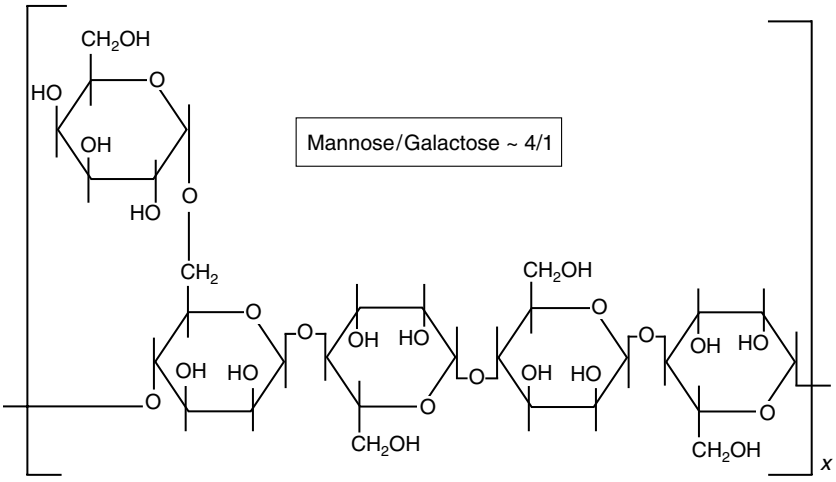

FIGURE 139.5 Structure of locust bean gum.

have been developed (11) to replace gelatin as gelling agent. Gelatin is not acceptable to some religious groups and has been recently associated with the incidence of mad cow disease, which has increased the demand for gelatin substitutes from the food industry.

2. Carrageenans: Protein-Reactive Gelling and Stabilizing Agents

Carrageenan, a water-soluble gum, is a sulfated, linear, anionic polysaccharide composed of D-galactose and 3, 6-anhydro-D-galactose derived from red seaweeds including *Eucheuma*, *Gigartina*, or *Chondrus* species. Carrageenans act as strongly anionic polyelectrolytes, a property that accounts for their high protein reactivity. Due to the presence of the ester sulfate groups, an interaction occurs with charged amino acid groups in proteins above the isoelectric point. The three common types of carrageenans — kappa, iota, and lambda — differ in degree and location of sulfated ester groups and the linkage of the repeating units (Figure 139.7). Bixler (12) conducted studies and reviewed the properties of refined and semi-refined carrageenans.

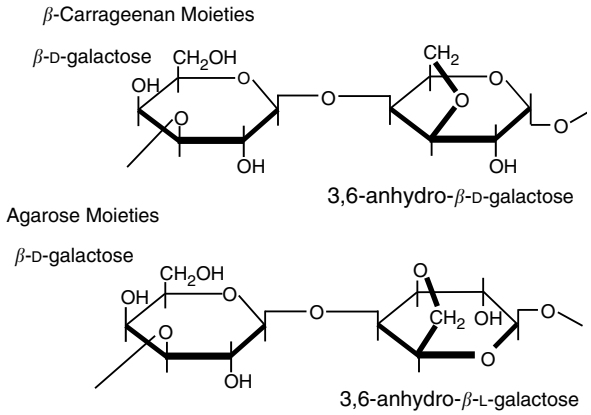

FIGURE 139.6 Repeating chemical units of gelling agents.

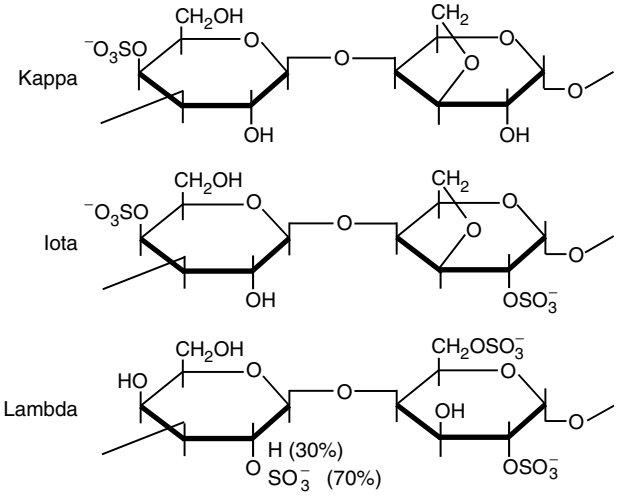

FIGURE 139.7 Repeating chemical units of carrageenans.

In terms of solubility in water, both kappa and iota hydrate at above 70°C, while the lambda type is soluble in cold water. In cold milk, lambda carrageenan disperses and thickens while both the iota and kappa carrageenans are insoluble.

Kappa carrageenan requires potassium ions to gel, while iota carrageenan requires calcium ions to form a heat reversible and flexible gel at 1.5% gum. The non-gelling type, lambda carrageenan is usually used to thicken milk, an action enhanced by tetrasodium pyrophosphate. Thomas (13) described the applications of carrageenans as thickening and gelling agents for food.

3. Alginic Acid Derivatives

Alginic acid is a high molecular weight linear polysaccharide derived from *Laminaria*, *Macrocystis*, *Lessonia*, and other related seaweed species. It consists of homo- and heteropolymic sequences composed of mannuronic and guluronic acid units (Figure 139.8). The guluronic and mannuronic acid content of the alginate affects the nature of the gel that is formed. Sodium alginate in the presence of calcium ions yields gels that are not thermally reversible. The method of addition and type of calcium salt added affects the properties of the final gel. A calcium sequestrant may be used to weaken the gel or delay its setting time. Gel systems may also be prepared using alginates by controlling pH. Neiser (14) characterized the gel formation in heat treated bovine serum albumin-sodium alginate systems.

4. Propylene Glycol Alginate: An Emulsifying Gum

An ester derivative of alginic acid, propylene glycol alginate is widely used as an emulsifier in salad dressings and other types of oil-in-water emulsions. Propylene oxide is reacted with alginic acid to esterify partially the hydrocolloid's mannuronic or guluronic acid units. The use of food colloids and polymers in emulsifying systems has

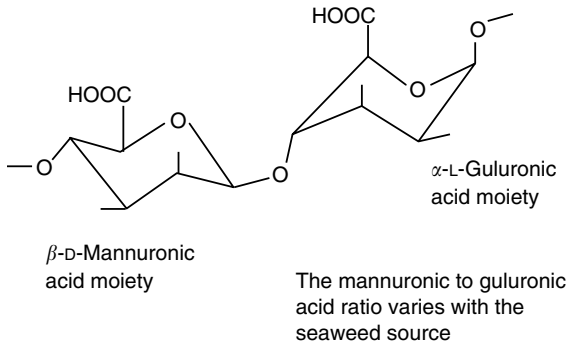

FIGURE 139.8 Glycosidic linkage repeating units in alginates.

been investigated extensively by Dickinson and Walstra (15).

F. Microbial Polysaccharides

1. Gellan Gum

Gellan gum (16) is a fermentation product of *Pseudomonas elodea* grown under aerobic, submerged condition. The active, high-acyl gellan gum consists of a linear sequence of tetrasaccharide repeating units. Cations such as potassium ions, in addition to interchain reactions and hydrogen bonding with water, help stabilize the structure that gives rise to gel formation. The influence of calcium ions, acetate, and L-glycerate groups in the gellan double helix has been investigated by Chandrasekaran and Thilambali (17).

By varying the degree of acylation, a range of gel textures can be generated. The viscosity of gellan gum solutions decrease markedly with increasing temperature, but functionality is retained upon cooling. Ratios of gellan gum and gum arabic at 1:1 exhibit an increase in gel strength by about 60% at 0.5% gum level. Gellan gum is used in food formulations that require gelling properties including jams, jellies, dessert gels, pie fillings, puddings, frostings, and dairy products.

2. Xanthan Gum

Xanthan gum is a highly branched polysaccharide consisting of repeating units of D-glucose, D-mannose, and D-glucuronic acid (Figure 139.9). It is a biosynthetic product of a pure bacterial culture of *Xanthomonas campestris* grown in a special nutrient medium under controlled conditions. It is approved for food use in many countries, including the United States and Canada. Food grade xanthan is also a good source of dietary fiber and should have an ash content that does not exceed 10.0%.

Xanthan gum solutions are extremely pseudoplastic and exceed most common gums in this respect. Viscosity is reduced with increasing shear; viscosity is regained after shear is released. This property is an advantage when pumping gum-thickened liquids.

Xanthan gum is an excellent emulsion stabilizer, although it is not an emulsifier by definition. It is typically used in salad dressing emulsions. Xanthan gum is stable over a wide range of pH (2 to 10) and temperature, which makes it an ideal stabilizer in a variety of applications (3).

G. Pectins

Citrus and apple byproducts have been widely used as sources of pectin. Other sources include tropical fruits such as guava, papaya, mango, etc. Under appropriate conditions, pectins (polygalacturonans) are gel forming. The main component of pectin is D-galacturonic acid partly esterified with methoxyl groups. The degree of esterification is initially high, but the pectin methylesterase enzyme present in most tissues can cause demethoxylation.

Pectins can be classified into high methoxy, low methoxy, and amidated. High methoxy pectins require more than 60% solids and low pH (less than 3.5) to form a heat-irreversible gel. Low-methoxy pectins (between pH 1 to 5) require calcium to gel and may yield a heat-reversible gel at 25 to 35% solids given the proper gelling

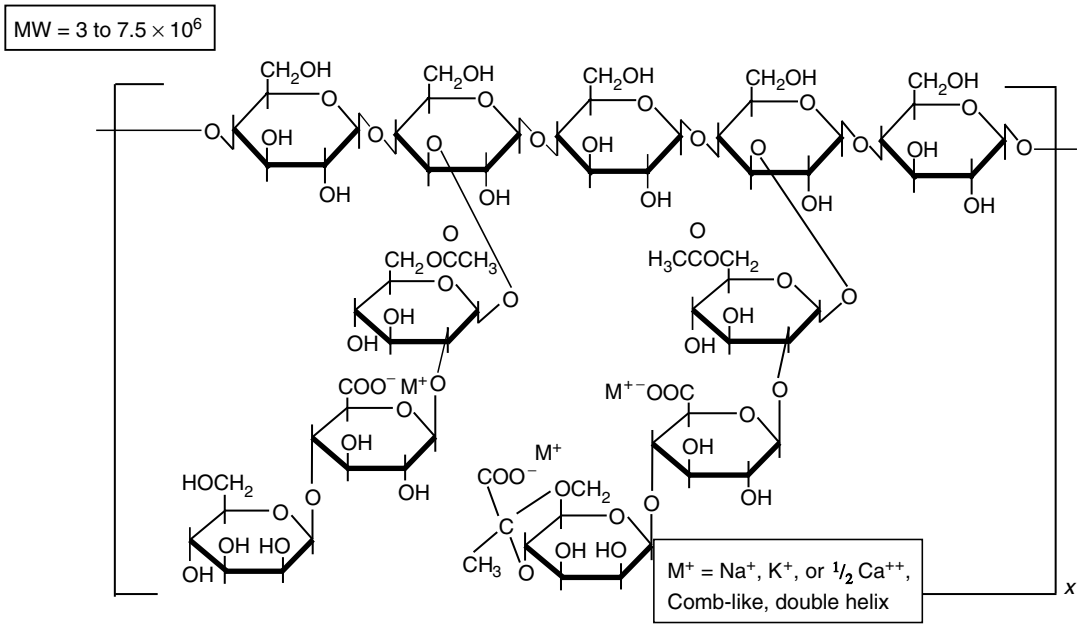

FIGURE 139.9 Structure of xanthan gum.

conditions. Schols et al. (18) describe the structural features of native and commercially extracted pectins.

H. Inulin: A Fructooligosaccharide

A relatively new food ingredient, inulin is isolated from the root of the chicory plant *Cichorium intybus* and other plant sources. It has gained wide use over the past several years due to the following features: readily soluble fiber, "neutral" taste, odor, and color, gelling properties, and ability to stabilize foams and emulsions. Inulin is a combination of fructose chains, the chain length varying from 2 to 60 fructose units. It has also been reported to provide only 1.6 Kcal/g as compared to 4.0 Kcal/g for starch and other carbohydrates (2). In addition, it has a glycemic index of zero, does not stimulate insulin excretion, has been claimed to be 100% soluble fiber, and is recommended in the modern diet for diabetics.

I. Cellulose Gum and Methylcellulose

Cellulose is a linear polymer consisting of beta-D-anhydroglucose units (Figure 139.10). Sodium carboxymethylcellulose (cellulose gum), derived from cellulose, is universally known as CMC. Purified CMC is a tasteless, odorless, and free-flowing powder and is widely used in the food industry. There are various types of CMC manufactured throughout the world. These differ in degree of substitution and viscosity. CMC is recommended in products where clarity is an essential feature. The manufacturer should specify the limits for % insolubles as well as turbidity values and degree of substitution, to ensure that the CMC grade meets the requirement for clarity in the finished product. Other derivatives of cellulose include methylcellulose and hydroxypropylmethylcellulose (HPMC). Methylcellulose, at suitable levels, gels upon heating, a property that makes it useful as a binder for products subjected to heating. Microcrystalline cellulose (MCC) is unmodified, insoluble cellulose that has been reduced to a small particle size and has been used as a fat mimetic in combination with CMC (11).

II. GENERAL APPLICATIONS IN THE FOOD AND BEVERAGE INDUSTRIES

Hydrocolloids, alone or in combination with other gums, other ingredients, and emulsifiers, are widely used in the dairy, bakery, confection, beverage, and snack food industries. They are also used in flavor emulsions, cereal products, candies, and confections. As indicated in the preceding section, their functionality is affected by the chemical nature of the gum as well other factors including pH, temperature, % total solids, presence of cations, and synergy or incompatibility with other ingredients.

Before actual production, planning equipment design, and scaling-up manufacturing procedures, the specific requirements of the gum or gum system should be taken into consideration by the engineer and food technologist. For example, if the filling viscosity is a limiting factor in production, gums that do not attain full viscosity in cold water are required. Shear forces at high temperature should be taken into consideration with some specific gums and starches to avoid excessive degradation. Similarly, high acid and high temperature can cause gum hydrolysis in the food system and should therefore be avoided where possible. For each food or beverage product, all the basic requirements to maximize functionality of the gum and the other ingredients should be adopted to achieve the desired sensory qualities and shelf-life stability. The oral behavior of food hydrocolloids and emulsions, including the relationship of zero shear viscosity and the maximum aroma intensity of guar, xanthan, and sodium alginate solutions, has been extensively investigated by Malone et al. (19).

A. Dairy Foods and Beverages

The conventional, older method of heat processing, batch heating at 145°F for 30 minutes, favored hydration of the gums. With the advent of HTST (high temperature-short time, 171°F for 16 seconds), hydration of gums requiring heat to unfold has become problematic. Ultra-high temperatures, 285 to 302°F for 2–3 seconds, further shorten

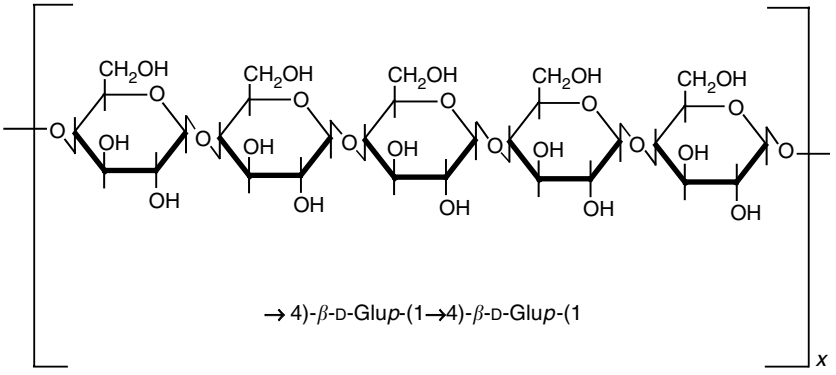

FIGURE 139.10 Structure of cellulose.

the time available for hydration as well as pose stability risks in acidic beverages. The extremely high heat of UHT processing denatures proteins that were not affected by the lower heat treatments. This unfolding can be utilized for additional viscosity, although precipitation problems may arise depending on the isoelectric point of the protein substrate.

1. Ice Cream and Other Frozen Dairy Products

Ice cream (20) is composed of milk ingredients, sweeteners, stabilizing agents, and flavoring. The milk ingredients used may include cream, milk, condensed milk, powdered milk, butter, and frozen cream. Fat is an important component in ice cream due to its mouthfeel and richness of texture. Whey solids are used in lower quality ice creams due to cost considerations. Whey consists of whey protein and other components that are not precipitated by high acidity. A by-product of the cheese industry, whey is now being used in beverages and nutritional sports supplements. Certain types of whey can impart a cheesy or salty flavor to the ice cream. Seventy-five percent of whey solids consists of milk sugar, or lactose. Too high a level of whey in the cream causes a defect, called "sandiness," due to specific structural forms developing. The "sand" or lactose crystals do not melt in the mouth.

Plain ice cream must contain at least 10% milkfat and 20% total milk solids. Air is whipped into the ice cream mix and the structure is quickly frozen. An ice cream with 100% overrun contains 50% air. Too much air causes rapid meltdown and is regulated by the Code of Federal Regulations.

Stabilizers in ice cream, particularly gums, provide smoothness in body and texture, retard ice and lactose crystal growth, and increase freeze-thaw stability. In addition, they contribute to creamier meltdown, lowered sensation of coldness, improved body, overrun control (product uniformity), and resistance to melting. The stabilizer, which increases viscosity and adsorbs to the air lamellae, also aids in the suspension of flavoring particles. Gums stabilize the product by restricting the movement of water and solutes. They hold free water as water of hydration or by immobilization within a gel structure.

In a sucrose-lactose solution simulating the colloid-free phase of an ice cream mix, the effects of CMC and guar gum on ice crystal formation were studied. Freezing profiles, obtained over short-term intervals, showed that the addition of guar gum significantly retarded ice crystal propagation in the sugar solution, whereas addition of CMC showed no effect (21).

Stabilizers are reported to have no significant effect on the amount of freezable water or enthalpy of melting. Although they exhibit no effect on the freezing point depression of ice cream, the gums do limit the growth of crystals during recrystallization (22). The size of ice crystals in ice cream determines the perception of iciness. Properly processed ice cream leaves the filler with small ice crystals. After transport, storage, and home freezing, ice crystal size grows. The consumer considers the ice cream defective, and sensory studies describe the defect as being coarse and icy. Defects in body and texture in ice cream are typically described by the following sensory properties: coarse or icy, gummy, weak, churned or greasy, soggy, and sandy. The use of polysaccharide gum helps inhibit the development of several of these defects.

Carrageenan is an excellent stabilizer and is used in chocolate milk and ice cream. It forms a lattice structure that holds water and keeps it from migrating. The kappa carrageenan component exhibits gel-forming properties. Used with other stabilizers to prevent wheying off, kappa carrageenan reacts with kappa-casein micelles in milk to form a weak pourable gel. It is used in ice cream, evaporated milk, infant formulas, freeze-thaw stable whipped cream, and emulsions in which milk fat is replaced with vegetable oil.

Guar gum is an excellent, cost-effective thickener that is cold-water soluble and is typically combined with locust bean gum and carrageenan at recommended ratios to maximize its functionality in the ice cream product.

Some gum systems form microscopic spherical particles that mimic the rheology and mouthfeel properties of emulsified fat. These systems may include locust bean gum, guar gum, carrageenan, xanthan gum, cellulose gum, and microcrystalline cellulose. Other frozen products in which gums are used include frozen custard or French ice cream, sugar-free ice cream, mellorine, frozen yogurt, fruit sherbets, and water ices. Mellorine is similar to ice cream but the milkfat is fully or partially replaced by vegetable or animal fat. It should contain not less than 6% fat.

2. Cream Cheese and Sour Cream

Gums, particularly combinations of carrageenan, guar gum, and locust bean gum, help minimize or retard syneresis or weeping in cream cheese and sour cream. Xanthan gum is also usually combined with guar gum and locust bean gum to form a synergistic component for cream cheese and similar formulations. The gum is added after the curd is formed by the inoculum, or, as in the case of imitation sour cream, after the protein is curdled with a lactic acid and citric acid mixture.

3. Acidified Milk Beverage

Acidified milk beverages that are subjected to UHT pasteurization may be stabilized by the use of pectin or a combination of pectin and a deodorized guar gum at 0.4 to 0.5%. A prototype formulation is shown in Tables 139.5A and 139.5B. The gum system is dry blended with sugar and added to the milk, then allowed to mix and hydrate. The orange juice and the remaining balance of the milk

TABLE 139.5A
Acidified Milk Beverage (1) (Prototype Formulation, pH 4.2 & 22°Brix)

Ingredient	%
Orange Juice	64.6
Whole Milk	25.0
Sucrose	10.0
Gum System*	0.4
Flavor (as required)	

* Pectin, deodorized guar gum, and propylene glycol alginate.

TABLE 139.5B
Acidified Milk Beverage (2) (Prototype Formulation)

Suggested Procedure

1. Pour milk into a mixing tank.
2. Dry blend sucrose and gum system.
3. Start blending at low speed, add the sucrose-gum blend to the mixer with the milk. Increase speed of the blender by 20%.
4. Let the gum hydrate for fifteen minutes in the mixing tank.
5. Add orange juice slowly and let mix for five minutes, adjust pH to 4.1–4.2 with citric acid, if necessary.
6. Pass through a thermal processing unit at 220°F (104°C) for 20 sec. Cool with chilled water to 40°F (4°C).
7. Package in sterile containers.

are then added to complete the formula. The UHT treatment involves heating at 220°F for 20 sec, after which the mixture is homogenized at 2500 psi and then cooled down with chilled water to 40°F and packaged in sterile containers. The product should show no significant wheying off or separation over a 6-week period. Pectin can also be used to stabilize UHT-treated fruit smoothies, buttermilk, fruit juice, milk drinks, and aseptic yogurt drinks. Pectin, which is anionic, stabilizes the milk protein and protects it from denaturation, thus keeping it suspended.

The effect of carrageenan on sensory properties of milk beverage model systems is described by Yanes et al. (23).

B. Bakery Products, Cereals, and Snack Foods

Hydrocolloids are used in bakery and snack foods (24, 25) due to their ability to bind water and improve the texture of the products as well as act as gelling agents. Gum arabic, used at 0.08 to 0.20 mg/kg of the flour, has been reported to improve the baking properties of rye and wheat flour (3). The anti-staling property of gum arabic and other hydrocolloids, when used in bread and cookies, has also been reported (3). Gum arabic is a main component in some glazing agents due to its adhesive properties. It also yields pliable and stable icing bases. The emulsifying ability of gum arabic is used in baker's emulsions, in combination with other gums such as gum tragacanth. As a surfactant and foam stabilizer, it may be used in whipped cream or toppings. Since gum acacia is high in dietary fiber, it may be used as a texturizer and bulking agent in powdered bakery mixes.

Cellulose gum prolongs shelf life in bread and increases water retention as well as volume of the dough. Comparison of the moisture content of reduced fat oatmeal cookies and cakes prepared with and without gums showed higher moisture levels in gum-treated samples. CMC may also be used as a film-forming coat and adhesive in doughnut glazes (24, 25).

Cellulose gum at 0.10% use level reduces ice crystal growth in frozen dough products and improves freeze-thaw stability. Fruit fillings with CMC in combination with gel-forming systems help reduce syneresis or weeping.

Methylcellulose is another derivative of cellulose that has been reported to increase moisture content and improve the sensory ratings of doughnuts. Microwaveable cakes showed uniformity of moisture distribution attributed to thermal gelation in methylcellulose-treated cake samples.

Carrageenan is used to strengthen and extend the protein ingredients in bread or cake mixes. It is also used as an additive in various dough products to help improve the loaf volume, loaf shape, and texture. The freeze-thaw stability of pasta products is improved by the addition of 0.05 to 0.10% of carrageenan. Kappa carrageenan is used in breading and batter mixes due to its protein reactivity. Lambda carrageenan, a non-gelling type, is used to bind or retain moisture. It also contributes viscosity to sweet dough products. Iota carrageenan, which requires calcium ions to form a heat-reversible and flexible gel, may be used in fruit applications. Cake and doughnut mixes with 0.1% carrageenan show better moisture retention and softer texture in the final product than mixes without the protein-reactive hydrocolloid.

Another important property of kappa carrageenan is its ability to form gels in the presence of potassium ions, and also to form rigid gels with locust bean gum. This gel-forming ability may be used in preparing piping gels, bakery jellies, and similar products. The ice crystal formation in frozen dough products is retarded by the addition of 0.1% carrageenan, thus improving the texture in frozen dough.

Alginates in combination with xanthan may be used to increase batter viscosity and increase cake volume. They also act as a cold-water gel base for instant bakery jellies and instant lemon pie fillings. Freeze-thaw stability of the fillings has been reported to improve in samples treated with alginates. In icings, alginates reduce stickiness and cracking. Alginates stabilize fat dispersion in whipped toppings and stabilize meringue products.

Some of the uses of agar important to the baking industry include its ability to stabilize icings or glazes by preventing water migration. It has also been used to reduce tackiness and to prevent adhesion of the sugar coating to the wrapper. Other applications include its use as a stabilizer

in pie fillings, piping gels, meringues, cookies, and similar products.

Bakery jellies that are heat reversible may be prepared with the use of 1 to 2% amidated pectins at 40 to 65% solids. Weeping or syneresis of pie fillings and glazes is also retarded or inhibited by the use of pectins, in combination with other gums.

Guar gum is used in cake mixtures to improve moisture retention in the finished product. It is a thickening agent and stabilizer for baked goods. Guar also helps to increase volume in yellow cake, probably by aiding in air entrapment. The whipping properties of toppings and icings are enhanced by the addition of 0.1 to 0.2% of guar based on the weight of the finished product.

Guar gum in combination with other hydrocolloids has been used to increase soluble dietary fiber content in bread. In a study, panelists evaluated "internal" scores for bread formulated with guar gum and carrageenan. The internal scores evaluated include grain, mouthfeel, crumb body, and taste aroma. Results of the study show high acceptability of the high-fiber bread with gums (24).

Guar is shown to have water-binding properties when used in bread doughs at 0.15%. When used at 0.1 to 0.2% in fruit pie fillings, it prevents the water from boiling out. Syneresis or weeping is retarded by the use of locust bean gum in gel desserts.

In bakery fillings, guar gum prevents water migration from the filling to the pastry due to its water-binding property. Freeze-thaw stability in frozen doughs is improved by use of xanthan gum. In baked goods, xanthan appears to inhibit starch retrogradation and improves shelf life of the finished product.

C. Salad Dressings and Sauces

"Full fat" salad dressings usually contain 30 to 60% oil and mayonnaise about 70 to 80%. Gums as thickeners, stabilizers, and emulsifiers are widely employed in these types of products industry. The most common emulsifying gum in high-oil salad dressings and sauces is propylene glycol alginate, an esterified form of alginate. Gum acacia may also be used to emulsify the oil but is used in combination with thickeners such as guar gum and xanthan gum. The synergy between xanthan gum and guar gum is well known (3) and utilized in stabilizing salad dressings. Xanthan gum adds acid stability and guar gum provides viscosity at lower cost than other thickeners. In products that contain milk protein such as creamy Italian or ranch dressing, a low concentration of carrageenan (0.05 to 0.10%) may also be used for its protein reactivity.

The formulation for a pourable creamy Italian salad dressing with 10% oil is shown in Table 139.6. The stabilizer used may include xanthan gum, guar gum, propylene glycol alginate, and starch. The sensory evaluation results of salad dressing bases using a 35% oil salad dressing and a 3% oil dressing using a fat mimetic gum system are shown in Figure 139.11. The attributes, opacity, cling, acidity, creaminess, and mouthfeel are comparable using a hedonic rating scale.

TABLE 139.6
Creamy Italian 10% Oil Dressing Formulation

Ingredients	%
Water	66.15
Vinegar (100 gr.)	7.00
Non fat dry milk	5.00
Sugar	4.50
Maltodextrin	4.50
Soybean oil	10.00
Salt	1.50
Xanthan/guar/gum acacia/starch system	1.35
	100.00

Procedure:

1. Add 10 parts to 1 part gum system to form a slurry.
2. Add oil/gum slurry to water while mixing. Hydrate for 10–15 min. with good agitation.
3. Add the rest of the ingredients.
4. Run through a colloid mill at medium setting to form a stable emulsion with small particle size.

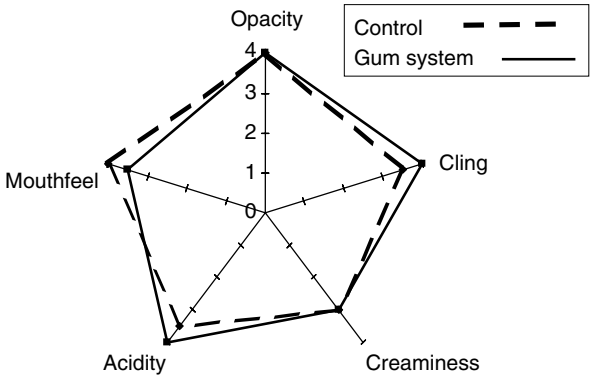

FIGURE 139.11 Sensory analysis of salad dressings (fat mimetic system vs. control).

D. Beverage Emulsions

Oil-in-water emulsions are employed widely in the food, beverage and pharmaceutical industries. Flavor components in beverage can be mainly oil-soluble, water-soluble, or a combination of both, and flavor retention in the beverage requires a good emulsifying system. Beverages mainly consist of water, sweeteners, acidulants (phosphoric acid or citric acid), flavors, and other additives such as coloring agents, weighting agents, vitamins, and minerals. The total solids may vary from 9 to 14% and the beverage may contain alcohol. Clear beverages require that any insoluble components of the citrus oils be removed by special treatment.

Typical beverage emulsion formulations, using a weighted or unweighted emulsion with gum acacia, an emulsifier with an HLB (hydrophile-lipophile balance) value of 10 to 11, are shown in Tables 139.7A, 139.7B, and 139.8, respectively). Weighted emulsions may contain SAIB (sucrose acetate isobutyrate), ester gum (glyceryl abietate) or BVO (brominated vegetable oil) as weighting agents to adjust the specific gravity of the flavor oil.

The emulsification procedure involves homogenization at about 3500/500 psi in a two-stage homogenizer. Homogenizers are special devices that disperse a mixture by forcing it through a tiny orifice under very high pressure. Microfluidizing equipment may also be used to prepare emulsions with very fine particle size (about 90% less than 2 microns).

TABLE 139.7A
Prototype Formulation: Weighted Beverage Emulsion (1)

Ingredients	%
Gum acacia, spray-dried*	15.0
Citrus oil/ester gum/SAIB**	10.0
Sodium benzoate	0.1
Citric acid	0.1
Water (added to make 100 mL)	

* May be replaced by 5% modified gum acacia.
** Sucrose acetate isobutyrate.

TABLE 139.7B
Prototype Formulation: Weighted Beverage Emulsion (2)

Procedure:
1. Add the preservatives to the water and mix thoroughly.
2. While mixing add the gum acacia gradually to the vortex of the solution.
3. Allow the gum to hydrate by mixing for 1 hour.
4. Dissolve the ester gum in the oil thoroughly by mixing for 2 hours.
5. Add the weighted oil from #4 to the gum solution.
6. Mix using a Ross mixer at medium speed for 10 min.
7. Homogenize at 3500/500 psi.
8. Pack into sterile containers.

TABLE 139.8
Prototype Formulation: Unweighted Beverage Emulsion

Ingredients	%
Gum acacia, spray-dried	15.0
Citrus oil	10.0
Sodium benzoate	0.1
Citric acid	0.1
Water (added to make 100 mL)	

Note: Procedure as in weighted emulsion.

E. Confections and Candies

Confectionery products include a spectrum of sweet goods, specifically candies and similar products. Sugar confectioneries include nougats, fondant, caramels, toffees, and jellies (e.g., gum drops and orange slices). Chocolate confections include chocolate and assorted chocolate-covered fruits, nuts, and cremes.

Gum acacia has the ability to retard or inhibit sugar crystallization and is used in the manufacture of pastilles and soft candy where sugar content is very high. In caramels, it will also help emulsify the fat to distribute it more uniformly and prevent oil from forming a rancid oily film. Gum acacia coacervates with gelatin are also used as chewy candy centers in many popular products flavored with peppermint or spearmint.

1. Gelatin Substitutes: Hydrocolloid Gelling Agents

Gelatin substitutes in gummy bears and similar products have been developed in recent years because gelatin is not acceptable to some religious groups and is sometimes associated with "mad cow disease." However, the properties of gelatin, including melting point, flexibility, and mouthfeel, are difficult to simulate with other hydrocolloids and textural differences between products prepared with gelatin and gelatin substitutes can be detected by the consumer. Gummy candies, using gelling agents such as pectin, agar, carrageenan, or combinations of these with modified starches have been introduced in the market, but with limited success. A formulation for a gummy candy without gelatin is shown in Table 139.9. A comparison of the texture profile analyzer (TPA) curves of gummy candy with gelatin and those prepared with some other gum systems containing agar and pectin as gelatin substitutes is shown in Figure 139.12.

F. Meat and Poultry Products

For poultry and meat injection, fine-mesh carrageenan incorporated with the brine significantly reduces cooking loss, thus increasing yield. Marinades may also be thickened and stabilized with guar gum and xanthan gum, a

TABLE 139.9
Gummy Candy with Pectin and Agar System

Ingredients	%
Sucrose	46.0
Glucose syrup	25.0
Agaroid gum system	2.0
Trisodium citrate	0.25
Citric acid (50%)	0.15
Water (to make 100%)	

heat-stable gum. In meat analogs or minced meat products, carrageenan at 0.5% to 1.0% level has been shown to reduce syneresis and act as moisture binder and adhesive (11).

III. FAT MIMETICS AND FUNCTIONAL FOODS

The typical North American diet provides a continuing challenge to the food industry to formulate highly acceptable low-fat products, particularly those low in trans-fatty acids, for the consumer. Unless an integrated approach is used, fat or oil mimetics may yield products that are inferior to the full-fat, high-calorie counterparts. Initially the role of the fat in the specific product has to be determined and then steps taken to simulate or mimic the functionality and sensory qualities of fat or oil being reduced. Some of the important factors to consider include the following: mouthfeel and texture characteristics, impact on threshold value or perception of flavor, functionality of the fat in the product, processing conditions during manufacturing scale-up, shelf life, microbial stability, and water activity. Hydrocolloid systems consisting of gums, starches, and other components may be used as fat mimetics (26). However, it is not recommended that all the fat or oil is replaced in the formulation, since the lipids have special functional properties that the gum systems may not be able to replace. Partial reduction of fat or oil up to 50% replacement may be feasible so as to prevent the significant changes in the threshold value of flavor compounds. The flavor components are significantly affected by the fat or oil content of the finished product as shown by significant changes in threshold value.

A combination of gum acacia, a food starch, and alginates has been successfully marketed for low-fat muffin and other bakery mixes (26). The main component of the system, gum acacia, is an unusual gum that offers advantages over other gums as a fat mimetic for the following reasons. Unlike other gums, it has low viscosity about 100 cps at 25% solids and contains 2 to 3% protein (which provides its good emulsifying properties). It imparts smooth mouthfeel and acts as a lubricant, inhibits ice and sugar crystallization, is high in dietary fiber, has adhesive properties, and may be used for spice adhesion instead of oil.

Fat mimetic systems using gums and starches incorporated in a low-fat cookie formulation have been shown to yield a product with longer shelf life, based on higher moisture content retention and lower hardness values measured using a Steven's Texture Analyzer.

Gelling agents such as carrageenan and agar may also be used in fat mimetic systems to simulate the texture of fat in icings and glazes. In developing low-fat systems, the fat is usually replaced with water and other solids. It is imperative that the formulator minimize the water activity gradient between the substrate and the filling or glaze, to reduce water migration.

The high soluble dietary fiber content of hydrocolloids makes them essential components of functional/nutraceutical foods and beverages. For example, the use of low viscosity guar gum and gum acacia in high-fiber beverages such as smoothies or fruit concentrates is increasing. In granola bars and dry beverage mixes, the health benefits are being augmented by adding gums as sources of soluble fiber including the following: inulin, gum acacia, polydextrose, and hydrolyzed guar.

IV. GUM SYSTEMS: SYNERGY AND INTERACTION

When certain specific gums are used in combination, the functional properties are significantly enhanced or modified due to synergistic action. For example, a combination of xanthan gum and locust bean gum at 1.0% gum level will form a heat-reversible flexible gel whereas the individual gums are not gel forming (27). The interaction of locust bean gum with kappa carrageenan, to yield

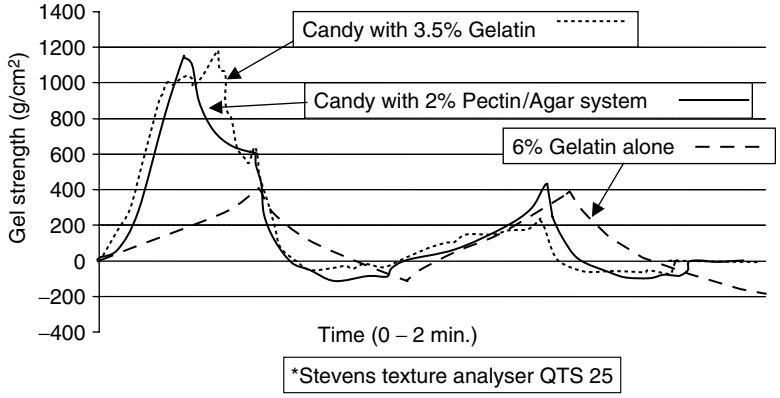

FIGURE 139.12 TPA of gummy candy with pectin/agar system vs. gelatin.

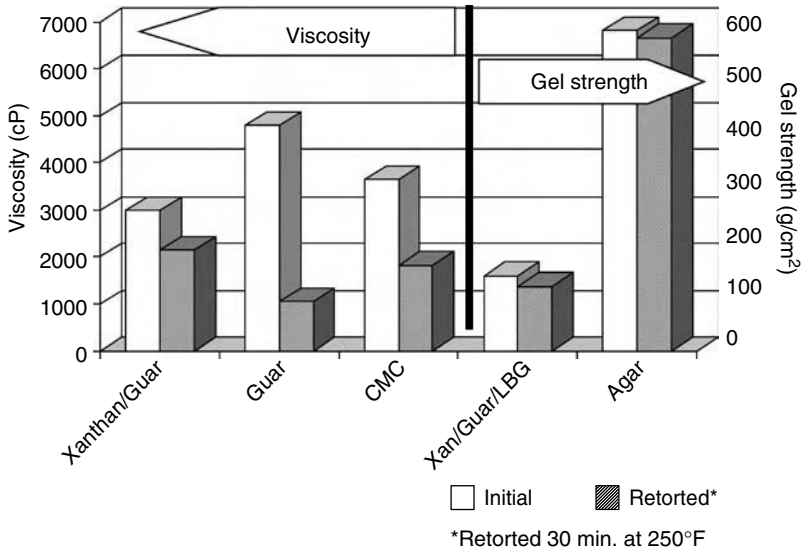

FIGURE 139.13 Effect of heat processing on various gums.

heat-reversible gels with lower degree of syneresis than gels made with kappa carrageenan alone, has also been used in baked goods. Synergy between alginate, gum acacia, and starches has been utilized to formulate fat-mimetic systems as discussed earlier. Guar/xanthan provide strong viscosity synergism when used in combination (1, 2).

A comparison of the effects of heat processing (retort temperature at 250°F for 30 minutes) on some gums and gum blends is shown in Figure 139.13. Some gums, due to their synergy, are more resistant to heat degradation when used in combination with each other.

V. MAXIMUM USAGE LEVELS AND QUALITY SPECIFICATIONS

The maximum permitted usage levels of gums in foods and beverages vary according to the Code of Federal Regulations.

The Food Chemicals Codex of the Food and Drug Administration also establishes the specifications for each gum, and a summary of the FCC standards for guar gum, as an example, is shown in Table 139.10. In addition, the food manufacturer should specify for each gum or gum system specific microbial limits, gel strength, viscosity, particle size distribution, and other relevant parameters, in order to avoid unwarranted variations in the quality of the finished formulation.

VI. PREHYDRATED OR AGGLOMERATED GUMS AND GUM SYSTEMS

Proprietary processes of agglomeration or "prehydration" of gums and gum systems have been developed by a number of ingredient manufacturers (11). The end products hydrate faster, have no lumping problems and are virtually dust-free, resulting in fewer incorporation problems, reduced dusting, mote efficient use of equipment, and production and labor costs. The agglomerated gums such as CMC and gum acacia have been shown to reduce motor load in a twin-screw extruder when incorporated at low levels with the initial dry mix (28). They also improve the mouthfeel and texture of corn cereal extrudates, based on sensory evaluation. These so-called prehydrated gum stabilizers are also preferred for use in low-oil salad dressings and in low-moisture systems.

VII. ANALYTICAL METHODS FOR EVALUATION OF GUMS

A laboratory designed to analyze and evaluate individual hydrocolloids and gum systems requires a number of essential instruments and equipment. For the study of viscosity and other rheological properties of gum solutions, a programmable rheometer (e.g., a Brookfield™ model DVIII)

is useful in characterizing the effect of shear rate, temperature, time, and stress. A Bostwick™ flow meter or consistency meter can be used to measure flow of a viscous fluid vs. time.

For the proximate analyses of gums and their basic composition, the laboratory should be equipped with instruments for measuring pH, ash, protein, fat, and moisture. HPLC (high pressure liquid chromatography) equipment with appropriate columns, refractive index measurement capabilities, and UV detectors may be used to analyze monosaccharide ratios of gums and help detect cross-contamination, adulteration, and the presence of bulking agents.

To analyze molecular weight changes and effects of various factors such as pH and temperature on the stability, hydrolysis, or degradation of gums, gel permeation chromatography using various known standards is useful. To save instrumentation costs, independent analytical laboratories may of course be utilized at any time whenever deemed necessary.

For gel strength measurements, programmable texture analyzers that can determine parameters such as hardness, cohesiveness, adhesiveness, and gumminess help evaluate the texture of the gel or the finished gelled product. This may help the sensory evaluation specialist by providing an objective comparison of the texture profiles of products prepared with gelatin with those containing polysaccharide gelling agents.

A useful instrument for evaluating emulsifying systems such as gums for beverage emulsions, is a particle size analyzer (e.g., a Coulter Counter). Preparation of stable emulsions requires a homogenizer that can operate at 2500 up to 6000 psi. A microscope equipped with a digital camera can be used to analyze the morphology of starches and the emulsion particle size of salad dressings, creams, and similar products.

A differential scanning calorimeter may be used to analyze melting point and gelling temperatures and other endothermic and exothermic properties such as glass transition temperatures of various hydrocolloid systems.

VIII. SUMMARY AND RECOMMENDATIONS

Hydrocolloids are highly functional ingredients in foods and beverages. Preferably, they should be incorporated with some of the dry ingredients such as flour or sugar to avoid lumping or incomplete hydration. The gum manufacturer should specify the various requirements for optimum functionality of the gum (pH, % solids, temperature of hydration, salts, co-factors, etc.). The impact of large-scale processing operations and the possible need for special equipment design should be jointly evaluated by the food technologist and the chemical engineer. This can reduce production problems during scale-up from the R & D or applications laboratory to the manufacturing plant.

In developing a fat mimetic system in food products, a systems approach should be used in which a variety of synergistic components, including gums, are used to duplicate the functional and sensory characteristics of the specific full-fat product. The development of a zero fat formulation is generally not recommended since significant changes in threshold value of flavor components in going from a high-oil to oil-free medium make it difficult to simulate the flavor of regular fat products. However, fat or oil reduction and increase in soluble fiber in the average American diet are essential, requiring the food manufacturer to make healthy alternative products and functional foods available to the consumer.

Using an individual gum for a certain application may not be adequate to achieve the desired quality attributes in the finished product. Instead, a combination of the optimum ratio of specific gums that exhibits synergistic properties may be required. The food technologist and the gum supplier should be familiar with the chemical and functional properties of each component in the food system and the resulting interactions between various ingredients and at varying processing conditions.

ACKNOWLEDGEMENTS

The authors would like to thank Steve Andon and Chris Andon, of TIC Gums, Inc., for administrative and financial support; and Ken Kuschwara & Jim Caulfield of the R & D Group of TIC Gums, Inc., for their technical assistance.

140 Pectins

Hans-Ulrich Endress, Frank Mattes, and Karl Norz
Herbstreith & Fox KG, Pektin-Fabrik Neuenbürg

CONTENTS

I. INTRODUCTION

Pectins belong to a group of closely related polysaccharides or pectic substances, located in the middle lamella and primary cell walls of higher plants (dicotyledons). The general term protopectin is often used to designate the native, insoluble pectins in the cell walls that cannot be extracted by methods that are non-destructive or non-degradative. The dominant feature of pectins is a linear chain of α-(1,4)-linked D-galacturonic acid units in which varying proportions of the carboxyl groups are esterified with methanol to methyl esters. This group of pectic substances covers the following:

- different methyl esters (pectins with different degree of esterification — DE), their salts (pectinates)
- unesterified pectic acid, its salts (pectates)
- different neutral polysaccharides linked to the polygalacturonan backbone such as arabinans, arabinogalactans, arabinoxylans, and galactans

Portions of these neutral polysaccharides are a part of the isolated, commercial pectins divided into HM pectins and LM pectins with correspondingly high and low methyl ester content. Amidated pectins are obtained by saponification of HM pectins with ammonia under alkaline conditions.

II. OCCURRENCE OF PECTINS

Beside cellulose, hemicelluloses, glycoproteins, and lignin pectins form a major part of the cell wall of all higher plants. The concentration of pectins is highest in the middle lamella, a tissue responsible for the adhesiveness of cells (1), and decreases from primary to secondary walls, where pectins are almost absent. Pectins participate in plant physiology: water retention, ion transport, porosity, growth, and the size and shape of cells. Pectins are involved in defense mechanisms against infections by plant pathogenic micro organisms, generating by their enzymatic attack (mainly using a polygalacturonase PG) oligogalacturonides with a degree of polymerisation between 10 and 15, which can be recognized by the plant (so called elicitors). This results in an activated metabolism (2). This reaction may be used to activate plant cell cultures for a higher productivity.

The specific functions of pectins in distinct parts of the cell walls or plant tissues are influenced by the amount and nature of specific molecules present (3).

III. CHEMICAL STRUCTURE OF PECTINS

Studies on pectins from many sources have illustrated that pectin is a heteropolysaccharide (see Table 140.1) (4). Pectins consist of a linear zigzag shaped structure of axial-axial linked α-(1,4)-D-galacturonic acid units, a result of the equatorial position of the carboxyl group. The poly-galacturonic acid chain is interrupted by "inserted" α-(1,2)-linked L-rhamnopyranosyl units resulting in a kink that determines the linear portion of the corresponding pectin segment (see Fig. 140.1) (5, 6).

Results from X-ray diffraction analyses fail to confirm:

- if the pectins are right- or left-handed double or single helix
- what the number of repeating units is

Pectin segments or fractions with low content of L-rhamnose are described as smooth regions of pectins or homogalacturonans. Those with high L-rhamnose content are known as hairy regions or rhamnogalacturonans.

The neutral sugar side chains consisting of mainly L-arabinose and D-galactose are bound by covalent linkages to the L-rhamnose units. L-fucose is found as the terminal end of these side chains. As minor sugars also D-xylose, D-glucose, D-mannose, and D-apiose are found next to further rare sugars. The minor sugars can occur as single unit side chain such as D-Xylose or as short side

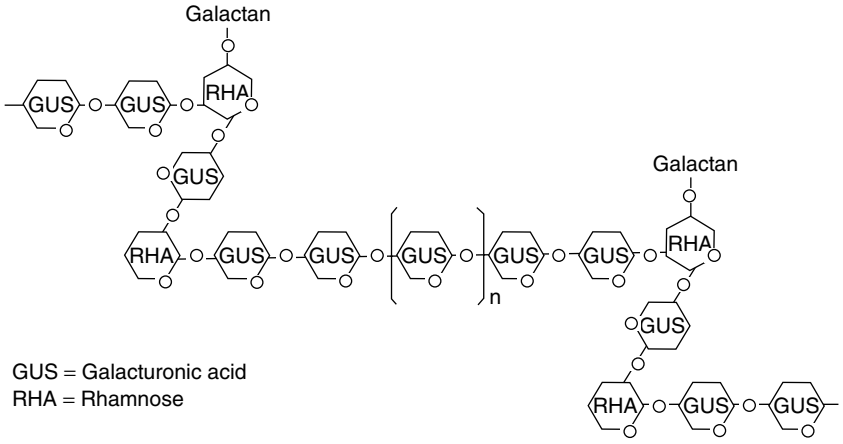

FIGURE 140.1 L-rhamnose in the galacturonan chain.

[g] Yield calculated from cell-wall material after SDS and DMSO treatments.

chains whereas L-arabinose and D-galactose form complex structures.

The arabinans are branched polysaccharides with a backbone of α-(1,5)-linked arabinofuranosyl residues with α-(1,2)- and α-(1,3)-linked arabinofuranosyl side chains. Pectins with attached arabinans can be isolated from many fruits and vegetables like apples, sugar beet, apricots, carrots, cabbage, onion, and pears.

Citrus fruits, potato, soy beans, grapes, apples, onions, tomatoes, and others contain arabinogalactans, described as two structurally different forms. Type I consists of a β-(1,4)-linked linear chain of D-galactopyranosyl residues with short chains of linear α-(1,5) arabinans connected to O-3. Type II is a highly branched polysaccharide with ramified chains of β-(1,3)- and β-(1,6)-linked D-galactopyranosyl residues terminated by L-arabinofuranosyl and to a smaller extent by L-arabinopyranosyl residues.

Albersheim and co-workers (12–14) studied the structure of suspension cultured sycomore cells and described rhamnogalacturonan I and II. Rhamnogalacturonan I was analyzed to have a linear structure of alternating α-(1,4)-linked D-galacturonosyl and α-(1,2)-linked L-rhamnosyl residues with a bunch of different neutral sugar side chains. Rhamnogalacturonan II is a very minor and complex heteropolysaccharide consisting of about 30 glycosyl residues.

Using chemical (β-elimination) or enzymatic (endo-PG or endo-PL) degradation techniques to split the polygalacturonan backbone, the following is observed. The L-rhamnosyl residues and the neutral sugar side chains are not homogeneously distributed over the pectin chain. Sequences rich in neutral sugars are interspersed with almost pure poly-D-galacturonosyl blocks. This finding distinguishes pectic polysaccharide as smooth or hairy regions (15–18) which are also homogalacturonans and rhamnogalacturonan I (13, 19, 20). The figures in literature on the length of homogalacturonan blocks vary from 25 (21) to 40–60 (22), and 72–100 galacturonic acid units (17).

But also non-sugar substituents (beside the methyl ester of the carboxyl groups or the amide groups at C-6) bound to C-2 or C-3 of the galacturonic acid like acetic acid and phenolic acids can be found with some pectic substances.

The degree of esterification (DE) or methylation (DM) is described as the percentage of esterified galacturonic acid units. If more than 50% of the carboxyl groups are esterified, the pectin is called high methyl ester (HM) pectin; if less than 50%, low methyl ester (LM) pectin. Pectic acid is defined to have a DE of $<10\%$.

The carboxyl groups (free and esterified) can be distributed statistically (random) or blockwise along the pectin molecules. The distribution pattern influences the reactivity of the pectins with bivalent cations and positively charged proteins. Acid treatment and most microbial pectin esterases (PE) deesterify HM pectins statistically. Plant pectin esterases work blockwise creating high reactive zones of negatively charged sequences. This property is ambiguous when used in commercial pectin applications. Also, this property distinguishes between intra- and intermolecular distribution of carboxyl groups. "Intermolecular" refers to an inhomogeneous pectin preparation.

The degree of acetylation (DAc) is defined as mol% of acetic acid calculated on the content of galacturonic acid. This may result in a DAc higher than 100% because C-2 and C-3 of the galacturonic acid and other sugars of the pectin can be acetylated. Apple and citrus pectins have a negligible DAc whereas beet pectin is highly acetylated. A DAc of about 25% can be found in some commercial beet pectins, e.g., those by Herbstreith & Fox.

Galacturonic acid content (GalA), degree of esterification (DE), and degree of acetylation (DAc; mol/mol) of some pectins extracted from different plants are summarized in Table 140.2 (4).

Fry (30), Rombouts and Thibault (8), and the research group of Ralet and Thibault (31, 32) described ester-linked ferulic acid units in beet and spinach pectin, linked to arabinosyl and galactosyl residues. Fry (33) was investigating the possible role of phenolic compounds of the primary cell wall in the hormonal regulation of growth. By these ferulic esters pectin chains can be cross-linked by phenolic coupling. In plant tissue these phenolic bonds are of big importance and can be used for firming fruits for food application. Also, gels from beet pectin can be formed by oxidative coupling, using phenoloxidase and peroxidase.

Isolated commercial pectins seem to belong to the group of homogalacturonans. However, they are obtained from apples, citrus fruits, sugar beet, or sunflower heads by extraction conditions cleaving covalent bonds to the hairy part of pectic substances firmer bound into plant tissue by neutral sugar side chains.

TABLE 140.2
Galacturonic Acid Content (GalA), Degree of Methylation (DM) and Degree of Acetylation (DAc; mol/mol)[a] of Some Pectins (4)

Origin	Extraction	GalA (%)	DM (%)	DAc (%)	Ref.
Mango	Acidic	54	68	4	(23)
Sunflower	Acidic	81	17	3	(23)
Sugar-beet	0.05 M HCl; 85°C	65	62	35	(8)
Carrot	0.05 M HCl; 85°C	61	63	13	(24)
Grape	Oxalate pH 4.5; 20°C	63	69	2	(25)
Sunflower	Oxalate	83	27	10	(26)
Peach	HCl to pH 2; 80°C	90	79	4	(27)
Siberian apricot	EDTA	64	57	8	(28)

Potato	HCl, pH 2; 80°C	40	53	15	(4)

[a] Calculated on the assumption that all acetyl groups are bound to galacturonic acid.

IV. BIOCHEMISTRY OF PECTINS

A most recent and excellent description of the biosynthesis of pectins is by Mohnen (34). Pectin is said to be the most complicated polysaccharide in plant cell wall. Since we do not know its exact composition and the synthetic process of various fractions of pectic polysaccharides, we may benefit from a summary of what information is available:

At least 12 activated sugar substrates (nucleotide-sugars), 14 distinct enzyme activities (for their production), and 58 glycosyl-, methyl-, and acetyltransferases are required for pectin synthesis. Mohnen (34) cites comprehensive reviews on:

- pectin structure, pectin and cell wall synthesis (35–40)
- nucleotide-sugar interconversion pathways (41)
- wall biosynthetic genes (38, 42)
- glycosyltransferases (43)

The synthetic process of pectin is often described as follows:

- synthesized as homogalacturonans in the cis-Golgi
- branched in the trans-Golgi cisternae
- highly esterified in the medial and trans-Golgi
- transported as high esterified, branched pectin to the plasma membrane in vesicles, which move along actin filaments via myosin motors, and subsequently inserted into the wall or the cell plate
- followed by deesterification to create calcium-reactive sequences

Other observations confirm that pectin synthesis may differ:

- in different cell types
- in different species
- at different points during development, or
- even at different locations in the same wall (cited in 34)

The precursors of the nucleotide-sugars for pectin synthesis are hexose-phosphates from photosynthesis and stored starch or sucrose. The main sugars of pectic substances are D-GalA, L-Ara, D-Gal, D-Man, L-Rha, D-Xyl, L-Fuc. They are synthesized accordingly:

1. All can be synthesized enzymatically via D-Glc-1-phosphate, uridine-diphosphate-D-glucose (UDP-D-Glc), and their corresponding uridine-diphosphates by different nucleotide-sugar transformation pathways.
2. All can be recycled from walls by the salvage pathway.
3. D-GalA, D-Xyl, and L-Ara can also be synthesised enzymatically by the myoinositol pathway from UDP-D-GlcA and the subsequent and corresponding UDP-sugars/UDP-sugar acids.

Examples of well investigated enzymes in these pathways are:

- UDP-glucose-6-dehydrogenase (EC 1.1.1.22), oxidating UDP-D-glucose to UDP-D-glucuronic acid
- UDP-glucuronate-4-epimerase (EC 5.1.3.6), transforming UDP-D-glucuronic acid into UDP-D-Galacturonic acid
- UDP-xylose-4-epimerase, transforming UDP-D-xylose into UDP-L-arabinose.

UDP-xylose is synthesized from UDP-D-glucuronic acid by UDP-GlcA-decarboxylase (EC 4.1.1.35). L-rhamnose is proposed to be produced from UDP-D-glucose via UDP-4-keto-6-deoxy-glucose (by UDP-Glc-4,6-dehydrogenase) and UDP-4-keto-6-deoxy-L-mannose (by UDP-4-keto-L-rhamnose-3,5-epimerase), with a final conversion via UDP-4-ketorhamnose-reductase.

The nucleotide sugars are transported into the Golgi and used as substrate by a pectin biosynthetic glycosyltransferase that transfers the glycosyl residue onto a growing polymer (34).

V. PECTINS IN CELL WALL ARCHITECTURE

Are pectins and their fractions including neutral sugar side chains covalently linked to other polysaccharides or

glycoproteins in cell walls? Some observations from complex early models suggest such linkages, the existence of which has never been proven (44, 45). Current accumulated reports suggest the following:

1. The existence of several woven but independent networks in the cell walls and pectin network is one of them, situated next to cellulose-xyloglucan-cellulose bridges (46, 47)
2. The existence of independent protein-protein structures (48) instead of the hydroxyprolin-rich protein extension structure crosslinked to pectin

Pectins are linked with each other through Ca^{2+}-bridges (21), via borate esters between apiose residues (40), diferulic acid bridges between arabinoxylans side chains (16), and finally esters between the carboxyl groups of the galacturonic acids (49). In growing plants, cell wall structures undergo a continuous change. Crosslinkages are made and broken, especially when a cell divides, expands, or matures. An in-depth discussion on interactions between pectins and other polymers is reported by Mort (50).

VI. DETERMINATION OF THE PECTIN CONTENT AND KIND OF PECTIC SUBSTANCES

To characterize pectic substances and their change during growth, ripening, storage, and processing in plant tissue a sequence of events is noted.

Pectins are enriched and purified from interfering plant components by washing with hot alcohol to remove alcohol soluble components from the tissue or by fractional extraction techniques. Native enzymatic activities in the plant material are inactivated instantaneously. The repeated washing with hot alcohol results in an AiR (alcohol insoluble residue) composed mainly of cell wall materials, protein, and starch (51). The latter have to be removed by degradation with pure enzymes under conditions not affecting the pectic substances. Starch can also be removed with 90% dimethyl sulfoxide. The cell wall material undergoes further characterization and fractional extraction techniques (chemically and/or enzymatically). Substances, soluble or solubilized under the respective extraction conditions, are yielded as watery extract to be precipitated in alcohol. The alcohol insoluble substance (AiS) is dried, grinded, and analyzed. Note that all extraction and fractionation conditions modify the pectic substances to a certain extent. The evaluation of the different fractions and the knowledge of the enzymatic activity provide us with the ambiguous image of the native pectic substances which we have today.

The chemical fractionation techniques exploit the different properties of pectic substances. A common procedure is the subsequent use of:

1. cold and/or hot water or buffer solutions for already soluble pectins, mainly HM
2. monovalent buffer solutions to solubilize pectins fixed by bivalent cations
3. chelating agents like EDTA, CDTA, oxalate, or hexametaphosphate for HM and LM pectins crosslinked and bound in cell wall by bivalent cations
4. cold and/or hot acid with different pH, temperature, and time regimes for HM pectins crosslinked with cellulose by neutral sugar side chains
5. cold alkali to prevent β-elimination such as sodium carbonate or sodium hydroxide, often in combination with sodium borohydride to protect the reducing end of polysaccharides, suitable for hemicellulose extraction crosslinked with pectins

Other chemicals for extraction are also used (4, 52).

Voragen et al. (4) give an overview on enzymatic extraction and fractionating procedures. One approach is based on the degradation of the rhamnogalacturonan backbone, using endo-polygalacturonase, pectin esterase/endo-polygalacturonase, endo-pectinlyase, or endo-pectatelyase, and recently rhamnogalacturonases. In general two fractions of degradation products are obtained, oligogalacturonides and rhamnogalacturonides, that are rich in neutral sugars. These fragments can be further characterized. Degree of polymerization depends on enzyme combination, sugars, and glycosidic linkages which clarify the structure of the heteropolysaccharides present.

The second approach is to use non-pectolytic enzymes for the extraction of unaltered pectins. This approach is often discussed as an alternative to industrial acidic pectin extraction. According to available data, it is not possible to yield comparable pectin quantities using combinations of cellulases and hemicellulases (53, 54). However, the use of an endo-glucanase in combination with an endo-pectinlyase can result in a significant pectin yield in the laboratory. But the gel strength of this pectin is poor.

VII. CHEMICAL, ENZYMATIC, AND MECHANICAL MODIFICATIONS OF PECTINS

Pectic substances can be attacked at the polygalacturonic main chain, the neutral sugar side chains, or at the methyl, acetyl, and phenolic ester groups. Glycosidic bonds between uronic acids are relatively stable against hydrolysis; arabinofuranosyl bondings are weak in acidic conditions. This difference is used for pectin extraction by

acidic hydrolysis to split the neutral sugar side chains, which connect the pectins with the cellulosic fibrils fixing pectin in the cell walls. This way the insoluble protopectin is converted to soluble pectin. The methyl and acetyl ester groups are partially hydrolyzed by the extraction procedure, which is sometimes used to extract pectins with a smaller degree of esterification.

Pectin solutions are stable at pH 2.5–4.5. At a lower pH the a.m. hydrolysis occurs. This is used to produce pectins with a lower degree of esterification, changing, within the region of HM pectins, their setting behavior from rapid set (DE $>$ 70%) to slow set (DE ca. 60%). Further deesterification results in low ester pectins. At low pH values also acetyl groups from sugar beet pectin are removed and jellifying beet pectins with poor gelling strength are formed.

At low pH, e.g., boiling in 12 M HCl, the galacturonic acid releases CO_2. This reaction quantitates the pectin content (55).

At pH $\geqslant$ 5 and elevated temperature, the glycosidic bonds of esterified polygalacturonic acid main chains are split at the non-reducing side next to a methyl esterified galacturonic acid unit. This is done by β-elimination, resulting in an unsaturated galacturonic acid molecule with double bonding between C-4 and C-5 (56). Because this reaction can occur wherever there is an esterified acid group in the molecular chain, a small amount of degradation can cause a large loss in viscosity, gelling power, and other functional properties. This reaction is slow at low temperatures. Increasing the pH accelerates saponification of ester groups, which competes with β-elimination. Pectic acid is stable in alkaline conditions. We can take advantage of β-elimination to decrease water binding capacity of pectins by soaking legumes in neutral mono-valent buffer solutions and by liming of fruit press cakes after juice production. Such treated residues can be further pressed to increase solids before drying. Pectins can also be degraded by oxidants.

The most common chemical modification is the alkaline amidation of pectins in alcoholic suspension, using ammonia. By this reaction methyl ester groups are converted to acid amid groups ($-CONH_2$). Free carboxyl groups cannot be amidated.

Pectins can also be esterified with methanol at a low pH in methanolic suspension, using sulphuric acid. As a by-product, sodium methyl sulphate can be produced with a limit of 0.1% in commercial pectins per FDA and FCC.

Crosslinking of pectins by epichlorhydrin is successfully used to prepare affinity chromatography columns to separate pectinases. Crosslinking by phenolic coupling was mentioned earlier.

There are several enzymes involved in pectin degradation.

1. glycosidases catalyzing the degradation of neutral sugar side chains (group of arabinanases, galactanases, xylanases, etc.)
2. esterases, pectin esterase (PE) (EC 3.1.1.11), and pectin acetyl esterase
3. enzymes splitting linkages between the galacturonosyl residues of the pectin main chain like endo- and exo-polygalacturonase (PG) (EC 3.2.1.15), endo- and exo-pectate-lyases (PAL) (EC4.2.2.2 and 4.2.2.9), and pectin-lyase (PL) (EC 4.2.2.10)

The reaction products of the hydrolases are identical with those from chemical hydrolysis. The lyases work by a trans-elimination mechanism. PG and PAL split low methyl ester pectins and pectates at an unesterified galacturonic acid unit. PL splits a site next to an esterified group, catalyzing the β-elimination reaction.

More recently a group of rhamnogalacturonases (hydrolases and lyases from *Asp. aculeatus*) were described, acting on highly branched regions of pectins, liberating oligosaccharides consisting of rhamnose linked to galacturonic acid and to galactose (optional) (18, 57).

Commercial pectinases are often mixtures of enzymes mentioned above and several hemi-cellulases, cellulases, and proteases. Producers may use one or both enzymatic systems:

1. a system based on pectin lyase, degrading pectin alone with the disadvantage of creating unsaturated oligogalacturonides that are sensitive to browning
2. a system based on polygalacturonase in combination with pectin esterase, converting HM pectins to LM pectins, the substrate for the polygalacturonase

Bock et al. (58) characterized pectins ground by a vibration mill as follows:

- The molecular weight was decreased by "mechanolysis."
- The degree of esterification, the neutral sugar content, and the reactivity against calcium ions, assuming the pectins could form a gel, was almost unchanged.

Ralet et al. (59, 60) and Ralet and Thibault (61) suggested extrusion cooking as a method for pectin production. The extrusion process converted the pectic substances of the cell walls of apple, citrus, and sugar beet into soluble pectins. The softening of plant tissue after extrusion cooking is also associated with this degradation. Bondar und Golubev (62) announced a new desintegration and extraction technique for pectins, using cavitation.

VIII. PECTINS AS POLYELECTROLYTES

Pectic substances are negatively charged polyelectrolytes. Their charge density and their apparent dissociation

constant pK_a calculated from pH measurement depend on the degree of dissociation. The pK_0 determined for pectins is independent of pectin concentration and of their degrees of polymerization, esterification, amidation, and acetylation. The values obtained are in the range of 3.0 to 3.3, close to that (3.5) of monomeric galacturonic acid (cited in (4)).

At pH $\leqslant$ 3.0, the dissociation of pectins is almost repelled; they are almost undissociated and uncharged. This is an important premise for pectin chain association in the case of jellification of HM pectins.

Monovalent cations (Na^+, K^+, etc. and NH_4^+) are bound to pectins electrostatically only. These ions can weaken pectin association in tissues as in thickened and jelled products. Magnesium ions do not support pectin jellification and follow also only electrostatical theories. The other alkaline earth cations cause pectin chain associations resulting in:

- tissue hardening
- increased viscosity
- gel formation of LM pectins
- precipitation of their pectinates

Such observations or effects are dependent on:

- cation concentration, ionic strength, and pH
- degree of esterification
- distribution of free carboxyl groups (random or blockwise) [for HM pectins]

When HM citrus pectins or HM pectins are slightly deesterified, using a plant, blockwise acting pectin esterase (creating blocks of free carboxyl groups), there is a significant increase in affinity and viscosity with calcium ions. This effect improves protein stabilization and increases the tendency towards syneresis which impairs jellification.

Ca^{2+}, Sr^{2+}, Ba^{2+}, Cd^{2+}, Ni^{2+}, and Pb^{2+} ions influence the circular dichroism behavior of pectins in the same way. That is, associate two pectin chains if blocks of free carboxyl groups with adequate length are present, i.e., 7, 10, and 20 units (21, 63). Practically LM pectins with a degree of esterification of about 40% and less show gelling properties by this mechanism. This chain association is described as "egg-box" gelling mechanism. Two pectin chains arrange parallel and symmetrically and form together (due to the axial-axial glycosidic linkages of the galacturonic acid polymer) negatively charged cavities in which the cations fit as eggs in a box. Thom et al. (64) and Debongnie et al. (65) describe Cu^{2+} ions to behave different, and circular dichroism spectra are also different.

In food processing usually calcium salts of different solubility (like calcium chloride, calcium lactate, calcium citrate, and calcium mono- and di-phosphates together with monovalent buffer salts to influence velocity of chain association) are used together with LM pectins (DE $<$ about 44%) to form gels at reduced soluble solids (sugar content). LM pectins are also described to bind heavy metals as an antidote for heavy metal poisoning and as an ion exchanger to remove heavy metals from effluents.

Calcium pectinate is used as fat replacer forming soft, creamy insoluble particles. Pectins can be precipitated as their aluminium salts (ancient pectin production method) or copper salts (ancient quantitative pectin determination method — Cuprizon method).

IX. RHEOLOGY OF PECTINS

Using pectins for technological reasons means that in general the producer has some means of influencing flow behavior and texture. The ability to form gels under acidic conditions is one such method under the disposal of the producer.

The rheological properties of native pectins are used in food industry. If these properties are negative pectins have to be degraded in the manufacturing process. Pectin degrading enzymes are used to extract and concentrate juices. To achieve a high yield or capacity for the pressing systems, pectinases with other cell wall degrading enzyme activities are used in mash treatment (liquifaction). Stored apples will respond best to treatment with these enzymes for their content of soft tissue and high soluble pectin facilitates the binding of juice in the mash. Berries like black and red currant, grapes, etc. are also treated with pectinases for juice production to increase yield and color intensity. Some of the anthocyanes are bound to pectic substances and will be released into the juice if the pectin is degraded. Tomato is handled in two stages in the cold break process: degrading the pectin and subsequent concentration to tomato concentrate. In the case of manufacturing tomato ketchup, the hot break process is used to maintain pectin quality and flow behavior by inactivating native pectinases immediately after squeezing the tomato juice.

Axelos et al. (66) reported the dividing line between:

- dilute and semi dilute pectin solution in 1 M NaCl: a concentration C* between 0.7% and 1.0%
- semi dilute and concentrated regime: a concentration C** between 8% and 10%

Up to C* the specific viscosity corresponds to $C[\eta]^{1.2}$ and beyond C** to $C[\eta]^{3.3}$. Values of the Huggins coefficient k_h, which characterizes the effect of molecular interaction on the viscosity, vary with the degree of esterification, ranging between 0.37 and 0.6.

Pectins are insoluble in organic solvents and soluble in water to give a viscous solution. Like other viscous gums, it needs care in dispersing the powder rapidly into the water. Lumps of powder easily become coated with a gel layer

which makes further solubility slow and difficult. Appropriate techniques to prepare pectin solutions:

- a high-shear mixer
- separating pectin particles by dilution with soluble powders like sugar (10 fold quantity of pectin)
- dispersing the pectin in high concentrated sugar syrups (at least 50% soluble solids to prevent significant swelling of the pectin) with subsequent dilution to less than 30% soluble solids. Under heating and moderate agitation the pectin will dissolve rapidly.

Pectin will not dissolve completely at high sugar concentrations. Thoroughly dissolved pectin will have no "fish-eyes" on a glass plate and will not feel gritty when rubbed between the fingers. Solutions with 3 to 4% pure pectin can be prepared easily. Industrial processing with more than 10% pectin in hot water will exceed the limit of complete pectin dissolution.

Pectins with a low degree of esterification dissolve better in the form of monovalent metal salts. Bi- and trivalent cations decrease the solubility of all pectins. Pectic acid is only soluble in water as ammonium, sodium, or potassium pectates at $pH > 6$. Pectins are also soluble in DMSO, formamide, dimethylformamide, and warm glycerol (67).

Industrial pectin solutions with unchanged molecular weight exhibit a pseudoplastic flow behavior. Depending on raw material and extraction conditions, the viscosity of pectin solutions varies. Often the viscosity of pectins is standardized with neutral sugars like dextrose and sucrose to achieve constant quality for every batch. Solutions of high esterified pectins show little elastic shares. The viscosity of a pectin solution decreases with increasing pH and ionic strength. In combination with calcium salts and some sugar, a solution of low esterified pectins will form a soft network with measurable elastic properties.

The viscous properties of pectin solutions are used in fruit juices, fruit based products, and soft drinks to increase viscosity, resulting in a better mouth feel and a higher impression of fruitiness and sweetness. The increased viscosity also improves cloud stability and reduces coalescence of oil droplets in emulsions (68). Cloud is also stabilized by bigger hydration if the cloud is positively charged and enveloped by a negatively charged pectin layer with high hydration (69).

Fruit preparations produced with low methyl ester pectins also shows pseudoplastic flow with shear thinning during mechanical stress like pumping and dosing. This lowers the forces acting on the fruits during these processing steps and reduces their destruction. To prevent fruit floating these fruit preparations are produced with pectins giving a significant yield point. In contrast a formulation using only viscosity for thickening will only delay floating. To prevent floating the yield point has to be higher than the lifting force of the fruit pieces. The yield point can be adjusted by the calcium reactivity of the pectin in combination with calcium concentration, soluble solids, and ionic strength. Fruit preparations produced with pectins show also little thixotropy and a high ability to regenerate after removal of the stress.

These factors are very important for fruit preparations for yogurt where fruit preparations are produced and filled aseptically in big containers which are shipped to the dairy plant. There the fruit preparation is pumped out of the container and an even distribution of fruit pieces is a quality criterion. After pumping the fruit preparation has to be mixed with the white mass of the yogurt or metered into the yogurt beaker with subsequent over-layering with yogurt without the reaction between low methyl ester pectin and free calcium ions of the yogurt.

Jams, jellies, and marmalades produced with pectins are visco-elastic solids. The ratio of viscous to elastic shares varies, depending on:

- degree of esterification of the pectins
- pH conditions
- kind of pectin used

Viscous shares increase with increasing pH and decreasing DE of high methyl ester pectins. Apple pectin gels show higher viscous shares with good spreadability whereas citrus pectins have less viscous and more elastic shares. The elastic shares make the products more brittle and less spreadable, with a higher tendency to syneresis. This also can be shown by the smaller linear viscoelastic range of citrus pectin gels compared to apple pectin gels. These figures can be obtained using rheometers with oscillating techniques. The phase displacement angle δ between stress and strain indicates the proportion of elastic (G') to viscous shares (G'') whereas

- pure viscous liquid, $\delta = 90°$
- pure elastic solid, $\delta = 0°$
- viscoelastic solid, $0° < \delta < 90°$.

X. THE MOLECULAR WEIGHT OF ISOLATED PECTINS

The figures on molecular weight of pectin published in the literature vary significantly from about 40.000 to more than 4 million Daltons. This variation is not only influenced by source of raw material, kind of plant tissue, and extraction conditions of the analyzed pectins but also by the analytical method itself. Owens et al. (70) first established that values, determined by viscosity measurements of pectin solutions with different concentrations and extrapolation to zero concentration, depend on the

constants (K) and (a) used in the Mark-Houwink-Sakurada equation $[\eta] = K \cdot M\eta^a$. Values for different pectins can be found in Voragen et al. (4) and literature cited. For the exponent (a) values between 0.8 and 0.9 seem to be confirmed, representing a slightly stiff conformation of pectins.

Polydispersity and aggregation phenomena are reasons for big discrepancies between weight-average (determined by laser light scattering) and number-average (determined by membrane osmometry or end group analysis) molecular weight values. Fishman et al. (71) published a critical re-examination of molecular weight and dimensions for citrus pectin. More detailed information on molecular weight distribution of pectins can be obtained by combinations of size exclusion chromatography (HPSEC) with multi-angle laser light scattering (MALLS) (72). The molecular weight for isolated pectins for food application as thickener or gelling agent is estimated to be 60.000 to 120.000 Dalton.

XI. PECTIN MANUFACTURING

In 1825 Braconnot was the first who isolated a substance from plants, which showed gelling properties. The term pectin has been derived by him from the Greek "πηχτος," meaning to congeal or solidify. It took up to 1917 until Ehrlich described pectic substances being composed of galacturonic acid. The high water binding and the ability to form gels of pectin quickly attracted the interest of the food industry. Before a defined pectin became available, the liquid pectin obtained from concentrated apple juice was used to decrease the influence of the natural content of fruit pectin in the raw material of the fruit processor. The first commercial application of pectin was as a gelling agent for jams, jellies, and marmalades, to balance the different pectin contents of the processed fruit. Kertesz (73) is giving the most comprehensive review of the early work on isolated pectins.

Despite the wide occurrence of pectins in nature only a few raw materials were established as sources for commercial pectins. Reasons for this are the facts that only a few plants contain pectins with suitable properties for food applications, still the main use for pectins, and that the raw material has to be available in a sufficient quantity and constant and storage stable quality. Still pectins are produced mainly from by-products of fruit juice industry, namely apples and citrus fruits whose fresh or carefully dried pomace or peels after washing to remove citric acid and sugars are used. In Central Europe, pectin is produced from dried apple pomace and dried lemon and lime peels, whereas in Central and South America, pectin used to be obtained also from fresh orange, lemon, and lime peels. At present, North America is no longer a supplier of pectin. Instead, it is a major consumer.

Sugar beet chips are of minor importance due to their lower pectin quality. Sunflower heads fail as a pectin source because pectin quality declines rapidly before harvest time.

The careful handling of raw material is essential in the manufacturing process of pectin. For example, in the production of apple pectin, the dried apple pomace from the manufacture of apple juice is the raw material. After the apple mash has been de-juiced, the pomace is dried immediately to prevent the degrading enzymes in the plant tissues from reducing the quality of the pectin. Drying also stabilizes the pomace by reducing micro-organisms to a minimum, permitting the product to be used to produce pectin year-round. Some producers use pectin degrading enzymes to increase fruit juice output and facilitate the de-juicing. The pomace from this operation cannot be used to produce pectin.

Apple pectins, especially from unripe apples are often associated with native starch, which can be removed by enzymatic treatment. The degree of esterification in unripe apples is nearly 100%. Industrial extraction yields 10 to 15% of pectin out of dried apple pomace (or about 0.5% calculated on fresh apples) with a degree of esterification of up to 80%. The distribution of free carboxyl groups is very even. Apple pectins show a higher proportion of neutral sugars than citrus pectins resulting in summary in gels with high viscous shares, low tendency to syneresis, and high internal gel strength.

Citrus pectin production uses the peels of de-juiced and de-oiled fruit. Washing the peels prior to processing is essential in the removal of remnants such as aromatic oils and bitter components. If such remnants cling to the peels and if these peels are used to produce pectin, they may cause an off-flavor, resembling a bitter, rancid taste in the end product. Thus for the production of a product that is stable when shipped and stored, the peels must be dried. If a producer wants to extract pectin from wet peels, he should do it in the vicinity of a citrus processing plant. Also, enzymes in the plant tissues will start to degrade the available pectin if bottlenecks develop in the extraction process or an excess of raw material prevails.

The yield of citrus pectins from dried lemon or lime peels is about 30 to 35%. Orange and mandarin peels are seldom used due to their lower pectin content and pectin quality. Grapefruit pectin is produced mainly for nutritional applications to lower cholesterol (74).

Citrus pectins usually have a lower content of neutral sugars and a higher concentration of D-galacturonic acid as apple pectins. Due to a higher pectin esterase activity in citrus fruits, acting block wise as all plant pectin esterases do, citrus pectins often show blocks of free carboxyl groups which are high calcium reactive. The citrus pectin gels are more elastic and brittle, and have a higher tendency to syneresis and pregelification with calcium ions present in the cooking. The advantage of the higher reactivity with calcium ions is the better protein stabilizing

property especially of heat sensitive casein in acidified milk drinks.

Sugar beet chips are of minor importance. Compared to apple or citrus pectin, pectins from sugar beet have higher neutral sugar content and are partially esterified with acetic acid and ferulic acid. The acetylation is preventing gelation, but even acidic or enzymatic deacetylation does not create proper gelling pectins due to the low molecular weight of beet pectin. However studies have been carried out that show improved gelation of sugar beet pectin through oxidative coupling (75). It could be shown that beet pectins have emulsifying properties due to their hydrophobic (acetyl and methyl groups) and as well hydrophilic (hydroxyl and carboxyl groups) nature (68).

Sunflower heads contain low ester pectins which are also acetylated. Interesting properties can be found in sunflower pectin as long as the sunflower is blossoming until an early mature state of the kernels showing a white and fluffy inflorescence. But when harvesting sun flowers for oil production the heads are dried out, sometimes after a killing frost, turning sunflower pectin almost to pectic acid with a very low solubility.

Several other plant raw material like cabbage, onion peels, mango, cotton, etc. have been investigated as sources for commercial pectins. Up to now all efforts failed to introduce a new source of pectin. Additionally several international pectin specifications limit the sources of pectins to apple, citrus, and beet.

Citrus fruits and apples are not processed with the main purpose of pectin production in mind. One of the main tasks of pectin producers is to secure the supply of high quality raw material by keeping in constant contact with fruit juice producers. The essential know-how of pectin producers is the manufacture and maintenance of pectins with a constant/consistent good quality despite adverse factors, which include variable contents and molecular weights. Such factors, as indicated above, result from differences within the raw materials and production parameters in the fruit juice processing plant.

At first the pectin containing extract is produced in an acidic medium. Here, the insoluble protopectin is converted into its soluble form. Additionally water-soluble ingredients like sugars and phenolic compounds will also be dissolved. The insoluble residue, which mainly contains cellulose and other water-insoluble matter, will be separated and dried and may be used as animal feed. The extract containing pectin is further purified to remove suspended particles. It is then added to an alcohol solution in which the insoluble pectin will precipitate. After the alcohol is removed using standard procedures, the pectin is dried prior to grinding and sieved. The ground and sieved pectin represents the base material for "standardization," i.e., the adjustment of pectin with sugar to ensure constant/consistent functional properties.

Citrus pectin is produced in much the same way as that for apple pectin. In contrast, the use of wet peels is possible for the production of citrus pectin. This reduces one energy intensive working cycle, i.e., drying of the citrus peels. However, this procedure depends on a close proximity between a pectin producer and a fruit juice producer for countries in Central or South America. Differences in the pectin quality within the raw material depend on fruit maturity and enzymatic activity and must be normalized or accounted for in pectin production. In contrast, dried citrus peels are available year round. Important suppliers are countries in Central and South America, Spain, and Italy.

Depending on the extraction conditions and quality of the raw material, large differences in the molecular weights of pectin exist. Nonetheless, the molecular weight of the manufactured pectin is an essential factor for its gelling properties and determines its commercial quality.

The degree of esterification has decisive influence on the gelling behavior and the application of the pectin. Pectin directly precipitated after extraction has, due to its natural properties, a very high degree of esterification. It is also known as rapid set pectin. Other types of pectin, like slow set pectins or low methylester pectins, which have a low degree of esterification, can be produced by adjusting some parameters of the extraction process, e.g., pH and temperature. It is possible to carry out de-esterification during or after the extraction. Pectins are amidated under alkaline conditions, in the presence of ammonia. In this process methylester groups will be transferred to amid groups. These pectins contain three functional groups: methylester, carboxyl, and amid groups.

The term pectin is generally used for a poly-galacturonan, which has been extracted from cell walls. Pectins with a defined structure can be produced via additional processing steps. In order to differentiate the large number of pectins, they can be classified according to their chemical nature (Table 140.3).

Because of the presence of free carboxylic acid groups, pectins have weak acid properties, which can affect and change the pH-value of a food system. Added pectins may

TABLE 140.3
Classification and Definition of Pectins

Description	Chemical Characterization
Protopectin	Water-insoluble native pectin network
Pectic acid	Polygalacturonic acid (degree of esterification <10%)
Pectate	Salts of the pectinic acid
Pectin	Partly or completely methylesterated polygalacturonic acid
Pectinate	Salts of not completely methylesterated polygalacturonic acid
Pectic substances	Collective term of above mentioned susbstances

initiate undesirable reactions during subsequent processing. Pectins can also act as buffer systems in combination with other organic acids to influence the overall buffering capability of the system. This effect will increase considerably with increasing free carboxylic acid groups, i.e., decreasing degree of esterification. Simultaneously, the affinity of pectin against di- or trivalent cations increases with increasing free carboxylic acid groups. In the production of pectins for individual food product applications, the degree of esterification should be adjusted accordingly. Because of the higher affinity towards divalent ions, the low methylester pectins always display additional properties in any application, when compared to high methylester pectins. This difference is one of the major criteria used to select one particular pectin for a specific application.

Low methylester pectins can form a network in the presence of divalent ions to produce gel structures, a fact used in the manufacture of low-calorie fruit preparations. A low methylester pectin with a high affinity towards divalent ions may result in strong cross-linking to form a water insoluble salt, "calcium pectate." Calcium pectate no longer displays any useful functional properties. Another possibility is the use of low methylester pectin as an ion exchanger. For example, pectinic acid loaded with sodium ions may be used as an ion exchanger for divalent cations. This reaffirms the fact that buffer systems and ion strength influence the properties of pectin including gelling.

The affinity of divalent ions is not only influenced by the degree of esterification (DE) but also by the distribution of the free carboxylic acid groups within the pectin molecule. A weak de-esterification of the native pectin can occur in the presence of native pectin esterase in citrus fruit. This behavior is very pronounced in oranges but slight in apples or apple pomace. Since plant pectin sterase acts blockwise, citrus pectin has a more block-by-block structure of free carboxyl groups and thus regions of higher affinity for divalent ions.

Besides traditional pectin types, low methylester amidated pectins offer new possibilities in the application of pectin. The presence of amidated groups plays an important role for the technological properties and will be characterized by the degree of amidation. The degree of amidation is defined as the ratio of amidated carboxylic acid groups to total galacturonic acid content.

One of the most important factors that determine the suitability of pectin as a gelling and thickening agent is its molecular weight. Its viscosity and rheological properties, similar to its gelling strength, depend on the molecular weight. Natural pectin exists in a wide range of molecular weights, which is determined by the different molecular weights of the protopectins prior to extraction. If the raw material is not carefully handled, a loss of pectin quality may occur quickly, due to the enzymatic degradation. Also, the extraction and production process of pectin has a decisive influence on the molecular weight of the final product.

Traditionally, pectins are blended with sugar to standardize their constant gelling, thickening, or stabilizing properties. This step is necessary to adjust the natural deviations of basic pectins and to guarantee consistent properties. To achieve this, a careful quality assurance of the chemical parameters (degree of esterification, degree of amidation, etc.) and the physical properties (gelling strength, viscosity, etc.) is implemented.

XII. PROPERTIES OF ISOLATED PECTINS

Pectins, because of their high molecular weight and molecule structure, are capable of binding water to form viscous solutions. Water binding is only one factor, the second being the formation of convolutions due to linear characteristic of the pectin molecule and the interactions between them. This increases the resistance of pectin to shear and results in shear thinning characteristics.

The most important property of pectin is its capability to form gels. Here a three-dimensional network is formed that is held together by the stable interaction between pectin molecules.

According to Jarvis (76) an aqueous gel consists of three elements:

- junction zones between the polymer molecules
- polymer chain links between the junction zones, which are relatively mobile
- water which is locked and entrapped in the polymer network

According to Figure 140.2, through the interactions between the molecules, junction zones develop and stabilize the network. Links of the molecules nearby not integrated in junction zones are able to bind water.

Important factors which influence the gel formation are (77, 78):

- molecular structure of pectin (pectin type)
- concentration and type of soluble solids (e.g., sugar)
- pH
- ionic strength
- valency and kind of ions
- temperature

Condition for initiating the gelation process at a given pH and a given concentration of soluble solids is a minimum concentration of the pectin. Pectin gels form when the expanded parts of the polymer chains associate to form orderly junction zones, which are stabilized by noncovalent interactions. The length of junction zones is influenced by steric factors. Limiting factors are deviations of

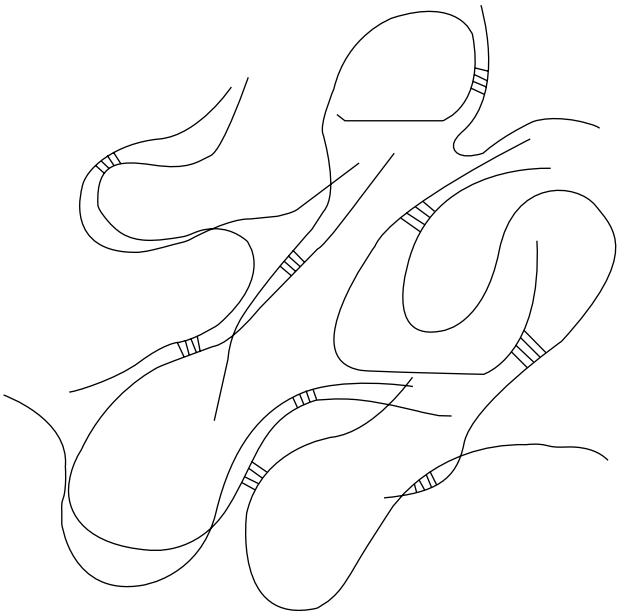

FIGURE 140.2 Schematic model of molecular network of a pectin gel.

the regularly distributed esterified and non-esterified areas as well as bends in the galacturonan chain, caused by L-rhamnose and neutral sugar side chains (79).

The gelling properties of pectin can be characterized in different ways (80–82). Traditionally they are evaluated by the "ridgelimeter" method. A sugar-water-gel is produced and placed in a defined "ridgelimeter glass." After 24 hours, it is removed to determine the sagging or shape change of this gel due to gravity (80, 81). In these experiments, the necessary pectin concentration is the variable and settlement, which will occur, will be evaluated as a function of pectin concentration. From this method, the standardization of pectin of its gelling strength of 150° USA-Sag was developed. The value 150° USA-Sag means that with a pectin concentration of 4.33 g/kg the model gel will sag by 23.5% of a sugar concentration of 649.5 g/kg. In other words: 1 g pectin with 149 g sugar will form a gel (tss: 65°Brix, pH 2.2) with a standard firmness and 23.5% sagging. If a gel with the same pectin concentration settles or sags less than 23.5%, it is assumed that the gel will have a firmer gel structure and the pectin will have a higher degree of USA-Sag.

However, it is not possible to describe the haptic (sensorial impression of texture in the mouth) properties of a gel with this method. For example, only a human taster can describe the wonderful sensory impression from destroying the structure of the gel during the eating process (chewing and swallowing). Another example is the appeal of the product. A visual feedback gives one an idea or a mild sensation about the texture and firmness of the gel structure when the product is taken out of its container or package.

Another possibility is to test the firmness of a gel by inserting a plunger into the sample. Since a dry film on the gel surface will affect the results, the top gel coat should be removed prior to the measurement. Such a film would affect the response of the gel by serving as an additional stress. In the measurement, the force required to submerge the cylinder in the gel will be determined. As a rule, the firmness is defined as the maximum required force prior to structural failure. In 1927 Lüers and Lochmüller (82) suggested a method which avoids this surface effect by determining the breaking point within a gel. This method is the basis of the actual Herbstreith Pektinometer. It is possible to measure an "internal gel strength" by inserting a probe into the gel structure. To measure the internal strength, the probe is first inserted into the gel. After a defined period of time, the measurement is obtained by pulling the probe out of the gel under a constant speed. Comparable to the penetration measurement a measuring device (transducer) will determine the maximum force needed to pull the probe out of the gel. The firmness of the gel structure is the maximum force prior to failure or breaking point of the gel.

Other important measuring devices in the quality control of pectin are rotational rheometers that measure the viscosity of pectin types (e.g., for the use in beverages) and oscillating rheometers that measure differences of gel structures without destroying part or all of the gel, e.g., confectionery products (83). Setting temperature and setting time of pectin formulations can also be measured (84).

A. High Methylester Pectin

High methylester pectins generally form gel structures at $pH < 3.5$ and a soluble solids content of $> 55\%$. It is assumed that the gel formation will take place after the complete dissolution of pectin and after addition of acid which is necessary to reduce the negative charges of dissociated free carboxylic acid groups, which would hinder pectin chains to associate. A high content of soluble solids, e.g., sugar, is necessary to influence the water activity of highly hydrated pectin molecules in order to facilitate interactions between the polymers. This gelling mechanism is also called sugar-acid-mechanism, since these are the main influencing factors for the gelling behavior of high methylester pectins. If any of these factors is not controlled, the gelling of pectins cannot be guaranteed.

The process of gelation can be described as follows. The galacturonic acid, one of the main components of pectin, contains carboxylic acid groups which partly dissociate while the pectin dissolves, causing the molecules to be negatively charged. Thus the pectin molecules repel each other. After the complete dissolution, the pectin molecules are hydrated. The high water binding capacity causes the formation of strong hydration bonds between water and pectin molecules. By decreasing the water activity the hydration will be reduced, so that the pectin molecules

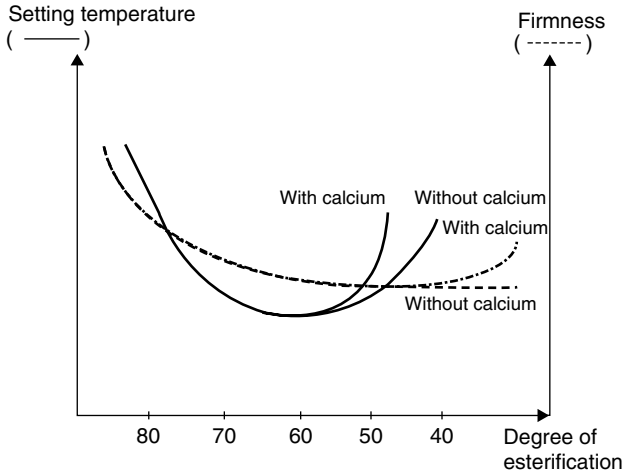

FIGURE 140.3 Gel strength and setting temperature of pectins as a function of the degree of esterification.

approach each other sterically. At this stage, if the pH of the system is higher than 3.5, the repulsive forces between the pectin molecules are so strong that the formation of interactions will not take place. By adding acid the dissociation of the acid groups will be reduced, entailing that the negative charge density and thus the repulsive forces between the molecules will decrease (85). Junction zones between pectin molecules develop through the formation of hydrogen bonds between the carboxylic acid groups of pectins. Hydrophobic interactions between the methylester groups of pectins additionally stabilize the network (86). Moreover, hydrogen bonding can occur between pectin and the secondary hydroxyl group of sugar molecules.

A connection exists between the degree of esterification (DE) and the gel strength, but setting speed or temperature (ST) will also be influenced. Based on a DE of 50% for high methylester pectins, the gel strength will increase with increasing DE and pectins with a DE of 70% will form very firm gels (87, 88). Therefore a setting speed or ST at which the gel is formed must also be monitored and recorded. Figure 140.3 illustrates the following:

- ST decreases as DE increases from 50% to 60%.
- ST rises as DE rises from 60% to 75%.
- A DE of 60% exists as the lowest setting speed or ST.
- Below a DE of 60%, an increasing affinity of the pectins towards divalent ions can be observed, which influences the gelation of these pectins.
- Calcium ions increase the firmness and ST of the pectins.

Based on the effect of degree of esterification on the setting time of high methylester (HM) pectins, one can define three types of commercial HM pectins: rapid set, medium rapid set, and slow set.

The ionic character of a pectin molecule, expressed by its pH, affects the product that is to be gelled and may also affect the structure of the formed gel. Pectins with an increased pH value have a longer setting time. The ionic strength of the product will also affect the setting behavior of the pectin used. If the batch used contains an excess of cations, it may prevent or reduce the repulsive forces due to a reduction in dissociation from the acid added. This results in weaker hydrophilic interactions that assist in the formation of junction zones.

Sugar content, calcium level, pectin concentration, and pH all have a significant influence on the setting temperature and gel strength of pectin gels (89). The gel strength is also influenced by the soluble solids content and the pH of the solution. Because of the water activity decreasing effect of sugar, which also varies based on sugar type, a minimum sugar content of 55% is necessary in order to initiate gelation. Pectins with a very high degree of esterification (>80%) still exhibit gelation properties even if soluble solids content is slightly lower.

Because of the high content of methyl ester groups, bonding zones are mainly formed by hydrophobic interactions between these methyl ester groups. If the soluble solids content is increased, the firmness of the produced gels also increases. Simultaneously, the setting speed of the respective pectin increases. It appears that an upper pH limit exists for the gelation of pectins. In solutions with a rather high pH the number of dissociated carboxyl groups and the negative charge density increases and therefore no gel formation will take place. The repulsive forces are so strong above a pH value of 3.5 that gel formation will not occur. Reducing the pH to just below 3.5 will result in a softer gel that will increase in strength with a further reduction in pH. Simultaneously, the setting temperature of the particular pectin type will increase. This shows that the pH value and the content of soluble solids affect the gelling behavior of pectin. The effects generated by the pH operate within a set of parameters. The same holds true for the content of soluble solids. The two sets of parameters act in opposition as gel strength increases with increasing soluble solids and decreasing pH value.

The application of pectin in products with a relatively high pH has certain limitations. Depending on pH and temperature, a depolymerization of pectin may occur by β-elimination of the glycosidic bonds between the galacturonic acid units. The reaction breaks the bond next to a galacturonic acid which is esterified. Consequently, the low methylester pectins are more stable in solutions with a neutral pH than high methylester pectins. Pectic acid is stable at a neutral pH (90–92).

B. Low Methylester Pectin

Pectins with a degree of esterification below 50% are able to form gels relatively independently of the content of soluble solids and pH value as long as divalent cations are

present. In the food industry calcium ions can serve as the cations. The explanation of the gelation mechanism is mainly based on the egg-box-model of Grant et al. (93). A bonding zone consists of two neighboring pectin molecules bound by calcium ions. Due to the glycosidic bonds between the galacturonic acid units, a zigzag or folded structure of the polygalacturonan chain may form. As a result two galacturonic acid units form a hollow body. The hollow body is so large that a calcium ion can be imbedded. On the opposite side of the dimer is another hollow body, which is formed by the two galacturonic acid units of the second pectin molecule. At least 7 consecutive free carboxylic acid groups within the chain segment should exist to ensure the formation of a bonding zone. Due to steric reasons only every second carboxylic acid group can be linked to a calcium ion. A methyl ester group can only then be incorporated in the bonding zone, if the carboxylic acid group on the opposite side is not esterified. At least 14 galacturonic acid units in the polygalacturonan chain must be present in chain segments which are partly esterified so that a bonding zone after the egg-box-model can form (21).

Thus, pectins with a degree of esterification >50% inter-act with calcium ions, if the chain segments of the pectin contain block-by-block arranged free carboxyl groups.

The calcium ions affinity of low methyl ester pectin depends on the degree of esterification. The gel strength of a pectin at a constant calcium level increases with a decreasing degree of esterification. This is because of the influence of the degree of esterification on the strength of calcium bonding to carboxyl groups of pectin. The density of the electric charge of the macromolecule also changes with the degree of esterification of a pectin. The higher density of an electro-negative charge of very low ester pectin increases the affinity of the pectin towards calcium ions (94). With the same calcium level a gel is formed that is firmer than one from a pectin with a higher degree of esterification (78). The way that calcium ions are added to the system also plays an important role in the gelation behavior of low methylester pectins. Readily soluble calcium salts, e.g., calcium chloride, will cause a quick gelation, whereas adding calcium citrate will result in a slower gel formation. Similar to the gelation of high methylester pectin, gelation of lower methylester pectin will occur at a characteristic temperature. The concentration of calcium ions will influence the setting temperature which increases with increasing amount of calcium added. The addition of an excessive amount of calcium ions may result in a water-insoluble salt, calcium pectinate.

Soluble solids content, pH, ionic strength, and presence of calcium binding substances, in addition to pectin level, will influence the gelation of low methylester pectin. Hence there is a need to determine the calcium requirements of a pectin type in order to obtain a gel with a defined structure. Lowering the pH and increasing the soluble solids content reduces calcium demand whereas the presence of calcium binding matters will increase the calcium requirements (77).

The introduction of amidated groups into the pectin molecule reduces calcium requirement while producing gels with the same gel strength. Thus, amidated pectins can be applied in a product formulation where non-amidated pectins will not form a gel, e.g., in products with a neutral pH. Also, amidated pectins are relatively tolerant towards erratic calcium concentrations.

C. Nutritional Aspects

Pectin is considered a soluble dietary fiber since its nutritional properties meet the definition set up by the American Association of Cereal Chemists (AACC) in January 2001: "Dietary fiber is the edible part of plants or analogous carbohydrates that are resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine. Dietary fiber includes polysaccharides, oligosaccharides, lignin and associated plant substances. Dietary fibers promote beneficial physiological effects including laxation and/or blood cholesterol attenuation and/or blood glucose attenuation."

The influence of pectin on the cholesterol level in blood has been analyzed thoroughly. Pectin has the ability to bind cholesterol that the liver develops and secretes into the small intestine. With a pectin-free diet, more than 50% of the cholesterol will be reabsorbed in the colon causing blood cholesterol level to remain at a constant high level. This applies mainly to individuals with a natural high cholesterol production. Another effect of a high-pectin diet is related to blood levels of LDL (low density lipoproteins) and HDL (high density lipoproteins). Pectin can alter the ratio of blood lipoprotein fractions to favor HDL. Low methylester pectins can bind and dispose of heavy metal ions and their radionuclides in the intestine due to their strong ionic character (95).

XIII. FOOD LEGISLATIVE ASPECTS

Pectin is a food additive which is produced from plant material by means of an extraction process. Thus pectins vary in their characteristics which will be balanced and standardized by technology used by pectin producers. This ensures that certain characteristics will remain the same between production runs. It is not possible to eliminate certain built-in variables when one isolates a heterogeneous polysaccharide out of a complex matrix. However, stringent criteria from private and public sources protect the integrity and quality of pectin. The sources originate from pectin producers, legislations, and international recommendations. They define the purity and identity of pectins, including those from the Codex Alimentarius, the European Union (96), Food Chemical

TABLE 140.4
Purity Requirements for Pectin

Criterion	Purity Requirements
Loss on drying	max. 12%
Acid insoluble ash (3 n HCL)	max. 1%
Free methyl, ethyl or isopropyl alcohol	max. 1%
Sulphur dioxide (in dry substance)	max. 50 ppm
Nitrogen content (ash free and dried)	max. 2.5%
Galacturonic acid (ash free and dried)	max. 65%
Degree of amidation	max. 25%

Codex (97), and the Joint Expert Committee on Food Additives (JECFA) of the FAO/WHO of the United Nations (98) can be viewed in Table 140.4.

For pectin to be an approved commercial gelling and thickening agent, the producers are also required to comply with other sanitation and safety criteria such as hygiene, pesticides, etc.

Pectins are generally permitted for use in foodstuffs in which no restriction for the use of permitted additives exists and in foodstuffs in which a limited number of additives may be added and pectins are mentioned as permitted additives. Some countries do issue government regulations for pectin used in such a manner. With the "Organic Directive," the European Union has issued guidelines for the application of pectin in organic products. According to this directive, the maximum level of ingredients from non organic origin permitted to be added is 5% for a prescribed list of food products or ingredients. With the exception of amidated pectins (99), all other pectins belong to that list.

XIV. DISSOLVING PECTIN

Pectins have very high water binding ability and, because of the gelation properties, the dissolution procedure is crucial to activating the entire amount of pectin added. To dissolve pectin, a high shear mixer is used to ensure the separation of all pectin particles in hot or cold water. The mixing tank is filled with hot water and the required amount of pectin is added into the vortex. If a lack of shear is noticed it may be better to mix the pectin with sugar. Depending on the temperature of water and potential shear rate, pectin solutions with a concentration of 8–10% pectin may be produced. Sugar will physically separate pectin particles and prevent lump formation. If high shear is not available, pectin can be mixed with 10 parts sugar or other dry ingredients, which is then added into the cold water or fruit (or fruit juice) under agitation. Pectin will dissolve properly after bringing the cold batch to a boil. A third possibility is the addition of pectin to glucose syrup (tss $>$ 70%). Although pectin will not dissolve because of low water content, an even distribution can be achieved. Pectin will finally dissolve after diluting the batch with water or fruit juice to reach a maximum of 30% for soluble solids content, followed by boiling. For any method of preparing a batch of pectin in a formulation, the producers monitor the content of soluble solids to make sure that it does not exceed 30%.

XV. JAMS, JELLIES, AND MARMALADES

The main application for pectin is in fruit spreads, preserves or jams, jellies, and marmalades. The pectin gives an identity and a remarkable texture to each product. About 50% of all pectin sold is used to manufacture these products. Although traditionally jams and jellies are breakfast items, they have a rather short history in the human diet. One of the main components is sugar which was known since crusaders brought it into the European market. Before then, honey or traded sugar from Arabia was used to sweeten the diet. For a very long time only the rich were able to afford sugar, similar to other spices used today, e.g., pepper. Sugar became commercially available when sugar beet was cultivated in Europe. A long interval elapsed before it was learned that a high concentration of sugar could preserve a food by reducing water activity. At a water activity of $>$0.86, the equivalent of a sucrose solution of 65.6%, the growth of pathogens is suppressed. These products can be described as hardly perishable. With that method it was possible to preserve fruit with sugar, the nutritional value of sugar as an excellent carbohydrate, and the refreshing taste of fruit with its nutritional benefits, for example, of high mineral and vitamin content to be available all year round. For a homemade product, differences in firmness and texture are of little concern. However, a commercial product has to deal with different raw material quality, depending on the fruit type and its pectin content. With consumers' increased expectations on the texture and firmness of fruit spread a demand for a quality product with consistent sensory attributes has been formed.

As for other products, legislation has established a standard of identity for fruit spreads to define quality products. They are jam, preserve, and marmalade. All have a defined sugar and fruit content and a list of permissible ingredients.

A. Traditional Jams and Jellies

To manufacture a traditional jam only fruit, sugar (including sugar syrups), pectin, and organic acids are used. The traditional products have a high content of total soluble solids, achieved by adding ~55% sugar to produce a product which can be stored and transported at ambient temperatures. Jams and jellies produced by major international brands adhere to a high quality standard. The quality of a

finished product is defined by the quality of raw material and the quality assurance of the manufacturing process. The quality of a jam or marmalade is characterized by an appealing appearance, a fresh and fruity taste, and an appropriate and defined texture.

Since no flavor or color is added, the sensory attributes (appearance, taste, etc.) depend on the quality of the fruit that is used. Fruit components to be used may include fresh fruit, frozen fruit, fruit puree or fruit juices, and their concentrates. The fruit should have an optimal ripeness; overripe fruit is less flavorful and disintegrates easily when boiled. Fruits with high water content have less flavorful components. Fresh fruit, mainly a seasonal product, are washed to remove impurities and foreign debris. Most of the fruit used are frozen, canned, or preserved, e.g., with sulfur dioxide. Other quality criteria include a color in the desired range and soluble solids content in agreement with the specification. The soluble solids content will contribute to the total soluble solids content of the finished product, thus influencing the boiling time or the addition of sugar during the manufacturing process. One must consider the acidity of the fruit or its pH value. It is easy to use acid to lower the pH to a desired value when the fruits have an inherent low acidity (high pH value). Fruit with an inherent high acidity (low pH), e.g., red currant, are more difficult to handle. For example, a batch of such fruit, to which pectin has already been added, starts to form a gel once the content of total soluble solids has reached the desired value. In this case the addition of sodium citrate to increase the pH during cooking may be appropriate.

TABLE 140.5
Typical Recipe for a Traditional Preserve

		Refractometer
40–80 g	Pectin solution (5% tss)	(5°brix)
450 g	Fruit (10% tss)	(10°brix)
420 g	Sugar (100% tss)	
200 g	Glucose syrup (80% tss)	(80°brix)
xml	Citric acid solution (50% tss) to adjust the pH value	(50°brix)
Input	Approx. 1150 g	
Output	Approx. 1000 g	
pH value	2.8–3.3 (depending on fruit type)	
Total soluble solids	63%	(63°brix)

Table 140.5 shows a typical jam formulation, in which the content of total soluble solids of the fruit is set to 10% to calculate yield and total soluble solids of the finished product. Next to the recipe, readings of the total soluble solids content taken with a refractometer are shown in °Brix. The yield depends on the content of total soluble solids reached in the finished product after evaporation. Although the used sweeteners have fixed soluble solids content, the soluble solids content of the finished product will depend on the soluble solids content found in the fruit used in the formulation. By using fruit with higher soluble solids content, the yield will be increased. However, it should be noted that the pectin content in the finished product will also be reduced, thus affecting the firmness of the finished product. It is always an option to adjust the addition of sugar if the fruit used has a large difference in soluble solids content.

The soluble solids content of the finished product can be calculated to estimate the yield which will be obtained using Equation (140.1).

The equation in principle can be used for all types of fruit preparations. The necessary pectin dosage depends on:

- desired firmness
- total soluble solids (quantity and type of sugar)
- pH
- fruit content

For products having fruit with a high pectin and fiber content, the use of less pectin may be required. However, fruit with high natural pectin content will be difficult to handle in production since protopectin is extracted in the manufacturing process. This may reduce the influence on the setting behavior of the batch, especially if pectin with rapid setting behavior is obtained. Jellies need a relatively high pectin dosage as the raw material only contains a small amount of soluble fibers. Insoluble fibers and pulp particles, although not part of the gelling system, will make jams firmer and will reduce the product's tendency to syneresis because of their water binding properties. Jams with high fruit content and/or higher content of soluble solids have a lower pectin demand (100).

The natural pectin content in fruit is dependent on:

- the type of fruit
- variety within the type of fruit
- stage of ripeness

$$tss_{Finished\ product} = \frac{(W \cdot tss)_{Pectin\ solution} + (W \cdot tss)_{Fruit} + W_{Sugar} + (W \cdot tss)_{Glucose\ syrup} + (W \cdot tss)_{Citric\ acid\ solution}}{Output} \cdot 100 \quad (140.1)$$

W : Weight
tss : Total soluble solids (%)

Grapefruit	7.20		1.45	9.6
Grape	16.6		0.38	13
Lemon	2.43		4.75	11

According to Table 140.6, the natural pectin content may influence the amount of pectin needed for getting an appropriate set. Acidity, content of total soluble solids, and calcium content are all important parameters affecting the gelation of pectin.

Sugars are the main constituent of jams, jellies, and marmalades; they extend shelf life and improve the taste and texture of the finished product. Because of the high concentration of sugar used, it is important to select the appropriate type of sweetener in view of potential re-crystallization. Pure dextrose (glucose) is not used because of its high tendency to crystallize. Refined sucrose is used, because of its availability and low tendency to re-crystallize. In the manufacturing process sucrose is partially inverted to glucose and fructose, which is a chemical process supported by low pH of the product. That additionally decreases the tendency of sugar crystal formation. Other influencing parameters are temperature and time of the cooking process. Usually a combination of different sweeteners is used in order to create decisive and characteristic sensory attributes. Sucrose is combined with glucose syrup since glucose syrup is less sweet, resulting in a fresh and fruity taste. Note that the sweetness of sucrose is short and sharp, compared to glucose. Also, high-fructose corn syrup, having the same relative sweetness as sucrose, is used in combination with glucose syrup. Glucose or corn syrups are derived from corn, wheat, or other types of starches by acid or enzymatic hydrolysis and, depending on the manufacturing process, contain glucose, maltose, maltotriose, and dextrins. Fructose containing glucose syrup is obtained by enzymatic induced isomerization of a certain amount of glucose in the syrup. Because of the higher content of fructose, high-fructose containing syrups have a relatively high sweetness (see also Tables 140.7 and 140.8).

In certain dietetic products, sucrose or glucose has to be replaced with other forms of specific sweeteners. For example, fructose is important because of its insulin independent metabolism and digestion. The main group of sugar replacers for dietetic jams and jellies with $>60°$Brix are sugar alcohols, including sorbitol, mannitol, maltitol, and isomalt as shown in Tables 140.7 and 140.8. As an alternative to adding a specific sweetener, syrups from fruits like refined grape juice concentrate or Herbasweet, an apple derived sweetener (Herbafood Ingredients, Germany), may serve to produce an "all fruit product," containing only fruit ingredients.

The choice of the appropriate pectin type to form a gel is determined by textural properties and processing

TABLE 140.7
Common Bulk Sweeteners for Traditional Jams and Jellies

Bulk Sweetener	Relative Sweetness	Concentration of Re-Crystallization
Sucrose	1	65.5%
Glucose	0.75	45%
Fructose	1.2	80%
Sorbitol	0.4–0.5	70%
Isomalt	0.5	25%
Maltitol	0.9	60%
Mannitol	0.4–0.5	12%

TABLE 140.8
Common Liquid Sweeteners for Traditional Jams and Jellies

Sugar Syrup	Relative Sweetness	Containing Sugars	Tendency to Crystallize
Glucose syrup (42 de)	0.35	glucose (17%), maltose (14%), maltotriose (13%)	low
Glucose syrup (62 de)	0.50	glucose (36%), maltose (31%), maltotriose (13%)	low
High fructose corn syrup (42% fructose)	0.95	glucose (53%), fructose (42%), maltose (3%), maltotriose (1%)	high
High fructose corn syrup (55% fructose)	1	fructose (55%), glucose (41%), maltose (2%)	low

parameters. A production using open kettles may have different requirements than a process using vacuum boiling. Finished products have a different color and taste if the ingredients have been exposed to less heat treatment in terms of time and temperature. Color, flavor, and fruit pieces will be much better retained in comparison to cooking at ~100°C (212°F). In a vacuum cooking process the batch starts to boil at ~60°C (140°F), preventing caramelization and excessive loss of flavor from evaporation. Caramelization of sugar occurs at >80°C (176°F). For a vacuum process slow set or medium rapid set pectins have to be used in order to permit an adequate filling time for the finished product. Because of the high cooking temperature, the appropriate pectin type for an open kettle process is determined by the filling procedure of the manufactured product.

A vacuum cooking process is essential if a large quantity of water has to be evaporated from the batch to achieve the desired content of total soluble solids, e.g., when using glucose syrups as a sweetener. Cooking in open kettles may enhance oxidation of certain fruit ingredients, leading to off-flavors. Cooking at ~60°C (140°F) in a vacuum process may not produce a microbiologically stable product. If so, pasteurization prior to filling the finished product into jars is one option. Figure 140.4 provides an illustration of this process.

In principle the addition of ingredients can be done in two ways. Pectin can be added as a powder at the beginning of the cooking process or added as a pectin solution at the end of the boiling process. The pectin solution is added once the fruit-sugar-batch has reached the necessary total soluble solids content. It should be noted that by adding the pectin solution the sugar concentration will be diluted. To induce gelation, citric acid solution is added to adjust the pH. The citric acid should be added at the end of the cooking process to permit a proper control of the filling time. If the total soluble solids content and pH are adjusted, weak interactions between the pectin molecules will commence and the setting process starts. Citric acid is preferably added as a solution. This allows for a better incorporation and an even distribution of the acid can be obtained quickly to bring about a lower pH.

If a high shear mixer is not available, pectin and part of the sugar can be added as a dry mix to the cold fruit batch. Although the dissolving properties of pectin depend on the total soluble solids content, the batch should have no more than 30°Brix to ensure good dissolution/dispersion (see also section 14). Pectin comes into solution by the subsequent heating step. After the rest of the sugar is added and the batch is cooked until a desired total soluble solids content is reached, citric acid solution is introduced.

Two definitions for the manufactured products are important:

- Setting time. The time between adjusting the essential product parameters for gelation and the moment when a gel network is formed.
- Setting temperature. The temperature when the gel network formation occurs is reached by exposing the filled jars to ambient temperature or water in a cooling tunnel, achieving a constant cooling rate.

The duration of the filling process also determines the choice of pectin. If the filling procedure requires a long setting time to fill, for example, portion packs properly, a slow set pectin is recommended. Products filled in large containers also need a long cooling time, since heat exchange by conduction is a slow process. To prevent potential burning in the center, these containers are filled at temperature as low as 60°C (140°F).

In sum, the setting temperature is influenced by:

- pectin type (see previous discussion)
- soluble solids content
- pH
- calcium content

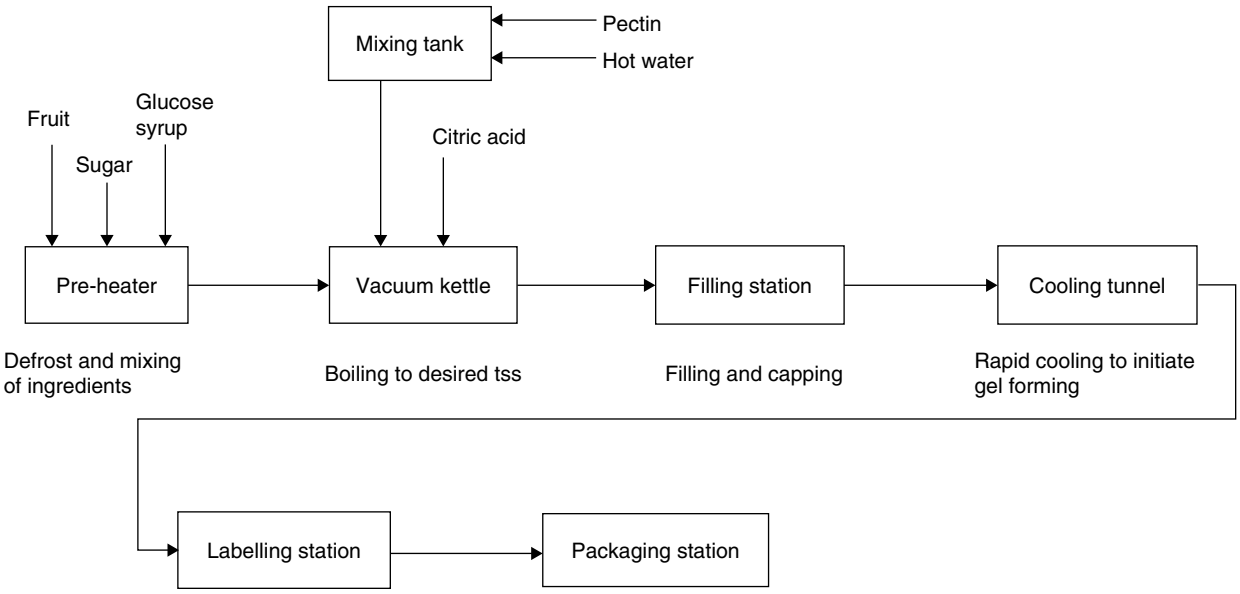

FIGURE 140.4 Manufacturing process of traditional jams and jellies.

An increase of the soluble solids content will lead to an increase of the setting temperature as well as a decrease of the pH from the addition of more citric acid solution. The presence of divalent ions, especially calcium ions, will increase the setting temperature of citrus pectins (see also section 12.1). However, the pectin level used has a relatively small influence on the setting temperature.

Choosing a pectin type that sets too fast for the given manufacturing process, will lead to a quality defect, i.e, a pre-gelled jelly. Pre-gelation is a process in which the pectin forms a network prior to the cooling process of the filled product. A regular network with a structure that can be sliced or cut will form only after filling above the setting temperature. Once the structure is set, it cannot regenerate after being exposed to shear caused by pumping or filling. A pre-gelled structure is softer and cannot be sliced or cut. Also, an increased tendency to syneresis may occur. These factors will lead to some preventive measures after the filling process. For example, filled products should not undergo excessive movements within the first 24 hours. Another important quality defect often results in the product when whole fruit is used. Fruit is naturally high in water and low in total soluble solids. On the other hand the serum during processing (cooking) has a high sugar content, causing a density that is higher than that in fruit. Thus, fruit has positive buoyancy leading to gravitational separation (floatation) after filling. This behavior is easily corrected by cooking the batch for an appropriate period to permit a "reverse" process of migration: water from fruit to serum and sugar from serum to fruit tissues. Additionally a faster setting pectin can prevent separation of the fruit as well as a pectin type that develops a high heat viscosity.

A product may be rejected because of an inappropriate set due to:

- undissolved pectin
- total soluble solids out of gelling range
- pH out of gelling range (see also section 12.1)

In order to prevent rejections, quality assurance from raw ingredients to finished products is of paramount importance. A re-working of the finished product is very difficult, as the sugar-acid-gelation of high methylester pectins is irreversible. Since the crucial point during the manufacturing process is the incorporation of pectin, we must pay attention to the following:

1. A properly dissolved pectin solution should be controlled with a refractometer.
2. The pH should be monitored during the process.
3. The content of total soluble solids should be assessed.
4. The temperature must be carefully regulated.

Automatic readings of the above three variables can be easily achieved with modern equipment such as meters. The temperature of the manufacturing process is important for three reasons:

- to prevent heat damage
- to produce a product that is microbiologically stable
- to avoid pre-gelation or fruit separation/floatation

With a well designed quality assurance program in the processing plant, quality products will be produced. The ultimate test for a quality product is a sensory evaluation or a measurement of the firmness of the product or both.

B. Low Sugar Jams and Jellies

In recent years, jams and jellies with a reduced caloric content have become increasingly popular. This is because consumers know more about nutrition and understand the high caloric content of sugar jams and jellies. To develop a product with a reduced sugar content without preservatives poses a major problem. The products have a short shelf life once opened, with or without refrigeration. Another reason is taste preference. Many consumers prefer less sweetness and more refreshing fruity note. Producers use these concepts also to market products with a high fruit content.

Selecting the appropriate pectin depends mainly on the content of soluble solids and the possibility of using calcium as a firming agent. The pH is of minor influence as long as it is within a typical range of 3.0 to 3.4. A conventional or an amidated pectin will serve as a low methylester pectin. Conventional low methylester pectins require a specific amount of calcium to form a gel. Yet the calcium demand depends on the soluble solids content.

Figure 140.5 shows the gelation behavior of a low methylester conventional pectin in model gels at different soluble solids content and pH as a function of calcium ion concentration. Adding a small amount of calcium to a pectin formula leads to formation of clusters. By increasing the calcium level, a gel may be formed whose firmness depends on the calcium dosage. By adding a high calcium concentration, very firm gels can be obtained with a highly brittle texture (77).

Increasing the calcium also increases the setting temperature of the given formulation. An excessively high dosage can lead to pre-gelation during the final stage of the manufacturing process. Pre-gelling can be detected since the gel is opaque and has a more pasty texture with a lower gel strength and a high tendency to syneresis.

Depending on the degree of esterification, pectin types can be obtained with a varying sensitivity to calcium. A more calcium sensitive pectin has an increased affinity to calcium ions and is forming tighter junction zones. Hence firmer gels will be obtained. Low methylester pectins with a high sensitivity to calcium are preferred for products with a very low soluble solids content.

Recipes with a relatively high sugar content have a lower calcium demand in order to form a firm gel. The calcium demand depends on the sugar and increases from sucrose to fructose to sugar alcohols, e.g., sorbitol. For many products, the calcium content of other ingredients, e.g., fruit, is high enough to act as a calcium donator. For products with lower soluble solids content, the addition of calcium is necessary. If the separate calcium addition is not desired, it is possible to obtain low methylester conventional pectins, that have been already standardized with calcium salts, to obtain a constant gelling behavior and gel strength. Such pectins are available for different soluble solids contents and different textural properties. As an alternative, low methylester amidated pectins can be used. Due to the introduction of amid groups, these pectins have a lower calcium demand. In comparison to conventional pectins, gel formation is achieved without separately adding calcium ions. Therefore amidated pectins are convenient and calcium addition is not a concern. Still, amidated pectins interact with calcium ions and form very firm and elastic gels with a rubbery texture. In comparison to amidated pectins, conventional low methylester pectins form gels with a smoother structure.

An increase in pH will lead to an increased demand for calcium. A higher pH increases the degree of dissociation and the repulsive interactions between the pectin molecules. More calcium has to be added to neutralize the repulsive effects. But the negative repulsive effects can only be partially balanced. At a certain pectin concentration, the calcium induced rate of gelation process is too high and pre-gelation will appear. Other organic acid salts or buffer substances become more negatively charged and interact with added calcium ions, which reduces the amount of calcium ions available for the interaction with pectin. The amount of buffer ions decisively influences the calcium requirement for gel formation.

The required amount of pectin that has to be added depends mostly on the soluble solids content. For products with a content of soluble solids of 50%, ~0.6% pectin is needed. The necessary amount increases up to 1.2% for products with 20% soluble solids. The manufacturing process does not differ from the manufacturing process for high sugar products (Figure 140.5). Depending on the filling facilities, the use of a preservative, e.g., potassium sorbate, may be appropriate. A separate addition of calcium salt is done in two ways. The necessary amount is added to the fruit at the beginning of the manufacturing process. Or, it may be added into the hot batch as a solution at a later stage of the production process.

There is a less tendency of the fruit separating to the surface (floatation), if the content of soluble solids in the serum reaches that of the fruit. There will always be some separation because of the air trapped in the fruit tissue. Filling the finished batch close to the setting temperature ensures an even fruit distribution in the jars. To produce a product that is stable to microorganisms, it is necessary to do the filling at ~85°C (185°F). Therefore, the setting temperature of the pectin has to be adjusted accordingly. If the filling temperature is too low because of the specification of product formulation, a longer cooking is

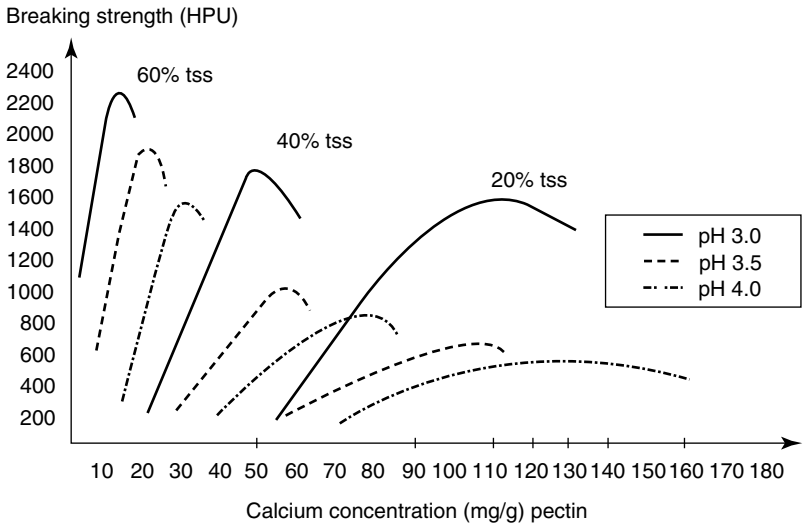

FIGURE 140.5 Firmness of model gels with low methylester conventional pectin as a function of added calcium ions.

required to achieve two goals that can prevent separation of the fruit to the surface, e.g.,

- escape of air bubbles
- equalization of content of soluble solids content in the serum and the fruit tissue

C. Gelling Powder and Gelling Sugar

Home canning of jams and jellies is still popular with consumers since they can use fresh fruits to prepare their own fruit spread. Because of the short boiling time, their preparations have excellent flavor and appearance. The products for home canning contain the proper pectin for a desired sugar content. These products require:

- excellent dissolving properties of the pectin used
- easy handling of the recipe and the manufacturing steps

In Europe, commercial processors offer gelling sugars or gelling powders that focus on the ratio of fruit to sugar, independent of fruit type. Consumers appreciate the convenience because they do not have to worry about the type of fruits used. If the addition of sugar is required, the type of pectin used must form an appropriate set with different fruits with different parameters: acidity, pectin, and sugar contents. The ideal pectin products that offer maximum convenience to the consumers are gelling sugars containing sugar, pectin, and citric acid in a gentle mix (Figure 140.6). Consumers have only to perform two steps: add the gelling sugar cold to fruit and/or fruit juice. Boil the preserve for a defined time. For gelling powders a defined amount of sugar has to be added separately after dissolving the gelling powder in the fruit and/or fruit

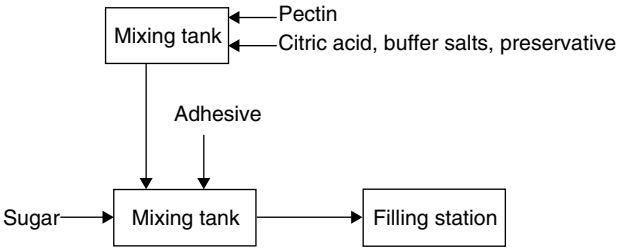

FIGURE 140.6 Typical manufacturing process of gelling sugar.

juice. Though consumers do not work with pH meters and refractometers for compliance with requirements, the producers must make sure that the pectin product has the appropriate gelation properties. Besides powdered products, some producers offer a pectin solution for use by consumers as a gelling agent.

Gelling powders and gelling sugars are manufactured by mixing the required ingredients to an even product mix. For gelling sugar pectin is first mixed with citric acid (often coated with fat to reduce pectin degradation) and then evenly mixed with sugar using an adhesive. For products that are designed to make reduced sugar fruit spreads, a preservative may be needed. A proper mixing process will prevent potential de-mixing of finished product caused by transport and packaging. Standard quality control procedures require testing of the even distribution of the gelling sugar and gelling powder at the respective stages.

XVI. FRUIT PREPARATIONS

Commercial fruit preparations are semi-finished products, tailor-made and specialized for application in different food products. Fruit preparations can be combined with bakery products (biscuits, cakes, etc.) or dairy products.

Glazings are one form of fruit preparations to enhance the appearance of fruit cakes. Specifications of fruit preparations and their manufacturing process are not as regulated as for traditional jams and jellies. Thus producers can make fruit preparations in different ways with numerous ingredients: hydrocolloids, colors, flavors (natural and artificial), and sweeteners. The quality of industrial fruit preparations is still defined by the raw materials, especially the fruit component. Low quality raw ingredients are hardly compensated by good manufacturing practices. Fruit preparations offer flavor, taste, and technical functions. Its important ingredient pectin serves to thicken and stabilize both fruit preparations and often also the final product applied to. Fruit preparations are specialized products and their manufacturing process is batch oriented: However, continuous production is possible if the producer takes into consideration the needs for pectin application. Figures 140.7 and 140.8 show examples of manufacturing processes for pectin based fruit preparations.

Requirements associated with the specific application of a fruit preparation will be discussed below. Filling temperatures have to be adjusted according to the container size to prevent thermal pectin degradation and weakening of texture in the center of the containers (Table 140.9).

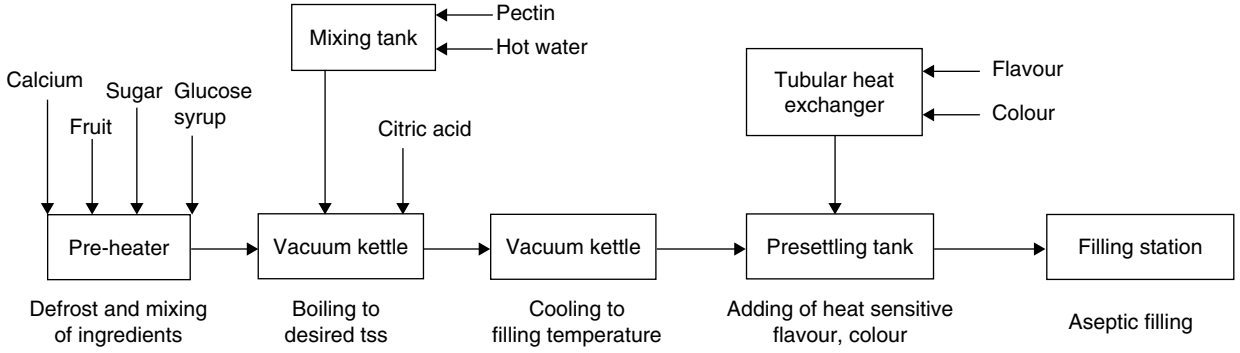

FIGURE 140.7 Batch production of industrial fruit preparations.

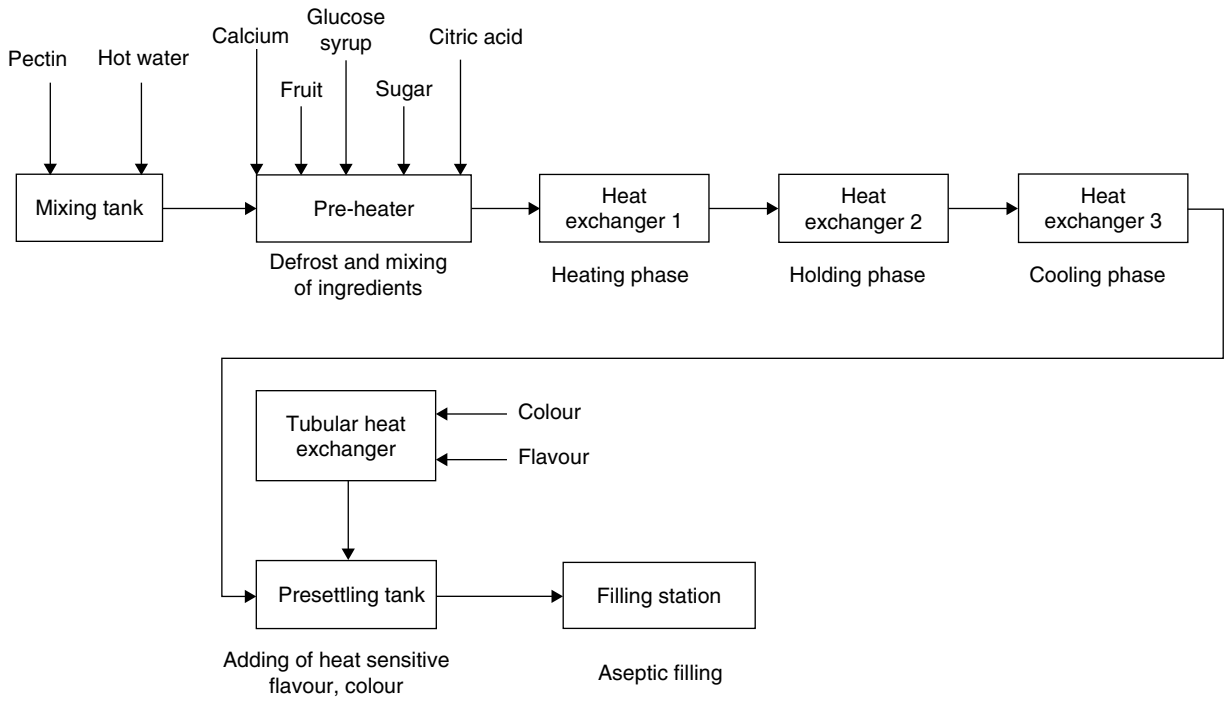

FIGURE 140.8 Continuous production of industrial fruit preparations.

TABLE 140.9
Filling Temperatures of Fruit Preparations According to Size of Container

Container	Container Size	Max. Filling Temperature
Jar	<1kg/<2.5lbs	95°C/203°F
Pail	1–50kg/2.5–110lbs	65°C/149°F
Drum	50–500kg/110–1100lbs	45°C/113°F
Container	500–1000kg/1100–2200lbs	30°C/86°F

A. Baking Stable Fruit Preparations

Fruit preparations for baked products give biscuits a fresh and fruity note. Besides the refreshing property, the use of fruit preparations in biscuits also serves as a source of moisture to prevent drying of the dough, thus increasing the shelf life of the biscuits. But the moisture content must be below a certain level to avoid wetting of the baked products. The fruit preparation can be added before or after the baking process. Normally the fruit preparation is purchased by the bakery and applied mechanically or manually to the dough as a topping or filler. The quality criteria for fruit preparations are two fold: avoid syneresis and apply good manufacturing or handling practices, especially the physical application of fruit preparation, and achieving thermal stability. Baking stability has a wide range of requirements, from high baking stability for biscuits to a certain thermal reversibility for forming a glossy topping. After baking, the thickener has to ensure texture stability during the shelf life of the baked product. Fillings should not show syneresis since this would affect the appearance of the baked product.

Pectin is an ideal ingredient to provide the desired structure and thermal stability for fruit preparations with a soluble solids content of more than 50°Brix. The gelling mechanism with sugar and acid provide the basis of thermo-irreversibility. High methylester pectin can be used in the type of fruit preparations small bakeries manually use in their products. The functions of high methylester pectins are similar to the application in jams that provide the desired firmness for fruit preparations. These fruit preparations are "baking-stable" because of the tight network formed by pectin. Once the structure is broken due to shear, a loss of thermal stability can be observed. This behavior relates to syneresis occurring after the broken gel pieces shrink and baking stability is only seen with the intact gel structure. This also means that fruit preparations have to be filled above the setting temperature for the given formula to receive a regular gel structure with tight bonding zones. A pre-gelled formula will not ensure the desired thermal stability and therefore might only be suitable for filling small containers or pails. Products manufactured with high methylester pectin do not show thixotropic characteristics. Their capability to regenerate after pumping is low. A popular method to achieve thixotropic flow behavior is to combine pectin with modified starch to produce a smooth and creamy fruit preparation. Modified starch, as a thickener, increases viscosity and improves the baking stability of the fruit preparations. The increased viscosity also remains once the fruit preparation has passed the baking process. Instead of starch, other hydrocolloids might be used to increase the gel structure's ability to retain liquid. Formulations and manufacturing processes are similar to those of jams and preserves with a high soluble solids content.

An important quality requirement of industrial fruit preparations, besides being "baking-stable," is the pumpability and the structure's ability to regenerate after pumping. Low methylester pectins provide thixotropic structures and, in combination with calcium ions, the desired baking stability. Low methylester conventional pectins seem to be more appropriate as they interact with calcium ions in a controlled fashion and provide gel structures with enhanced recovery ability. Pectin type and the amount of calcium ions added influence textural properties and thermal stability of the finished fruit preparation. Table 140.10 shows a typical recipe.

In addition to the gelling mechanism with sugar and acid, junction zones, in the presence of calcium ions, will form affecting the setting temperature and the melting temperature of the formula. The calcium concentration for an optimal gelation depends on the pectin type and the parameters for fruit preparation, such as total soluble solids content, sugar alcohols, a_w, pH, and ionic strength. Calcium ions will increase the firmness and the thermal stability, but an excess can interact with pectin to form a non-homogeneous gelation. The full functionality of pectin will be lost resulting in a fruit preparation with an increased tendency to syneresis. Insufficient calcium ions will result in a fruit preparation with unacceptable firmness and heat stability.

TABLE 140.10
Recipe for Bakery Fillings

49%	Sugar
30%	Fruit puree
15%	Glucose syrup
12%	Water
0.8–1.2%	Low methyl ester conventional pectin
0.01%	Sodium citrate
0.01%	Calcium citrate
	Flavor, color, citric acid solution (to adjust pH value)
Input:	Abt. 108%
Output:	Abt. 100%
TSS:	Abt. 65%
pH value	3.5

The addition of calcium salts is adjusted according to the requirements. Although there are many influences on the calcium demand seen, pectin is fairly tolerant for variances of the calcium content in different fruit types, so that it is also possible to obtain from the supplier pectin standardized to thermal stability with calcium salts.

A higher soluble solids content or a lower pH will decrease the calcium demand, whereas an increase of ionic strength and pH in the presence of sugar alcohols increases the required calcium salt addition. Calcium salts can be added at the beginning of the manufacturing process (Figure 140.8). It is also possible to add calcium as a slurry at the end of the manufacturing process, once the pectin has dissolved. If a pectin solution is not feasible, e.g., low water content in fruit preparations, there is an option. Pectin is dispersed in the sweetening syrup with 80°Brix which is reduced to 30°Brix by diluting the batch with fruit and water, in which the calcium has also been dissolved. The dilution to 30°Brix results in a dissolution of all ingredients, forming a homogenous gel structure.

For a fruit preparation with thermal instability, one must identify the proper amount of calcium to be added in combination with a specific pectin type. This is of course the objective of R&D (research and development). A pectin producer will develop the proper combination of calcium addition and manufacturing steps. As proprietary information, it will most likely not be in public record.

B. Cake Glazing

Cake glazings are preparations used to enhance the freshness of fruit cakes by extending the shelf life. A layer on top of the cake will prevent water evaporation from the fruit, giving the cake an appealing glossiness. Cake glazings are finished products with a neutral taste. They may contain fruit to enhance the fresh and fruity character. The total soluble solids content of glazings ranges between 35–50%. At this level of sugar, the products show an excellent melting behavior. Depending on the bakery application, cake glazings are available in many distinct types. Each type has specific requirements for the gelling agent and the manufacturing process. Cake glazing concentrates are re-diluted with water once they are used by the bakery and sprayed or brushed hot onto the cake. The liquid is turned into an elastic gel structure once it drops to ambient temperature. Direct sprayable glazings do not have to be diluted. The product is conveniently connected to a sprayer in which the preparation is heated and sprayed on. Cake glazing concentrates are produced with a water activity low enough to ensure good shelf life properties. Directly sprayable products have to be filled aseptically. Otherwise, preservatives are added. Also, glazings with a thixotropic gel structure can be produced to give the product convenient handling properties. They can be spread at ambient temperature on the cake without addition of acid. Table 140.11 shows a typical recipe for a concentrated cake glaze which can be manufactured as shown in Figures 140.7 and 140.8.

TABLE 140.11
Recipe of Concentrated Cake Glaze to Be Diluted with 30–50% Water

47%	Sugar
37%	Water
18%	Glucose syrup
1.2%	Low methyl ester amidated pectin, buffered
0.05%	Citric acid solution (50% (m/m))
	Flavor, color
Input:	Abt. 104%
Output:	Abt. 100%
TSS:	Abt. 65%
pH value	3.6

Besides the melting property, the re-setting behavior after diluting and heating of the preparation has to be considered. The fruit preparation needs to adhere sufficiently to the fruit to form the protective layer. Syneresis should be absent. A firm gel should be obtained. Products that are sprayed need a low heat viscosity.

For optimal melting behavior, low methylester amidated pectins are used in combination with calcium, acidity regulators, or buffer salts. The pectin type will give the industrial products a characteristic gel structure with a defined melting and re-setting behavior. Calcium ions are used to adjust the melting and setting behavior as well as the firmness of the finished product. All these requirements can be adjusted accordingly and it is also possible to obtain buffered pectin for general use. Directly sprayable glazings need to have the same soluble solids content as the finished product. The manufacturing process of the sprayable glazings requires vigorous agitation during cooling to prevent the gel structure from forming. Thus, the producer obtains a product with low viscosity, possessing good thermal reversible properties.

Glazes can be manufactured for products that do not necessarily need to be heated. With low methylester amidated pectin, thixotropic gel structures can be obtained for products that can be spread directly onto the cakes. Also glazings, which set by the addition of acid can be manufactured. In these products, the gelation properties of high methylester pectin are used to manufacture a liquid semi-finished product, containing pectin and final total soluble solids content. This forms a firm gel based on sugar-acid-mechanisms after the proper amount of acid is added. The setting speed or kinetics can be adjusted through the pectin type and through the addition of retardant substances.

C. Dairy Fruit Preparations

Dairy products, e.g., yogurt and cream cheese, are popular in modern supermarkets, especially in western countries. However, only the combination with fruit offers the large variety of different types of product consumers encounter and prefer. Fruit preparations for dairy products have to overcome two technical problems: sanitation considerations and potential interactions with the dairy phase. Protein and calcium that dairy products contain, apart from fat and lactose, could show potential interactions with a pectin thickened fruit preparation and become a factor in most applications to be avoided.

Dairy fruit preparations can be used in two major ways: layered (bottom or top of the dairy product) or in separate compartments. Consumers can mix the fruit preparation with the dairy product or enjoy the two products separately. Many dairy products contain a fruit preparation stirred into the dairy phase. As these products are produced separately, the mixing behavior between fruit preparation and the dairy ingredient is an important quality requirement. Most dairy products are consumed as a fruit yogurt or cream cheese. The texture of these dairy products, e.g., yogurt, is formed by fermentation and is defined by the casein as the gel forming protein. Protein gels are sensitive to shear stress and are not able to regenerate. High shear stress applied after the fermentation process has finished will lead to a soft texture and loss of mouthfeel. To obtain a fruit yogurt, the mixing process of the dairy product with the fruit preparation will affect the appearance of the finished product. Fruit preparations with shear thinning flow property show a good mixing behavior with the dairy phase. Only low shear has to be used to incorporate the fruit preparation. This has a positive impact on the structure of the finished fruit yogurt.

Low methylester pectin as a gelling agent forms shear thinning gel structures and is an ideal base of a hydrocolloid system that can be used as a thickener and stabilizer. Pectin will yield the desired gel structure and produce fruit preparations that have good pumpability without the tendency to form syneresis. Another quality parameter for a fruit preparation to be filled into a container is an even fruit distribution inside the container. The formation of a weak network with yield stress prevents fruit separation and guarantees a low viscosity during pumping and filling. It also allows easy metering, especially suitable for layered products. Low viscosity during the manufacturing process also decreases shear rates in the fruit preparation as soon as the product is pumped through a tubular heat exchanger. This enhances fruit integrity.

Dairy fruit preparations have a close pH of 3.5–4.0 to the dairy product. This prevents unexpected interactions between the two entities if the pH difference is high. Low methylester pectin is a charged hydrocolloid that can interact with proteins and cations such as calcium ions. Interactions of a dairy fruit preparation with a dairy product can be described as post gelation that is induced by the interaction of negatively charged carboxylic acid groups with calcium ions or protein. This post-gelation process will cause an uneven mixing as well as destabilizing and results in a product with poor appearance and increased tendency for syneresis. In layered products, the migration of calcium ions from the dairy phase to the fruit phase will have an effect on the fruit preparation's texture. Saturating the carboxylic acid groups with, for example, calcium, will prevent profound and unpredictable interactions. The amount of calcium that has to be added to the fruit preparation depends on pectin type, pH, and soluble solids content. The required amount is available from the pectin producer. Or, it may be in the pectins that have been mixed with calcium salts, and standardized to constant flow behavior from the pectin supplier. Table 140.12 shows a typical recipe for a dairy fruit preparation.

A low methylester pectin should be selected as an appropriate pectin type. With a low methylester conventional pectin, a producer can manufacture a fruit preparations with a smooth-viscous gel structure, rich mouthfeel, and enhanced reversibility. For fruit preparations with a short-brittle gel structure, low methylester amidated pectin may be the pectin type of choice. Reversibility of the gel structure will also depend on the calcium affinity of the pectin used and suitable soluble solids content. In fruit preparations with high soluble solids content, low methylester pectin with low calcium affinity is preferred. The advantage is that the finished fruit preparation will not have a tendency for syneresis in case excess calcium is present. Because of possible interactions with the dairy phase, a calcium tolerant pectin is of advantage especially when fluctuations of calcium levels in the fruit occur.

Dairy fruit preparations are specialized products. Therefore, the manufacturing processes are batch oriented. However, for volumes with a respective turnover, a

TABLE 140.12

Output:	Abt. 100%
TSS:	Abt. 40%
pH value	3.6–3.8

continuous production is possible. In the batch production, the fruit is mixed with sugar, liquid sweetener, calcium salt, and acidity regulators. Heat sensitive flavor and color may be added at a later stage. The batch is preheated to defrost the frozen fruit and to dissolve the dry ingredients. Finally the pectin solution is added and the whole batch is pasteurized. Then, the batch is cooled to an appropriate temperature for subsequent aseptic filling into a container. Flavor and color can be added into the sterile tank after a short heat treatment prior to filling. Pasteurization and cooling can take place in one kettle or two separate and specialized kettles to reduce energy cost.

For continuous production of fruit preparations, the soluble solids content of the finished product will influence the process steps. For products with a soluble solids content of <30%, pectin can be added as a dry mix with sugar or as a dispersion in liquid sweetener in the cold batch. The pectin will dissolve completely during subsequent heating. If the soluble solids content exceeds 30%, a pectin solution is made available to be added to the heated batch of product. For example, after pre-heating the fruit, sugar, liquid sweetener, and other dry ingredients, the pectin solution is added, and the batch is pasteurized and filled aseptically after the product is cooled to filling temperature. Figures 140.7 and 140.8 show typical processing steps also valid for dairy fruit preparations.

Quality control in fruit preparations from raw materials to a finished product means the careful supervision of pH, content of soluble solids, and viscosity or flow behavior. Most producers monitor the mixing behavior of the finished fruit preparation with the dairy phase, especially if fluctuations in the quality of the raw materials are observed.

XVII. CONFECTIONERY

The gelling properties of pectin are widely used in the confectionery industry. Confectionery products can be acidic jelly fruits or fruit slices with a firm texture. Also, gummy textured products and aerated products containing egg white, e.g., Snowball, can be manufactured. All confectionery products have a soluble solids content of 75–85%, which is established with a characteristic sweetener profile. To prevent re-crystallization at this high soluble solids content, a combination of sugar and glucose syrup is used. In the production, inversion of sugar and isomerization of some sugar will influence the sweetener profile. The sweetener composition, especially that for glucose syrup, will affect the viscosity of the batch during the manufacturing process and its deposition behavior. Confectionery recipes with pectin have a rather high setting temperature. This means that easy handling during the process is important in influencing the quality of the finished product. The production batch has to be deposited above the setting temperature to receive a firm product with the desired textural properties. Products deposited below the setting temperature will have a structured texture and show a lack of firmness. The short gelling time will give the pectin formulation the advantage of being able to be processed very quickly in order to finish packaging and storage on pallets.

Jelly fruits are manufactured with high methylester pectin standardized to a constant setting temperature. Typically, slow set pectin is used in combination with buffer salts that have retardant properties, e.g., sodium citrate or sodium potassium tartrate, to influence the gelation behavior of the pectin type used. Buffer salts can be added separately to achieve a unique product profile. Pectin types that have been already standardized with buffer salts can also be obtained. Apple pectin will provide soft textures with a smooth-viscous gel structure and are typically tolerant to calcium ions. Calcium ions may originate from the water or other ingredients. Jelly fruits with firm gel structures and a short-brittle texture can be manufactured with citrus pectin. The retarding agent used has also texture influencing properties. Sodium citrate enhances the smooth gel structure, whereas sodium potassium tartrate will result in products with elastic properties. In jelly fruits, typically 1.3% pectin or ~1.7% buffered pectin is used. With a dosage of ~2.5% pectin, gummy-like products with viscous-elastic gel structures and firm chewable textures can be obtained (Table 140.13). For these products, the buffer salt composition may be adjusted to the pectin type used and the manufacturing process selected.

In the manufacturing process the gelation behavior of pectin must be considered. Fruit jellies are manufactured within a pH range of 3.2–3.5. At this range the products have a fresh and fruity character, which emphasizes the release of the flavor by the acidity. In a batch oriented process, pectin is pre-mixed with part of the sugar and buffer salts, assuming the latter has not been incorporated into the original pectin. Cold water is added to the

cooking vessel and the pectin pre-mix is added while stirring. Heating dissolves pectin and the other dry ingredients. Then, the remaining amount of sweetener, e.g., sugar and glucose syrup, is added. While boiling, the pH should be adjusted to 3.8–4.5. At this pH, pectin will not start to form a gel, but is still stable towards degradation. At a relatively low pH, the tendency to invert sucrose is increased while caramelization will also be increased. Although manufacturing a standard 5% pectin solution may be responsible for adding too much water, a pectin solution with a relatively high content of soluble solids can be prepared in a pressure vessel with a high shear mixer. This method is especially suitable for a continuous manufacturing line (Figure 140.9). After adjusting the soluble solids content, flavor and color are added in the required amounts. Finally the citric acid solution is added to decrease the pH.

As the pectin types used are standardized to a constant gelation behavior, the required amount of citric acid for the pectin type used will be constant, as predetermined during the research and development stage. Depending on the buffer salts used and dissociation of pectin, an equilibrium is reached so that the drop in pH is controlled. The gelling process is irreversibly induced by the addition of acid solution. The batch is then deposited into the molds at 85–95°C (185–203°F). Molds made of plastic have the advantage of permitting the products to be quickly processed further. After depositing the batch into starch based molds, it is possible to run the products through a final drying process to harden the gel structure. Then, after the products are removed and sticking starch cleaned off, they are covered with a parting compound, e.g., sugar or wax. This process can include whipping of the batch before depositing to produce zephyr, a Russian confectionery product.

With the appropriate pectin type, it is also possible to produce non-acid confectionery products. Low methylester amidated pectin is the recommended pectin type for Turkish Delight or other high pH products. Turkish Delight is a soft gelled product covered with chocolate or sugar that has a pH of ~4.5. The manufacturing process is the same as for other pectin based jellies. Also, for aerated confectionery products, e.g., Angel Kiss or Snowball, pectin is an appropriate gelling agent (Table 140.14).

XVIII. BEVERAGES

A. Juices and Soft Drinks

Low caloric soft drinks lack mouthfeel because of the use of artificial sweeteners. However, the mouthfeel contributes decisively to the consumer acceptance of a beverage. A beverage without a mouthfeel offers a watery character not appreciated by a consumer. The addition of more flavoring substances does not reduce this negative response. By adding high methylester (HM) pectin, the viscosity and the mouthfeel of low caloric beverages will be enhanced. The contact between the drink and the taste buds on the tongue is more intense if the viscosity of a soft drink is increased. The enhanced aroma/flavor transfer or detection will create

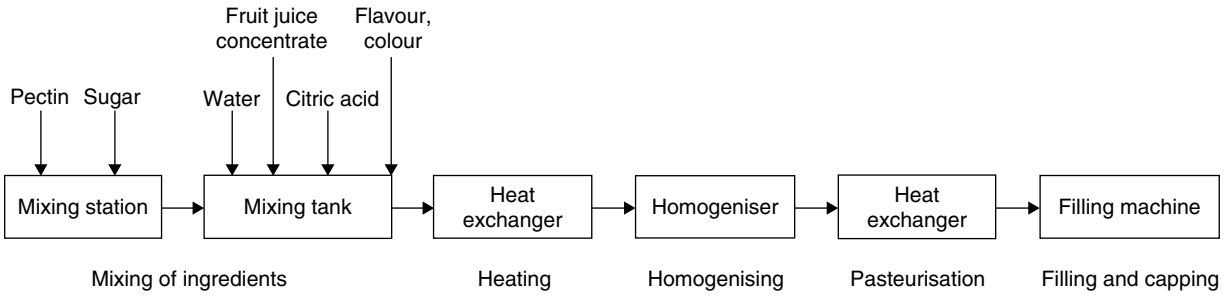

FIGURE 140.10 Manufacturing process of soft drinks.

a better impression of the intensive flavor. By varying the pectin dosage it is possible to increase or decrease several aroma notes, thus affecting indirectly the flavor contribution of the beverage. However, the addition of a large amount of pectin results in a full-bodied product. Thus, the addition of ~0.1% pectin should be sufficient to give the right mouthfeel to a low caloric beverage.

Besides apple and orange juice, exotic fruit juices have become very popular, thus increasing the demand for raw material and the need for fruit juice concentrates. However, beverage bottlers have only limited possibilities to influence the quality of the re-diluted juice. For example, pineapple juice and passion fruit nectar are unstable products, marked by sediment and clear supernatant. This means the consumers usually have to shake the bottle before drinking. The addition of pectin increases the serum viscosity, thus reducing the sediment rate and permitting interaction with the cloud particles to form a stable juice. Additional processing steps, e.g., homogenization, lead to an increase in beverage stability (Figure 140.10) (69). In addition to powder pectin, the pectin industry is able to supply agglomerated pectin to ensure lump-free incorporation without the use of high shear. These pectin types will dissolve during the final pasteurization step.

B. Dairy Beverages and Soy Drinks

Combining milk and other dairy products, e.g., yogurt with fruit, offers nutritional benefits with fresh, fruity, and refreshing beverages. Because of the relatively low pH of the dairy drink, the acid sensitive caseins become unstable and precipitate once the product has been heat treated. Casein at a pH of ~6.8 in milk is embedded in stable protein micelles enabling dairy companies to produce and distribute milk with long shelf life once heat treated. Lowering the pH, e.g., with fruit juice, influences the charge of proteins and subsequently their solubility. Caseins have an isoelectric point at which they become insoluble at pH 4.6. As the pH decreases, the casein slowly loses its hydrate shell and starts to form aggregates. This process is sensitive to temperature changes. At ambient temperatures, casein is able to form a gel if it is not affected by shear at the same time. High temperature and shear that occur during heat treatment will dehydrate casein particles and destabilize the beverage. Casein particles will form sediment in the heat exchanger once the finished product has been filled.

Due to its molecular structure, high methylester pectin is able to bind to casein and form a protective cover (102). Stable interactions are formed by ionic interactions between partially negatively charged pectin molecules and the positively charged casein complex. Also hydrophobic interactions can be observed. In order to get strong interactions, the charge density of casein and pectin has to be considered. Casein has strongly positive charges below pH 4.6, thus enabling interactions with negatively charged pectin molecules. Above pH 4.6, negative charges in the casein molecule will be in the majority, resulting in the repulsion of negatively charged pectin molecules. If the pH of the finished product is adjusted too low, the negative charge density of pectin is reduced, leading to weaker interactions with casein. This observation confirms that a pH of 4.0–4.2 may be the most appropriate pH range, at which a strong protective cover is formed. It is possible to pasteurize the dairy drinks, so that a long shelf life can be guaranteed.

Pectin may be added as a dry mix with sugar or as a pectin solution into the milk prior to mixing with fruit juice or after fermentation of the yogurt (or dissolved in fruit juice). Then, the product has to be homogenized in order to separate already coagulated casein and to enable the formation of a pectin casein complex. After homogenization, the product can be pasteurized or UHT treated to obtain a long shelf life product (Figure 140.11).

The protein content will influence the amount of pectin needed to stabilize the dairy drink. Further influences, e.g., pH and acidity, might be considered as well as the fat content, which has stabilizing properties because it binds casein. Calcium will have an impact on the stabilizing properties of pectin, especially if soluble calcium is used to fortify the beverage. Positively charged calcium might hinder interactions of pectin with casein by blocking negatively charged carboxylic acid groups. Calcium tolerant apple pectin might be selected for these products. The addition of calcium salts to the pectin solution should be avoided.

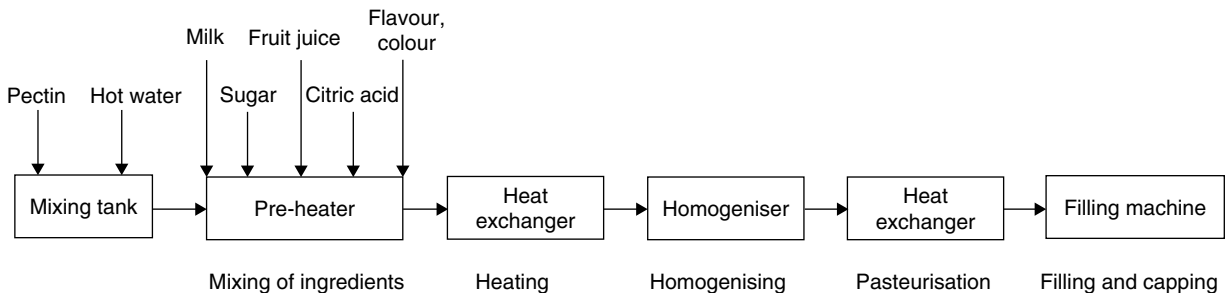

FIGURE 140.11 Manufacturing process of acidified milk drinks.

Soy proteins are, similar to casein, acid sensitive, but they have a different isoelectric point. To obtain a stable product, the pH of soy protein drinks might be more acidic than for dairy drinks and can be adjusted to ~3.8. In the production of soy beverages, the raw material influences the tendency to form sediment. In general dried soy products are used, e.g., soy powder or isolated soy proteins, as raw material. Similar to other dried proteins, soy protein is difficult to re-hydrate. For the development of soy beverages, the product must consider the properties and a proper incorporating technique according to the raw material used. Additionally, soy powder contains a large portion of insoluble fiber, which will form a precipitate eventually. In order to obtain fully hydrated soy protein, an extra operation is necessary. Run a separate processing step with a high shear mixer or homogenizer to manufacture a soy protein solution before it is added to the main process.

XIX. ICE CREAM AND SORBETS

Ice cream is a complex system of different phases and different ingredients that define texture and sensory properties. The liquid phase is an aqueous system that contains dissolved substances, e.g., sugar or hydrocolloids. In the solid phase ice crystals, fruit particles, and fat globules can be found and after aeration air bubbles or nitrogen bubbles form the gaseous phase. The composition of ice cream varies. In dairy ice cream, milk products or derivatives are used to give texture and the decisive taste. Although the fat content is an important factor, oils or fats derived from plant are often used. Proteins and emulsifiers used play an important role in stabilizing the aerated finished product. Sugar or other sweeteners, e.g., glucose syrups, increase the viscosity and mouthfeel of the aqueous phase and improve ice cream structure. Dissolved substances, especially the sweetener used, influence the product's freezing point. The composition of the sweetener determines the rate of lowering the freezing point. Glucose has a stronger effect than sucrose. The freezing point will not only influence the temperature profile of the freezing process, but will also have an influence on the melting behavior and the taste during consumption. Ice creams get their typical smooth structure from the aeration with air or nitrogen in combination with water forming the aqueous phase and the ice crystals. The crystal size affects the structure of the frozen product and defines the mouthfeel. The crystal size is affected by:

- the temperature profile of the manufacturing process
- the soluble solids content
- hydrocolloids added

Because of taste and its influence on the ice crystal size the optimum soluble solids content is 35–40%. Other ingredients, e.g., fruit or fruit preparations, are added as well as other flavoring preparations. Hydrocolloids are added to stabilize the ice structure and have an impact on ice crystal growth. Other functions are the increase of viscosity and mouthfeel. With an appropriate stabilizing system the shelf life of the product will be prolonged. With its flavor enhancing properties and acid stability, pectin can be used as an excellent stabilizer for fruit ice cream and fruit sorbets to control the ice crystal growth.

Crystallization is a time dependent process. Under the right conditions and temperature, a small nucleus is formed which then grows through the deposition of crystals on its surface. The main force holding the ice crystal together is provided by hydrogen bonds. The crystal growth strongly depends on the temperature, mass transport, and effect on the interface. Additionally, re-crystallization can be found to form spherical shaped ice crystals, because of their low interfacial surface energy. Furthermore, a migration process of small crystals towards big crystals can be seen and an agglomeration of ice crystals which are in contact with each other (103). The viscosity does not influence the growing rate of ice crystals, but pectin influences the process, because of its water binding properties to immobilize water molecules. Pectin can influence crystallization by forming hydrogen bonds with the ice crystal and by interactions between negatively charged density of the pectin molecule and the polar charged water molecules. The strong water binding properties of pectin immobilize free water, so that the free water for the ice crystal growth is withdrawn from the system. Pectin also enhances the fruit flavor transfer of the

finished product. So that pectin is an appropriate hydrocolloid to stabilize fruit sorbets and fruit preparations for ice cream fillings. It also serves to stabilize frozen yogurt or other ice cream products with a relatively low pH.

In the manufacturing process of sorbet (Figure 140.12, Table 140.15) all ingredients are mixed and heated to pasteurization, dissolving the dry ingredients. If the recipe contains dairy products and vegetable fat, the batch is homogenized after pasteurization and cooled down to ~2°C (35°F). Whole fruit or other solid ingredients are added to the batch after homogenization. At this stage, heat sensitive flavor, color, and the yogurt base are added. The freezing process is conducted in a continuous system with a freezer in which rotating knives scrape the ice film off the inner wall. Air is introduced into the freezer with excess pressure to aerate the batch. Once the product is removed, the batch is cooled to ~ −5°C (20°F). At this stage the product has a very soft texture, and after filling, is firmed up in the storage freezer at −40°C (−40°F). A product with a long shelf life is produced when ~90% of water is frozen.

Fruit fillings or other preparations can be introduced into the dairy ice cream after the ice cream batch has passed the freezer. In order to prevent freezing or too strong ice crystal growth, such preparations should have a relatively high soluble solids content containing monosaccharides such as glucose or fructose, so that they exert the most lowering effect on the freezing point.

Pectin also enhances the structure of frozen ice pops by providing a softer and crunchy structure for a more tasteful consumption.

XX. OTHER FOOD APPLICATIONS

A. Savory Products

Tomato sauces often need to be thickened and pectin is a suitable stabilizer. Medium methylester to low methylester pectins give similar textures as the natural tomato pectin and a pulpy texture can be obtained with a fruit enhancing mouthfeel. The choice of pectin depends on the application of the tomato product, because it will have a major influence on the melting behavior. A medium methylester pectin will give a low melting point but a smooth texture. Products requiring a higher melting behavior, to be able to consume the product as a hot dish or condiment, employ low methylester pectin, used in combination with calcium. Fruit sauces as condiments are easy to prepare with low

pH value:	3.5

methylester pectin. Although these sauces have a low soluble solids content, pectin can be added to the cold batch and mixed with other dry ingredients. The pectin will then be dissolved in the heating process, in case it is not possible to prepare a pectin solution. Table 140.16 shows a typical recipe for a tomato sauce.

Condiments, like mint sauce or fruit jellies and other fruit condiments, can also be texturized with pectin. The choice of the correct pectin type depends on the soluble solids content and pH of the product. Condiments have a soft and smooth texture to give the meal an appropriate accompanying taste. The quality requirements and the manufacturing process are similar to those for making jams and jellies.

B. Desserts and Other Dairy Products

Pectin can be used in a variety of dessert products. It is possible to gel milk systems, flavored water, or juice (jellies). A very convenient possibility to produce a milk dessert for food service or refrigerated retail products is to combine a fruit preparation containing low methylester pectin with milk. During the cold mixing process low methylester pectin interacts with milk-calcium to form a viscous-elastic gel. The time for the product to set needs to be adjusted to the estimated mixing time. However, a few minutes after mixing, a weak gel is formed which will harden in time when refrigerated. This product concept can also be used to manufacture a fruit preparation that permits a consumer to add the required amount of milk. Depending on the recipe, a fruit preparation can be used as a base for milk desserts or milk shakes.

Water jellies and trifles manufactured with pectin will get a very fruity and refreshing taste. With low soluble solids content, these products require low methylester amidated pectin to form the typical elastic and brittle texture. The addition of calcium might enhance the elastic characteristic of the finished product. In comparison to other commercial gelling agents, e.g., gelatin and carrageenan, pectin is more acid stable, especially when required for acidic flavors. In general the combination of calcium requires increased filling temperatures than for products with gelatin. However, cold-filling of pectin based trifles is also possible. Products can be distributed as dessert powders with different flavors for homemade trifles according to the recipe. After refrigeration the product is ready for consumption. It is also possible to make ready-to-eat retail products, with the possibility of adding a favorite item such as cream, yogurt, and so on.

The interaction of low methylester pectin with calcium and milk protein will provide possibilities to enhance the firmness and creaminess of yogurt products. After fermentation of milk with lactic acid producing bacteria, casein becomes positively charged once the pH of the dairy product drops below 4.6. A weak protein gel is formed, which is stabilized by the interactions between casein micelles. Pectin, being negatively charged, interacts with the positively charged casein as well as with the calcium ions to increase the stability of the protein gel. The addition of low methylester pectin will also enhance the mouthfeel of the yogurt, which is especially suitable for low-calorie products with a reduced milk fat content. However, this technique is limited in application. Low methylester pectin can only be added before the fermentation has taken place. Because of interactions with positively charged casein and calcium in the dairy product, the addition of low methylester pectin can lead to an uneven mixing behavior of the pectin used. Figure 140.13 shows a possible manufacturing process for the application of pectin in low-fat yogurt.

Another limitation is the amount of pectin that can be added to the milk at the beginning of the process. If $>0.2\%$ pectin is used, interactions with milk proteins will result in destabilization of the milk. This is caused by the formation of a pectin-casein precipitate and further processing of the batch will fail.

After fermentation, the yogurts will settle and this will increase their firmness and stability during transport. Pectin will increase the firmness of stirred yogurts but provide a smooth and creamy mouthfeel.

In milk desserts the addition of low methylester pectin will show benefits to increase the firmness and transport stability of puddings. In these products, pectin can be used in combination with other hydrocolloids or starches. The creamy texture and mouthfeel is determined by starch. A low methylester pectin will yield a gelled structure, increasing elasticity of the dessert.

C. Bakery Products

The buying patterns of consumers have changed. The demand for freshly baked bread rolls for breakfast every day of the week expresses this pattern, with a simultaneous demand for convenience products such as frozen dough or part-baked semi-finished dough. Also, food service has an increased demand for convenience products in order to enhance customer service and offer a variety of products. In

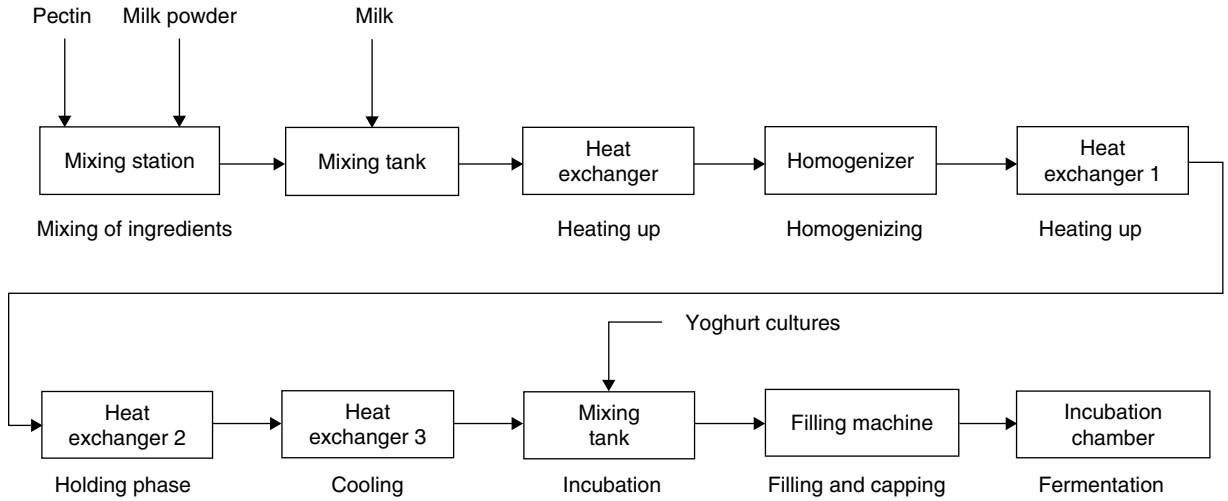

FIGURE 140.13 Manufacturing process of stabilized low fat yogurt.

part-baked products starch tends to undergo retrogradation. This is a process in which the swollen starch recrystallizes and the dough loses its water binding properties. This behavior will have the effect of a rather dry crumb structure. Adding pectin improves the quality of the finished products. In frozen products pectin influences the growth of ice crystals. Large ice crystals obstruct the smooth structure of the dough which may lead to an uneven baking behavior. Pectin also has a positive influence on the retrogradation behavior of starch and in general increases the dough stability. After baking, the finished product shows a thinner dry edge of the crumb which will remain for 24–48 hours. This is a significant extension of freshness, an important consumer preference. Pectin is added at 0.1–0.3% and evenly blended with the flour. After adding the other ingredients, the dough is kneaded and formed.

XXI. SUMMARY

The applications for pectins have changed over the last decades when they were used mainly as a gelling agent for jams and jellies. As a texturizer in fruit preparations, pectin is currently used to manufacture quality products with a high consumer preference. Pectins can affect the taste, enhancing freshness and fruitiness. This is one of the major reasons why they serve as appropriate ingredients to texturize fruit preparations and to gel dessert products or confectioneries. With this premise, pectins have many other applications as a natural texturizer to enhance the appearance and taste of processed food, e.g., low fat margarine or low fat mayonnaise. Other applications including the emulsifying properties of sugar beet pectin (5) and encapsulation of ingredients for food or drug (38) are in research. Another new possibility is in the manufacture of nutraceuticals and functional foods (105). For example, as a soluble dietary fiber with cholesterol reducing properties, pectin will play a major role in a balanced human diet (26). With the increasing demand of processed food, pectin can serve as a functional ingredient in numerous products traditionally not considered.

Department of Process Engineering, University College Cork

CONTENTS

I. INTRODUCTION

Mathematical modelling is a powerful tool in process design, assessment and optimisation. For a given situation it is very important to identify a mathematical model with an adequate functional form, but even the more complex model is of little use if the model parameters are not known with precision and accuracy. The estimation of kinetic parameters from experimental data involves the application of statistical methods in two phases: experimental design

and data analysis. Although much more emphasis is often put on the latter, one should realise that the general value of the information contained in the data is actually established when the experiments are designed and even a very careful data analysis is unable to recover information that is not present in the data (1, 2). As Lenz and Lund (3) stressed, much of the data currently found in the literature could have been obtained with considerable less effort by proper choice of experimental conditions. Furthermore, the lack of quality of the experimental data many times compromises the precision and accuracy of the parameters estimates. This is of utmost importance when microbiological or chemical model parameters are used in process design, assessment or optimisation (4).

This chapter addresses some basic concepts related to the study of kinetics of quality and safety indicators: (i) presentation of experimental design, particularly the concept of optimal designs aiming at improving parameter estimation when the mathematical model is known, (ii) discussion of data analysis strategies, particularly in relation to situations of interest in food research and (iii) presentation of the basic concepts of some fundamental mathematical models (primary models: zero-order, first-order, second-order, Weibull, Logistic, Gompertz and Michaelis-Menten models; secondary models: Arrhenius, Bigelow and Q_{10} models).

II. EXPERIMENTAL DESIGN

In mathematical modelling of experimental data, it is important both to assess whether the model is of the correct functional form and to accurately estimate the model parameters (5). This is clearly affected by the experimental design. The assessment of model adequacy requires the collection of experimental data throughout the whole process, and sampling times are selected on the basis of heuristic designs, such as equally spaced sampling times, equally spaced sampling concentration values and equally spaced logarithmic sampling times. The accurate and precise estimation of model parameters on the other hand usually requires a number of replicates of a limited number of sampling times (often as many as the model parameters) that must be carefully selected. This section discusses mostly experimental designs aiming at improving parameter estimates, assuming that the mathematical model is known, while the use of experimental design for product development and optimisation will be thoroughly discussed in chapter 143 (by Schrevens and Portier).

A. Selection of Sampling Times

Kinetic studies involve the analysis of the decay/growth of a given compound/property/microorganisms over time. Processes can seldom be measured continuously, thus leading to the use of discrete sampling times. The selection of these sampling times is very important as they greatly affect the ability of testing the quality of the fit of the model and parameter estimation.

1. The Concept of Optimal Design

If one is confident that a given non-linear model $E[yi] = f(\mathbf{x_i}; \theta)$ is appropriate for a certain experimental situation, then there is the question of designing the experiment, i.e., choosing the vector $\mathbf{x_i}$ of experimental points (in this case sampling times) so that the unknown parameters θ are estimated in an optimal fashion (6).

Traditionally, the motivation underlying the theory of optimal design is that experiments should be designed to achieve a level of statistical inference as precise as possible. Design optimality was first addressed by Smith (7), and early work in the subject was done by Wald (8), Hotelling (9), and Elfving (10). The major contributions to the area, however, were made by Kiefer (11–13), and Kiefer and Wolfowitz (14), who synthesised and greatly extended the previous work. Reviews on research work on optimal design have been made by St. John and Draper (15), Atkinson (16), and Steinberg and Hunter (17). More recently, Atkinson and Donev (18) wrote a book on optimum design of experiments.

In practice, the application of optimal design theory requires a criterion for comparing experiments and an algorithm for optimising the criterion over the range of possible experimental designs. The classical criteria are derived from linear modelling theory, which assumes that the experimental data can be represented by the equation:

$$Y_i = \mathbf{f(x_i)^T}\,\beta + \varepsilon_i \qquad (141.1)$$

where Y_i is the measured response from the ith experimental run, $\mathbf{x_i}$ is a vector of predictor variables for the ith run (in this case sampling times), $\mathbf{f}$ is a vector of p functions that model how the response depends on $\mathbf{x_i}$, $\boldsymbol{\beta}$ is a vector of p unknown parameters, and ε_i is the experimental error for the ith run, with independent errors and constancy of the error variance.

The variance of the parameter estimate is a natural indicator of the quality of statistical inference with respect to a single parameter. If the errors are uncorrelated and have a constant variance σ^2, the variance-covariance matrix of the least square estimator, $\hat{\boldsymbol{\beta}}$, is (16):

$$\mathrm{var}\{\hat{\beta}\} = \sigma^2(\mathbf{X^T X})^{-1} \qquad (141.2)$$

where $\mathbf{X}$ is the n*p matrix whose ith row is $\mathbf{f(xi)^T}$. The quality of inference may also be assessed in terms of the variance of the estimated response at $\mathbf{x}$, which, from Equation 141.1, is given by:

$$d(\mathbf{x}) = \sigma^2\mathbf{f(x)^T}(\mathbf{X^T X})^{-1}\,\mathbf{f(x)} \qquad (141.3)$$

TABLE 141.1
Most Common Optimality Criteria for the Design of Experiments Under Linear Conditions (According to Steinberg and Hunter (17))

Optimality Criterion	Description	Objective
D-Optimality	A design is said to be *D*-optimal if it minimises $\det(\mathbf{X^TX})^{-1}$, where det denotes determinant.	Minimise the generalised variance of the parameter estimates.
A-Optimality	A design is said to be *A*-optimal if it minimises $\mathrm{tr}(\mathbf{X^TX})^{-1}$, where tr denotes trace.	Minimise the average of the variances of the parameter estimates.
E-Optimality	A design is said to be *E*-optimal if it minimises the maximum eigenvalue of $(\mathbf{X^TX})^{-1}$.	Minimise the variance of the least well-estimated contrast.
G-Optimality	A design is said to be *G*-optimal if it minimises $\max d(\mathbf{x})$, where the maximum is taken over all possible vectors **x** of predictor variables.	Minimise the variance of the predicted response.
I_λ-Optimality	A design is said to be I_λ-optimal if it minimises $\int \mathbf{d(x)}\lambda\,(d\mathbf{x})$, where λ is a probability measure on the space of predictor variables.	Minimise the average integrated variance of the predicted response.

Both Equations 141.2 and 141.3 depend on the experimental design only, trough the full rank $p \times p$ matrix $(\mathbf{X^TX})^{-1}$, and suggest that a good experimental design will be the one that makes this matrix small in some sense. Since there is no unique size ordering of the $p \times p$ matrices, various real-valued functionals have been suggested as measures of "smallness" (see Table 141.1).

The criteria referred in Table 141.1 have been widely applied to the design of experiments for studying systems that follow linear and polynomial models. From those, the most used one is the *D*-Optimality criterion (18). Recently, De Aguiar *et al.* (19) presented a tutorial on *D*-optimal designs, which clearly illustrates the use of this technique.

2. The *D*-Optimal Design

The *D*-optimal design was first proposed by Box and Lucas (20) as an optimum design criterion for non-linear models, based on establishing the sampling conditions (in this case sampling times) that lead to a minimum confidence region, for a standard situation of a number of observations (n) equal to the number of parameters (p). In their pioneering paper on experimental design for non-linear models, Box and Lucas (20) showed how the *D*-Optimality criterion could also be applied to non-linear models, by introducing a linear approximation.

For any choice of the design variable (i.e., the independent variable, t) the size of the parameters joint confidence region is proportional to the Jacobian $|(F^TF)|^{-½}$ of the derivative matrix F (where $F \equiv [f_{i,j}]$, with $f_{i,j} = \partial\eta_i/\partial\theta_j$ evaluated at $t = t_i$, with i ranging from 1 to n; η represents the system response and θ a kinetic parameter). Thus a logical choice of the design criterion is to choose sampling points so that the size of this joint confidence region is minimised, that is, the determinant $D \equiv |F^TF|$ should be maximised.

The main goal of Box and Lucas (20) algorithm is to design a series of n experiments where the levels of the different conditions at which observations are taken (in this case sampling times) are selected in view of optimum parameter precision. Generally some restrictions must be applied, for instance, negative values of time have no physical meaning.

Hill (21) described a non-linear regression model $\eta(\theta,\mathbf{x})$ as being non-linear with a subset of non-linear parameters μ. He showed that the *D*-optimal design for estimating θ depends only on μ. This finding was later confirmed by Khuri (22).

It was also found that, for several chemical reactions involving non-linear models, the optimal design for n experiments (with $n > p$) consists of n/p replications of each of the optimal sets of levels (in this case sampling times) for the case $n = p$ (23–25). This has certainly simplified the evaluation of optimal designs. According to Box and Lucas (20), in the case where $n = p$, the *D*-optimal design can be simplified from the maximisation of $D \equiv |F^TF|$ to the maximisation of $\Delta \equiv \mathrm{mod}(|F|)$ (Δ denotes the modulus of the determinant of the matrix F).

An important drawback of this approach, for a non-linear response function, is that the efficiency of any particular design depends on the initial estimates of the parameters (20, 23, 26). If the estimates upon which the design is based are poor, the design may be inefficient, with the robustness of the criterion to poor estimates depending upon the particular model being studied. The application of the *D*-optimal design may seem strange at first sight, as in order to use the criterion one must initially have estimates of the parameters; after all, it is the purpose of the experiment to obtain such estimates. Actually, this paradox is also common to empirical designs, as when designing any experiment the experimenter is relying either on his/her previous knowledge or on his/her intuition. The efficiency of any design is therefore also dependent on the "guesses" of the experimenter. In the limit, if nothing is known about the experimental situation, then, strictly speaking, no experiment can be planned (27).

Because a good choice of design depends on the true values of the parameters, the idea of sequential design is a natural one. Ford *et al.* (26) have made the distinction between two sequential designs: batch-sequential and

fully-sequential. In batch-sequential design, the total of n observations are divided into b batches, in the ith batch, a set of n_i (the batch size) observations are taken. The sampling values for the (i + 1)th batch are chosen based on the analysis of the first i batches. In fully-sequential design, the batch sizes are all unity, except possibly for an initial larger batch. Ford *et al.* (26) emphasise that sequential designs can pay off, particularly if the initial estimate of the parameters is poor, but that a batch-sequential design with only a few batches is likely to be sufficient.

The non-linear *D*-Optimality criterion was first applied to a first order growth/decay model with Arrhenius temperature dependency at isothermal conditions, the Mitscherlich equation and to a system of two consecutive first-order reactions (20). These models have been further used to illustrate the application of *D*-optimal design to non-linear models (2, 6, 18).

More recently, the criterion was applied to kinetic studies of enzyme-catalysed reactions (28), to the Bigelow model in thermal processing studies (29), to diffusion processes described by Ficks's 2nd law model (30, 31) and to calibrate chemical and enzymic time-temperature integrators (32). An applied example and a more detailed reference of recent applications may be seen in Chapter 144.

3. Heuristic Designs

In practice, scientists tend to use alternative experimental plans that are easier to implement than *D*-optimal (DO) design, such as equally spaced sampling times (ET), equally spaced sampling concentration values (EC) or equally spaced logarithmic sampling times (ELN).

a. ET design

Sampling times are defined in such a way that they are equidistant in the time scale. This plan does not depend on initial estimates of the parameters, and the same measurement-time plan can be used for different levels of a given factor (e.g., at different temperature values). One should be cautious, however, in using this kind of plan because it ignores the functional form of the model and any previous knowledge of the process. In addition, it is necessary to define the period the experiment will cover. If the experimenter does not have a preliminary idea on the process rate, data can be obtained for small extensions of the process only or, quite on the contrary, there may be a lack of information on the early stages of the process, thus compromising the results.

b. EC design

The idea behind this design is to choose the sampling times so that the expected amount of observed degradation/growth between two consecutive times is constant. The EC design depends on: (i) the period defined for following the process, (ii) the parameter estimates and (iii) the "guessed" model (the plan can be very sensitive to differences between the "guessed" and the "true" model). In contrast to the DO design, the EC design has the following advantages: (i) it is easier to compute, (ii) it is not sensitive to small changes in the initial estimates (33) and (iii) when $n > p$, which is usually the case, the plan allows for testing the quality of the fit of the model and allows for testing models other than the "guessed" one.

c. ELN design

The sampling times are defined in such a way that they are equidistant in the log-time scale. This implies that samplings are more frequent at short times that at long times. The rationale for this is that the process rate often decreases with time. Thus, it makes sense to get more observations early when the degradation/growth rate is faster (33). This design shares most of the advantages and disadvantages of the ET design.

B. Selection of Experimental Conditions

Usually, experiments aim at studying the effect of time on the evolution of a certain decaying/growing quality/safety factor, "C," and are performed in a medium with constant characteristics (temperature, pH, water content, etc.). However, it is often important to assess the effect of the experimental conditions on the process kinetics. In food research, temperature is probably the experimental condition most tested. Thus, this section focus on the analysis of temperature effects, although most of the discussion may be generalised to other experimental factors, provided adequate functional relationships between the model parameters and the experimental factor of interest are used.

Methods for estimation of kinetic parameters may be broadly divided into constant and varying-conditions methods, in the case of temperature, isothermal and non-isothermal methods.

The isothermal analysis of kinetic data involves a considerable amount of experimental work at constant temperatures under a specific range of interest, resulting in an expensive and time-consuming procedure. An additional problem may arise if the parameters estimate correspond to a biased solution, that is, although yielding a good fit to the experiments performed are actually quite different from the true values. In this situation, when they are used for predicting processes under non-isothermal conditions, they may lead to significant deviations (34). However, isothermal methods are necessary for assessing the dependency of the kinetic parameters on temperature.

Non-isothermal methods, on the other hand, are based on a single experience in which temperature and the factors under study are recorded as function of time. Thus, kinetic parameters are evaluated from a single test covering the desired temperature range. These methods have significant advantages: minimisation of experimental

requirements, overcoming thermal lag problems and providing a dynamic situation closer to the reality of most thermal processes. Of course, they require the previous knowledge of the functional relationship between the kinetic parameters and temperature.

Isothermal methods are the classical procedure for estimation of kinetic parameters. Despite the advances in data analysis, most kinetic studies in food and pharmaceutical science/engineering still result from isothermal experiments. Thus, techniques for kinetic parameters evaluation are widely and well documented (35).

In the classical isothermal method, rate constants are estimated by fitting the kinetic model to the data sets gathered at different constant temperatures. A model is then identified to describe the dependence of these constants on temperature and its parameters are estimated. The dependence of the rate constants on temperature is usually described by an Arrhenius-type equation. Other models describing the temperature effect are also discussed in the literature (36) and will be further presented.

In terms of defining the experimental conditions, usually a range of temperatures is defined and experiments are taken at temperatures equidistant within this range, with the number of selected temperatures varying from 3 to 6 (see Table 141.2). The concept of the *D*-optimal design may however be also applied to select the temperatures that lead to maximum parameter precision, once the model that relates the kinetic parameters with temperature is known. Box and Lucas (20), suggested for the first-order Arrhenius model, that two experiments should be performed, one at each of the extreme temperature values of the assumed temperature range. Furthermore, at each temperature samples should be taken at a time such that the fractional conversion of the factor under study is equal to e^{-1} (equivalent to a degradation of 36.8% of the initial amount).

At each of the chosen temperatures, the conversion of the decaying/growing factor should be carefully followed. Even when a linear plot is obtained, conclusions must be drawn cautiously from the data, especially if the data points correspond to no more than 10–20% conversion, because mathematical functions are roughly linear over a sufficiently small range of variables (34). According to Arabshahi and Lund (53) reactions should be followed, where possible, through at least 4–5 half-lives. If the method of analysis is not sufficient to measure response values as low as this, the longest heating times possible should be used (3). According to Hill and Grieger-Block (54), one should perform at least experimental runs in which data are taken at 40%, 50% or higher conversions. For example, with regard to nutrient loss, the error in the rate constant, if one goes only to 30% loss, will be greater than ±25% (55). However, for up to 50% loss, the error in the rate constant is less than ±5% (56).

C. Testing Experimental Designs — "Pseudo-Experimental" Data Generation

Parameter estimates greatly depend on the model, on the regression scheme and/or on the experimental design. The first two effects are extensively reported in literature (5, 35, 52, 57, 58).

The comparison of different regression schemes and of different experimental plans requires a great number of experiments and the analysis of the accuracy and precision of the estimated parameters can only be made if the "true"

TABLE 141.2
Typical Temperature Levels Used in Thermal Kinetic Studies Under Isothermal Conditions

System	Temp. Range [°C]	Temp. Increments [°C]	Number of Temp. Levels	Reference
Inactivation of horseradish peroxidase	60–94	4–10	5	(37)
… at different ionic strengths	70–95	5	3–5	(38)
… at different water contents	125–150	5	4	(39)
… at different acid solutions	60–90	5–10	3	(32)
… at different alkaline solutions	40–95	2.5–10	3–4	(32)
Inactivation of α-amylase from *B. amyloliquefaciens*	135–150	5	4–5	(40)
Inactivation of α-amylase from *B. licheniformes*	96–108	4	4	(41)
Inactivation of *B. stearothermophilus*	111–125	2	5	(42)
	110–130	3–5	6	(43)
Inactivation of *C. sporogenes* PA3679	121–140	4–5	5	(44)
	110–121	3–5	4	(45)
Inactivation of *S. uvarum*	35–52	1.5–5	6	(46)
Formation of galactose in milk	90–150	10	6	(47)
Formation of galactose and tagatose in milk	115–135	5	4	(48)
Degradation of thiamin	25–55	5–10	4	(49)
Degradation of anthocyanins	50–80	10	4	(50)
Colour change in pea puree	110–125	5	4	(51)
Quality changes in green peas and white beans	100–122	6–10	4	(52)

TABLE 141.3
Use of Computer Generated Data Sets

Regression Model	Error Structure	Objective	Reference
Isothermal first-order model with Arrhenius temperature dependency	Variance proportional to the response function X_i and $X_i \sim N(X_i, (e \times X_i)^2)$, with $e = 0.08$	Study the influence of three least squares regression methods on the estimation of the Arrhenius model parameters	(5)
Non-isothermal first-order model with linearly increasing temperature profile	Variance proportional to the response function X_i and $X_i \sim N(X_i, (e \times X_i)^2)$, with $e = 0.04$ and 0.008	Study the influence of different integration methods and of two different regression procedures on the accuracy of the parameters	(35)
Fick's 2nd law model with diffusion constant showing a Arrhenius temperature dependency and linearly increasing temperature profile, applied to mass diffusion in spheres	Constant variance and two normally distributed error sets with a standard deviation of 0.05 and 0.06, respectively	Study the influence of the experimental design and of the temperature profile on the estimation of the model parameters	(30) (62)
Fick's 2nd law model considering both internal and external resistance to mass transfer in cubes	Constant variance and error sets drawn from a population of errors, ε, with $\varepsilon \sim N(0, 0.05^2)$	Study the influence of the experimental design and the Biot number on the estimation of the model parameters	(31)
First-order growth model	Constant variance and error sets drawn from a population of errors, ε, with $\varepsilon \sim N(0, 0.05^2)$	Study the influence of the experimental design on the size of the asymptotic joint confidence interval of the model parameters	(6)

values are known. An alternative is to generate data sets by computer simulation (59). Data generation was first applied with the Monte Carlo method. The designation Monte Carlo was first used in World War II in relation to the simulation of stochastic atomic collision processes (60). Since then, it has been widely used to characterise the statistical distribution of a response that is dependent on a number of factors with well known statistical distributions (61). Data generation to compare regression techniques was first used in food research by Haralampu *et al*. (5). Data sets were generated with the following assumptions: (i) data follow a given regression model and (ii) the error structure is known. Since then, similar works have been reported in the literature (see Table 141.3). The use of simulated data eliminates biases in the parameter estimates due to faulty assumptions in terms of the data error structure. Some authors assume a proportional variance, but care should be taken with this approach, as it demands for variable transformation or weighted least-squares, to avoid heteroscedasticity (63). Care should also be taken in the choice of the random number generator.

According to Law and Kelton (64) a "good" computer generator should have the following properties: (i) the generated values should follow a uniform distribution without any auto-correlation, (ii) it should be fast without large memory needs, (iii) it should possess the capability of regenerating the same pseudo-random sequence at least for two times and (iv) it should have a sufficiently long generation cycle (high number of possible outcomes).

Varga (61) presented a comprehensive review on random number generators and developed a computer program in FORTRAN 77 that fulfils the above described properties. This program uses a linear congruential random number generator that generates, from a uniform distribution, random variates following a normal distribution, using the inverse transform method (64).

The computer simulation is divided in three steps:

- An exact set of data is generated according to a certain model using some previously chosen parameter values (these will be considered the "true values") and following a particular sampling plan.
- Using the random number generator, a set of independent and identically distributed (I.I.D.) errors following a normal distribution with a given constant variance is obtained.
- A set of simulated "pseudo-experimental" data is then generated by scattering the exact data with the random normally distributed proportional errors.

An example of simulated "pseudo-experimental" data for the Bigelow model is shown in Figure 141.1.

III. DATA ANALYSIS

When using a given model for predictive purposes, errors may occur because of several reasons: (i) the kinetic model may not have the correct functional form, (ii) it may not consider all the factors that influence the process or (iii) the model parameters may have not be correctly estimated. Data analysis techniques are therefore most important to ensure that the quality of the fit of the model to the data may be truly assessed and that the model parameters are precisely and accurately estimated.

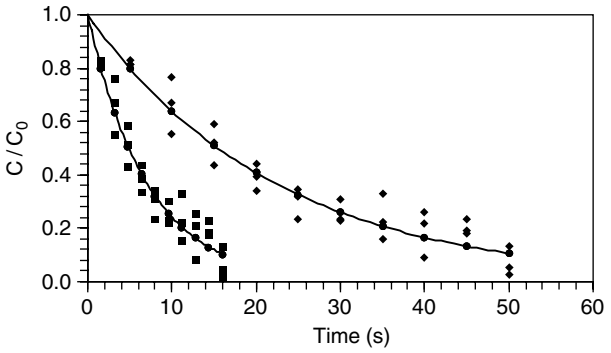

FIGURE 141.1 Computer generated "pseudo-experimental" data for the Bigelow model (Equation 141.19) with D_{ref} = 0.21 min, z = 10°C and T_{ref} = 121.1°C (From Ref. 51). The points show the "pseudo-experimental" data and the lines represent the exact model data. An equally spaced sampling times plan was used and normally distributed random errors, obtained from a population with zero mean and 0.05 standard deviation ("experimental error" = 5%) were added to the exact model data. (♦) T = 115°C; (•) T = 120°C.

A. Basic Concepts

1. Fitting Models to Experimental Data

Fitting procedures are not much different for models with different degrees of complexity, e.g., a simple first-order model or a very complicated reaction network, only the mathematics are more intricate (4). According to Seber and Wild (6), there are different estimation methods, which can be divided in the following groups: least squares estimation, maximum-likelihood estimation, quasi-likelihood estimation, LAM estimation, L1-norm estimation, robust estimation and Bayesian estimation. Least-squares fitting is the most common procedure in food research. This method consists basically on searching the parameters values that minimise the sum of squares of residuals between experimental and predicted values (SSR) (also called the norm, or objective function):

$$SSR = \sum_{i=1}^{n} [y_i - f(x_i, \theta)]^2 \qquad (141.4)$$

where y_i are the experimental data (e.g., reactant concentrations), $f(x_i, \theta)$ is the model function at the experimental design points x_i (x_i is, for instance, time t_i, temperature T_i, or a vector of both, and the model function is, for instance, the first-order model) and θ the parameter(s) (e.g., the rate constant at a given temperature and the activation energy).

At this point, it would be useful to clearly distinguish between linear and non-linear models. A linear model is not necessarily represented by a straight line. A model is linear (in the parameters) if the first derivative(s) of the model in order to the parameter(s) is (are) independent of the parameter(s), and therefore higher order derivatives are equal to zero; in a non-linear model, at least one of the derivatives of the model function with respect to the parameters depends on at least one of the parameters. A model with parameters a, b and c, with the form:

$$y = ax + bx^2 + cx^3 \qquad (141.5)$$

is a linear model (although not linear in x), while a model with the form:

$$y = \frac{ax}{b + x} \qquad (141.6)$$

is non-linear in the parameter b. In general, and in particular in food research, most of the kinetic models are non-linear in relation to the parameters (examples are presented in Section IV).

The linear least-squares method, which is a particular case of the least squares method, has the following advantages: (i) the values of the parameters follow directly from the regression procedure, (ii) the confidence intervals are exactly defined and (iii) there is no need to provide initial "guessed" values of the parameters. Conversely, when the model is non-linear in the parameters, there are no explicit analytical solutions for the parameters or for the confidence intervals, and a solution must be found by linear approximation. This solution is found iteratively (following a specific numerical algorithm — e.g., Gauss-Newton, Levenberg-Marquardt, Quasi-Newton approximation), starting from initial values supplied by the analyst or estimated by a computer program. Resulting confidence intervals for parameters are only approximate. Moreover, the objective function may have local minimum values and the fitting procedure may converge to one of these local minima, rather than to the absolute minimum value. This can be overcome by searching with different starting values for the parameters. If the same parameter values are found with different initial values, a global minimum has likely been found. Good starting values also allow any iterative technique to converge to a solution much faster.

Since linear least squares are easier to solve than non-linear least squares, frequently data is transformed in such a way that linear regression can be applied (e.g., a first-order model can be linearised simply by taking the logarithms of the data). However, this may violate some assumptions required for linear regression, resulting in biased parameter estimates.

Least-squares fitting is very generally used but it is only appropriate when the following assumptions are fulfilled (2, 4):

1. The model (expectation) function is correct;
2. The response is the sum of the model function and a disturbance (the experimental errors);
3. The disturbance is independent of the model function;

4. The experimental errors are normally distributed;
5. The average of the experimental errors is zero;
6. The experimental errors have constancy of variance;
7. The experimental errors are independently distributed.

Because one cannot know *a priori* whether the different assumptions are valid, an iterative approach should be used, as described in Box *et al.* (65): (i) a plausible statistical model for the data is assumed, (ii) the data is analysed on the basis of this model and then (iii) diagnostic tools, such as plots of residuals, are applied to evaluate the assumptions. If the diagnostic indicates failure of assumptions in either the deterministic or the stochastic components of the model, the model must be modified and the procedure repeated from (i) to (iii).

The statistical assumptions above listed encompass different aspects of the regression model. It is also important to recognise that the design of the experiment and the method of data collection can affect the chances of assumptions being valid in a particular experiment (2, 6). There are some important points that should be considered when assessing these assumptions.

a. *The model (expectation) function is correct*

Ensuring the validity of this assumption is, to some extent, the goal of all science. Researchers aim at building up a model able to predict the natural phenomena under study. However, models should be treated, in general, only as a reflection of the reality, as the underlying physical or chemical mechanisms are so complex that the researcher does not have a complete view of the process. A given model may be more appropriate than another to fit a given set of experimental data, but it is possible that neither of them really corresponds to the underlying mechanisms of the process under study. Nevertheless, it is very important that the expectation function includes all the important predictor variables in precisely the correct form, and that it does not include any unimportant predictor variable.

An important aspect that should be discussed in relation to the model is the functional form used for fitting the data. In kinetic parameter estimation, it is quite common that the models are fitted to experimental data in the form of relative concentrations. According to Arabshahi and Lund (53) this is a common mistreatment of kinetic data, as the initial concentration value is also uncertain, as it is measured experimentally. This may be overcome by increasing the number of replicates in the measurement of the initial concentration, so that its experimental error is minimised. Alternatively, the initial concentration may be considered as an additional model parameter. Significant differences between the estimate and the experimentally determined value may indicate a problem with the model specification.

b. *The response ('the y-value') is the sum of the model function and a disturbance (the experimental errors, ε_i)*

$$y_i = f(x_i, \theta) + \varepsilon_i \qquad (141.7)$$

In this case, the probability distribution of y can be estimated from that of the experimental errors. The requirement is thus that residuals are a measure of random uncertainties in data (63). The lack of additivity of the disturbance will manifest itself as a non-constant variance in the diagnostic plots and the corrective action should be either to use weighted least-squares or to use a transformation of the response (2).

c. *The disturbance is independent of the model function*

This implies that the independent variables have no error; only dependent variables contain experimental error. This is seldom true, but may be accepted as such if the errors in x are much smaller than those in y. In most kinetic studies, the independent variable is time, temperature and possibly initial concentrations. It should be possible to control these variables with good precision (4).

d. *The experimental errors are normally distributed*

This assumption is usually fulfilled because the actual experimental error is composed by many small errors. According to the Central Limit Theorem, the resulting error is normally distributed, even if the contributing errors themselves are not (65). The assumption of normally distributed errors can and should be checked by examining the residuals. Care should be taken when transformations of variables are used. The exponential model serves as a good illustration. The model in the natural (untransformed) variables produces an additive error and the transformed variables from the linearised model present a multiplicative error. The only transformations that do not alter noise distribution are addition/subtraction of or multiplication by a constant (66). Incidentally, a transformation may change a non-Gaussian distribution into a Gaussian one, which is actually desirable. For instance, if the error in a first-order model is multiplicative, the model demands for logarithmisation (67). The work reported by Machado *et al.* (68) clearly shows the benefits of such transformation, applied to heteroscedastic data fitted by the Weibull model.

e. *The average of the experimental errors is zero*

This means that systematic bias should be absent. Systematic errors should be removed by the researcher or incorporated in the model function. Frequent calibration, use of reference materials and participation in ring tests are ways to detect systematic errors (4).

f. The experimental errors have constancy of variance

This assumption, when not valid may be simply overcome, because unequal variances (heteroscedasticity) may be dealt with by using weighted least squares methods (63) or by applying transformations. A quite common case of heteroscedasticity is that of constant coefficient of variation (CV). This means that the standard deviation of y_i increases proportionally with y_i. Heteroscedastic error due to a constant CV can be transformed into homoscedastic by logarithmic transformation. However, care should be taken as logarithmic transformation may violate assumption 4. Assumption 6 implies that it is necessary to have an idea of the magnitude of experimental error and how it varies with the response. The only way to get some idea of the experimental error is to perform independent replications.

g. The experimental errors are independently distributed

This means that experimental errors in one measurement do not depend on those in another measurement, i.e., they are uncorrelated. If this assumption is not true, one can correct by considering the covariances of the experimental responses, but the covariances must be determined. Usually, the assumption of uncorrelated errors can be justified, but in kinetic studies correlation can sometimes occur. For example, a reading may be made on a reaction mixture when the measuring device was still influenced by the previous measurement (4). In that case, the error in a measurement may depend on that in the previous one (serial correlation).

2. Confidence Intervals of the Parameters

In data analysis it is also very important to have a realistic measure of the statistical confidence of the parameter estimates. A confidence interval should be specified, and the probability associated to it should be reported. According to Van Boekel (4) three statements must be reported: (a) the most probable value of the parameter, (b) the confidence interval of the parameter and (c) a probability statement about the confidence interval.

For non-linear models, estimation of confidence intervals is not straightforward, and they are not symmetric; the extent of asymmetry depends on the non-linearity of the function, on the number of data and on the experimental design (6). The problem lies in the fact that the parameters are estimated with regression algorithms based on linear approximations and, consequently, the parameter estimates and their confidence intervals are only as good as the linear approximation. Often the calculated confidence intervals are asymptotic and therefore they may underestimate the real confidence intervals (4).

When a model has more than one parameter, the confidence interval of each parameter does not provide full statistical information, because of the correlation that exists between the different parameters. In this case, it is necessary to analyse the joint confidence regions of the parameter estimates. Although joint confidence regions of parameter estimates are well described in statistical books, they are seldom reported in scientific publications. Actually, their use is very recent (69, 70). For linear-models, the joint confidence region, also called joint-confidence interval, may be calculated using the following expression (2, 6, 63, 65):

$$SSR_{x\%} = SSR_{min} * \left(1 + \frac{p}{n - p} * F_{((100-x)\%,p,n-p)}\right) \tag{141.8}$$

where $SSR_{x\%}$ is the sum of squares of residuals at x% confidence level, SSR_{min} is the sum of squares of residuals of the estimated solution, p is the number of parameters, n is the number of experimental data points and $F_{((100-x)\%,\,p,\,n-p)}$ is the value of the F distribution for p and $n - p$.

According to Haralampu *et al*. (5) the extremes of the 90% joint confidence ellipses correspond approximately to the ends of the 95% individual confidence intervals of the parameter estimates (the joint probability of two events at 95% probability is approximately 90%, i.e., $0.95^2 \approx 0.90$). This is illustrated in Figure 141.2, that relates to the fit of the Bigelow model to thermal inactivation of *Bacillus amyloliquefaciens* α-amylase data (71).

For linear models the region defined by Equation 141.8 corresponds to a contour of the SSR. This is not true for most non-linear models, Equation 141.8 providing only asymptotic results. In non-linear models the contours of SSR are often asymmetric about $\hat{\theta}$ and may be twisted, with the shape of p-dimensional bananas (18). The validity of using Equation 141.8 to calculate joint confidence regions for non-linear models may be assessed by analysing the maximum relative intrinsic curvature of the parameters and the maximum relative parameter-effects curvature. Equation 141.8 provides acceptable results when the maximum relative intrinsic curvature of the parameters and the maximum relative parameter-effects

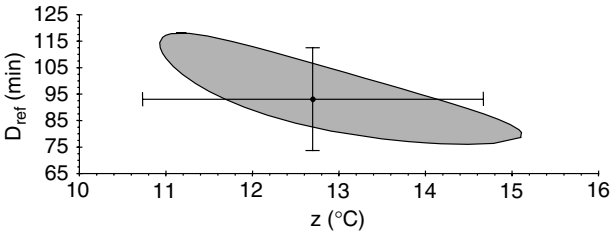

FIGURE 141.2 Asymptotic joint confidence region and individual confidence intervals of the kinetic parameters estimated by fitting the Bigelow model (Equation 141.19) to thermal inactivation of *Bacillus amyloliquefaciens* α-amylase data (From Ref. 71).

curvature are small compared to the confidence region relative curvature. In this situation the solution locus is approximately linear over the confidence region and the parameter co-ordinates projected onto the tangential plane are approximately parallel and uniformly spaced over the confidence region (2).

B. One-Step and Multi-Steps Methods

As earlier referred (Section II-B), when analysing the effect of the experimental conditions on the process kinetics, experiments are often performed at different levels of the factor under study (e.g., temperature). Each experiment allows for estimating the rate constant at a given level of the factor under study and an analysis of the estimates obtained for the different levels allows for identifying how the rate constant depends on that factor. It is therefore important not only to estimate the rate constants, but also the parameters of the model that relates the rate constants to the factor of interest. The estimation of these parameters may be accomplished by two different methods, usually referred to as individual (two-step) or global (one-step) methods. For the sake of simplicity the basic concepts underlying these two methods will be discussed considering temperature as the factor under study, but this discussion may be generalised for other factors.

In the two-steps methods, the rate constants are estimated by fitting the kinetic model to the data gathered at different constant temperatures, this being the first step. In the second step, a model is then identified to describe the dependence of these constants on temperature and its parameters are estimated by fitting this model to the rate constants estimated in the first step. The one-step method consists of combining the kinetic model with the model relating the rate constants to temperature in a single equation, which is then fitted to the whole set of data, directly estimating the parameters of the model that relates the rate constants to temperature. Two-steps (or multi-steps) regression has the disadvantage of applying regression to parameter estimates earlier obtained by regression, thus violating one of the assumptions behind least-squares fitting (assumption 3 in Section III-A-1 — the disturbance is independent of the model function). The two-steps methods also generally result in relatively large confidence intervals of the parameters estimates because of the small number of degrees of freedom (72). Haralampu *et al*. (5) and Cohen and Saguy (57) also showed that parameters estimated by the one-step method were more accurate and precise than those obtained by the two-steps method.

However, as earlier referred, individual fitting of the experiments is required to assess the quality of the fit of the model and to assess the dependence of the rate constants on temperature. Furthermore, this analysis yields estimates that may be used as initial values in the one-step regression procedure, thus accelerating its convergence.

IV. KINETIC MODELS

A. Zero-Order

In zero-order reactions the rate is independent of the concentration. For a degradation reaction:

$$-\frac{dC}{dt} = k \tag{141.9}$$

where C is the concentration, t the time and k the zero-order reaction rate constant, which by integration results in:

$$C = C^i - k \times t \tag{141.10}$$

where C^i and C are, respectively, concentrations at time zero and at any time t.

This may occur in two different situations: when intrinsically the reaction rate is independent of the concentration of reactants, and when the concentration of the reacting compound is so large that the overall reaction rate appears to be independent of its concentration. The second case seems to be the most common situation when this order reaction is observed in food systems (73).

B. First-Order

First-order reaction kinetics is considered by many authors to be an acceptable empirical model for describing chemical and microbiological changes in food processing and storage.

The mathematical expression for a first-order degradation reaction is as follows:

$$-\frac{dC}{dt} = k \times C \tag{141.11}$$

where k is the first-order reaction rate constant. By integration this equation becomes:

$$C = C^i \times e^{-k \times t} \tag{141.12}$$

Although a number of compounds follow this reaction order in a food product, most compounds in a model product will not follow true first-order reaction kinetics but rather, a pseudo-first-order reaction (73). For simplicity sake, pseudo-nth-order reactions are usually referred to as simply nth-order reactions.

C. Second-Order

There are two important types of second-order kinetics: type I, $A + A \rightarrow P$:

$$-\frac{dC_A}{dt} = k \times C_A^2 \tag{141.13}$$

and type II, $A + B \rightarrow P$

$$-\frac{dC_A}{dt} = k \times C_A \times C_B \tag{141.14}$$

where C_A and C_B are concentrations of the reactant species A and B at time t, and k the second-order reaction rate constant. For type I, the integrated expression yields:

$$C_A = \frac{1}{\frac{1}{C_A^i} + k \times t} \tag{141.15}$$

and for type II, it becomes:

$$C_A = C_B \frac{C_A^i}{C_B^i} \times e^{[-(C_A^i - C_B^i) \times k_2 \times t]} \tag{141.16}$$

where C_A^i and C_B^i, C_A and C_B are the concentrations of species A and B at time zero and time t, respectively.

It should be stressed that in the case of type II reactions if one of the components is present in excess the reaction may follow pseudo first-order kinetics with respect to the other component.

D. Dependence of Rate Constants on Temperature

When the effect of temperature is to be assessed, the so-called Arrhenius and Bigelow models are the most common. Both rely on first-order type kinetics.

1. The Bigelow Model

For more than 80 years, the model resulting from the empirical observations made by Bigelow (74) has been the basis for the design of thermal processes used in the canning industry for low acid foods (35). This model is also known as the thermal death time model. It is commonly accepted that at high temperatures and for relatively short times (i) the logarithm of the number of viable cells decreases linearly with time, the slope being the reciprocal of the decimal reduction time (D), and (ii) the logarithm of D decreases linearly with temperature, the reciprocal of the slope being named the z value. The D value at a reference temperature (D_{ref}) and the z value are the basis of the thermal death time method (TDT), which is the current standard in industrial practice for most sterilisation processes (35). Modelling of quality losses in thermally processed foods is also commonly based on a similar kinetic model (e.g., Shin and Bhowmik (51) have used this model to describe kinetics of colour change in pea puree).

The Bigelow model is written in terms of decimal logarithms and of a given temperature (T):

$$\eta_i = \frac{C_i}{C_0} = 10^{-\frac{t_i}{D_r}} \tag{141.17}$$

where η_i is the fractional concentration of colony forming microbial units, or of a quality factor, at time t_i, and D_T is the decimal reduction time at the experimental temperature, T.

$$D_T = D_{T_{ref}} 10^{-\frac{T - T_{ref}}{z}} \tag{141.18}$$

The model has two parameters: $D_{T_{ref}}$ and z, with $D_{T_{ref}}$ being the value of the decimal reduction time at a reference temperature, T_{ref}, that will be further referred to as D_{ref}, and z the thermal death time parameter.

$$\eta_i = 10^{\left[-\frac{t_i}{D_{ref} 10^{\frac{T_{ref} - T}{z}}}\right]} \tag{141.19}$$

2. The Arrhenius Model

For the Arrhenius model natural logarithms are used. Starting with the basic assumption of a first-order model:

$$\frac{dC}{dt} = -k_T C \tag{141.20}$$

Integration leads to:

$$\eta_i = \frac{C_i}{C_0} = e^{-k_T t_i} \tag{141.21}$$

and applying the Arrhenius relationship:

$$k_T = k_0 e^{-\frac{Ea}{RT}} \tag{141.22}$$

This model considers an activation energy (Ea), and an exponential relation of the rate constant (k_0) with the reciprocal of the absolute temperature (K^{-1}) instead of the temperature (°C) used in the Bigelow model. However, the major difference is that this form of the Arrhenius model does not use a finite reference temperature. Hence, k_0 is the reaction rate constant at an infinite temperature, becoming a value with a very large order of magnitude, quite apart from the rate constant values in the range of interest. Some researchers (particularly in chemical reaction engineering and biocatalysis) say that to consider an arbitrary reference temperature is subjective and therefore should be avoided. Besides the generation of values outside and far from the range of interest (usually a narrow temperature range), if an infinite reference temperature is used, the model parameters (k_0 and Ea) will have a very high correlation factor (expressing colinearity), which greatly hinders the regression convergence. This was recognised by Nelson (75), who suggested the use of dummy variables:

$$\delta = (\ln k_0) - \frac{Ea}{R}\beta \tag{141.23}$$

$$\beta = \frac{1}{m} \sum_{j=1}^{m} \frac{1}{T_j} \tag{141.24}$$

where m is the number of temperatures used in the experiments.

Although this was not recognised by this author, this transformation corresponds to using a finite reference temperature, equal to the harmonic average of the temperatures used in the experiments:

$$k_T = k_{ref}\, e^{-\frac{Ea}{R}\left(\frac{1}{T}-\frac{1}{T_{ref}}\right)} \qquad (141.25)$$

where $T_{ref} = \beta$ and $k_{ref} = e^{\delta}$.

Joint variable-parameter transformations are indeed very common to improve the estimation procedure (2). Frequently transformations aim at centering or scaling the data. The use of a reference temperature is simply the result of considering the model in terms of the reciprocal absolute temperature, rather than temperature, and centering the data on $1/T_{ref}$ (2). This has been used by some researchers (5, 53, 57), but seems not to have been picked up by many food researchers.

If the Arrhenius equation seems to be suitable for describing the temperature dependence, linearisation followed by linear regression for determining Ea and k_{ref} should not be automatic, because errors may not be distributed normally after transformation and the residuals weights are changed. Non-linear regression should be used instead. Also, if the dependence of the rate constants on temperature has been properly assessed, it is better to incorporate Equation 141.25 directly into the rate equations by substituting the right hand side of Equation 141.25 for the rate constant, rather than estimating each k at each temperature studied and subsequently determining Ea and k_{ref} via Equation 141.25 (4). This non-linear regression, often referred to as one-step methodology in opposition to the traditional 2-steps method, has shown not to introduce bias (5). Non-linear least square methods of analysis are thoroughly reviewed by Johnson and Frasier (76).

For the Arrhenius model the use of a reference temperature would yield:

$$\eta_i = e^{\left[-k_{ref}\, e^{\left(-\frac{Ea}{RT}\left(\frac{1}{T}-\frac{1}{T_{ref}}\right)\right)} t_i\right]} \qquad (141.26)$$

This allows for a straightforward relation between the Bigelow and the Arrhenius models:

$$k_{ref} = \frac{\ln(10)}{D_{ref}} \qquad (141.27)$$

$$Ea = \frac{R\, T\, T_{ref} \ln(10)}{z} \qquad (141.28)$$

Although Ea and z-values are assumed temperature independent, the two parameters are related to each other trough temperatures T and T_{ref}. Equation 141.28 implies that if Ea is constant over a temperature range, then z cannot be constant in that temperature range and vice versa. Lund (77) suggested that if T is substituted by $T_{ref} - z$, the two models provide similar results over small temperature ranges around T_{ref}. Ramaswamy *et al.* (78) demonstrated that the conversion of z to Ea or vice versa is strongly influenced by the chosen reference temperature and temperature range. According to Hendrickx *et al.* (79), this relationship should be used cautiously, only to estimate the z-value order of magnitude from a known activation energy or vice versa, when raw kinetic data are no longer available.

Several researchers that have directly compared the two models, suggested that both fit experimental kinetic data well (40, 42, 43, 46, 80). Both the Arrhenius and the Bigelow models have merit and have been proven adequate to study degradation kinetics. In spite of the never-ending discussion about the relative merits of each model, both are empirical and the variability of most kinetic data does not allow distinguishing between the quality of the fit of the two models (81).

3. Q_{10} Model

In living systems such as microorganisms, animals and plants, enzymes catalyse most of the reactions. As enzyme activity is highly temperature sensitive, mathematical models have been used in both the food and pharmaceutical sciences to describe how much faster a reaction will proceed if the product is held at some high abuse temperature. If the temperature-accelerating factor is known, then extrapolation to lower temperatures, such as those found in distribution, could be used to predict true product shelf life in those conditions. In the study of food shelf life, this accelerating factor is sometimes called the Q_{10} factor and is defined as:

$$Q_{10} = \frac{\theta_{s(at\ T)}}{\theta_{s(at\ T+10)}} = \frac{k_{T+10}}{k_T} \qquad (141.29)$$

where T is the temperature (°C), and θ_s is the shelf life at the indicated temperatures (82). For any temperature difference Δ, different from 10°C, this becomes:

$$(Q_{10})^{\Delta/10} = \frac{\theta_{s(T_1)}}{\theta_{s(T_2)}} \qquad (141.30)$$

Thus, for example, if the Q_{10} is 3 and the published shelf life θ_s was 6 month at 35°C, the shelf life at 20°C would be:

$$\theta_{20} = \theta_{35} * (Q_{10})^{\Delta/10} = 6 * (3)^{15/10} = 31.2\ months \qquad (141.31)$$

In many cases, the Q_{10} is not given, so one must establish the mathematical relationship (83), which is done by means of kinetic modelling.

E. The Weibull Model

The Weibull distribution is one of many probability distribution functions used to describe the behaviour of systems or

events that have some degree of variability. It was named after the Swedish physicist, Waloddi Weibull, who first used it to represent the distribution of the breaking strength of materials (84, 85) and later for a variety of other applications (86). The close agreement that Weibull demonstrated between observed and predicted data was quite impressive (87).

The probability density function of the Weibull distribution may be described as (67):

$$f(t) = \begin{cases} \frac{\beta}{\alpha}\left(\frac{t}{\alpha}\right)^{\beta-1} e^{-\left(\frac{t}{\alpha}\right)^{\beta}}, & t > 0 \\ 0, \text{ elsewhere} \end{cases} \quad (141.32)$$

with $\alpha > 0$ and $\beta > 0$. The corresponding cumulative distribution is:

$$F(t) = \int_0^t f(t)\,dt = 1 - e^{-\left(\frac{t}{\alpha}\right)^{\beta}} \quad (141.33)$$

This model has an interesting potential for describing ecological, microbial, enzymatic and chemical degradation kinetics (failure of the system after a given time subjected to stress conditions), reliability and life testing (time to failure or life length of a component), considering the scale parameter (α) as a time constant (the reciprocal of the rate constant) and the shape parameter (β) as a behaviour index. The model reduces to a first order decay/growth kinetics for $\beta = 1$ (see Figure 141.3a). As discussed by Hahn and Shapiro (88), Nelson (89), Gacula and Kubala (90) and Johnson *et al.* (87), the failure rate for the Weibull model is an increasing function of time for $\beta > 1$ and a decreasing function for $\beta < 1$. When $\beta = 1$, the failure rate is constant. These authors also emphasise that α is a characteristic time to failure, as it corresponds to the $100 * (1 - 1/e) = 63.2$ percentile of the distribution, regardless of the value of β (see Figure 141.3b).

As a time parameter, α is temperature sensitive and $1/\alpha$ often follows an Arrhenius-type behaviour (91–93):

$$\frac{1}{\alpha_i} = \frac{1}{\alpha_{ref}} e^{\left[-\frac{Ea}{R}\left(\frac{1}{T_i} - \frac{1}{T_{ref}}\right)\right]} \quad (141.34)$$

The β parameter may be expected to be related to the kinetic pattern and thus to be temperature independent, at least within a limited range of temperature. This parameter gives the model a wide flexibility, making it a potential good model to describe different reaction kinetics. This has been verified in published works (92–94). Equations 141.33 and 141.34 may be combined to yield:

$$\eta_i = e^{\left\{-\left(\frac{t_i}{\alpha_{ref}} e^{\left[-\frac{Ea}{R}\left(\frac{1}{T_i} - \frac{1}{T_{ref}}\right)\right]}\right)^{\beta}\right\}}, \quad i = 1, 2, 3 \quad (141.35)$$

Therefore the kinetic parameters of the model are α_{ref}, Ea and β.

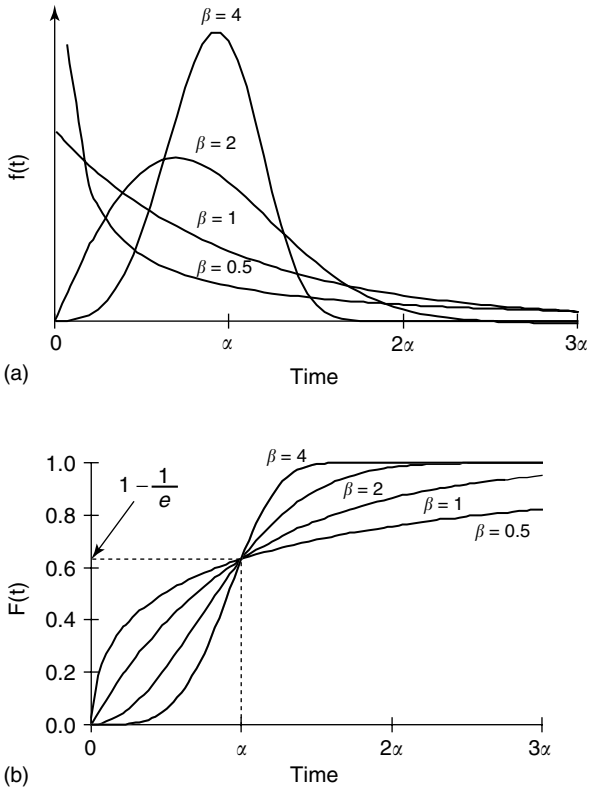

FIGURE 141.3 Effect of the shape parameter β on (a) the Weibull probability density function — f(t), (b) the Weibull distribution function — F(t).

The Weibull distribution was successfully applied to describe shelf-life failure (90, 95). Page (96) developed an equation to describe thin-layer drying of shelled corn, similar to the Weibull probabilistic model that was later used to model thin-layer drying of yellow corn (97, 98), of soybeans (99), of pigeon pea (91) and of adzuki beans (100). This model was also used to describe the drying kinetics of rough rice (101–103) and of Thompson seedless grapes (104). Chhinnan (94) evaluated four mathematical models, i.e., the exponential model, the diffusion model, an approximation of the diffusion model and the Page (Weibull) model, for describing thin-layer drying of in-shell pecans, recommending the Page (Weibull) equation for future modelling studies. Moreover, the Weibull distribution has been used to model failure of apple tissue under cyclic loading (105), grape pomace elutriation (106) and water uptake and soluble solids losses during rehydration of dried apple pieces (92). The Weibull model adequately described moisture uptake and soluble solids losses by breakfast cereals immersed in water (107) or milk (68), after unsuccessful attempts to use the Peleg (108), the diffusion and the first-order models (93). The Weibull model has also been used to describe microbial death kinetics under high-pressure conditions (109), enzyme inactivation under high pressure (110), isothermal heat-resistance of *Bacillus cereus* (111, 112), and shrinkage of potato during frying (113).

Van Boekel (114) made a systematic review of the use of the Weibull model to describe thermal inactivation of microbial vegetative cells (data published for different microorganisms). α and β were calculated from 55 sets of data and it was found that β = 1 in only two cases, which pinpoints the fact that the use of first-order kinetics to model microorganisms death should be the exception rather than the rule.

F. The Logistic Model

The Logistic model is another example of model used to represent growth rate that does not steadily decline, but increases to a maximum before declining to zero. This is shown in the growth curve by an S-shaped, or sigmoidal, pattern.

$$\frac{df}{dx} = \frac{k}{\alpha} f(\alpha - f) \qquad (141.36)$$

where $k > 0$ and $0 < f < \alpha$ (6).

Thus from Equation 141.36 the relative growth rate $f^{-1}df/dx$ decreases linearly in f until f approaches α. Equation 141.35 has a general solution, which can be written as

$$f(x) = \frac{\alpha}{1 + e^{-k(x-\gamma)}} \quad -\infty < x < \infty \quad (141.37)$$

the so-called logistic model (6).

Equation 141.36 is an empirical model derived by Verhulst in 1838 to describe growth in the size of a population or organ. This equation also describes the rate of consumption of a monomolecular chemical substance as it breaks down in an autocatalytic reaction.

Equation 141.37 has asymptotes $f = 0$ as $x \to -\infty$ and $f = \alpha$ as $x \to \infty$. These asymptotes are never actually attained, and that causes modelling difficulties as at time at which growth begins to be monitored $f > 0$. The maximum growth rate is $w_M = k\alpha/4$, and the growth rate is symmetrical about $x = \gamma$. As k acts as a scale parameter it influences the growth rate (6).

Probably the most common parameterisation is

$$f(x) = \frac{\alpha}{1 + \beta e^{-kx}} \quad -\infty < x < \infty \quad (141.38)$$

where $\beta = e^{k\gamma}$ in Equation 141.37.

Bartali *et al.* (115) used multiple logistic models to evaluate whether inadequate intake of selected nutrients could be predicted by nutrition-related difficulties of persons living in two towns of Tuscany (Italy). Jenkins *et al.* (116) described the growth of *Zygosaccharomyces bailii* in acidified products with log-logistic models for time to growth and probability of growth, which is useful for spoilage risk assessment.

G. The Gompertz Model

The Gompertz model is often used for population and animal growth in situations where growth is not symmetrical about the point of inflection. The growth rate is

$$\frac{df}{dx} = kf(\log\alpha - \log f) \ (k > 0, \alpha > 0) \ (141.39)$$

and the relative growth rate declines with log(size). From Equation 141.39,

$$f(x) = \alpha \times e^{\{-e^{[-k(x-\gamma)]}\}} \qquad (141.40)$$

The point of inflection for Equation 141.40 is at time $x = \gamma$ with $f = \alpha/e$, at which point the maximum growth rate, $w_M = k\alpha/e$, occurs (6). For the Gompertz curve log f is monomolecular. The Gompertz function has the property that any power of f is Gompertz. This means that several measures of size such as weight, surface area and length may all provide growth curves of the same shape.

Huang (117, 118) developed a new methodology to describe and classify accurately the bacterial growth as a process using *Clostridium perfringens* as a test organism. He used the Gompertz model to calculate the equivalent growth times under different temperatures and estimated the bacterial population under temperature fluctuations. The model was validated in ground beef maintained under fluctuating temperature conditions.

H. The Michaelis-Menten Model

The theory of enzyme-substrate complex formation, to describe enzyme kinetics was proposed by Michaelis and Menten (119). This is depicted in the following reaction scheme:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} E + P \qquad (141.41)$$

where E is the enzyme, S the substrate, ES the enzyme-substrate complex and P the product. The rate constants for the forward and reverse reactions are k_1, k_2 and k_{-1}, k_{-2}, respectively (120). Both reactions are reversible in general case.

A characteristic of enzyme-catalysed reactions in food is that when the substrate concentration is very small, the forward reaction to form ES is first-order in S, and at very large substrate concentration, this same reaction is zero-order in S as the reaction rate is only dependent on the concentration of enzyme.

Michaelis and Menten (119) applied the steady-state kinetic analysis to Equation 141.41 and derived the following equation to describe the velocity of an enzyme-catalysed reaction:

$$v = -\frac{dS}{dt} = \frac{dP}{dt} = \frac{V_{max}[S]}{K_m + [S]} \qquad (141.42)$$

where v is the velocity, V_{max} is the maximum velocity when the enzyme is saturated with substrate, K_m is the substrate concentration at which $v = 0.5V_{max}$ and $[S]$ is

the substrate concentration at any time t. In this analysis, k_{-2} is assumed to be zero. Most kinetic studies on enzymes are completed at a very small conversion ratio (<5%) in order to remove complications that can take place when substrate concentrations decrease or product concentration increases.

Determination of K_m and V_{max} may be obtained by linearising Equation 141.42, which is done taking the reciprocal of both sides of Equation 141.42:

$$\frac{1}{v} = \frac{1}{V_{\max}} + \frac{K_m}{V_{\max}} \times \frac{1}{[S]} \qquad (141.43)$$

A plot of $1/v$ versus $1/[S]$ results in a straight line with intercept $1/V_{max}$ and slope K_m/V_{max} (121), commonly known as the Lineweaver-Burk equation.

One mechanism of inactivating/controlling the activity of enzymes is the use of inhibitors, compounds that interact with the enzyme reducing its activity. Inhibitors can be reversible or irreversible. Reversible inhibitors may compete in three different ways (120):

a. **competitive** inhibition occurs when the inhibitor binds reversibly with enzyme competing with the substrate for active sites. Slope and y intercept values for the Lineweaver-Burk equation are $\left[1 + \frac{I_0}{K_i}\right]\frac{K_m}{V_{\max}}$ and $\frac{1}{V_{\max}}$, respectively, I_0 being the concentration of the inhibitor and K_i the inhibitor-enzyme complex dissociation constant.

b. **noncompetitive** inhibition occurs when the inhibitor does not compete with the substrate for binding the enzyme but rather both the inhibitor and the substrate can bind to the enzyme simultaneously. Slope and y intercept values for the Lineweaver-Burk equation are $\left[1 + \frac{I_0}{K_i}\right]\frac{K_m}{V_{\max}}$ and $\left[1 + \frac{I_0}{K_i}\right]\frac{1}{V_{\max}}$, respectively.

c. **uncompetitive** inhibition occurs when the inhibitor can bind to the enzyme-substrate or one or more of the intermediate complexes. Slope and y intercept values for the Lineweaver-Burk equation are $\frac{K_m}{V_{\max}}$ and $\left[1 + \frac{I_0}{K_i}\right]\frac{1}{V_{\max}}$, respectively.

A more complex reversible inhibition can occur when the inhibitor binds to the multi-subunit enzymes. Whitaker (122) presents an analysis of complex kinetics, which arise when this kind of inhibition takes place.

Irreversible inhibitors form covalent bonds with enzyme, enzyme-substrate or enzyme-product complexes. Kinetically, irreversible inhibitors can be treated through rate equations and not through Lineweaver-Burk or Michaelis-Menton equations. The effect of temperature on enzyme activity and inactivation is usually treated by the Arrhenius equation (Equation 141.22).

V. CONCLUSIONS

When dealing with kinetics of quality and safety indicators, many different models may be considered; it was the authors' options to present a few of the most representative ones.

This chapter intends to alert the less experienced researcher or student to some of the basic concepts to bear in mind when studying their particular food system, from the experimental design to the data collection and analyses.

The topics here presented will be further developed in subsequent chapters of this handbook.

CONTENTS

I. INTRODUCTION

Shelf life may be defined as the period of time during which the food product will remain safe, be certain to retain desired sensory, chemical physical (1) and microbiological characteristics, and comply with any label declaration of nutrition data, when stored under recommended conditions. The dependence of the kinetics of microbiologic growth/death or of nutrient loss on environmental factors varies from product to product and process to process and must, therefore, be established for each specific case to be evaluated. It is the responsibility of the food manufacturer (together with the retailer for their own label products) to determine shelf life of food.

For forecasting shelf life of a product it is imperative to select adequate shelf life indicators. Shelf life indicators are microorganisms or compounds that have a notorious influence on the product safety and on quality (nutritional value, appearance or flavour characteristics). Critical shelf life indicators are those that first reach the respective threshold levels and thus limit the product shelf life.

The food safety concept is linked with the food preservation by heat, eliminating and reducing to an acceptable level pathogen and spoilage microorganisms, respectively. But this concept cannot be extrapolated to minimally processed foods, as the preservation techniques (non-severe thermal treatments, i.e., up to 100°C) used in these methods

are not directly focused on the total inactivation of the microbial population present in the unprocessed material. Therefore the microbial safety of minimally processed food products, during their shelf life, depends on refrigeration that should prevent the growth and/or toxin production of microorganisms hazardous to the consumer health.

II. SHELF LIFE OF FOODS

There are different types of shelf life studies, in respect to the purpose they serve while the product is being developed:

- Initial shelf life studies (ISLS) are carried out once the concept of a new product has been agreed;
- Preliminary shelf life determinations (PSLD) are the first shelf life determination carried out to the whole product (including package);
- Confirmatory shelf life determinations (CSLD) are carried out at the end of the product development process;
- Routine shelf life determinations (RSLD) are conducted so that the shelf life of any existing product can be monitored and to check if it is still correct for different environmental conditions to which it can be subjected.

The exact test is often product-specific and is selected to measure the end-point of the shelf life. Because these tests are highly expensive (either in house or contracted tests) it is critical that companies use the most cost effective tests in their shelf life studies. Tests may involve one or a combination of sensorial, microbiological, chemical and physical determinations.

It should take in consideration scaling-up factors (any fluctuations that might occur in for a given product formulation), safety and quality aspects.

The final shelf life should be set to give a clear margin of safety, and particularly in the case of a high risk category product a date should be set based on data that relate to the "worst case" manufacturing and storage scenario.

A. Methods for Shelf Life Estimation

Shelf life estimation can be done by means of direct or indirect methods. Direct methods are usually used for products with short shelf life, as shelf life determination is based on monitoring quality factors, chemical and/or microbiological, in a situation that exactly replicates the real conditions of packaging, storage and distribution (2).

When the product shelf life is expected to be relatively long, it is possible that the product may be launched before any confirmatory shelf life determination can be completed. Because of this and economic aspects, it is highly desirable that faster methods for predicting shelf life are available. These indirect methods are generally based on the principles of accelerated shelf life determination. Accelerated tests are done exposing the food product to abusive storage conditions, i.e., high temperature, high oxygen content, or others (humidity, light, etc.) relevant to the deteriorative reaction mechanism involved (1). Accelerated tests in complex food systems present a problem because published kinetic data is scarce, contradictory or even unavailable. Therefore, accelerated tests must be developed in the face of many unknowns. In this respect, foods present more difficult problems than other chemical systems.

Accelerated tests have been used mostly for dried products. A number of reviews on accelerated tests may be found in the literature (3–8).

B. Accelerated Tests for Shelf Life Estimation

1. Accelerated Tests at Elevated Temperatures

Typically foods are subjected to storage at 37 and 51°C, and various correlations (usually based on the Arrhenius relation or the Q_{10} model) are used to extrapolate the results to the expected storage temperatures (6). When more accuracy is desired, several elevated storage temperatures (usually 5 to 6) are used and the Q_{10} value or activation energy is determined experimentally, based on the assumption that they are independent of temperature. However, this is often not the case, leading to erroneous extrapolation. Usually reaction rates are more sensitive to temperature in the range used in accelerated tests, thus implying that shelf life may be overestimated, which causes a major problem to food producers.

2. Accelerated Tests at High Oxygen Pressures

Conducting stability tests at high oxygen pressures can sometimes accelerate reactions involving oxidation. The potential for acceleration is not very great because oxidation reactions typically become independent from the oxygen concentration above some critical concentration level, which varies with temperature and other conditions (6). Nevertheless, traditional accelerated tests for oxidation-susceptible oils use exposure to high oxygen pressures to assess the relative stability of such oils.

One aspect on ASLT, which calls for certain precautions, is the change in the water solubility of oxygen by temperature. In oxygen sensitive products, this has to be corrected for by the use of increased partial oxygen pressure at elevated test temperatures.

C. Predictive Food Microbiology

Predictive food microbiology is an emerging multidisciplinary area of food microbiology. It covers different areas such as mathematics, microbiology, chemistry and engineering to apply mathematical models to predict microbial growth and/or toxin production to specified environmental

variables in order to replace traditional time-intensive challenge studies.

The need to ensure the microbiological safety and quality of increasingly complex food products has stimulated interest in the use of mathematical modelling to quantify and predict microbial behaviour. Buchanan (9) goes through models used in predictive microbiology coupled with 'user-friendly' applications software and the development of expert systems. These applications provide powerful new tools for rapidly estimating the effects of formulation and storage factors on the microbiological relations in foods.

Cheftel (10) reviews the effect of high-pressure on microbial inactivation and food preservation, as it affects biological constituents and systems.

McDonald and Sun (11) reviewed predictive microbiology for the meat industry, with shelf life predictions focusing on *Escherichia coli* O157:H7 and *Listeria monocytogenes*.

Heldman and Newsome (12) gathered information and summarized plenary presentations of the IFT second Summit (January, 14–16, 2003) relating to the understanding of microbial inactivation kinetics and models for non-log-linear survivor curves (kinetic models) and identified needs for future research.

III. ASPECTS THAT FIX LIMITS OF FOOD SHELF LIFE AND KINETIC OF NUTRIENT LOSSES — DEPENDENCE ON ENVIRONMENTAL FACTORS AND FOOD COMPOSITION

In the following sections, a brief discussion of kinetics of microbial survival and of the mechanisms of deterioration of nutrients (ascorbic acid, browning and some off-flavours) is presented, with reference to relevant studies reported in literature.

A. Microbiology

The food safety crisis that appeared in the late nineties has made consumers more concerned about food security. Guaranteed food safety is now a priority in the policies of most developed countries. Although the use of mathematical models in food microbiology is not new, developing predictive mathematical models has gained recognition because of its usefulness as a tool that helps ensure food safety. In this context, the main objective of predictive microbiology is to act as a fast microbiological method for controlling changes during processing and predicting the consequences of food storage from a microbiological viewpoint. These predictions are very useful when making decisions under uncertain conditions and when developing risk assessment systems.

As a result of social changes in modern society, consumer demand for fresh-like products is growing throughout the world. Processing products of this kind involves the use of mild heat treatments accompanied by other techniques such as acidification or refrigeration after pasteurisation in order to reduce damage to the products' sensorial and nutritive properties. These preservation conditions have allowed the appearance of new emerging pathogens such as *Bacillus cereus*, spores of which are not totally inactivated by these combined techniques, and surviving spores of this pathogen can grow under refrigeration conditions.

Geeraerd *et al.* (13) thoroughly compare the performances of several models (two models from Casolari, Sapru model, Whiting model, Baranyi model, Chiruta model, Daughtry model, Xiong model and a new model developed by the authors of the paper) to deal with the typical non-loglinear behaviour of survivor curves (*Bacillus cereus*, *Yersinia enterocolitica*, *Escherichia coli* O157:H7, *Listeria monocytogenes* and *Lactobacillus sake*) occurring during mild heat treatment of sous vide or cook-chill food products. As the thermal treatment is not as intensive as canning, besides the reduction of pathogenic and spoilage vegetative cells there may occur growing of surviving thermo resistant microorganisms or of their spores, during the later stages of production, storage and distribution. Some models, such as the modified Gompertz growth model, were excluded from this study. Authors explain the requirements and limitations of each model, and conclude that both Baranyi and the author's model fulfill the requirements necessary to describe accurately microbial inactivation during a mild heat treatment.

Despite documented evidence that specific pathogens are capable of survival in fruit juice, until recently it was widely accepted that most low pH/high acid foods were of minimal concern for food poisoning outbreaks. This was based on the knowledge that organic acids have an inhibitory and sometimes microbicidal effect on many bacteria (14). Outbreaks of food poisoning from *Salmonella* and *E. coli* O157:H7 were traced to nonpasteurised orange and apple juices, respectively (15–17).

Many studies have been carried out to model the combined effect of temperature and acidification on the thermal resistance of various strains of microorganisms (18–21). However, models that include parameters with biological significance are scarce. Gaillard *et al*. (22) and Mafart and Leguerinel (23) developed various mathematical models that took into account parameters with biological significance assuming a linear logarithmic relationship between the number of surviving microorganisms and the treatment time.

The Weibull model is gaining increasing importance in microbiology to fit non-linear death curves. Various researchers agree that one valid way of overcoming the lack of fit motivated by the presence of shoulders and tails

in survival curves (24) when describing complex microbiological inactivation kinetics is to use the Weibull distribution (19, 24–31). The effect that external factors such as temperature, pressure or pH have on the parameters of the Weibull model has been studied (19, 24, 27, 28, 32).

Bacillus cereus is a ubiquitous spore. Its presence has been reported in many products, like nuts, dairy products, vegetables, meat, spices and others (33). It is considered a food contaminant, as it is capable of causing an emetic or diarrhoeal syndrome because of its ability to produce two types of toxin (34). Fernández *et al.* (35) developed a model with 4 parameters to describe the effect of temperature and pH on the inactivation of *Bacillus cereus* in vegetable substrate, using parameters (Ea and k) that are common in food engineering or food chemistry but not in microbiological studies. As a continuation of this study, Collado *et al.* (36) developed a model based on the Weibull distribution to describe the combined effect of pH and temperature on the heat resistance of *Bacillus cereus* in carrot juice. It was shown that temperature and pH did not have a significant effect on the shape parameter (β), and the effect of temperature on the scale parameter (α) was modelled by the z concept.

Van Boekel (31) thoroughly studied the application of the Weibull model to describe the thermal inactivation of microbial vegetative cells. He used 55 sets of data (for different microorganisms) taken from the literature and obtained the parameters of the Weibull model. The shape parameter had very different values for the different cases over the temperature range studied. It was found that β equalled one only in two cases, indicating that the classical first-order kinetics approach is the exception rather than the rule. It was concluded that the Weibull model can be used to model nonlinear survival curves, and may be helpful to pinpoint relevant physiological effects caused by the heat.

Shelf stability of some 100% fruit juice products stored at room temperature is maintained by the combination of a heat process and low pH. The high acidity ($pH \leqslant 4.5$) limits the types of microorganisms that can grow in the juice, yet several have been isolated from orange juice (acid-tolerant bacteria, yeasts and moulds) although few of them can cause spoilage (pathogenic) (37). Therefore, in aseptically processed and packed food, microbial growth does not set the storage limit of the product, unless erroneously processed.

Saccharomyces cerevisiae, *Rhodotorula sp*. and *Zygosaccharomyces sp*. are the most common yeasts present in juice (38). *Saccharomyces cerevisiae* is the yeast most commonly associated with spoilage of pasteurised citrus juices. This organism produces an alcoholic fermentation resulting in a fermented off-flavour due to the presence of ethanol and carbon dioxide. Yeasts not capable of alcoholic fermentation may cause turbidity, flocculation and clumping in juice. *Zygosaccharomyces* is an osmophilic yeast and species of this yeast can readily survive the high osmotic pressures and low water activity of frozen concentrated orange juice (39) and it is frequently associated with spoilage of concentrates (38). The presence of *Rhodotorula* may be indicative of poor post-pasteurisation hygiene.

Moulds that have been isolated from orange juice include *Aerobasidium pullulans*, *Aspergillus niger*, *Botrytis sp. Fusarium sp.*, *Geotrichum sp.*, *Muccor sp. Aspergillus fumigatus*, *Cladosporium sp.* and *Penicillium sp.* Moulds are usually of small concern in processed citrus products because of their slow growth rates (40) and although they grow well in acid media, they require abundant oxygen and are generally sensitive to heat treatment and thus easily destroyed by pasteurisation. However isolated cases of mould spoilage by *Penicillium sp*., *Aureobasideum pullulans* and *Cladosporium sp.* occasionally occur (40). With the introduction of long-term chilled storage of single strength orange juice in nonaseptic cartons with oxygen barriers, mould growth in citrus juice has become a more important issue (38).

Acid and acidified foods ($pH \leqslant 4.5$) generally are not heat processed sufficiently to destroy all bacterial spores because that process (sterilization) may adversely affect the quality of the product and is not necessary as most spores will not germinate and grow in such products. The major bacterial spoilage agents in citrus juices are *Lactobacillus* and *Leuconostoc* species (also termed lactic acid bacteria). These organisms are responsible for production of diacetil, which imparts an undesirable buttery flavour to juice (41). *Leuconostoc* and many species of *Lactobacillus* also produce large amounts of CO_2. A thermo-resistant spore-forming acidophilic bacteria was isolated from shelf-stable juices, named *Bacillus acidoterrestris* (42), and later reclassified in a new genus called *Alicyclobacillus* (43). *Alicyclobacillus* are of concern as they can germinate, grow and cause spoilage of products with a pH previously considered below the range of spore-forming bacteria (44). This contamination is introduced into the manufacturing process through unwashed or poorly washed fruit, and it causes a flat sour type of spoilage (no gas production was observed), producing an offensive-smelling compound, guaiacol, and other taint chemicals in orange and apple juices and juice-containing drinks (45). Splittstoesser and co-workers (46) also reported the detection of guaiacol in apple juice contaminated with *Alicyclobacillus*. The worldwide occurrence of alicyclobacilli in non-spoiled fruit juices and rapid growth cycles culminating with sporulation of cells, strongly indicate that spoilage of fruit juices by alicyclobacilli is incidental, requiring a combination of adequate conditions for growth of the organisms in the juice, such as low pH and high temperatures for long periods of time (47). A response surface model was developed to describe the effects of temperature (35 to 55°C),

pH (3.5 to 5.5) and water activity (a_w, 0.960 to 0.992) on germination of *Alicyclobacillus acidoterrestris* spores by Sinigaglia *et al.* (48), was validated with data not used in its development, and results indicated that the model provided reliable predictions of growth of spores.

B. Nutrient Loss

Nutrient loss in juice products is essentially synonymous with vitamin loss. Since consumers derive major vitamin benefits from citrus juices, factors that impact on vitamin retention are of considerable importance (39).

Vitamins can be grouped according to whether they are soluble in water or in nonpolar solvents. The water-soluble vitamins are vitamin C and a series known as vitamin B complex.

Ascorbic acid (vitamin C) is the one of the most important nutrients in orange juice. Some other fruits contain more ascorbic acid than oranges, such as kiwi, strawberries and blackcurrant, but fewer are as popular. Ascorbic acid is essential for the synthesis of collagen, the most abundant protein in mammals, and a lack of this vitamin leads to scurvy (49).

Ascorbic acid is a natural antioxidant and its loss in juices is closely related to the availability of oxygen in packages. The loss of this vitamin in processed citrus juices is due to aerobic and anaerobic reactions of nonenzymatic nature (39) or through catalysed or uncatalysed aerobic pathways (50). Several researchers studied ascorbic acid decomposition, and several studies focused on the influence of oxygen, packaging systems and other chemicals on ascorbic acid contents. It is possible that the various mechanisms of deterioration can operate simultaneously. Which one predominates depends on the storage temperature and on the availability of oxygen, thus highly complicating the treatment of kinetic data (50).

The anaerobic pathway is independent of oxygen (as the name implies) and is mainly driven by the storage temperature. Losses caused by this pathway cannot be prevented by package type (38), lowering the storage temperature is the only way to minimise its rate (51). This mode of degradation is prevalent in hermetically sealed packages. Under anaerobic conditions ascorbic acid decomposes to 2,5-dihydro-2-furoic acid, 3-deoxy-D-pentosone, carbon dioxide and furfural (39, 52, 53).

The aerobic pathway needs oxygen and is therefore related to the presence of headspace oxygen, dissolved oxygen and the oxygen-barrier properties of the package (38). In cases where permeation of oxygen into a package is considerable, headspace oxygen is present or oxygen is dissolved in the product, the contribution of anaerobic degradation to the total vitamin C loss is small compared to aerobic degradation (50).

The scheme shown in Figure 142.1 helps to visualise the influence of oxygen and heavy metals on the route and products of degradation reaction.

In the presence of oxygen, ascorbic acid (H_2A) is degraded primarily via its monoanion (HA^-) to dehydroascorbic acid (A), involving the formation of a metal anion complex, which combines with oxygen to give a metal-oxygen-ligand complex ($MHAO_2^{(n-1)+}$). The exact pathway and overall rate is a function of concentration of metal catalysts ($M^{n+} = Cu^{2+}$, Fe^{3+}) in the system. The

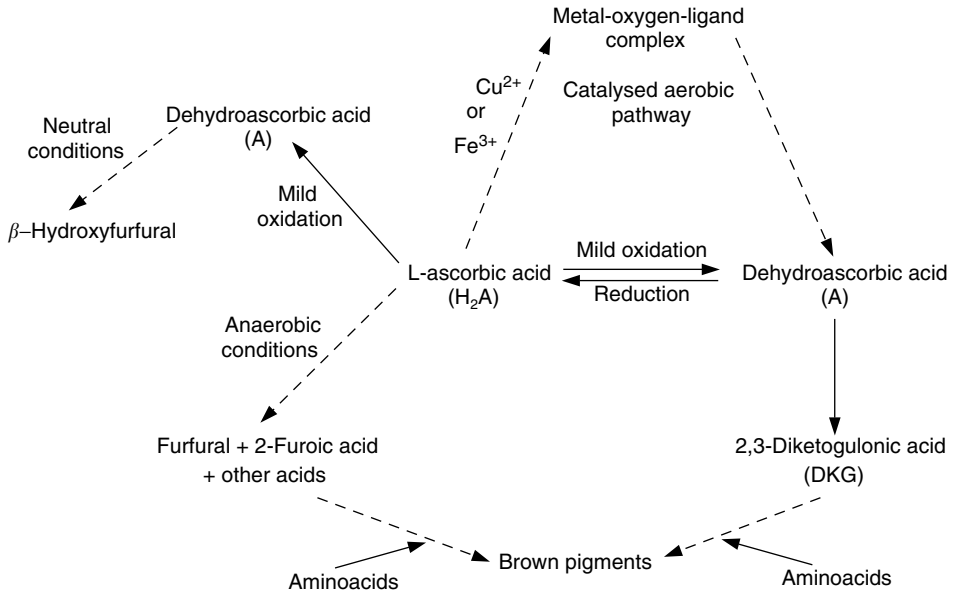

FIGURE 142.1 Schematic representation of degradation pathways of ascorbic acid. Adapted from Tannenbaum *et al.* (55) and Villota and Hawkes (50). Dashed arrows represent simplification of several distinct reactional steps, here grouped as a single one for simplicity sake (from Manso (54)).

rate of formation of dehydroascorbic acid is approximately first-order with respect to $[HA^-]$, $[O_2]$ and $[M^{n+}]$. When the metal catalysts are Cu^{2+} and Fe^{3+}, the specific rate constants are several orders of magnitude greater than the spontaneous oxidation, and therefore even a few parts per million of these metals may cause serious losses of vitamin C in food products (55).

In the non-catalysed oxidative pathway the ascorbate anion (HA^-) is subjected to direct attack by oxygen in a rate-limiting step, to give first the radical anions ($A^{\bullet}$) and ($H_2O^{\bullet}$), followed rapidly by formation of dehydroascorbic (A) and H_2O_2. Thus the catalysed and uncatalysed pathways have common intermediates and are undistinguishable by product analysis. Since dehydroascorbic acid is readily reconverted to ascorbate by mild reduction, the loss of vitamin activity comes only after hydrolysis of the lactone to form 2,3-diketogulonic acid (DKG).

Under anaerobic conditions ascorbic acid degradation yields furfural, 2-furoic acid and other acids (50). The maximum degradation occurs at approximately pH 4, followed by a decrease upon a decrease in pH to 2, followed by a rate increase with an increase in acidity (53).

Many researchers studied ascorbic acid degradation kinetics and factors that affected its rate in food or model food products. Table 142.1 presents a summary of some published studies, stressing the most important findings.

Most studies report L-AA degradation to follow first-order kinetics (56–64). These studies cover a wide range of products (e.g., model food systems, fruit juices, peas, cereals) and conditions (anaerobic, aerobic non-catalytic and aerobic catalytic), as well as different processes (e.g., thermal processing, concentration) and storage in different packages. In many cases the retention of ascorbic acid in the conditions and times tested is relatively high, what may explain the adequability of this simple mathematical model to describe L-AA degradation.

A smaller number of researchers report L-AA degradation to follow zero-order kinetics (65, 66) or second-order kinetics (67–69). Kanner *et al.* (70) reported different reaction orders below 25°C (first-order) and above 37°C (different from first-order). More complex mechanisms have been suggested to describe L-AA degradation by Vieira *et al.* (71), Sakai *et al.* (72), Hughes (73), Lee *et al.* (74), Singh *et al.* (69) and Khan and Martell (75, 76). Manso *et al.* (77) presented a study where a first-order, the Weibull model and a mechanistic model were used to describe the L-AA degradation in orange juice under aerobic conditions, and showed that first-order models could describe well for relatively low conversions (retentions $\geqslant$80%), but if the reaction was followed for longer times, up to total ascorbic acid loss, then it would be preferable to use the Weibull model for predictive purposes.

The dependence of the rate constants on temperature is reported to follow an Arrhenius-type equation. Nagy and Smoot (57) reported two distinct Arrhenius profiles, with a critical transition region between 22 and 26.7°C.

Hsieh and Harris (78) reported that the mechanism of L-AA degradation in canned orange juice depends on oxygen concentration, being different above and below 2 ppm, and Kennedy *et al.* (79) observed that after the dissolved oxygen in juice packed in TB cartons reaches an equilibrium, L-AA decomposition occurs independently of oxygen.

L-AA degradation during storage of lemon juice protected from light was reported to be independent of initial oxygen contents (61).

Similar results found by Singh *et al.* (69) in infant formula protected from light, whereas in samples exposed to light increased initial oxygen led to faster L-AA degradation.

The vitamin B complex group is composed of thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin, a group comprised of pyridoxine, pyridoxal and pyridoxamine (vitamin B_6), pantothenic acid, biotin, folic acid and cobalamin (vitamin B_{12}). All B complex vitamins have been detected in citrus juice, except for vitamin B_{12} (39).

Folic acid is the one found in more significant amounts (38). This vitamin is very important as it is required for DNA synthesis and its deficiency is first expressed in tissues with high rates of cell turnover (49).

Limited studies have been conducted on the stability of the B complex vitamins in citrus juices (80). Folic acid is quite heat-sensitive, but the vitamin C in citrus juices protects it from degradation during heat treatment (38). Davey and Cerf (81) presented a mathematical model to predict the concomitant denaturation of vitamin during sterilization as influenced by combined temperature and liquid pH over a range of exposure times in batch thermal processing. The procedure was illustrated using published data for denaturation of thiamine (vitamin B-1) and ascorbic acid (vitamin C).

C. Colour Stability

Citrus juices colours are primarily due to carotenoids present in plastids located in the juice vesicles (82, 83). Citrus carotenoids are C-40 compounds that can exist as either hydrocarbon carotenes or oxygenated xanthophylls and are primarily responsible for the red, orange and yellow pigments. The main carotenoids in orange juice are α-carotene, β-carotene, zeta-carotene, α-cryptoxanthin, β-cryptoxanthin, antheraxanthin and violaxanthin (84). Juice colour is an important standard for determining quality of orange juice (84). Legally, blending with more highly coloured juice is the only method for enhancing 100% fruit juice colour (85).

Carotenes are relatively unstable and must be protected from oxygen, and stored under refrigerated conditions (86). The colour of processed red and pink grapefruit

TABLE 142.1
Kinetic Studies of Ascorbic Acid Degradation, Nonenzymatic Browning and of Flavour (HMF, Furfural and PVG) Formation

Food/Model System	Package/Storage Conditions	Compounds Under Study	Other Compounds	Compounds/Factors Affecting Degradation	Atm. Cond.	Applied Kinetic	Retention (%)	Fit Quality	Observations	Ref.
Aqueous solution	2 temperatures (T): 0.4, 25°C 7 O_2 contents: 11.1, 8.9, 6.7, 4.5, 2.3, 1.1, 0.4 ppm 9 pH levels: 2–5.5	Ascorbic acid (H_2A)		Cu(II) Fe(III) Temperature Oxygen pH	Aer./ Anaer.	• Spontaneous Oxidation - First order, in relation to HA^- - [0.40; 1.0] atm O_2: $-\frac{dAA_{Total}}{dt} = k_1[HA^-][O_2]$ • Cu^{2+} Ion Catalysed Oxidation - First order, in relation to H_2A, pH = [1.5; 3.5] • Fe^{3+} Ion Catalysed Oxidation - First order, in relation to H_2A, pH = [1.5; 3.85] $-\frac{dAA_{Total}}{dt} = k'_1[H_2A][M^{n+}] + k'_2[HA^-][M^{n+}]$	n.a.	Good*	The rate of the non-catalysed oxidation of AA was found to be proportional to oxygen concentration at 20% or higher. In the pH range investigated [2–5.5] only the monoionic species of AA was found to be reactive toward O_2 A mechanism is proposed whereby O_2 takes part directly in the oxidation of the ascorbate anion, HA^- The rates of the ferric and cupric anion catalysed oxidations were found to be 1st order with respect to O_2 A reaction path involving O_2 bound to metal-ascorbate complex is proposed The catalytic activity of cupric ion was found to be more than that of ferric ion toward the oxidation of the ascorbate anion; in the oxidation of the neutral species, ferric ion is a better catalyst than cupric ion The mechanistic implications of the catalysed and unanalysed reactions are discussed	(75)
Aqueous solution	2 T: 0.4, 25°C Oxygen: 80–5% 5 pH levels: 2.25–3.45	Ascorbic acid (H_2A)		Cu(II)-EDTA Cu(II)-HEDTA Cu(II)-NTA Cu(II)-HIMDA Cu(II)-IMDA Fe(III)-DTPA Fe(III)-CDTA Fe(III)-EDTA Fe(III)-HEDTA Fe(III)-NTA Fe(III)-HIMDA Temperature Oxygen pH	Aer./ Anaer.	Catalytic activity of Cu(II)-IMDA > Cu(II)-HIMDA > Cu(II)-NTA > Cu(II)-HEDTA > Cu(II)-EDTA Catalytic activity of Fe(III)-HIMDA > Fe(III)-NTA > Fe(III)-HEDTA > Fe(III)-EDTA > Fe(III)-CDTA > Fe(III)-DTPA	n.a.	Good*	The metal chelate catalyst is totally inactive for the oxidation of the un-ionised species of AA Mechanism proposed for metal chelate catalysed oxidation of AA: direct participation of metal chelate species in an electron-transfer process A mixed ligand chelate of ascorbate anion, HA^-, and metal chelate, ML^{n+}, is formed in a pre-equilibrium step. This is followed by an electron transfer within the mixed ligand chelate, $HAML^{(n-1)+}$, then dissociates in a fast step to the lower valence metal	(76)

Food/Model System	Package/Storage Conditions	Compounds Under Study	Other Compounds	Compounds/Factors Affecting Degradation	Atm. Cond.	Applied Kinetic	Retention (%)	Fit Quality	Observations	Ref.
						$-\frac{dAA_{Total}}{dt} = k_1[H_2A][ML] + k_2[HA^-][ML]$			chelate $ML^{(n-1)+}$ and a semiquinone Oxidation of the lower valence metal chelate and semiquinone by molecular O_2 takes place in subsequent steps The catalytic activities of the cupric and ferric chelates were found to be independent of O_2 concentration, which is in agreement with this mechanism	
SSOJ (var. Hamlin, Pineapple, early and late Valencia)	Can (46 oz) 5 T: −18, 4, 16, 21, 35 (°C)	Furfural Flavour evaluation		Temperature	Anaer.	No kinetics for furfural, but by visual observation of the graphs a zero or first-order is not applicable		n.a.	Juices with lower pH the ones with higher % of citric acid produced more furfural at 35°C	(100)
Seaweed Mixed Cereal Orange Juice	Package system: n.a. 4 T: 23, 35, 40, 45°C 7 a_W content: 0.32, 0.51, 0.67, 0.75, 0.84, 0.88, 0.93 10 moisture content: 1.1 to 33.3 $gH_2O/100\,g$ sol	Ascorbic acid		Water activity Moisture content Temperature	n.a.	First-order the rate of AA loss increases with increasing a_w	n.a. ($a_w = 0.93$) 11 ($a_w = 0.84$) 80 ($a_w = 0.32$)	Good*	Ascorbic acid destruction rates increased with increasing a_w Ascorbic acid was more rapidly destroyed in the desorption system than in the adsorption system due to a decrease in viscosity and possible dilution of the aqueous phase	(56)
Infant formula	Closed cells (boxes) 20 hours 3 initial dissolved oxygen content: 1.0, 4.86, 8.71 ppm 5 light intensities: dark, 1071, 2142, 3213, 4284 lux T: 7.2°C	Ascorbic acid		Temperature Oxygen Light intensity	Aer.	Second-order Describes reaction scheme: $AA + O_2 \xrightarrow{k} DHAA + H_2O$ $-\frac{d(AA)}{dt} = k(AA)(O_2)$ $\ln\left[\frac{AA}{O_2}\right] = [AA_0 - O_{20}]\,kt + \ln\left[\frac{AA_0}{O_{20}}\right]$	≈33	n.a.	In samples exposed to light an increase in initial dissolved oxygen content increased the second-order rate constants The rate constants under dark conditions for different initial dissolved oxygen concentration remain unchanged Increasing light intensity above 1756 lux did not increase the rate constant, and below that the rate constant increases linearly with light intensity	(69)

Tomato Juice	Can (8 oz) 6.3 months 4 T: 10, 18.3, 29.4, 37.8°C Initial conc (Cu): 2.6 and 10 ppm pH: 3.53, 3.78, 4.06, and 4.36	Ascorbic acid	Temperature pH Metal catalyst — Cu	Aer.	AA loss is first order in relation to AA AA = f(T) Arrhenius relation Describes 3 reactions involved in the overall destruction of AA: $AH^- \xrightarrow{k_1}$ Product; $AH_2 \xrightarrow{k_3}$ Product $AH_2 + AH^- \xrightarrow{k_1}$ $AH_2.AH^- \xrightarrow{k_2}$ Product $AA_r \xrightarrow{k}$ Product; $-\frac{d(AA)}{dt} = k(AA_T)$	≈60	Good*	The rate of AA destruction was influenced by pH, reaching a maximum near pK of AA The rate of copper-catalysed destruction of AA increased with copper conc. and was affected by pH Ea changes with pH, with a minimum at pH 4.06 (3.3 kcal/mol) A mathematical model was developed for the rate of AA loss as function of T, pH and Cu A computer simulation program was developed to predict AA stability in tomato juice Predictions were in good agreement with results of the shelf-life tests	(74)
SSOJ (Var. early, mid and late Valencia)	Can (6 oz) 11 T: 4.4, 15.6, 21.1, 29.4, 32.2, 35, 37.8, 40.6, 43.3, 46.1, 48.9°C 12 weeks	Ascorbic acid	Temperature	Aer./ Anaer.	First-order Two distinct Arrhenius profiles [4.4, 21.1] and [29.4, 46.1]°C Employment of orthogonal polynomials in the analysis of variance indicates that the mechanism of AA degradation was not the same at all temperatures	92–6	Good $0.97 < R^2 < 0.99$	Values of U.S. RDA of vitamin C are given At each specific temperature all 14 juices, regardless of plant or processing season, showed essentially similar percent vitamin C retention The Arrhenius plot showed two distinct temperatures regions, with a critical transition region between 22 and 26.7°C	(57)
Model system	Mixing bowl (with tight-fit cover); Steady-state experiment: 4 T: 71, 79, 92, 105°C 25 min 3 a_w content: 0.69, 0.80, 0.90	Ascorbic acid	Water activity Temperature	n.a.	Zero-order	≈57.5	Good $R^2 > 0.97$	Rates of AA degradation are dependent upon O_2 availability, which is in turn dependent upon temperature and moisture content The equation derived to predict the amount of AA lost during an unsteady state heating process was successful when tested under conditions approximating a linear T rise (error for the final predicted value <5%)	(66)

(*Continued*)

TABLE 142.1 (*Continued*)

Food/Model System	Package/Storage Conditions	Compounds Under Study	Other Compounds	Compounds/Factors Affecting Degradation	Atm. Cond.	Applied Kinetic	Retention (%)	Fit Quality	Observations	Ref.
									The same equation yielded less accurate predictions of AA losses during extrusion (error for the final predicted value <10%)	
Grapefruit Juice	60 min Initial AA content: 34.8, 112.5, 204.8 mg/100 g °brix: concentrated during the study from 11 to 62 °brix	Ascorbic acid		Added AA concentration °brix	Anaer.	First-order Dependent on T by Arrhenius Eq. Ea = 5 kcal/mol (11°brix) Ea = 11.3 kcal/mol (62°brix) Arrhenius coeff. dependent on °brix Polynomial curve fitting, empirical kinetic equation correlating rate of reaction with temperature and degree of concentration	<85	Good $0.972 < R^2 < 0.999$	Initial AA conc. has no significant effect either on rate of deterioration or mechanism A model combining kinetic data with process variables was developed and proved useful in predicting and optimising vit. C retention processes where grapefruit juice is subjected to any combination of thermal and concentration treatments	(58)
Peas	TDT cans 5 T: 110, 115, 121, 126, 132°C 6 hours	Ascorbic acid	O_2 monitored	Temperature	Aer./ Anaer.	First-order	30–96	Reasonable good*	Discussion on the values of Ea for this study and others, both for aerobic and anaerobic conditions, reaching the conclusion that the differences on Ea indicate that kinetic studies should be conducted for different food systems	(59)
Intermediate moisture food material	Jacketed, stirred reactor with air space above reactants Temperature: 60 to 110°C 3 a_w: 0.9, 0.8, 0.69	Ascorbic acid		Oxygen mass transfer a_w	Aer./ Anaer.	Second-order	n.a.	n.a.	The effect of oxygen transport on degradation rate was determined by comparing the experimental observations with theoretical predictions for a series of four regimes (a regime is characterised by different relative rates of O_2 mass transfer and chemical reaction) The most likely explanation for the experimental data is regime III — the chemical reaction rate is sufficiently fast that all the oxygen reacts in a thin film near the interface between the food and the gas phase, which enhances the mass transfer rate due to chemical reaction	(68)

Orange Grapefruit Tangerine Lemon Lime	Whole Fruit Can	Ascorbic acid	- Production factors - Climate - Position of fruit on the tree - Maturation - Rootstock effects - Citrus variety (and fruit parts) - Processed products: seasonal variability, processing effects, storage time and temperature - Vitamin C destruction: reaction order and reaction rates (aerobic and anaerobic mechanisms) - Effects of container - Influence of juice constituents			First-order			The variability of vitamin C in fresh fruit is due to variety, climate, horticultural practice, maturity stage and storage conditions Processing fruit into juice products results in minimal loss of vitamin C potency but subsequent storage finished of the product at higher temperatures results in considerable loss From the point of view of the consumer, numerous investigations have shown that fresh processed single strength and reconstituted citrus juices may be kept in a refrigerator for a reasonable length of time (4 weeks) without serious loss of vit C; even when juice is stored at room temperature, storage time is limited more by loss of palatability than by loss of vit C Aerobic and anaerobic mechanisms are mainly responsible for loss of vit C in processed products The mode of breakdown of vitamin C can best be explained by a 1st-order reaction but a significant quadratic time effect has been determined by polynomial regression calculations Plots of log rate (vit C loss) vs. 1/T for canned orange juice showed two distinct Arrhenius profiles, whereas canned grapefruit showed only one	(60)
Buffered model system (pH = 6.1)	Closed system with headspace and control of head-space gases 4 T: 30 to 55°C Initial AA conc = 30, 35, 40, 50, 65 g/L 3 O_2 levels = 10, 15, 21%	Ascorbic acid		Temperature Ascorbic acid addition Oxygen	Aer.	Second-order	>75	Good $0.96 < R^2 < 0.99$	Oxygen concentration was maintained throughout the experiment Ascorbic acid autoxidation is dependent on dissolved oxygen concentration It appears that the rate of oxygen dissolution into the AA solution is dependent on both temperature and headspace oxygen levels	(67)
SSOJ (var. Valencia) and OJ concentrate	Can (6 oz) 18 months 6 T (°C) = −18, 5, 12, 17, 25, 37 4°brix = 11°, 34°, 44°, 58	Ascorbic acid	Browning Furfural Sensorial changes	Temperature °brix	Aer./ Anaer.	T ⩽ 25° first-order T = 37°C different from first-order	95–10	Good*	AA loss depends on the degree of concentration of the O. J. (increase with °brix)	(70)

Valencia)	Package system: n.a. 6 T: 20, 25, 30, 35, 40, 45°C O_2 contents: [4.7; 5.7] ppm	Ascorbic acid (aa) Browning	Dehydro-ascorbic acid (daa) pH	Oxygen Temperature	Aerobic	AA: - Weibull model - Mechanistic model $\frac{dC_{AA}}{dt}=-k_1C_{AA}+k_2C^2_{AA}C_{DAA}$ $\frac{dC_{AA}}{dt}=-k_1C_{AA}+k_2C^2_{AA}C_{DAA}-k_3C_{DAA}$ Browning: Weibull model	AA:0%	AA: Weibull R^2_{adj} = 0.995 Browning: R^2_{adj} = 0.999	AA: Weibull model: $((1/\alpha)_{32.5}\times 10^3$ =64 ± 1 h^{-1}; Ea = 38.6 ±1.6 kJ/mol, β_{ref} = 1.65 ± 0.35; 0.042 ± 0.007°C^{-1}) Mechanistic model: (Ea_1 = 94 ± 11 kJ/mol, k_{1ref} = 0.33 ± 0.07 h^{-1}, Ea_2 = 107 ± 13 kJ/mol, k_{2ref} = 7.5 ± 1.9 h^{-1}, Ea_3 = 27 ± 9 kJ/mol, k_{3ref} = 0.044 ± 0.005 h^{-1}) Browning: Weibull model: $((1/\alpha)_{32.5}\times 10^3$ = 32 ± 3 h^{-1}; Ea = 66 ± 3 kJ/mol, β_{ref} = 1.6 ± 0.1; C^{∞} = 0.328 ± 0.007 mg/L) The Weibull model provided a good description of the kinetics of AA degradation and the browning index in the range of T and conversions tested, and therefore is appropriate for predictive purposes. The T dependency of the rate constants ($1/\alpha$) was well described by the Arrhenius law. The shape constant (β) was T independent for browning but decreased with T for AA degradation. The later behaviour might be explained by the reconvertion of DAA into AA, following first-order kinetics in relation to DA and second-order reaction in relation to AA and by different sensitivities of the different reaction rate constants to T. Browning appears to follow a single reactive pathway.	(77)

fades during ambient temperature storage with a simultaneous darkening of the juice. The rate of colour degradation and browning are highly associated with storage temperature for aseptically prepared orange juice. The darkening of citrus juices during storage occurs most often in citrus juices that are stored at ambient temperature in containers that are not effective oxygen barriers and in the absence of antioxidants (87).

Handwerk and Coleman (88) reviewed browning as it occurs in citrus juices and model solutions. The role of amino acids, sugars, ascorbic acid, buffers and catalysts, sulphur dioxide and S-containing amino acids and thiols was discussed. According to the authors, sugar breakdown through the Maillard reaction is initiated by formation of hexose amines from amino acids and sugars present in citrus juice and proceeds through the Amadori or Heyns rearrangement to produce deoxy and amino hexoses. These deoxy compounds go through a series of reactions and through one of two pathways. One of these pathways produces furanones and pyrones, whereas the other produces furfurals and pyrroles. Both pathways are known to be operable because all four types of compounds have been found in citrus juices. However the actual compounds responsible for browning, i.e., the brown pigments, were not identified.

Marcy *et al.* (89) studied concentrate orange juice aseptically packed in flexible bags and stored at 4, 15, 22 and 30°C for 6 months. Nonenzymatic browning was measured monthly using a Hunter colour meter and absorbance at 420 nm. They found the greatest browning for high temperature stored samples and least browning in the samples stored at the lowest temperatures.

Browning compounds are formed during the Maillard reaction, which occurs between sugars and aminoacids, polypeptides, or proteins, and between polysaccharides and polypeptides or proteins (90). There are many pathways and literally thousands of compounds that might contribute to the formation of these coloured compounds, but when it comes to mathematically modeling nonenzymatic browning, most researchers use zero-order reaction kinetics. This linear model may not be the most adequate to describe the complex group of reactions involved in orange juice browning. Nevertheless, it is a very simple model and it proved to be effective to predict the browning of orange juice in a different range of temperatures. Table 142.1 summarises studies reported in literature. Rojas and Gerschenson (91) reported a zero-order kinetic for browning in a sweet aqueous model system. The same order of reaction was reported by Robertson and Samaniego (61) but these authors suggest the existence of a lag period, dependent on initial oxygen content, being greater for the lower initial concentrations. Nagy *et al.* (92) reported that it is inaccurate to define browning by a simple zero or first-order reaction, especially within the temperature region of 30–50°C.

D. Flavour/Off-Flavour Development

Moshonas and Shaw (93) quantified 24 volatile constituents in samples of fresh Valencia and Temple orange juices. Nispieros-Carriedo and Shaw (94) quantified 20 volatile constituents in 15 fresh orange juice samples. Their study is important because it compares volatile flavour compounds in different types of orange juices. Shaw *et al.* (95) used the same technique to quantify 19 volatile compounds in a different set of 4 fresh orange juice samples. Moshonas and Shaw (96) quantified 46 volatile juice constituents in 13 fresh orange juice samples, hand and mechanically squeezed of 6 different cultivars. The results reported in their study provide the most complete database yet determined for quantities of volatile flavour compounds present in fresh orange juice. Nine of the 17 oil-soluble constituents present at higher levels in mechanical obtained juices include α-pinene, myrcene, limonene, octanal, nonanal, decanal, neral, geranial and linalool. From these, only limonene has an established optimum level, and for processed orange juice it is about 135–180 ppm. The seven water-soluble constituents quantified that are considered important for flavour of orange juice include ethyl acetate, ethyl propianate, methyl butanoate, ethyl butanoate, ethyl-3-hydroxylhexanoate, ethanol and (Z)-3-hexen-1-ol. Acetaldehyde and (E)-2-hexanol, two additional components considered important in orange flavour, were identified but not quantified. The components present at highest levels (10-fold or higher above their aroma thresholds) and important in orange flavour are limonene, myrcene, α-pinene, decanal, octanal, ethyl butanoate and linalool.

The highly desirable aroma and flavour of fresh squeezed citrus juices is difficult to stabilize and preserve. Once heat treatment has been applied to the juice to stabilize it from the microbiological and enzymatic point of view, certain chemical processes have been initiated which will ultimately degrade the flavour of the product due to the formation of off-flavours during storage.

Changes that occur during processing and storage of citrus juices can differ widely for the different products because of differences in starting material (juice), processing conditions, packaging materials and storage conditions. For instance, the initial flavour compound contents vary for different types of orange juice (94).

Several factors have been recognized as contributing to the development of off-flavours during thermal processing and subsequent storage. Two aldehydes that are indicative of temperature abuse in fruit juice are 2-furaldehyde and 5-hydroxymethyl-2-furaldehyde (97). Reduction or removal of oxygen from the headspace and minimization of initial dissolved oxygen in the juice may partially reduce the short-term production of off-flavour (39). However, other major off-flavours are formed from the acid-catalysed hydrolysis of citrus oil components, the

formation of sulphur-containing juice components, and the chemical degradation of flavourless precursors to produce off-flavours.

Tatum *et al.* (98) isolated 10 degradation compounds from canned single strength orange juice (SSOJ) stored at 35°C for 12 weeks. Of the compounds identified, 4-vinyl guaiacol, 2,5-dimethyl-4-hydroxy-3(2H)-furanone and α-terpineol were found to be the most responsible for the malodorous properties of time-temperature abused juice. The first imparted an old fruit or rotten fruit aroma, the second imparted the pineapple-like aroma typically observed in aged orange juice and the last one was described as stale, musty or piny. Acid degradation of sugars was probably responsible for 2-hydroxyacetyl furan and 3-hydroxy-2-pyrone formation.

These authors also state that furfural was formed from the degradation of ascorbic acid, which was mentioned in Section III.B.1, via its anaerobic degradation pathway (52, 53).

There is little information in literature regarding kinetic modelling of off-flavours, although a number of studies are published showing the effect of the temperature, pH and a_w on sensorial properties (aroma, flavour and threshold values) of these compounds and formation/degradation chemical pathways. Some studies on kinetic modelling of furfural, HMF and PVG are summarised in Table 142.1.

Robertson and Samaniego (61) reported HMF formation in lemon juice to follow a first-order reaction, and Körmendy *et al.* (99) reported a lag phase for the same kinetics. Furfural formation was reported to follow a zero-order kinetic both in orange juice (65) and lemon juice (61). The later researchers concluded that initial oxygen content did not affect the rate of furfural formation. Data reported for furfural (100) no kinetics is presented, though data visualisation suggests that zero or first order are not applicable. Marcotte *et al.* (101) reported PVG formation to follow a zero-order kinetic reaction. The mechanism of formation of PVG has been mainly studied by Fiddler *et al.* (102) and later in citrus by Lee and Nagy (103), Peleg *et al.* (104, 105) and Naim *et al.* (106, 107).

The dependence of the reaction rates of these compounds on temperature was considered to follow an Arrhenius-type relationship.

E. Oxygen

In some situations the amount of oxygen is limited to a level that causes no significant effect in food. In other cases, the total amount of oxygen potentially able to react with nutrients is significant, and the effect of oxygen concentration (or partial pressure) on the rate of oxidative reactions must be considered (7, 108, 109).

The mathematical modelling of oxygen uptake by packaged foods has been mainly applied to dried and fatty foods (5, 110, 111). For liquid foods, several studies report the effect of oxygen on quality degradation during storage, but few of them report changes of oxygen concentration. Scarcer are studies where the changes are mathematically modelled and even scarcer the ones that use a packaged liquid food (in a real package material). Singh (112) developed a mathematical model to describe ascorbic acid and dissolved oxygen concentration changes in an infant formula packaged in glass bottles and stored at 7°C. This model was based on Fickian diffusion of oxygen accompanied by a second order chemical reaction in the liquid food. Barron *et al.* (113) reported a study where a finite element method was applied to the modelling of simultaneous oxygen diffusion and chemical reaction in packaged apple juice, stored at 25°C, using a cylindrical high-density polyethylene package (top and bottom insulated). Hertlein *et al.* (114) presented a study of prediction of steady state oxygen transmission from transient state measurements. Two models were tested, one with an equation describing the transient state, another using a partial pressure pulse instead of a constant change in partial pressure. The study included testing of both models in different films (mono and multilayers) and it was concluded that both models were valid only for ideal conditions. Ahrné *et al.* (115) presented a study of modelling of oxygen changes in liquid foods packaged in aseptic cartons. This study combines oxygen uptake from the outside environment with oxygen consumption by first order oxidative reactions in packed juice during storage. The model was applied to orange juice aseptically packaged in Tetra Brik Aseptic cartons, during storage up to 5 months at six different temperatures, ranging from 4 to 50°C, and was further tested with data reported in literature. It was found that it adequately describes the dissolved oxygen concentration changes during storage.

IV. CONCLUSIONS

The shelf life of a food is the time period for the product to become unacceptable from sensory, nutritional or safety perspectives (116). From the viewpoint of the food industry, shelf life is based on the extent of quality loss that the food company will allow prior to product consumption while ensuring safety. For consumers, the end of shelf life is the time after which food no longer has an acceptable look or taste. Although food systems have very complex mechanisms of deterioration, shelf life of food products can be determined, and subsequently predicted, based on some primary mode of deterioration (116).

This chapter addresses particularly aspects that fix the limits of foods (microbiology, nutrient loss, colour stability, flavour/off-flavour development), as well as kinetics of nutrient losses and their dependence on environmental factors and food composition. Mathematical models are also discussed, particularly in relation to quality characteristics decay.

CONTENTS

I. INTRODUCTION AND OBJECTIVES

Product development in food engineering involves finding combinations of constituents that produce foods as a result of certain processes. These foods should have desirable properties and should be created in an economical and reliable manner. While achieving these goals can be easy, more often the food engineer has available a wide range of options to choose from when making a product. Finding the specific settings for these factors that satisfy quality, reliability and cost goals can often be difficult.

In this chapter experimental design is introduced with discussion on how this set of statistical tools can be used to optimize quality, reliability and cost by finding the best combinations of constituents and processes for a new product. The concepts and tools discussed here are not new, having been around for over 70 years. These basic methods have proven their utility in a large number of disciplines from food production to medicine and from agriculture to consumer sciences and bio-informatics. As you will see, these methods can be valuable tools in food engineering tasks as well.

This chapter will only introduce a small portion of the full set of statistical design tools available and the interested reader is encouraged to read further in any of the large number of experimental design books available. The reader is assumed to have basic knowledge about statistical concepts of design of experiments and linear modelling. The general objective is to elaborate a methodological framework for product development and optimisation in the food sciences based on optimal experimental design. This framework relies heavily on response surface models to link the experimental factors to the response variable of interest. This presentation is structured into an introductory part in which the basic concepts of experimental design and response surface modelling are elaborated, followed by a discussion of design strategies that accommodate unconstrained and constrained factors. Each section is illustrated with real life examples.

II. A MODELLING APPROACH TO EXPERIMENTAL OPTIMISATION

Experimental optimisation in product development is a multi-step process involving:

1. Identification of the important product ingredients and processes variables involved in producing the target product. The more important factors are selected as the experimental factors and define the region of interest also called the experimental factor space.
2. Development of a predictive mathematical model to describe the relationship between levels of the experimental factors and the produce responses of interest. These process

responses are numeric or categorical product attributes that relate to product quality, cost, physical or chemical feasibility.
3. Construction of an optimal design that spans the experimental factor space in relation to the assumed model.
4. Fit the model to the data and evaluate its fit.
5. Obtain the optimal treatment combination by examination of the mathematical model and or return to step 3 for the next experiment.

Each of the steps above will be discussed in more detail after we introduce some basic concepts of response surface models and associated experimental designs.

III. BASIC CONCEPTS OF RESPONSE SURFACE METHODOLOGIES

Assume a product attribute, denoted y, depends on the levels of a set of numeric factors, coded as $x_1, x_2, \ldots, x_k$. These experimental factors reflect relevant product composition, processing conditions or even socio-economic cues, thought to be important to product objectives. Further assume that the levels of the x's can be controlled by the experimenter with negligible error in comparison with the variance of y. Traditionally, the x's are called independent variables or experimental factors. The response y is called the dependent variable and at this point is considered to be numeric.

The dependence of y on the x's can be formalised in a model

$$y = f(x_1, x_2, \ldots, x_k)$$

Usually the mathematical form of the function f is unknown, but in most cases this function can be approximated satisfactorily, at least within the experimental region, by a polynomial function in the x's. Because polynomials are notoriously untrustworthy when extrapolated, rarely will the polynomial approximation function be used to predict responses for values of x outside the experimental region.

A first order polynomial model, also called a linear approximation model, can be written as:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k$$

This approximation is used when the range of the x's is so small that little curvature is to be expected in the response function f. The fitting of such a linear polynomial is considered as a special case of multiple linear regression. In order to estimate the regression coefficients β_i in this model each independent variable x_i must take at least 2 levels. This model is only able to estimate the main effects of the experimental factors and does not account for either interactions or curvilinear effects. Specific designs for first order models are elaborated in later chapters. For k factors, at least $k + 1$ data points are needed to estimate the $k + 1$ unknown parameters.

Different graphical representations of a first order model are presented in Figure 143.1. Displayed is the response model, $y = 50 + 8X_1 + 3X_2$ over the experimental region of X_1 and X_2 each at levels from -1 to $+1$. Clearly the response y increases with increasing levels of X_1 and X_2, but the main effect, the per unit increase in response for a unit increase in the factor is greater for X_1 than for X_2.

The approximation model can allow more complex relationships by adding to the first order model the 2-factor interaction terms. This model is

$$y = \beta_0 + \sum_{i=1}^{k} \beta_i x_i + \sum_{i<j}^{k} \sum \beta_{ij} x_i x_j$$

To fit this model requires that each factor be examined at 2 levels and treatments must be replicated. There are $1 + k + k(k-1)/2$ unknown parameters in the model and hence at least this many observations are required. In Figure 143.2 is displayed the response model $y = 50 + 8X_1 + 3X_2 - 4X_1X_2$. When compared to the first order model, we note that the interaction model accommodates for the mutual influence of the levels of X_1 on the levels of X_2. In other words, both experimental factors interact with each other; the response of y to X_1 depends on X_2 and vice versa. Still, the main effects of X_1 and X_2 on y are linear. In choosing the levels of X_1 and X_2 that will make up the experiment, factorial treatments can be shown to have certain optimality properties.

If the fitting of f involves more curvature, a quadratic or second order model becomes necessary.

$$y = \beta_0 + \sum_{i=1}^{k} \beta_i x_i + \sum_{i=1}^{k} \beta_{ii} x_i^2 + \sum_{i<j}^{k} \sum \beta_{ij} x_i x_j$$

This model contains linear-, squared- and cross-product terms and is referred to as the full quadratic model. This model requires at least $1 + 2k + k(k-1)/2$ data points and each variable x_i must be measured at a minimum of at least 3 levels. Specific designs to fit second order models are described in later chapters.

Figures 143.3 and 143.4 illustrate two second order models. The first model specifies $y = 50 + 8X_1 + 3X_2 - 7X_1^2 - 4X_1X_2$, and is quadratic in X_1, linear in X_2 and models the interaction between X_1 and X_2 by adding the term X_1X_2 (Figure 143.3).

The second model illustrates $y = 50 + 8X_1 + 3X_2 - 7X_1^2 - 3X_2^2 - 4X_1X_2$, and included quadratic effects in X_1 and X_2 and includes an interaction term X_1X_2 (Figure 143.4).

When a polynomial (either first or second order) accurately approximates the real underlying function f, the values of the X_i that produce the optimal response can

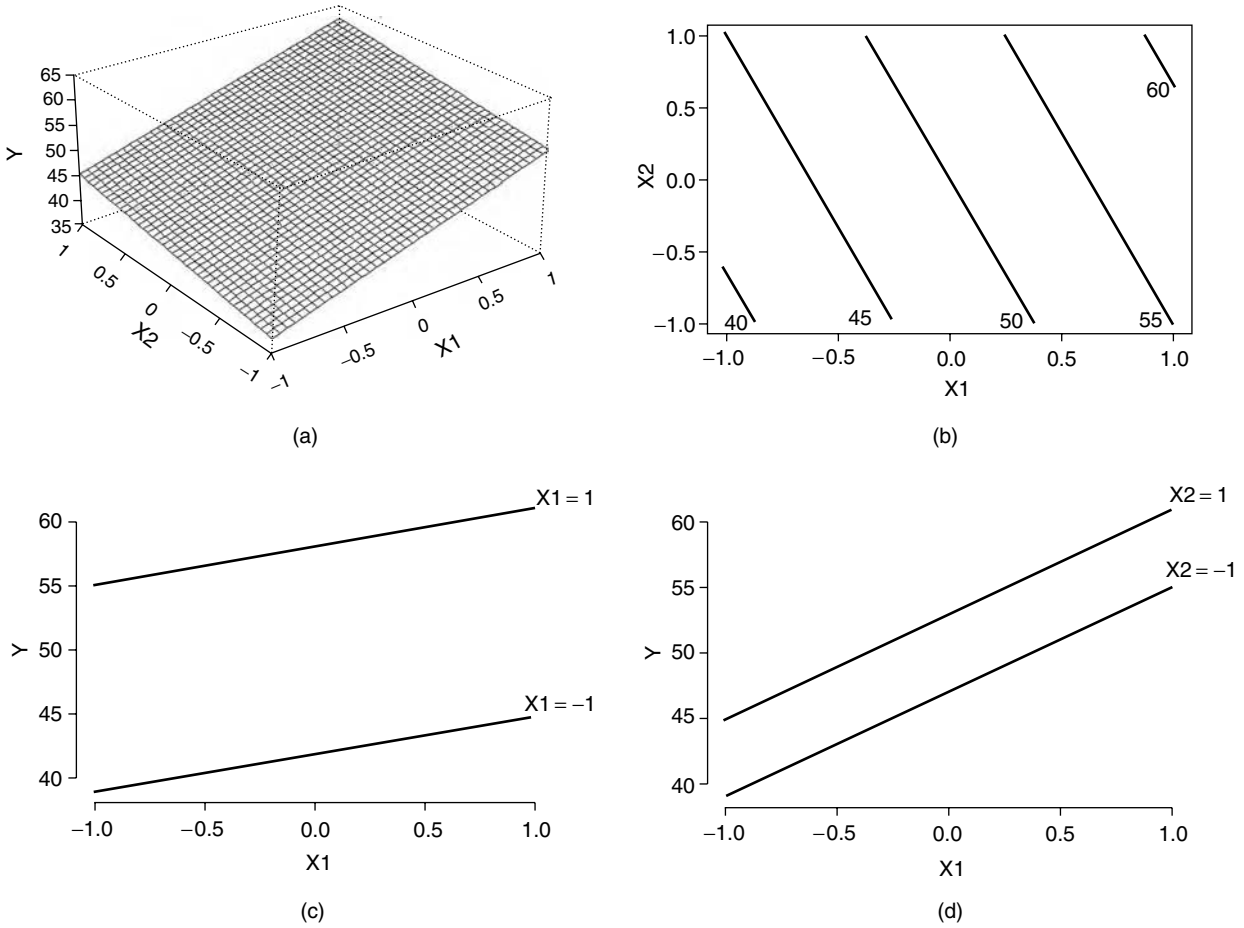

FIGURE 143.1 Different graphical representations of the first order model: $y = 50 + 8X_1 + 3X_2$. Perspective plot (a), Contour plot (b), Line plot $y*X_2 = X_1$ (c), $y*X_1 = X_2$ (d).

be determined mathematically using the fitted function. The precision of this estimate will depend on getting the form of the approximating polynomial correct and estimating the parameters precisely. This being so, the more important problem is determining at which levels of the X_i should the response be measured so that the form and parameters of the model can be most precisely estimated. That is, what factor level combinations should be used as treatments? Before this topic is addressed, the basic concepts of liner regression and experimental design are reviewed. Further discussions on response surface methodology, which is the parent discipline of these models, can be found in Meyers (1), Meyers and Montgomery (2) and Khuri and Cornell (3).

IV. PARAMETER ESTIMATION IN RESPONSE SURFACE MODELS: THE METHOD OF LEAST SQUARES

Without getting too deeply involved in the underlying mathematics, some basic concepts have to be explained as prerequisites for the understanding of some specific properties of experimental designs for response surface models.

The polynomial models described in the previous paragraph can be formulated in matrix notation as follows:

$$Y = X\beta + \varepsilon$$

where Y is an nx1 vector of observations y_i on the independent variable or the response, X equals an n*p matrix of known levels for each individual experimental factor, including cross-product and quadratic terms, β is a p*1 vector of unknown parameters β_i, n is the number of experimental units and ε is an n*1 vector of random errors.

Parameters β_i are estimated using the method of least squares in which we search for the values of the parameters that minimizes the sum of squared differences between the observed response and the corresponding expected value. The sum of squared differences, also called the residual sums of square or error sums of squares, are given as:

$$SSE(b) = \sum_{i=1}^{n} [y_i - E(yi|b)]^2$$

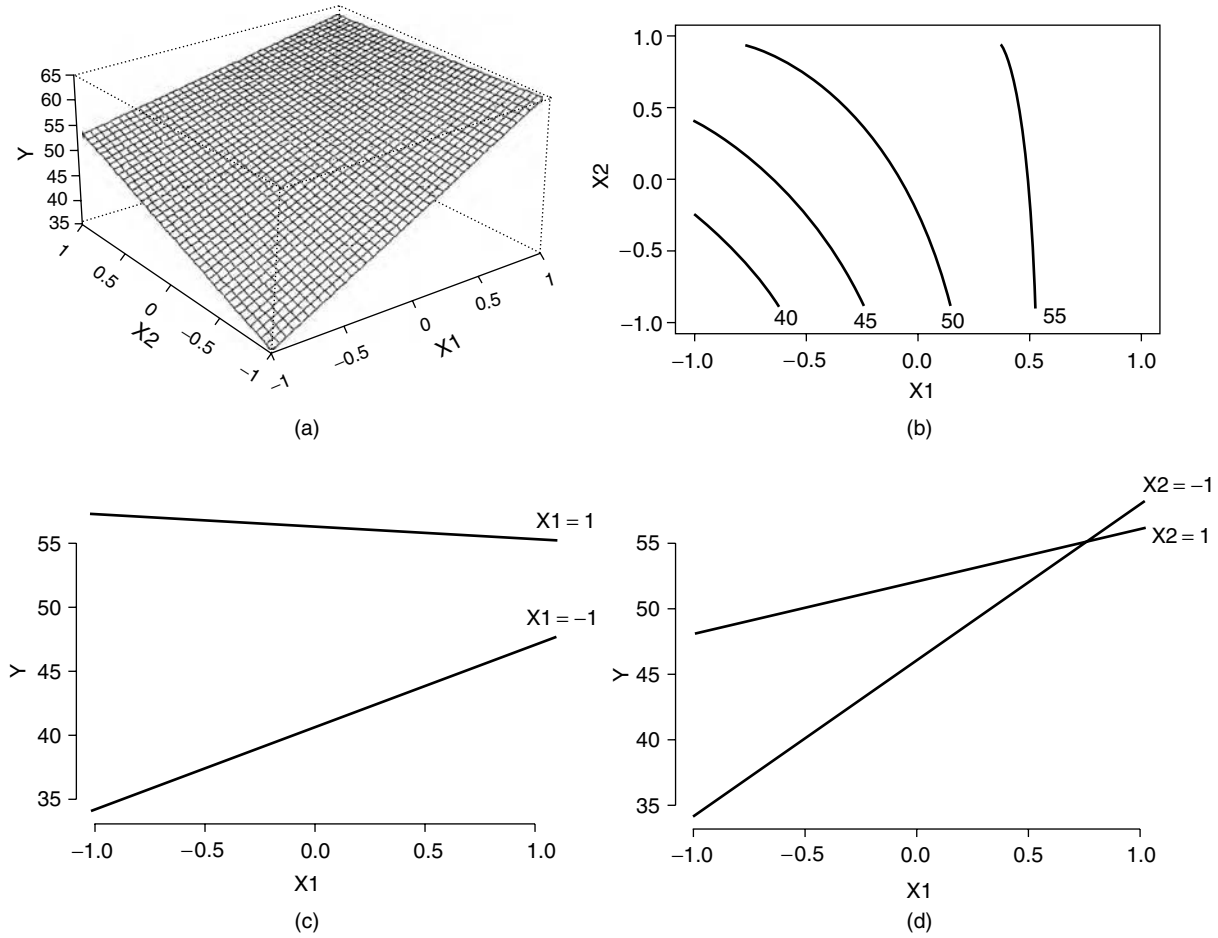

FIGURE 143.2 Different graphical representations of the first order model with interaction term: $y = 50 + 8X_1 + 3X_2 - 4X_1X_2$. Perspective plot (a), Contour plot (b), Line plot $y^*X_2 = X_1$ (c), $y^*X_1 = X_2$ (d).

Because this function is a quadratic in the unknown parameters, finding the minimum is a matter of using calculus to compute the first derivatives of the function with respect to each parameter and then solving the resulting system of equations. The resulting parameter estimates are functions of sums and sums of squares and cross-products of the response, y_i, and the predictors, x_1, x_2, ….

In the case were the $(X'X)$ matrix is not singular, the least squares estimation of the parameters b of β is given by:

$$b = (X'X)^{-1}X'y$$

The variance-covariance matrix of b is expressed in the following equation:

$$\text{var}(b) = \sigma^2 (X'X)^{-1}$$

with σ^2 the error variance. The elements of the matrix $(X'X)^{-1}$ are proportional to the variance and the covariances of the elements of b.

The variance of the prediction in a specific point x is given by:

$$\text{var}(xb) = \sigma^2 x'(X'X)^{-1}x$$

For each factor x_i that is discrete we create a corresponding set of indicator variables that are then used in the multiple-regression model above. So, for example, consider different leavening agents in a biscuit baking process, e.g., effects of yeast, enzymatic fermentation or baking powder on the final weight of the biscuit. For the three levels of leavening agent we would define two indicator variables:

$$z_1 = \begin{cases} 1 & \text{If leaving = yeast} \\ 0 & \text{If not} \end{cases}$$

$$z_2 = \begin{cases} 1 & \text{If leaving = baking powder} \\ 0 & \text{If not} \end{cases}$$

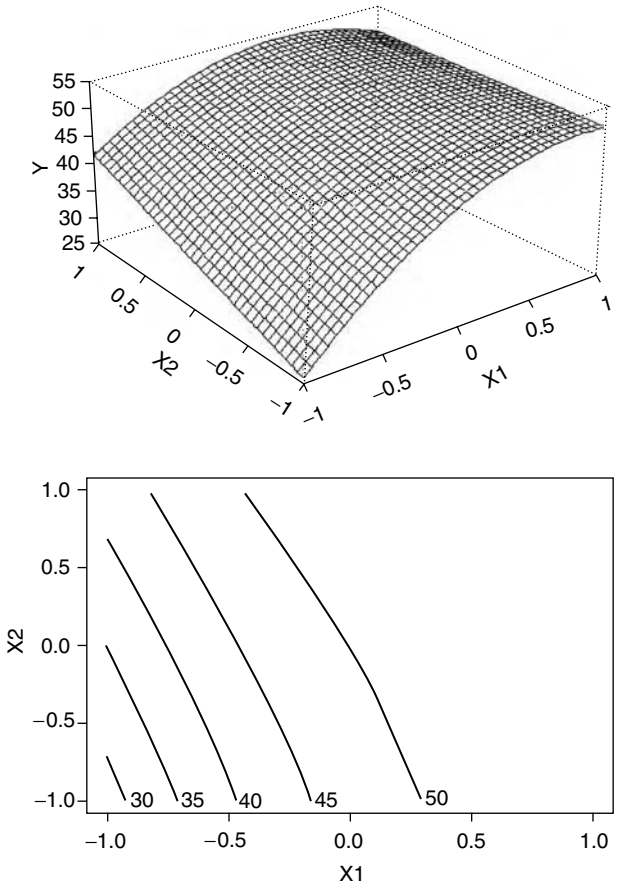

FIGURE 143.3 Perspective and contour plot of the second order model: $y = 50 + 8X_1 + 3X_2 - 7X_1^2 - 4X_1X_2$.

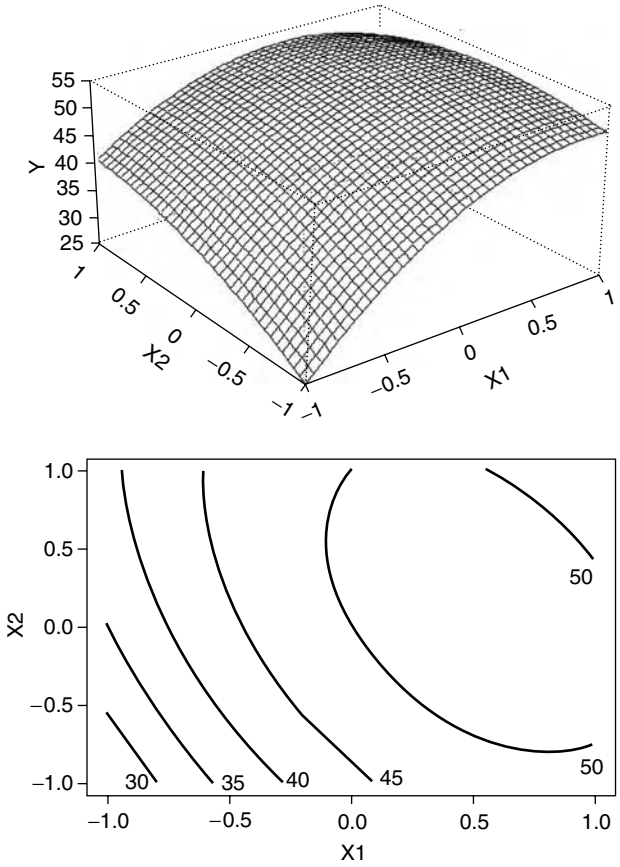

FIGURE 143.4 Perspective and contour plot of the second order model: $y = 50 + 8X_1 + 3X_2 - 7X_1^2 - X_2^2 - 4X_1X_2$.

By creating indicator variables, so called dummy coding, categorical variables can be included in response surface models.

For good reference books see Draper and Smith (4), Gunst and Mason (5) and Neter, Kutner, Nachtsheim and Wasserman (6).

V. BASIC CONCEPTS OF EXPERIMENTAL DESIGN

Experimentation is a basic part of scientific research. In experimentation, the researcher deliberately introduces certain changes in a process or product composition and makes observations to determine the effect of the different changes on a response. The success of the experimentation is a combination of having a good study plan or experimental design and careful and competent implementation of the treatment protocols. The key to a good experimental design is ensuring that the measurements taken will be relevant to the study objectives. Study objectives may be simple, such as getting the correct texture in the final product or may be quite complex involving an array of quality, cost and reliability measures.

All statistical experimental designs have a set of basic concepts in common. Let's elaborate the definitions and basic characteristics (7, 8).

A. Some Definitions in Experimental Design

An experimental factor or independent variable is a fixed variable, which is supposed to determine at least partially the system under study (and thus affects the dependent variable(s)) and which can take at least two different values or factor levels. A factor is denoted x_i for $i = 1, 2, \ldots, k$ and k is the number of experimental factors in the study.

An experimental treatment is a specific combination of a level for each factor. A treatment corresponds with a row vector consisting of a level for each factor ordered in an arbitrary way. Vertical concatenation of all these row vectors gives the treatment matrix.

The number of observations or measurements of the independent variable for each treatment are called replications.

An experimental unit is the smallest subdivision of an experiment to which a treatment is applied in a single trial. An experimental unit corresponds to a row vector representing a treatment.

The design matrix of an experiment consisting of n experimental units and k factors is a n*k matrix, with rows the experimental units.

The region of interest, the factor space of the experiment or the experimental region is the hyper-volume spanned by the points in the treatment matrix. Thus a treatment matrix has a geometrical equivalent. In classical experimental design theory both hyper-cubical and hyper-spherical experimental regions are most common.

The size of an experiment equals the number of treatments multiplied by the number of replications per treatment or the number of experimental units n.

The expanded design matrix is the design matrix extended with a certain number of columns depending on the assumed model. The total number of columns of this matrix equals the number of parameters to be estimated. For instance, for the second order model ($y = 50 + 8X_1 + 3X_2 - 7X_1^2 - 3X_2^2 - 4X_1X_2$) the design matrix consisting of the levels for X_1 and X_2 is augmented with columns representing X_1^2, X_2^2, X_1X_2 and a column of 1's for the intercept.

B. Basic Principles of Experimental Design

1. Replication

A key aspect of a scientific finding is that it can be replicated. In statistical experimental design we formalize this concept by requiring that each treatment be replicated a number of times. Replication allows us to quantify the degree of variability in the response within each treatment. By pooling this variability across all treatments we are able to assess the importance of average response differences among treatments. Without replication we are unable to tell whether the differences in response observed when the treatments are different are due to natural variability in the response of the experimental unit to any treatment or actually reflect a true shift in the underlying process.

Thus replication or measurement of the dependent variables for repetitions of the same treatment has two goals.

Firstly it allows us to obtain an estimate of the experimental error. This estimate of error becomes a basic unit of measurement to determine whether observed differences in the dependent variable are really statistically different. Thus the size of a detectable effect is determined by the number of replications.

Secondly replication permits obtaining more precise estimates of possible differences between treatments.

2. Randomisation: Protection Against Unknown Bias Introducing Factors

By randomisation is meant that both the allocation of the treatments to the experimental units as well as the order in which measurements are taken should be determined at random. The different treatments should be randomised over the experimental units when carrying out the experiment. This means that each treatment should have the same probability of being exposed to bias generating factors not included in the experiment. Thus randomisation of the treatments excludes the introduction of systematic bias into an experiment, by averaging out the possible effects of extraneous factors.

The use of randomisation is the keystone of the application of statistical theory to the design of experiments.

3. Blocking: Protection Against Known Bias Introducing Factors

Often, experimental units are grouped into homogeneous blocks at the start of the experiment. Blocking can be done to control for time or resource constraints, to ease implementation of large experiments or to account for a factor which is known to affect the response but which is not of primary interest. For example, if we are baking cookies in a small oven, the size of the oven places a limitation on how many cookies can be baked at one time. Each batch of cookies baked in the oven at the same time becomes a block. In the analysis of the resulting data, block effects will first be removed before we examine treatment effects. In this way, the final treatment comparisons are said to be independent of or adjusted for the blocking factor.

The blocking factor should be designed as independent (orthogonal) as possible with the other experimental factors. If this factor is not interacting with other factors, the blocking factor has a pure additive effect and is not interfering with the interpretation of the main factors.

4. Factorial Treatment Structures

When there are multiple factors that are of interest in the experiment it is typical that the treatments examined are formed by combining levels of one factor individually with all levels of the other factors: so called factorial experiments. Information obtained from factorial experiments is more complete than that obtained from a series of single factor experiments, because factorial experiments permit one to estimate the effects of several factors simultaneously and allow the evaluation of interaction effects. An interaction effect between experimental factors occurs if the difference in response between the levels of one factor is not the same at all the levels of the other factors. In the context of response surface estimation this involves the presence of significant cross product terms in the model.

A class of factorial designs that are used many times in the first stages of product development, namely for the screening of important experimental factors, are two level factorial designs. This design consists of all possible combinations of a low and a high level for k factors. Geometrically the treatment matrix describes a hyper-cube. For

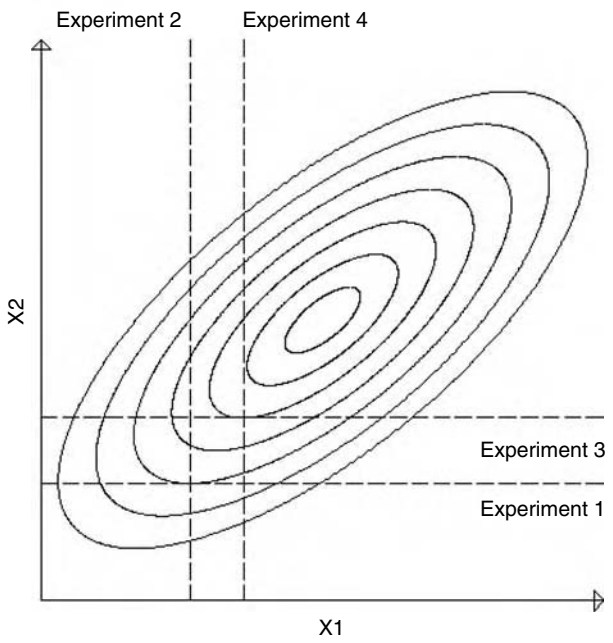

FIGURE 143.5 One-factor-at-a-time approach: an undefined number of experiments is necessary to attain the optimum.

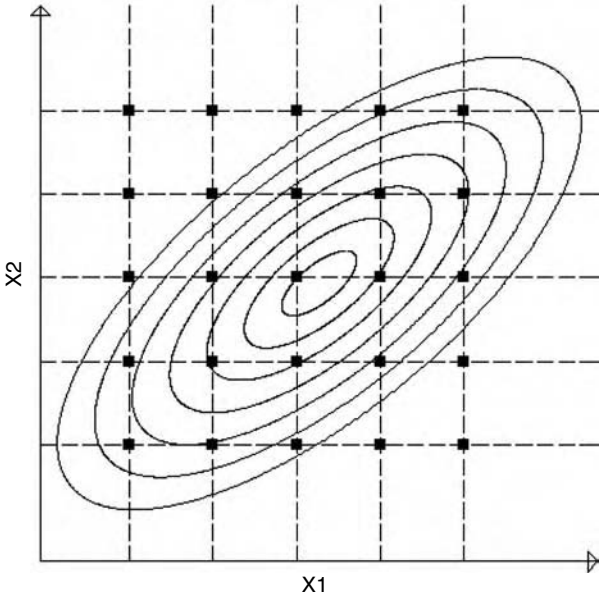

FIGURE 143.6 Factorial approach to optimisation.

example a 2^k factorial design consists of all combinations of the two levels for k factors.

It is natural to wonder why one should experiment with factorial treatments instead of using only simple treatments defined by levels of only one factor. Clearly, such an approach to experimentation is feasible, but the one factor at a time approach has a number of drawbacks. The major drawback is that it does not take into account the interactions that are known to exist among different factors that make up a processed food.

Suppose the contour plot of the real model looks like Figure 143.5. The main objective is finding the values for X_1 and X_2 were y is maximal, in other words find the top of the mountain. Proceeding with the one-factor-at-a-time approach could start with experiment 1. In this experiment X_2 is kept constant and X_1 is varied in several levels, resulting in an optimum value for y. Consecutively an experiment 2 is carried out with X_1 constant at the optimum of experiment 1 and the levels of X_2 changing. Again an optimum for experiment 2 is reached. As demonstrated in Figure 143.5, even for a simple response surface, a large number of experiments is necessary. Depending on the specific shape of the model and the chosen factor levels possibly the optimum is never reached, because this approach is extremely sensitive to local optima.

On the other hand if a factorial type of design, demonstrated by the grid on Figure 143.6, would have been imposed, the approximate shape of the model and the approximate location of the optimum would have been discovered in one experiment.

The sum of all the experimental units of all the one-factor experiments is most of the time much larger than the number of factorial combinations. Taking into account that the one-factor-at-a-time experiment does not guarantee finding the optimum, while the factorial does, it is obvious that factorial type experiments are by far more efficient in optimisation strategies.

Secondly the efficiency of finding significant effects increases with the number of factor combinations included in the experiment. Factorial experiments are very efficient in terms of the resources needed to achieve the experimental objective. In the separate one-factor experiments, the estimate of remaining uncertainty is based on replicates of only a few treatments. The factorial experiment typically uses a larger number of treatments and pools the information on residual uncertainty to produce more precise treatment effect estimates used in factor comparisons.

Finally, factorial treatment structures offer more flexibility in how the full set of treatments are implemented, allowing you to run a different subset of factor combinations in each block yet still incorporate factor interactions in the subsequent analysis.

5. Coding

When fitting first order models to 2^k factorial experiments, it is convenient to code the experimental factors as -1 for the low level and $+1$ for the high level. This corresponds to the transformation:

$$X_i^c = 2\left(\frac{X_i - \overline{X}}{\Delta_i}\right)$$

with X_i^c the coded factor level, X_i the original factor level, $\overline{X}$ the average of X_i and Δ_i the range of X_i.

For instance, if factor X_1 takes values 30 and 50, the coded X_i^c becomes:

$$2\left(\frac{30-40}{20}\right) = -1 \quad \text{and} \quad 2\left(\frac{50-40}{20}\right) = 1$$

Coded in this way, the parameter estimates of the first order model become contrasts in the measured response divided by the number of experimental units. This approach is equivalent to the classical analysis of variance procedures. In the sequel all treatment matrices will be coded like this.

C. Important Properties of Experimental Designs

1. Orthogonality

A design for a first order model is orthogonal when its coded design matrix D is an orthogonal matrix. The product of an orthogonal matrix with its transpose is a diagonal matrix, thus $D'D = I$, with I the unit matrix. Recall that the variance-covariance matrix of the model parameters in a least squares fit of a linear model is:

$$\text{var(b)} = \sigma^2 (D'D)^{-1} = \sigma^2 I$$

with σ^2 the error variance.

In this case the covariances of the model parameters are zero, in other words the parameter estimates can be assessed independently. Thus no confounding between experimental factors arises and effects can be interpreted directly. These designs are especially useful when a large number of experimental factors have to be screened to separate important from less important factors.

How to construct orthogonal designs? Combining each level of each factor an equal number of times always leads to orthogonal factorial designs. Replication of centre points retains orthogonality. A classical example of an orthogonal design is the 2^k factorial.

2. Rotatability

An experimental design is called rotatable if the variance of the predicted response depends on the distance to the centre of the design and not on the direction (7). Since the main aim of fitting a model that relates product attributes to ingredients and process variables is to optimise the predicted response, the variance of this predicted response is most important. The variance of the prediction in a specific point x is given by:

$$\text{var(xb)} = \sigma^2 x'(X'X)^{-1}x$$

The property of equal precision at any given distance from the centre point is desirable because it is not usually known in advance which direction from the centre will lead to optimal conditions. Rotatable designs are especially suited for second order models. The geometry of the discussed rotatable designs is hyper-spheric.

VI. EFINITION OF THE REGION OF INTEREST

A. Determination of the Important Factors and their Ranges

In this context two situations occur:

1. Sub-optimal operating conditions are known. In product development most of the time some 'sub-optimal' operating conditions are available or at least some knowledge exists about important and less important factors and their specific levels in function of the process under study. Starting from the actual operating conditions, namely a specific ingredient composition and/or process conditions, an optimal 'factorial type' design is constructed to explore the neighbourhood of these 'sub-optimal' conditions. In this case the experimental region is defined as a design centred at the 'sub-optimum.' Thus for each factor a range is chosen with as centre the sub-optimum. Some particular combinations of the levels of each experimental factor describe the vertices of a hyper-volume, centered at the sub-optimum. The choice of the actual range per factor depends on a priori knowledge about the effect of the factor on the response variable, on the nature of the factors (mixture or unconstrained) and on the assumed model as will be explained later.
2. No or not enough a priori knowledge about the process is known. When a priori knowledge about the importance of experimental factors or about the approximate location of the optimum is missing, an overall optimisation in multiple steps is necessary. In the first steps screening experiments are used to separate important components from less important ones over a relatively large experimental region, thus involving relatively large ranges for each factor. Once the key factors are determined, the approach in situation 1 can be followed to determine the region of interest.

B. The Choice of the Statistical Model for the 'Factorial Type' Approach

As demonstrated previously experimenting with all important factors simultaneously included in a 'factorial' type experiment is a far better approach than one-at-a-time approaches.

Once this multi-factor experimental region is defined, a model form has to be chosen that will be used to relate the experimental factors with the measured response within the experimental region. In a response surface approach the preferred models are polynomials of first and second degree, namely, linear and quadratic models.

First order models with or without interaction terms, (need at least experiments with 2 levels per factor) are appropriate in three situations:

1. Screening experiments to select the important factors out of a set of possible factors of influence.
2. Experiments in such narrow ranges that the expected effect on the response variable can be assumed to be linear. This approach is especially suitable in the 'Method of Steepest Ascent' (9).
3. When the real model is known to be linear.

A first order model fits a hyper-plane over the experimental region and as a consequence the maximal response will always occur on the border of the region if the plane has slope. This model only provides information about the main effects of the factors. If the fitted surface has no slope the experimental factors have no main effects within the experimental region; in other words a zone of equal response is found.

The model with interaction terms can take into account the fact that the response of one factor differs in function to the levels of other factors, but the response in the main effects is still linear.

Second order models (need at least experiments with 3 levels per factor) provide information about linear, interaction and curvature effects with respect to all or most of the independent variables. These models are widely applicable to describe experimental data in which system curvature is abundantly present. Thus these models are most appropriate to optimise a response over the experimental region, in other words to discover the levels of the ingredients and process conditions of the product that result in optimum product attributes.

The choice of the model is unquestionably linked with the choice of an optimal design and the nature of the factors. Upgrading from a first to a second order model involves an exponential increase of the amount of necessary treatments.

C. Practical Considerations

Optimisation of all the compositional factors of a product, together with all relevant process conditions necessitates a large number of component combinations or treatments, due to the high dimensionality of the experimental region or the high number of possible product ingredients and processing variables.

Of course the number of treatments has to be multiplied by the number of desired replicates per medium to get the real size of the experiments and a good estimate of the work and costs involved.

Although optimal from a theoretical point of view it is obvious that these large sized factorial experiments make no practical sense in optimisation. Although models fitted on these designs will increase the insight in the system, the estimation of the high order interactions is not necessary to find the optimum operating conditions. Response surface modelling emphasises the optimisation of a predicted response with an as 'simple' model approximation as possible. Thus, in most cases, the interpretation of the model parameters is of less importance, because the emphasis is on the estimation of the predicted response, resulting in the optimum conditions.

Moreover, in most practical optimisation situations in the food sciences (and in industry in general) the size of an experiment is restricted to a 'reasonable' number of experimental units due to external factors: product and equipment availability, limited time period to carry out measurements, financial limitations, manpower, etc. Especially in these high dimensional systems the practical feasibility of the experiment is the determining factor for the optimisation strategy, compromising between the number of factors and the complexity of the statistical model.

In practice, methodologies are searched for that have a high probability to find the optimum taking in account as small a number of treatments as possible, resulting in the impossibility to estimate high order interactions. These are defined as screening and response surface modelling designs. Distinction has to be made here between designs for unconstrained experimental regions and designs for constrained regions (mixture systems). What if the wrong model is assumed?

It is good practice to introduce a treatment in each experiment that can be used as a checkpoint to control the lack of fit. A simple approach is to fit the model based on all treatments except the checkpoint and then compare the predicted response in the checkpoint with the real measured value. In particular, this is used to test for possible curvature while fitting a first order model. The statistical approach to lack of fit uses a partitioning of the error sums of squares into pure experimental error and lack of fit as the foundation for formal tests (2).

VII. Optimisation Phase: Obtaining the Optimal Composition by Investigation of the Fitted Mathematical Model

A. Possible Situations

In the optimisation step the fitted response surface is used in the search for the optimum. Different situations result

as a function of the location of the optimum:

1. The optimum is located on the border of the experimental region. In this situation a principal direction of improvement can be defined, directed to the new optimum. A new experiment has to be carried out centered at the new sub-optimum, followed by re-evaluation. This is actually a search for the region of maximal response by consecutively fitting first order models. This procedure in which the experimenter proceeds sequentially along the path of maximum increase in response is called the 'Steepest Ascent Procedure' (9). Once the approximate location of the optimum is found a second order model is used to determine the optimum.
2. Within the experimental region no optimum is found. This means that the response is not affected by the changes of the factors within the range of the experiment. In other words the experimental region can be considered as a region of sub-optimal response. If desirable a new experiment can be set up centered at the sub-optimum but increasing the ranges of all factors. When fitting first order models carry out the lack of fit test to make sure that no curvature is present in the real model.
3. The optimum is found within the experimental region. The objective is reached. Double-check in case of local optima can be necessary. The fitted second order model can be investigated and the optimum can be determined.

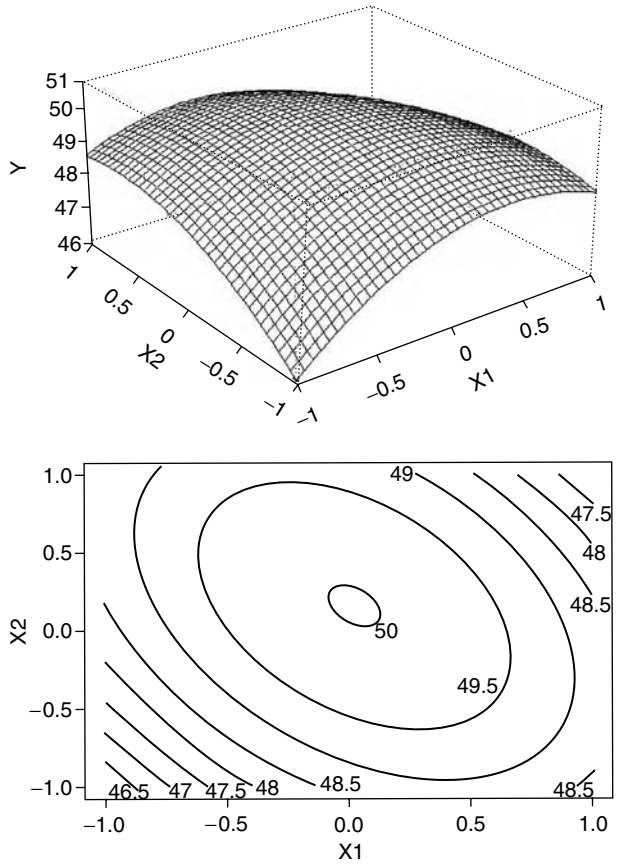

FIGURE 143.7 Perspective and contour plot of the second order model: $y = 50 + 0.2X_1 + 0.3X_2 - 1.5X_1^2 - 1X_2^2 - 1X_1X_2$. The stationary point is a maximum.

B. Determination of the Optimum for a Second Order Model

1. Contour and Perspective Plots

A contour plot is a two-dimensional graph showing contours of constant response in an axes system defined by two experimental factors X_i and X_j, while the other experimental factors are kept constant. In most practical situations the fitted model should be plotted to allow preliminary evaluation of the model and determination of the optimum. Perspective plots are a useful aid in interpretation of fitted models (see Figure 143.7)

2. Mathematical Procedures

If a second order model is fitted, the direct way to find the optimum is by differentiating the response function with respect to the X_i's. Setting all partial derivatives

$$\frac{\partial y}{\partial X_i} = 0$$

will determine the stationary point if it exists. It has to be emphasised that this point can be either a maximum, a minimum or a saddle point of the fitted function (Figures 143.7 and 143.8).

To determine the nature of the fitted surface and the stationary point, a canonical analysis has to be carried out. This analysis consists of two steps. First, the origin of the axes system is translated to the stationary point. Next, the axes system is rotated in such a way that the new axes correspond to the principal axes of the response surface or contour system.

In the new coordinate system, defined by W_i, the response function is given by:

$$y = y_0 + \lambda_1 W_1 + \lambda_2 W_2 + \cdots + \lambda_k W_k$$

where y_0 is the estimated response at the stationary point. This is called the canonical form of the fitted second order function. If all λ_i are negative, a move in any direction from the stationary point results in a decrease in y. Therefore, the stationary point represents the point of maximum response. If all λ_i are positive the stationary point is a minimum. When λ_i differ in sign the stationary point will be a saddle point.

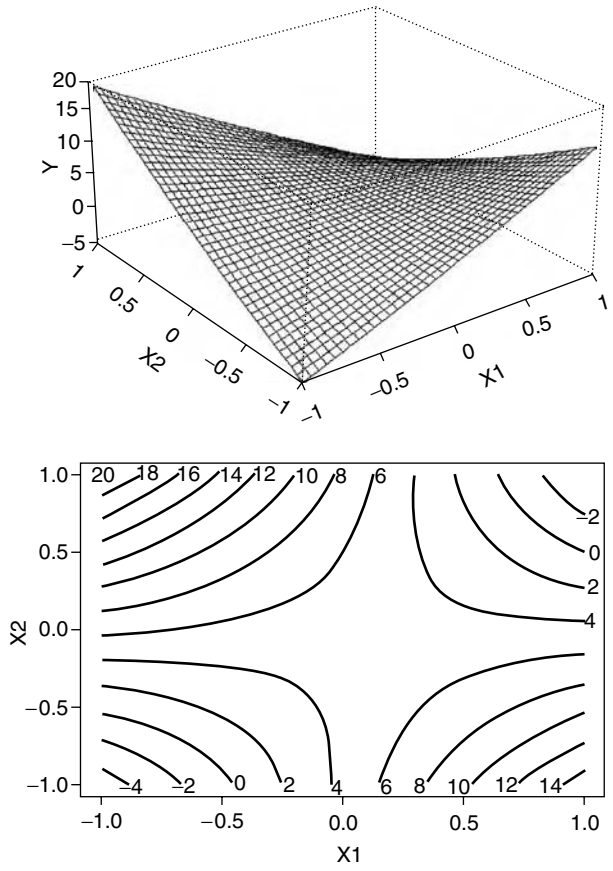

FIGURE 143.8 Perspective and contour plot of the second order model: $y = 5 - X_1 + 1.5X_2 + 0.5X_1^2 + X_2^2 - 11X_1X_2$. The stationary point is a saddle point.

For detailed description of the underlying mathematics the interested reader is referred to the specialised literature (1) (2).

C. Multiple Response Variables

Until now, methodology is described to optimise one response variable. In many situations, however, more than one response variable has to be optimised at the same time. When multiple responses are observed there is a need to reach some type of compromise as far as the optimal product attributes are concerned.

A simple approach is overlaying the contour plots of the fitted models for each individual response variable and then searching for regions of 'satisfactory' compromise. For a few responses this procedure mostly solves the problem. For multiple dimensions in response surface methodology the reader is referred to the specialised literature (1, 2). More general approaches, like multivariate analysis of variance and canonical correlation analysis can be found in multivariate analysis books (10, 11).

VIII. MIXTURE THEORY: IN SEARCH OF OPTIMAL COMPOSITION

Many products consist of a mixture of different ingredients, mixed together in a certain composition, for instance cake dough: a mixture of flour, butter, sugar and baking powder. As a function of the relative proportions of the different components the properties inherent to the final cake product differ. In the general mixture problem, the response that is measured is only a function of the proportions of the ingredients present in the mixture and not of the amount of the mixture. The textural properties of the cake or rheological characteristics of the dough are functions of the relative composition of its constituent and not of the amount of dough prepared.

In this chapter the possibilities and the major advantages of mixture experiments are briefly presented. More detailed information on mixture experiments can be found in the work of Cornell (12), Schrevens (13–15), Goel (16) and De Rijck (17).

A. Basic Concepts of 'Mixture Systems'

1. Whole Simplex Mixture

Mixture experiments can be distinguished by the fact that the independent variables represent proportionate amounts, rather than unrestrained amounts. The proportion of each component must be nonnegative. If the proportions are expressed as fractions, they must sum to unity. For a mixture system consisting of q components, with x_i the fraction of the ith component the following equations are valid:

$$0 \le x_i \le 1 \qquad \text{for } i = 1, 2, 3, \ldots, q$$

$$\sum_{i=1}^{q} x_i = 1$$

The q components of a mixture system are called 'mixture variables.' The proportion of each mixture variable can vary from 0 (the component is not present) to 1, a mixture with only one component, called a 'pure mixture.' If in a q component mixture the proportion of q–1 mixture variables is determined, then the proportion of the qth mixture variable is also determined:

$$x_q = 1 - \sum_{i=1}^{q-1} x_i$$

In this way the mixture equations reduce the q dimensional factor space to a q–1 dimensional simplex (18). This reduction in dimensionality is represented in Figures 143.9 and 143.10 for respectively a two and a three component mixture system. For a two component mixture the simplex factor space is an interval on a straight line (Figure 143.9). If there are three mixture variables the three dimensional space is reduced to a two dimensional surface, resulting in a sim-

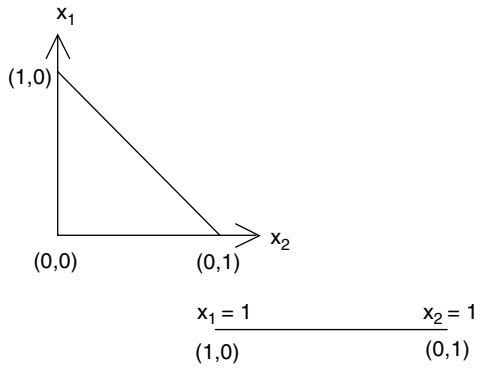

FIGURE 143.9 Simplex factor space for a two component mixture.

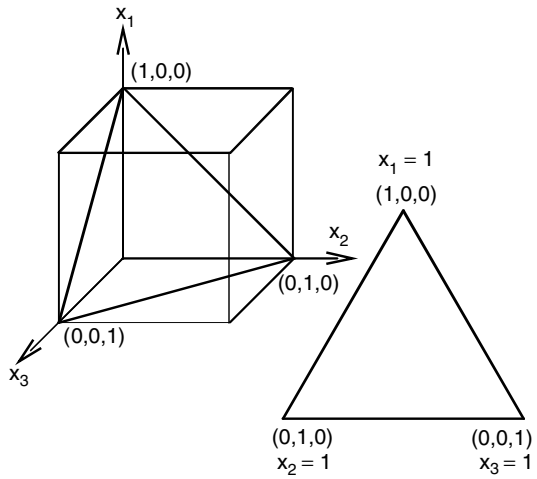

FIGURE 143.10 Simplex factor space for a 3 component mixture.

plex factor space represented as an equilateral triangle (Figure 143.10). Each point within the triangle represents a certain mixture, represented by its co-ordinates. The co-ordinate system used for the values of the mixture components is called a 'simplex co-ordinate system' or 'trilinear co-ordinates.' A four component mixture can be represented by a tetrahedron (Figure 143.11). For a mixture system with more than four components the factor space is a q–1 dimensional simplex or q–1 dimensional hyper-tetrahedron.

A typical whole simplex mixture model is the blending of different fruit juices (orange, pineapple, lemon) to optimise the taste of the mix. In this example pure mixtures, for instance 100% orange juice are possible treatments in the experiment.

2. Constrained Mixture System

In some cases the whole factor space is not feasible. Physical, physiological, chemical or economical considerations in mixture experimentation often impose constraints on the

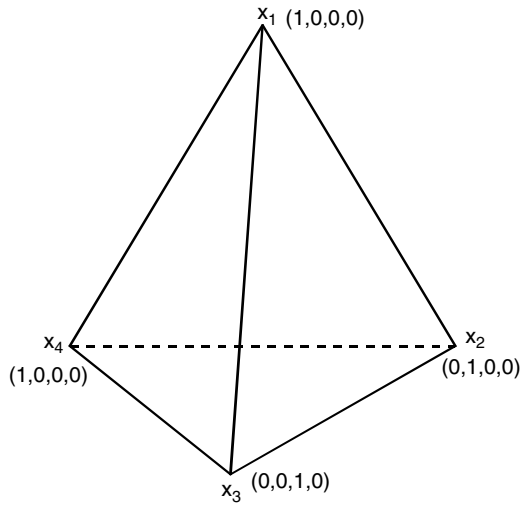

FIGURE 143.11 Simplex factor space for a 4 component mixture.

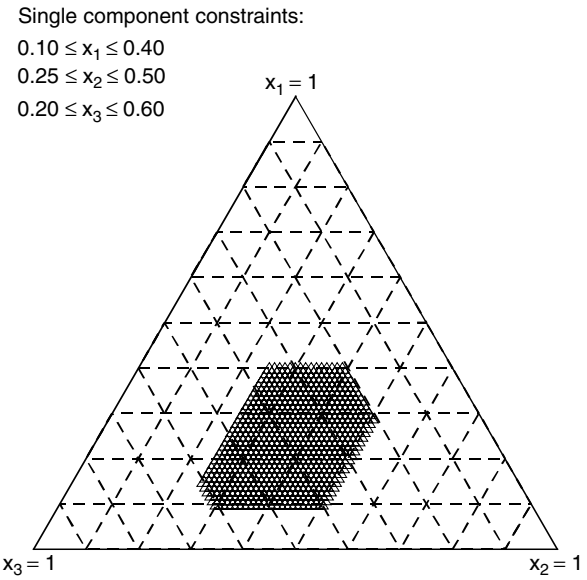

FIGURE 143.12 Subregion of a 3 component mixture.

levels of components in the mixture. These constraints define the region of interest and hence play an important role in the design and analysis of the mixture experiment (19). These constraints reduce the factor space to a sub-region. For instance cake dough as a mixture of flour, butter, sugar and baking powder is a good example of a constrained mixture.

Imposing a certain lower (l_i) and/or upper (u_i) bound on the proportion of the mixture variables, reduces the factor space to a sub-region (Figure 143.12) of the $(q - 1)$ — dimensional simplex, defined by the following equations:

$$0 \leq l_i \leq x_i \leq u_i \leq 1$$

with l_i and u_i respectively the lower and upper bound imposed on the component x_i. Taking into account the mixture equation, the following constraints are imposed on l_i and u_i:

$$\sum_{i=1}^{q} l_i < 1$$

$$\sum_{i=1}^{q} u_i > 1$$

$$l_i \neq u_i$$

If these equations are not satisfied only one component combination is possible ($l_1, l_2, \ldots, l_q$) or ($u_1, u_2, \ldots, u_q$) or none at all. For each $l_i = u_i$, the dimensionality of the factor space is reduced by 1 and the remaining components must sum to $(1 - l_i)$.

If the settings of the other constraints make it impossible for a component to reach its lower or upper bound then the sub-region is called "inconsistent" (19). Single component constraints are consistent if the sub-region contains the points ($x_1, x_2, \ldots, x_q$) so that for each component $x_i = l_i$ and $x_i = u_i$. Consistency of the constraints can be checked, using Piepel's method. Inconsistent single component constraints can be made consistent by decreasing the upper bounds or increasing the lower bounds in such a way that:

$$u_i + \sum_{j \neq 1}^{q} l_j = 1$$

$$l_i + \sum_{j \neq i}^{q} u_j = 1$$

3. Process Variables

If a mixture experiment includes factors besides the mixture components that are not bound by the mixture constraint, these are called 'process variables' (20). Changing the process variables may affect the blending properties of the mixture components. For instance the time of mixing dough may effect the properties of the dough. The mixing time is not a component of the mixture but a process variable of the mixture experiment. The experimental region of a mixture experiment with process variable(s) is the combined region of the mixture components and the process variable(s) (Figure 143.13). The dimensionality of the combined experimental region equals the sum of the dimensionality of the separate experimental regions. The 3 dimensional prism (Figure 143.13a) is the combined experimental region of the two-dimensional simplex (x_1, x_2, x_3) and the one-dimensional experiment in process variable z. In Figure 143.13b a 2^2 factorial design in the process variables is carried out at each of the treatments of a 3 component mixture design.

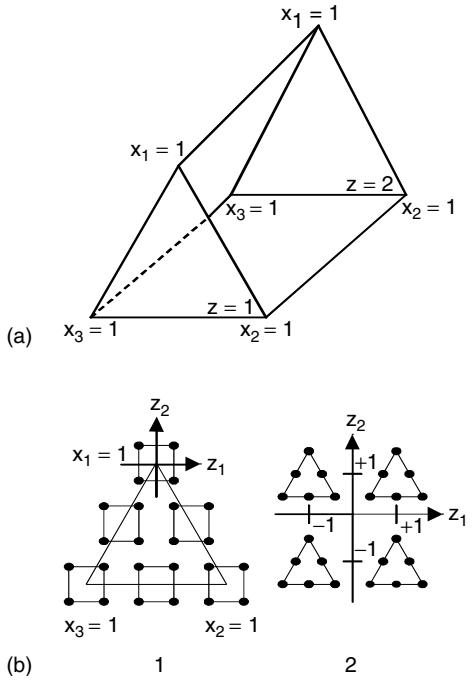

FIGURE 143.13 a: Combined region for a 3 component mixture (x_1, x_2, x_3) and 1 process variable (z); b: Combined region of a 2^2 factorial design and a {3, 2} simplex lattice design. 1: factorial design plotted per lattice treatment. 2: lattice design plotted per factorial treatment.

In some cases the response is a function of the amount of the mixture. For instance the mixing modalities of dough could be related to amount of dough. These kinds of mixture experiments are called 'mixture amount experiments' (21). The mixture amount experiment is a special case of a mixture process variable experiment.

B. Response Surface Models for the Analysis of Mixture Experiments

1. Specific Mixture Models: Canonical Polynomials

The first step in the design and analysis of mixture systems is the choice of a model to describe the response as a function of the mixture variables. As explained earlier polynomials are used to approximate the real model. Incorporation of the mixture constraint (sum of the proportion of the mixture variables equals 1) into polynomial models results in specific mixture models, named canonical polynomials (22).

This renders the following first order canonical polynomial:

$$y = \beta_0 \sum_{i=1}^{q} x_i + \sum_{i=1}^{q} \beta_i x_i = \sum_{i=1}^{q} \beta_i^* x_i$$

with: $\beta_i^* = \beta_0 + \beta_i$ for all i = 1, 2, …, q

Through analogous derivation the second order canonical polynomial is found to be:

$$y = \sum_{i=1}^{q} \beta_i^* x_i + \sum_{i<}^{q} \sum_{j}^{q} \beta_{ij}^* x_i x_j$$

for all i, j = 1, 2, …, q, i < j

In some cases a special cubic canonical polynomial could be of interest:

$$y = \sum_{i=1}^{q} \beta_i^* x_i + \sum_{i<}^{q} \sum_{j}^{q} \beta_{ij}^* x_i x_j + \sum_{i<}^{q} \sum_{j<}^{q} \sum_{k}^{q} \beta_{ijk}^* x_i x_j x_k$$

for all i, j, k = 1, 2, …, q, i < j < k

2. Models for the Inclusion of Process Variables

As defined by Cornell (12), process variables are factors in a mixture experiment that do not form any portion of the mixture, but whose levels, when changed, affect the blending properties of the ingredients. To model the response of the combined experiment, a combination is made of the model in the process variables and the mixture model.

For instance multiplication of a 'first order model with interaction' in two numeric process variables z_1 and z_2 with a second order mixture model in three components and combining the parameters δ_i and β_j in one parameter κ_{ij} renders the following combined model:

Process variable model: $y = \delta_0 + \delta_1 z_1 + \delta_2 z_2 + \delta_{12} z_1 z_2$

Mixture model: $y = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_{12} x_1 x_2 + \beta_{13} x_1 x_3 + \beta_{23} x_2 x_3$

Combined model:

$$y = \kappa_1 x_1 + \kappa_2 x_2 + \kappa_3 x_3 + \kappa_{12} x_1 x_2 + \kappa_{13} x_1 x_3 + \kappa_{23} x_2 x_3 + \kappa_{11} x_1 z_1 + \kappa_{21} x_2 z_1 + \kappa_{31} x_3 z_1 + \kappa_{121} x_1 x_2 z_1 + \kappa_{131} x_1 x_3 z_1 + \kappa_{231} x_2 x_3 z_1 + \kappa_{12} x_1 z_2 + \kappa_{22} x_2 z_2 + \kappa_{32} x_3 z_2 + \kappa_{122} x_1 x_2 z_2 + \kappa_{132} x_1 x_3 z_2 + \kappa_{232} x_2 x_3 z_2 + \kappa_{112} x_1 z_1 z_2 + \kappa_{212} x_2 z_1 z_2 + \kappa_{312} x_3 z_1 z_2 + \kappa_{1212} x_1 x_2 z_1 z_2 + \kappa_{1312} x_1 x_3 z_1 z_2 + \kappa_{2312} x_2 x_3 z_1 z_2$$

In these combined models, reduction in numbers of terms is desirable and can be accomplished using stepwise- or all-possible-regression model building procedures.

C. Design Strategy to Optimise Mixture Systems

The mixture design used for a specific situation must be constructed to accommodate the region of interest. The shape of this region and all associated constraints has a very strong influence on the final experimental design used.

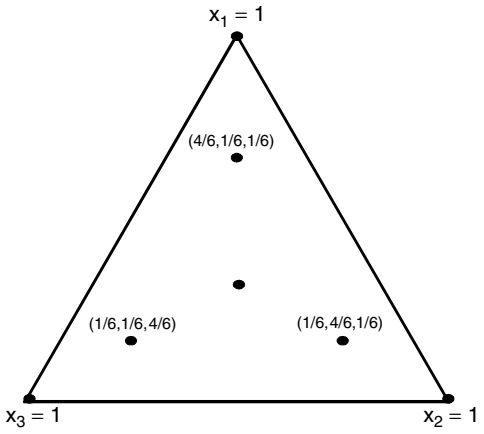

FIGURE 143.14 Three component simplex screening design.

1. Whole Simplex Mixtures

If no additional constraints are imposed on the system the experimental region is defined by the mixture constraint and thus coincides with the whole simplex.

To explore the whole simplex, the designs mostly used are the simplex screening, the simplex lattice and the simplex centroid mixture designs.

a. The simplex screening design

The simplex screening design (23) is appropriate for fitting a first order model. These designs are proposed when more than six components are involved in a screening experiment. These preliminary experiments try to gain more insight into the importance of the mixture components.

A q component simplex screening design consists of:

- q pure components: q permutations of (1,0,0,0,…,0)
- the overall centroid: 1/q, 1/q, 1/q, …, 1/q
- q interior points of the form: $[(2q)^{-1}, (2q)^{-1}, \ldots, (q + 1)/2q, \ldots, (2q)^{-1}]$

With this design q components can be screened with (2q + 1) treatments. An example is shown in Figure 143.14.

b. The simplex lattice design

A design used to explore the whole factor space is the '{q, m} simplex lattice design.' Each mixture variable varies with m + 1 equally spaced values from 0 to 1 (18):

$$x_i = 0, 1/m, 2/m, \ldots, 1 \quad \text{for } i = 1, 2, \ldots, q$$

In the design all possible treatment combinations with these proportions for each mixture variable are used (Figure 143.15). The number of points in the simplex lattice design can be calculated as follows (22):

$$\binom{q + m - 1}{m} = \frac{(q + m - 1)!}{m!\,(q - 1)!}$$

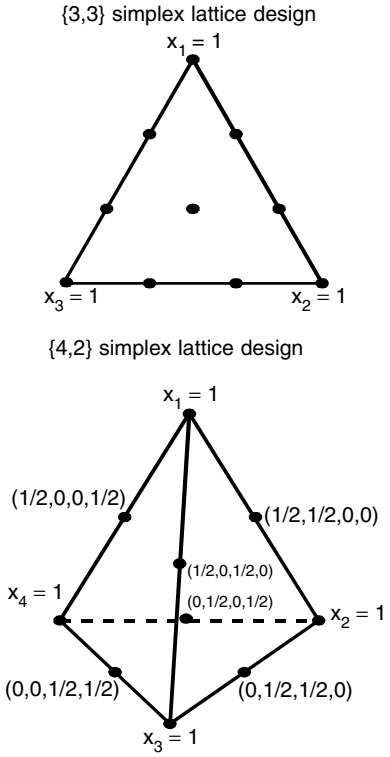

FIGURE 143.15 {q, m} Simplex lattice design.

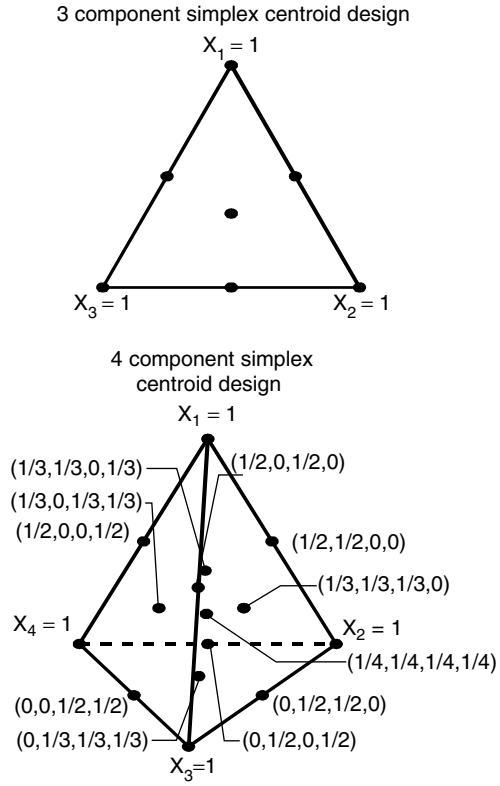

FIGURE 143.16 Simplex centroid designs.

The {q, 1} simplex lattice design is appropriate for first order models, while the {q, 2} and {q, 3} are suited respectively for a second order and special cubic canonical polynomial mixture model.

The {3, 2} simplex lattice design consists of the six points: (1, 0, 0), (0, 1, 0), (0, 0, 1), (½, ½, 0), (½, 0, ½) and (0, ½, ½). The first three mixtures are "pure mixtures" since they only consist of one component. The other mixtures are "binary mixtures" or two component mixtures.

b. The simplex centroid design

The simplex centroid design (20) consists of $2^q - 1$ points or mixtures:

– q pure components: q permutations of (1,0,0,0, …, 0)
– $\binom{q}{2}$ binary mixtures with equal proportions: $\binom{q}{2}$ permutations of ($^1/_2$,$^1/_2$,0,0, …, 0)
– $\binom{q}{3}$ ternary mixtures with equal proportions: $\binom{q}{3}$ permutations of ($^1/_3$,$^1/_3$,$^1/_3$,0, …, 0)…
– one q-nary mixture with equal proportions: the mixture ($^1/_q$,$^1/_q$,$^1/_q$,$^1/_q$, …, $^1/_q$)

The simplex centroid design includes the vertices of the centroid of the simplex and the centroid of all lower dimensional simplices, contained within the (q − 1)-dimensional simplex. For a given number of components there exists only one simplex centroid design, while different simplex lattice designs are possible. As an example a two and three component simplex centroid design is shown in Figure 143.16.

The simplex centroid design is especially suited to fit a special cubic canonical polynomial or to fit a second order model where the q-nary mixtures can be used as checkpoints for lack of fit.

2. Constrained Mixtures

Most mixture experiments are carried out in a sub-region of the total factor space defined by constraints. In functions of the imposed constraints the experimental region can be homomorphic with the simplex or can be a convex irregular polyhedron.

a. Homomorphic experimental region

If the experimental region is homomorphic or has the same shape as the whole simplex, the sub-region can be transformed into the whole simplex using a pseudocomponents transformation. In the transformed sub-region whole simplex designs in pseudo-components can be used as discussed in the paragraph on whole simplex designs.

Two cases occur: lower and upper bound constraints.

b. Lower bound restrictions

If in a mixture system consistent lower bounds are imposed on some or all of the components the resulting sub-region retains the shape of a simplex (Figure 143.17):

$$0 \le l_i \le x_i \le 1$$

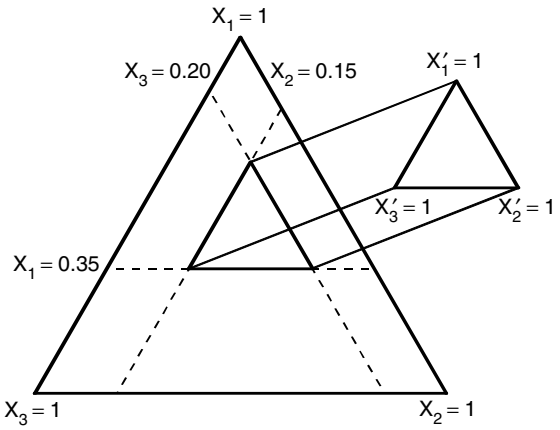

FIGURE 143.17 Transformation to L-pseudocomponents.

$$\sum_{i=1}^{q} l_i < 1$$

Some of the lower bounds l_i can be equal to zero. If the lower bounds are the same for each component, the centroid of the sub-region is the same as the centroid of the factor space. To describe the response surface over the sub-region with a polynomial equation, the model can be written using either the original mixture components with constraints or a lower-bound pseudocomponents transformation. The model calculations are more straightforward and easier to interpret when the lower-bound pseudocomponents approach is used. 'L-pseudocomponents x_i' are defined as follows (24):

$$x_i' = \frac{x_i - l_i}{1 - \sum_{i=1}^{q} l_i}$$

$$\text{with: } \sum_{i=1}^{q} l_i < 1$$

In Figure 143.17 this transformation is demonstrated. The resulting sub-region for a three component mixture system (x_1, x_2, x_3) constrained with the lower bounds $x_1 \geq 0.35$, $x_2 \geq 0.15$ and $x_3 \geq 0.20$, is transformed to L-pseudocomponents (x_1', x_2', x_3'), resulting in a whole simplex in L-pseudocomponents x_1', x_2' and x_3'.

c. *Upper bound restrictions*

Upper bound restrictions on some or all the components in a mixture system can be defined as:

$$0 \leq x_i \leq u_i \leq 1$$

Not all the mixture components need to be constrained by upper bounds. Upper bounds reduce the factor space to a simplex with the opposite orientation of the original simplex and enclosed in the whole simplex if and only if (25):

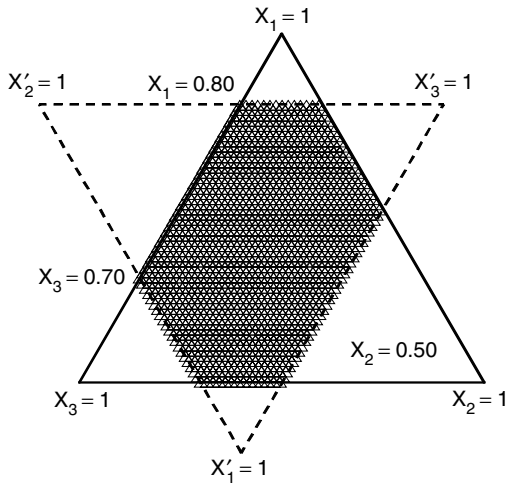

FIGURE 143.18 Transformation to U-pseudocomponents.

$$\sum_{i=1}^{q} u_i - u_{\min} \leq 1$$

with: u_{min} the minimum of the q upper bounds (exception made for the trivial case $q = 2$).

To transform the restricted simplex to a standard simplex the following pseudocomponent transformation can be used:

$$x_i' = \frac{u_i - x_i}{\sum_{i=1}^{q} u_i - 1}$$

Since the pseudocomponents simplex is opposite orientated, the effects of the pseudocomponents will also be opposite to the effects of the original components. If the boundaries of this simplex extend beyond the boundaries of the original simplex, the experimental region is an irregular hyper-polyhedron. The experimental region constrained by the upper bounds $x_1 = 0.80$, $x_2 = 0.70$ and $x_3 = 0.50$ in Figure 143.18 is an irregular hyper-polyhedron with 6 vertices.

d. *Lower and upper bound restrictions*

In practice, mixture components are quite often constrained by both lower and upper bounds. A mixture system constrained at the same time with lower and upper bounds can be defined as:

$$0 \leq l_i \leq x_i \leq u_i \leq 1$$

The resulting sub-region is homomorphic with the total factor space if the ranges ($u_i - l_i$) of all the components of the consistent set of constraints are equal and if the sub-region is positioned within the original simplex. Since

many sets of inconsistent constraint can define the same experimental region, while the region defined by consistent constraints is unique, the consistency of the constraints has to be checked first.

If a consistent set of constraints imposes an equal range on each component, the experimental range for both the lower and the upper bound simplex has to be calculated. The appropriate pseudocomponent transformation will be indicated by the smaller simplex. If this simplex is orientated in the same way as the original simplex, lower bound pseudocomponents are used; in the other case upper bound pseudocomponents are appropriate.

e. Convex irregular hyper-polyhedron

Most mixture experiments are carried out in sub-regions with an irregular shape due to the imposed constraints. In these cases a specific optimal design has to be computed for each specific situation using general optimal design theory. If high dimensional hyper-polyhedrons are investigated, the use of computer-aided design of experiments is essential.

An algorithm is necessary to list candidate points for the design, consisting of the vertices and the centroids of the faces of different dimensions, eventually extended with a number of interior checkpoints. These checkpoints will be used to test the goodness of fit of the model.

Once the candidate points are listed, a second algorithm selects an optimal set of design points from this list of functions of an optimal design criterion, related to the chosen model. This methodology falls beyond the scope of this text (12, 26–31).

D. Examples of Product Development Based on Mixture Theory

Although mixture experimentation strategies have been available since the sixties (oil, pharmaceutical, fertilizer, ceramics and explosives industries) it took until the eighties and even the nineties before these procedures were used in food engineering. Following are some extra examples of mixture product development and optimisation representing real industrial problems, solved by the research group of the main author.

1. The Experimental Region is the Whole Simplex: Optimisation of a Mixture of Different Fruit Juices

In a mixture experiment the consumer preference of a blend of orange-, pineapple- and grapefruit juices is optimised. Since non-linearity in response preference is expected a second order model is used and as a result a design to support the model is chosen. Table 143.1 and Figure 143.19 show a {3, 2} simplex lattice design in the three mixture components and the corresponding observed consumer preferences. A quadratic mixture model is appropriate (Table 143.2). This model has a coefficient of determination of 0.99, meaning that 99 % of the total variability is explained by the model. The contour plot of this model demonstrates that the pure mixture of orange juice is preferred above blends of different juices (Figure 143.19).

TABLE 143.1
{3,2} Simplex Lattice Design in Orange-, Pineapple — and Grapefruit Juice and Observed Average Consumer Preference Scores

Treatment	Proportion Orange Juice	Proportion Pineapple Juice	Proportion Grapefruit juice	Observed Preference. Average of 10 Consumers
1	1	0	0	85
2	0	1	0	78
3	0	0	1	65
4	0.5	0.5	0	80
5	0	0.5	0.5	68
6	0.5	0	0.5	70

2. A Constrained, Homomorphic Experimental Region: Optimisation of the Consumer Preference in Relation to Flour Composition of a Multiple Grain Cracker

In general, crackers are baked with only wheat flour. To develop a new type of cracker, part of the wheat flour was replaced with buckwheat, oats, barley and/or rye flour. To optimise the mixture of these 5 types of flour, the flour in the cracker dough was considered as a 5 component mixture system. Using mixture theory, a multifactorial {5,2} simplex lattice design was set-up in the wheat, buckwheat, oats, barley and rye factor space, resulting in 15 treatments (Table 143.3). The {5,2} simplex lattice design makes it possible to estimate both the main and the interaction effects of the experimental factors. Based on foreknowledge of the food technologist a lower bound constrained experimental region was selected, homomorphic with the total factor space and shifted towards the wheat vertex, meaning that the wheat proportion was partially replaced by the other flours.

The homomorphic experimental region was transformed to the whole factor space with a pseudocomponents transformation, resulting in a minimal confounding structure of the experimental design and thus more efficient parameter estimation.

The complete second order model in pseudocomponents proportions with 15 terms was fitted to the results. Using stepwise regression a reduced model with 6 terms was selected, representing the results with a coefficient of determination of 0.76.

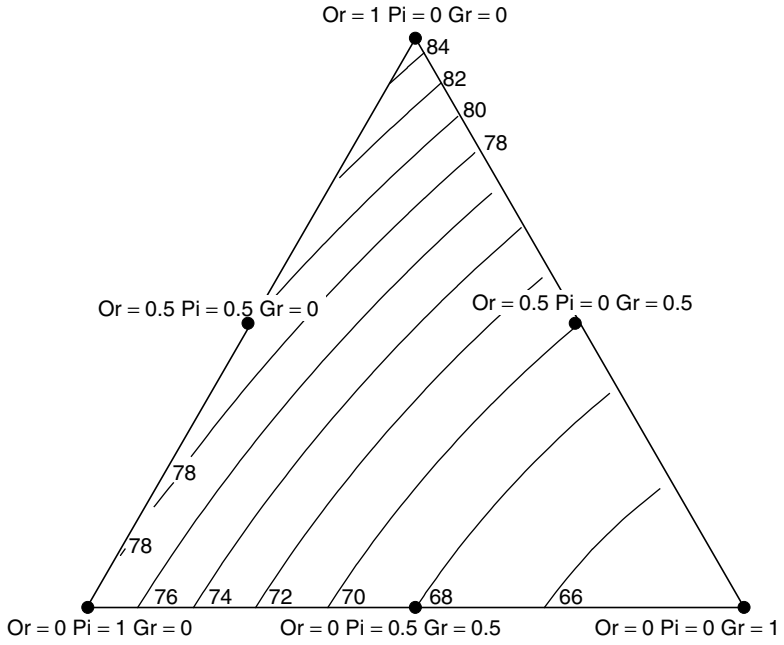

FIGURE 143.19 Contour plot of the quadratic mixture model, relating consumer preference with proportions of orange-, pineapple- and grapefruit juice. The treatments of the {3, 2} simplex lattice are labelled on the simplex.

TABLE 143.2
Parameter Estimate and Statistics of the Quadratic Mixture Model, Relating Preference with Fruit Juice Proportions

Variable	DF	Estimate	Standard Error	t Value	Pr > |t|
Orange	1	85.00000	1.31233	64.77	<.0001
Pineapple	1	78.00000	1.31233	59.44	<.0001
Grapefruit	1	65.00000	1.31233	49.53	<.0001
Or*Pina	1	−6.00000	6.42910	−0.93	0.3691
Or*Grape	1	−20.00000	6.42910	−3.11	0.0090
Pina*Grape	1	−14.00000	6.42910	−2.18	0.0501

This reduced model looks as follows:

$$\text{Preference} = 66.62\ \text{wheat} + 76.51\ \text{buckwheat} + 62.41\ \text{oats} + 40.99\ \text{barley} + 32.81\ \text{rye} - 129.39\ \text{wheat*buckwheat}$$

The reduced second degree model was used to represent the response surface over the experimental region. Since the experimental region is 4 dimensional and also the response has to be presented, a graphical representation demands a 5 dimensional factor space. For this reason the response surface was represented in two figures.

Figure 143.20 presents for 3 wheat and buckwheat levels (major horizontal and vertical axis respectively) and the response surface for oats, barley and rye. Increasing the wheat proportion and/or the buckwheat proportion reduces the maximum proportion of the other grains and consequently the size of the response surface.

TABLE 143.3
Pseudo-Component Proportions of the 15 Experimental Design Points of the {5, 2} Simplex Lattice Design. The Actual Mixing Proportions are Given Between Parenthesis (Proportion = 0 Are Not Marked)

Mixture	Wheat	Buckwheat	Oats	Barley	Rye
1	1 (1)	0	0	0	0
2	0 (0.84)	1 (0.16)	0	0	0
3	0 (0.84)	0	1 (0.16)	0	0
4	0 (o.84)	0	0	1 (0.16)	0
5	0 (0.84)	0	0	0	1 (0.16)
6	0.5 (0.92)	0.5 (0.08)	0	0	0
7	0.5 (0.92)	0	0.5 (0.08)	0	0
8	0.5 (0.92)	0	0	0.5 (0.08)	0
9	0.5 (0.92)	0	0	0	0.5 (0.08)
10	0 (0.84)	0.5 (0.08)	0.5 (0.08)	0	0
11	0 (0.84)	0.5 (0.08)	0	0.5 (0.08)	0
12	0 (0.84)	0.5 (0.08)	0	0	0.5 (0.08)
13	0 (0.84)	0	0.5 (0.08)	0.5 (0.08)	0
14	0 (0.84)	0	0.5 (0.08)	0	0.5 (0.08)
15	0 (0.84)	0	0	0.5 (0.08)	0.5 (0.08)

The more the response surfaces are positioned to the right (top), the higher the wheat (buckwheat) proportion. In each of the 6 response surfaces the oats and the barley proportions are represented. The point where the oats and the barley proportion equals 0, the rye proportion equals 1. The rye proportion is calculated as 1 minus the sum of the proportions of wheat, buckwheat, oats and barley. In each of the six response surfaces the preference can be read as a function of the proportion of the 5 grains.

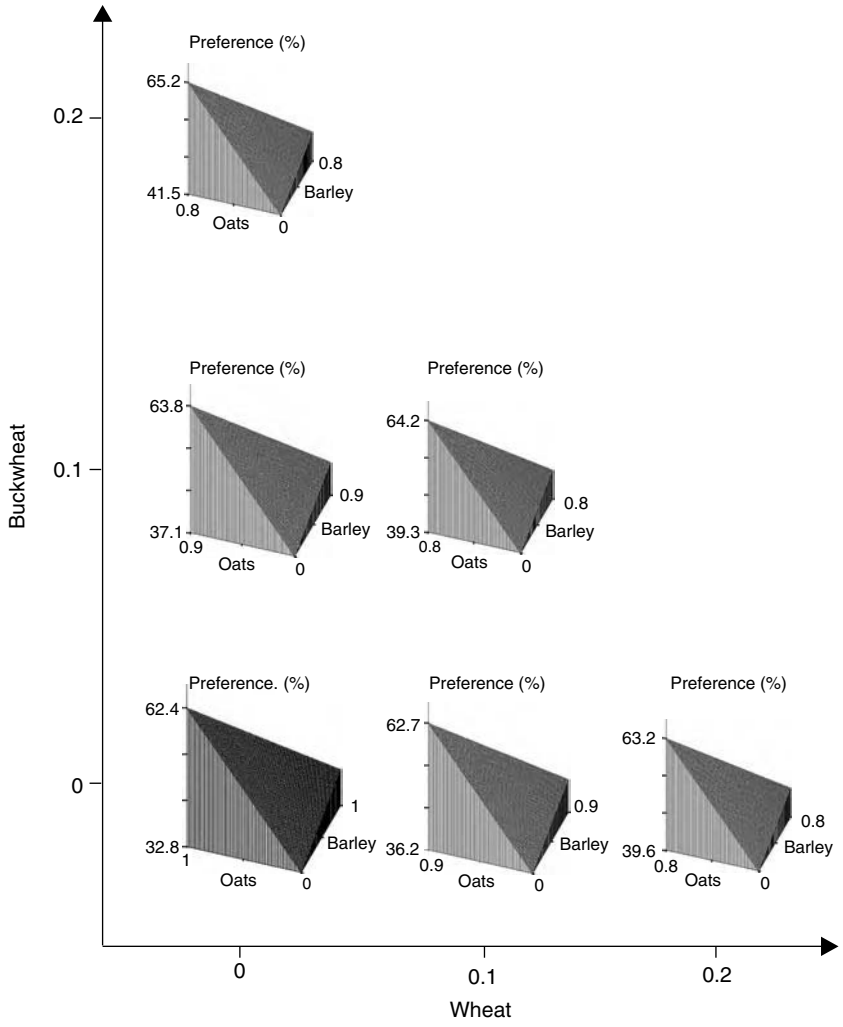

FIGURE 143.20 Preference over the oats, barley and rye factor space for 3 wheat and buckwheat levels.

The oats proportion of the mixture had a strong positive influence on the preference at low rye proportions. Reducing the oats proportion reduced the preference and mainly in the rye direction. Increasing the wheat and the buckwheat proportion from 0 to 0.2 increased the preference. Barley resulted in negligible differences in preference.

Figure 143.21 represents for 3 levels in oats and barley (major horizontal and vertical axis respectively) and the response surface for wheat, buckwheat and rye. Buckwheat had a strong positive influence on preference at low rye proportions. Reducing the buckwheat proportion reduced preference mainly in the rye direction. Buckwheat and wheat interacted antagonistically on preference. Increasing the barley and/or the oats proportion from 0 to 0.2 reduced preference at a high buckwheat and wheat proportion, while preference at a high rye proportion decreased.

The highest preference (76.5%) was obtained with a high buckwheat proportion combined with low wheat, barley, oats and rye; while a high rye proportion yielded the lowest preference (32.8%).

3. A Constrained, Homomorphic Experimental Region, Combined with Two Process Variables: Fat Reduction in the Cream of a Biscuit

This example investigates the possibility of reducing the fat content in the cream of a biscuit from 32 to 27%. The cream consists of 3 ingredients: cacao, sugar and fat. Reduction of the fat proportion involves an increase in the sugar and the cacao proportion. To keep the same high quality of the cream two compensating components are added in very low proportions: aroma and emulsifier. Measurements of intrusion forces in time (texture) are considered as response variables.

The cream is considered as a mixture system, because the total amount of cream should stay constant when cream composition is changed. A {3, 1} simplex lattice screening design (Table 143.4) is proposed to fit a first order model.

To prevent high collinearity between the independent variables due to the small range of the emulsifier (0–1%) and the aroma (0–0.2%), these variables are considered as

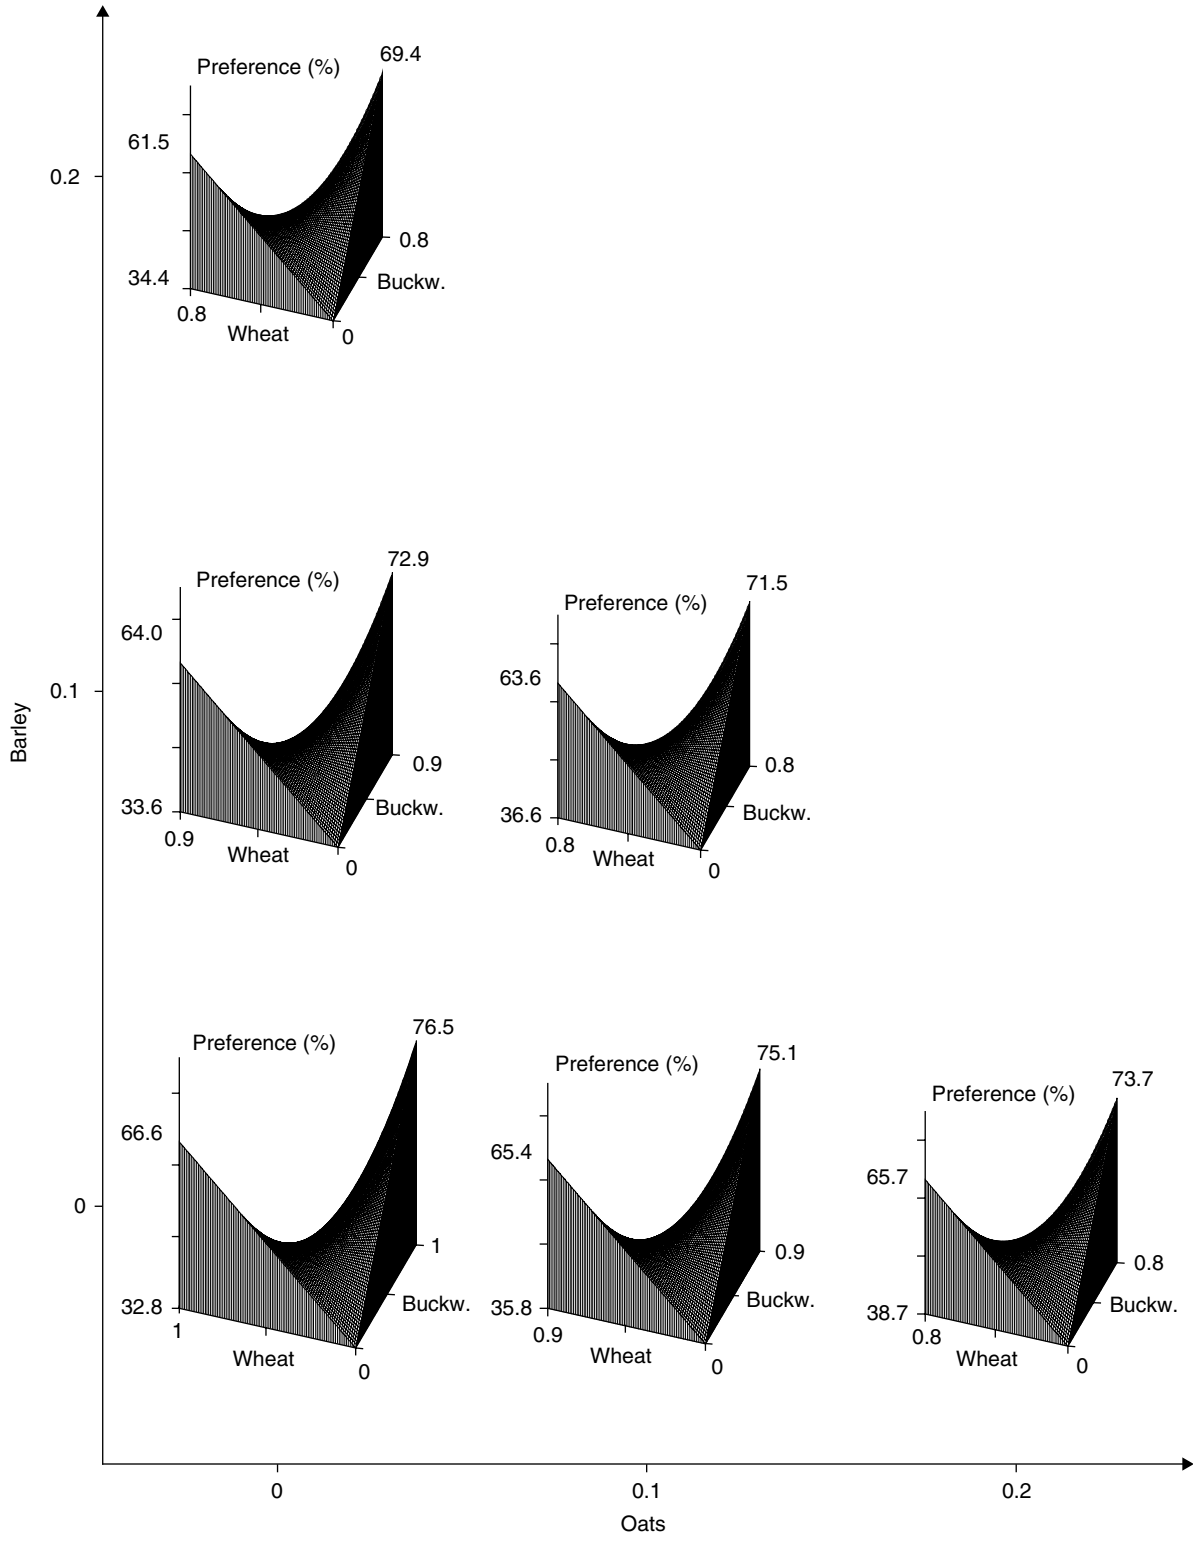

FIGURE 143.21 Preference over the wheat, buckwheat and rye factor space for 3 oats and barley levels.

process variables with a 2^2 factorial design is used for these factors (Table 143.5). The combination of both experimental designs (Table 143.4 and Table 143.5) results in a total of 12 (3*4) treatments and investigates a four dimensional experimental region, determined by 5 independent variables (Figure 143.22).

Each of the 12 creams was prepared 5 times, according to general practice. Penetrometer intrusion force

TABLE 143.4
Proportions of the Experimental Design Points in the Mixture Components

Mixture Treatment	Cacao Proportion	Sugar Proportion	Fat Proportion
1	0.12	0.56	0.32
2	0.17	0.56	0.27
3	0.12	0.61	0.27

TABLE 143.5
Proportions of the Experimental Design Points in the Process Variables

Treatment	Emulsifier	Aroma
1	0	0
2	0	0.002
3	0.01	0
4	0.01	0.002

(force 1) of the cream was measured 1 hour, 1 day and 1 week after preparation of the cream at a temperature of 22°C. In this way, time is considered as a process variable and extends the 4 dimensional experimental region to 5 dimensions.

The complete combined model (Table 143.6) represents the data with a coefficient of determination of 0.84. In the complete combined model only the parameter estimates of the variables cacao, sugar, cacao*time, sugar*time and fat*time are significantly different from zero. Using stepwise regression a reduced model with 8 terms is selected (Table 143.7), still representing the results with a coefficient of determination of 0.81. The reduced model consists of the main effects cacao, sugar and fat, their interaction effects with time and the triple interactions sugar*emulsifier*time and fat*emulsifier*time. The emulsifier interacts antagonistically with sugar and time and with fat and time.

The reduced second degree model is used to represent the response surface over the experimental region. The complete experimental region is 5 dimensional (6 factors). Since aroma has no significant effect on the texture of the cream, this factor can be removed from the experimental design, reducing the experimental region to 4 dimensions.

Figure 143.23 represents for 2 emulsifier and 3 times (major horizontal and vertical axis respectively) and the response surface for cacao, sugar and fat. The right horizontal axis represents the sugar pseudocomponent proportion and the left horizontal axis represents the cacao pseudocomponent proportion. The pseudocomponent proportion of fat equals 1 minus the pseudocomponent proportion of cacao and sugar.

The major changes in force 1 (penetrometer intrusion force) are caused by time. Increasing time increases force 1. Increasing the amount of emulsifier from 0 to 10 grams reduces force 1 and even more as time increases. If no emulsifier is added to the cream, force 1 increases as the sugar proportion increases. If 10 gram of emulsifier is present, the highest force 1 is reached at a low sugar and fat proportion and a high cacao proportion.

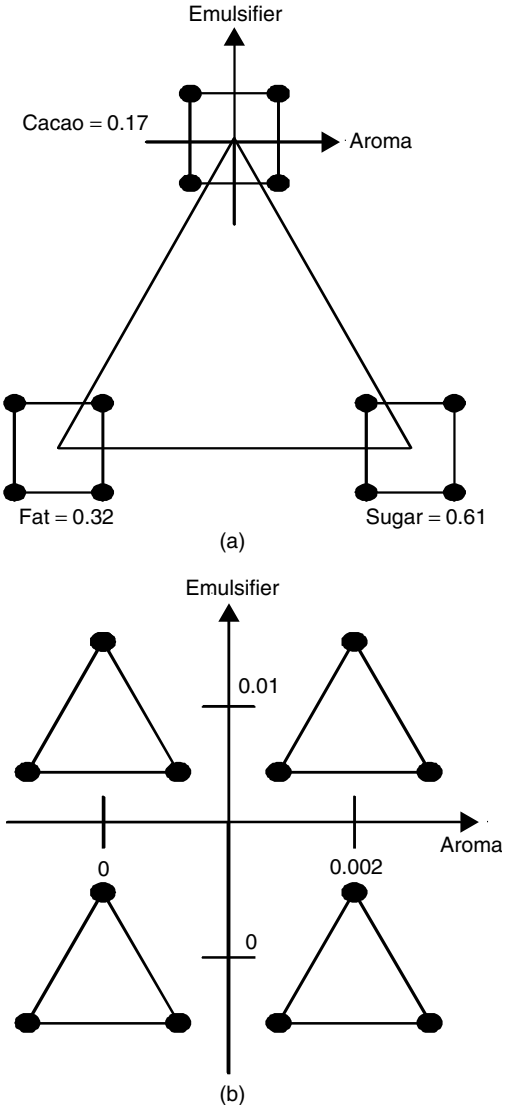

FIGURE 143.22 Combined experimental design of a 2^2 factorial design in emulsifier and aroma and a {3,1} simplex lattice design in cacao, sugar and fat. Factorial design nested in the mixture design (a). Mixture design nested in factorial one (b).

IX. DESIGN STRATEGY TO OPTIMISE UNCONSTRAINED EXPERIMENTAL FACTORS

Typically in the development of a food product, unconstrained experimental factors represent processing conditions or additives. Usually the latter are applied in small amounts and thus do not have to be considered as

compositional experimental factors, bounded by the mixture constraint. To optimise these factors classical experimental design theory can be used. Since the optimisation strategy described in this chapter highly relies on response surface fitting, designs for first and second order response surface models are emphasised. General reference books are (7, 8).

A. Designs for First Order Models

As previously explained the fitting of these models involves designs with 2 levels per factor and at least k + 1 treatments (with k the number of experimental factors). For screening experiments with large amounts of components the Plackett-Burman and fractional factorial designs are most appropriate.

1. Placket-Burman Designs

A Plackett-Burman design is an orthogonal screening design, consisting of a fraction of a 2^k full factorial with its main property a tremendous reduction of the amount of treatments (32). As a consequence no interactions between factors are estimable, but all main effects can still be interpreted through a first order model.

In Table 143.8 a 12 treatment Plackett-Burman design is given as an example. To apply these designs, the experimenter assigns a column to each chosen experimental factor under study (columns in the table) and then allocates treatments randomly at least 5 more than the number of experimental factors to allow the estimation of experimental error and valid test statistics about the model.

For instance, to run a 7 factor screening experiment, 7 columns are chosen in Table 143.8 and the 12 treatment combinations are assigned. The data are analysed with a first order polynomial regression model. For 7 to 15 experimental factors the 20 treatment Plackett-Burman is especially suitable. For more than 12 and less than 23 components the 28 treatments Plackett-Burman is appropriate (32). For screening of less than 7 factors the 12 treatment design can be chosen, although for these cases fractional factorial designs are also available. Table 143.9 shows which design to choose as a function of the number of experimental factors.

2. Fractional Factorial Designs

These designs are also fractions of 2^k full factorial designs, but only a few fractions are allowed because these designs emphasise 'balance' in estimating factor effects. In other words the estimation of each specific main effect should consist of geometrically balanced differences of measured responses on high and low factor levels. The geometry of a 2^3 factorial is compared to the geometry of a ½ fraction in Figure 143.24. The reduction in the number of treatments results in higher order interactions, the specific ones depending on the fraction chosen (33). A schematic overview of possible designs is given in Table 143.10. To use these designs in 6, 7 or 8 factors, select respectively the first 6, 7 or 8 columns of Table 143.11 and assign the 16 treatments.

3. Addition of Points in the Centre of Screening Designs

The centre of a coded design corresponds with the treatment coding (0, 0, … , 0). Addition of replicated centre points makes possible lack of fit test that essentially checks whether the real response surface is linear. This lack of fit

16	−1	−1	−1	−1	−1	−1	−1	−1

is calculated as the difference between the mean responses of all design points (equally replicated) and the mean response in the centre point. To test the curvature for specific factors requires a design for a second order model.

B. Designs for First Order Models with Two-Factor Interaction Terms

1. Reflected Plackett-Burman Designs

A reflected Plackett-Burman design arises from a specific Plackett-Burman design augmented with the same design but all '+' changed to '−' and vice versa. Thus the 12 run design is augmented to a 24 treatment design, the 20 run to 40 runs and the 28 to 56 treatments.

The addition of these treatments makes the independent estimation of main effects and 2-factor interactions possible. A summary is given in Table 143.12.

2. Fractional Factorial Designs

When a larger fraction of a 2^k full factorial is taken, not only main effects but also 2-factor interactions can be estimated (Table 143.13). An example for 6 experimental factors is given in Table 143.14. Additional fractional factorial design plans can be found in the literature (34, 35) or in specific software packages for experimental design (36).

C. Designs for Second Order Models

Experimental designs for fitting second order models require at least three levels of each experimental factor so that the parameters of the model can be estimated. An obvious choice for such a design would be a 3^k factorial, namely a factorial experiment with each of k factors at three levels in all possible combinations. For small numbers of factors (2 or 3, resulting in respectively 9 and 27 treatments) this approach is still feasible. For 4 factors, 81 treatments are involved to fit only 15 model parameters (one intercept, four first order coefficients, four full quadratic and six cross-products) in a full quadratic second order model. Starting with 5 factors the number of treatments becomes prohibitively large ($3^5 = 243$). Several authors have suggested specific second order designs that offer a compromise between relative precision in model parameter estimates and the amount of experimental effort measured as the number of treatments. The Box-Behnken and central composite designs are mostly used. Typically, these designs are appropriate for second order models in two to eight factors (37) (9). If more than eight factors are involved the designs become unpractically large.

8	1/4 fraction of 2^8: 64 treatments

1. Box-Behnken Designs

Box-Behnken designs are subsets of 3^k factorial designs (37). Except for the centre points, all points are centroids of the edges (or faces) of a hypercube with dimensions

31	−1	+1	+1	+1	+1	−1
32	+1	+1	+1	+1	+1	+1

equal to the number of factors. Thus all these treatments lie on a single hyper-sphere and thus are equally distant from the centre. This geometrical property is associated with rotatability, or the variance of the predicted response depends only on the distance to the centre of the design and not on the direction. These designs have a hyperspheric geometry as can be deduced from Figure 143.25 and are especially useful for experiments in 3 to 7 experimental factors. As an example a design plan for four experimental factors is given in Table 143.15.

2. Central Composite Designs

The central composite designs, introduced by Box and Wilson (9) are by far the most used designs for second order models. These designs consist of a 2^k full factorial or a fractional factorial, augmented with 2^k star points and n_c centre points. If a fractional factorial is used, the main and two-factor interaction effects should be estimable (see designs for first order models with two-factor interaction terms). The star points are located on the main axes of the coded design the same distance from the centre as the factorial points. In other words, both the factorial and the star points are located on a hyper-sphere around the centre of the design. The centre point is replicated to estimate pure error. This design involves five levels for each factor coded as $(-\alpha, -1, 0, 1, \alpha)$, α being the distance from each star point to the centre. To provide the design the desirable property of rotatability, α has to be chosen according to Table 143.16. This choice assures that star and factorial points belong to the same hyper-sphere (Figure 143.26).

7 (1/2)	½ replication	2.83	64	14	10	88

The sequential nature of these designs is very useful in many problems. Firstly the factorial part of the design, including centre points, can be run to estimate a first order model. If the lack of fit test, based on the replicated centre points, indicates that additional curvature is necessary, in a second step the design can be augmented with the star points to provide degrees of freedom for a second order model. For example, the three-factor central composite design in Table 143.17 consists of a 2^3 factorial (first 8 treatments), augmented with 2*3 star points ($\alpha = 1.68$) and 6 centre points.

D. Example of Process Optimisation for Unconstrained Experimental Factors

1. A Box-Behnken Design for a 3 Factor Optimisation Experiment

Suppose the work on a new product has proceeded to the point where three experimental factors are thought to be important in affecting a quality property. The experimental factors are temperature, pressure and concentration; the independent variable is a numeric quality attribute.

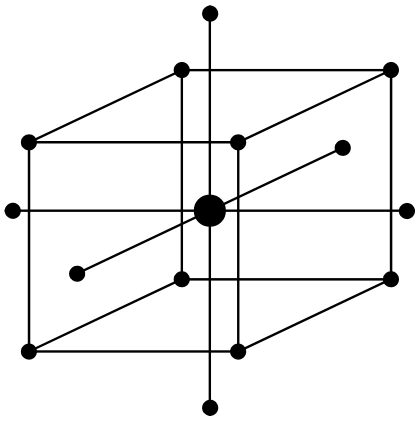

FIGURE 143.26 Geometry of a three-factor central composite design for a second order model.

From preliminary screening experiments the ranges for the factors were set. It is decided to use a Box-Behnken design in search of the optimum response over the experimental region.

Table 143.18 shows the coded design points, the actual values and the measured quality index (response).

A second order full polynomial is fitted by ordinary least squares to estimate the parameters of the model. Model

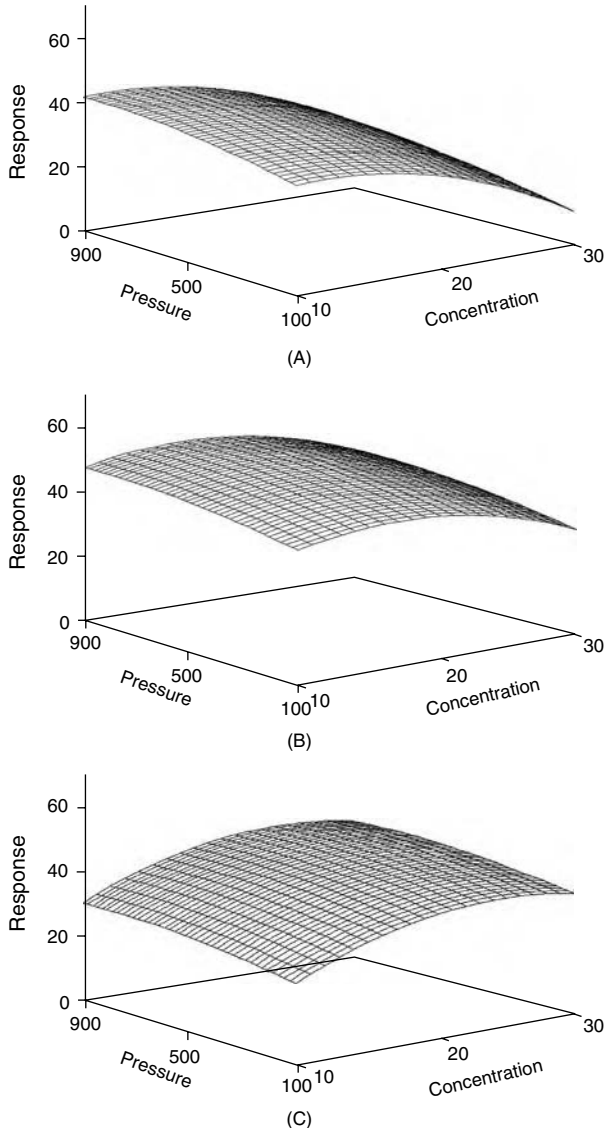

FIGURE 143.27 Perspective plot of response in relation to pressure and concentration at different temperatures. A: temperature = 20°C, B: temperature = 50°C and C: temperature = 90°C.

parameters and statistics are given in Table 143.19. As can be concluded from this table, all parameters are highly significant except the pressure-temperature and the pressure-concentration cross product coefficients. This model is represented as three perspective plots of concentration versus pressure at three different temperatures (Figure 143.27).

A canonical analysis revealed that the optimum is a maximum. At a temperature of 59.6, a concentration of 19.7 and a pressure of 962 the quality index was maximised and reached a value of 52.6%.

This simple example elucidates the design and analysis strategy elaborated in this chapter: determination of the factors of interest, design and model selection in relation to objectives and results of preliminary screening, model fitting and computation of the optimal conditions based on model predictions.

X. CONCLUSIONS

In this chapter experimentation strategies to optimise product attributes in function of ingredients and process conditions during product development and optimisation are elaborated.

The nature of the experimental factors, mixture- or unconstrained components, determines in a large part the design and modelling procedures must be followed.

A generic approach based on response surface methodologies is proposed, due to the high dimensionality of the compositional problem and the high probability of interacting experimental factors.

Emphasis is put on the geometry of experimental regions and the specific designs to explore the region of interest in relation to the assumed model. In addition many designs are given to aid the experimenter and to provide a framework for experimentation.

CONTENTS

I. INTRODUCTION

Food engineering and technology groups a multidisciplinary approach towards safer and better quality food products. This involves the application of methodologies developed in basic sciences (e.g. chemistry, biology, physics and mathematics) and applied sciences (i.e. biochemistry, microbiology and statistics) into the applied field of food. Mathematical modelling of food phenomena has a long tradition with early examples as the development of the Student t-test to study brewing (1) or the Bigelow model in the area of sterilisation (2).

A mathematical model is a representation that captures the interesting properties of the food system of interest. The form of this representation can be: (i) an algorithm, (ii) an equation, (iii) a graphical representation, (iv) some form of experimental data or (v) any combination of them.

Mathematical modelling as such provides powerful tools to (3):

- **Construct** models of the situation under study.
- **Analyse** interactions between components of the food systems.
- **Research** and complement other methodologies to study and master the complexities of the food systems and the complex interactions that happen during the whole food chain (4).

With the advances of analytical and microbiological techniques the paradigm in food technology of studying single food processes analysing their components with powerful analytical and microbiological tools has produced the body of the present technology applied in the food industry and this paradigm has satisfactorily solved most of the problems to both research and the industry. However, with the spread of affordable IT systems that have placed mathematical modelling tools in the hands of the researchers, the former methodology has been complemented with the addition of mathematical modelling techniques. This change has provided an integrating tool able to tackle some of the most complex problems in food technology and engineering (3).

II. OBJECTIVES OF MODEL BUILDING

Mathematical modelling is an objective oriented task where the whole model building process is greatly influenced by the particular application the model is developed for. The objectives of the work, the particular task that the model will perform and even the particular field on which the models are applied will actually determine many of the features of the model. A typical example is the utilisation of Bigelow's model in food microbiology, where this model is widely accepted and used to study the thermal treatment of bacteria/spores (e.g. pasteurisation/sterilisation). Despite the fact that this model is almost equivalent to the first order reaction model with an Arrhenius temperature dependence (used to describe kinetics of chemical reaction and widely extended in many fields of science), the Bigelow equation is still used and will most probably be used in future studies in the areas that have as an objective the study of heat treatment of bacteria (at least while the model and their parameters are useful to transmit information by microbiologists).

Mathematical models are widely used for different purposes in food and engineering, falling usually in one of the following general categories (3).

A. Prediction and Forecast

Model predictions and forecasts are used when an estimation of the property of interest in the future is sought. Generally food phenomena are time dependent and in this way the study of kinetics in food (observing the variation of a property in food during time). Moreover, since most food processes are operated in batch mode, food processing models usually need to include time as an important variable. Some typical examples are:

- The prediction of microbial growth in foodstuff: Mathematical models are generated using previous knowledge and experimental data to be employed in the prediction of the future microbial population in the foodstuff (5, 6, 7) although not exhaustive, provide two typical examples of research work in this area.
- The prediction of food shelf life where mathematical models are used to forecast the time of failure of the critical quality factor(s) of a certain product. The modelling of accelerated shelf life studies can provide an estimate of the product shelf life at retail temperatures (8).
- The modelling of food process phenomena where the food is subjected to different environmental conditions during the time of the process (9).

B. Scenario Modelling

Scenario modelling is used to study the behaviour of the system of interest under new conditions. Some typical examples of scenario modelling are:

- Secondary models in predictive microbiology. The behaviour of microbial growth under different conditions of pH, temperature and other factors is mapped, in order to map the different scenarios of product formulation and storage/distribution that have not been previously tested (9, 10).
- The study of the influence of environmental factors in the processing/storage/retail of foods.

C. Sensitivity Analysis

Sensitivity analysis uses simulation of different scenarios to examine the behaviour of the response(s) in a model with the systematic variation of the different variables involved in it. The main objectives of the sensitivity analysis are:

- To rank the different model inputs by their influence in the response.
- To discover new interactions of the different variables that are involved the model.

Sensitivity studies are closely linked to the study of the derivatives of the models in respect to the input variables. They are usually linked to the further optimisation and control of the particular phenomena and are a particular tool in the area of food engineering (11, 12) where they serve as a preliminary analysis to select the most appropriate variables that can be subjected to optimisation and control.

D. Optimisation and Control

Optimisation and control make use of the mathematical model to meet process/product specifications and direct the phenomena towards target points. The optimisation of food processes is largely based on mathematical models and it has a long tradition (13) since the optimisation of

heat sterilisation from Teixeira et al. (14). Other areas include drying and mass transfer (15, 16). Optimisation and control of food processes presents considerable challenges (13):

- Food phenomena are usually noticeably non-linear and models that are capable of describing fundamentally the phenomena are complex.
- The constraints that have to be fulfilled for an appropriate optimisation and/or control are as well significantly non-linear coming from costing or quality.
- The process is usually affected by many variables that can be global or locally distributed in the product. This complicates the process given that models have to be built to describe the local property variation, usually involving the interaction of several transport phenomena. This usually implies the solution of one or more partial differential equations (PDEs). For example, the drying of spaghetti can involve under reasonable drying conditions a global temperature dynamic, a local moisture content and possibly a local stress field (16).
- Variability and uncertainty in the product and process conditions can present additional difficulties to the optimisation process. An optimal policy for an "average" product may result in significant losses of product that presents different characteristics (17).

One of the most significant benefits of model building is actually to be able to control or to optimise the process/phenomena under study (e.g. 18). This can yield to significant gains in profit and quality of the food products that arrive to the consumer. Despite this fact and the wide appearance of mathematical models in the food engineering area, the exploitation of mathematical models via optimisation and control has yet to become a mainstream activity (13).

E. Metamodelling

Metamodelling is a modelling task that intends to condense the information from complex mathematical models into simpler models. Metamodelling is a modelling tool that makes complex modelling results accessible. Two typical examples of metamodelling:

- Hayakawa et al. (19) studied hygrostress modelling where the information about the stress during the drying of a sphere or a plate was condensed in charts. The charts can be used to produce predictions of stress during a certain drying process without the need of having or knowing how to use simulation software.
- Silva (20) studied optimal sterilisation policies using transient heat transfer PDA in two dimensions together with quality and microbiology thermal kinetics equations. After finding the optimal temperatures for different conditions, polynomial models that allowed for the calculation of the optimal temperature with a reasonable precision were developed. In this way, optimal sterilisation temperatures could be calculated for a new process with a simple spreadsheet and without having to use the heat transfer model.

III. MODEL BUILDING PROCESS

Model building involves the procedure to construct a mathematical model from a particular situation. It usually involves the following tasks (3):

i) **Identification:** *What is the phenomenon to be explored? What is the purpose of a model in these circumstances? What is the information already available? What experiments have to be made? What are the assumptions one can reasonably make? What approach should be taken?*
ii) **Estimation:** *What are the parameters one is looking for? How to obtain parameter estimates for the model? How to solve the problem?*
iii) **Validation:** *Is the model valid for application in the particular situation under study?*
iv) **Application:** *For what is the model needed?*
v) **Maintenance and Iteration:** *Is the problem solved? Does one need to do further work and build more detailed or simpler models? Does one need to revise initial assumptions?*

These steps provide a methodology to develop models applied to a particular situation, and although is rarely the case in practice where they are followed sequentially, they show the different tasks to be taken into consideration. While estimation, validation and application of a mathematical aspects of the model building have been studied by operation research and statistics extensively, model identification, maintenance and iteration of the mathematical model are not yet as developed as the former methodologies.

IV. TOWARDS AN ECLECTIC APPROACH IN MODEL BUILDING

Model building in food has benefited from methodologies already developed to use them for the advance of food technology and engineering. In this way two main

approaches for model building have been laid out from developments in physics and chemistry respectively:

a) Inductive or empirical model building.
b) Deductive of fundamental model building.

Both modelling approaches provide sound methodologies to solve problems in the area of food technology and engineering, with their advantages and pitfalls (21, 22). Gilchrist (23) proposed a somehow "mid-way" between the two of them in an eclectic approach to model building.

A. Inductive Modelling

Inductive modelling uses the *observational approach*, with experiments and inductive modelling techniques to build one or more empirical models that can approximate the particular situation under study. The estimation and validation steps of the model gain a bigger weight, where parameters have to be estimated with a maximum precision to ensure a prediction and the model or the models group is validated to ensure a good model selection process. Given the dependence of the model building process on the experimental data, statistical methods are the basis of inductive modelling (22).

Empirical models can involve different constructions that mimic the behaviour of the system under study and aim at extracting some of the useful information that experimental data from the study can provide. They also can be used to reproduce the behaviour of the system in questions as a *black box* model, to be used for control, optimisation or sensitivity analysis purposes. A particular example of empirical modelling is the classical linear regression model, where a vector response y is expected to behave in a linear fashion in respect to a matrix of X and an error term.

One can hope that this relationship holds under a limited range of study of the independent variables and then can be applied in this range for all uses (24). Other empirical models can include (generalised) linear models, survival models, multivariate statistical models, time series models, modern regression methods, spatial statistics, Markov Chain Monte Carlo models, AI models (neural networks, SOM, Fuzzy logic, etc.), decision trees or data mining techniques (25).

Empirical model building can involve several steps in the building of a model:

i) Experimental design
ii) Parameter estimation
iii) Model assessment
iv) Model validation
v) Model maintenance

1. Experimental Design

The development of an experimental design that will offer reasonable chances to build the model is of prime importance in the model building procedure. Performing experiments is usually a costly task in both academy and industry and often a "one-off" opportunity: Once the set of experiments is done, the possibility of repeating or modifying the experiment is rarely available. In this view, each experiment needs to be rigorously designed to extract the maximum information from the phenomena. The "old-way" of trying-each-thing-at-once has been long time ago demonstrated to be a very inefficient way of laying an experimental design, bound to lose the more complex interactions of the phenomena (24). The statistical design of experiments allows for the minimisation of resource wasting and ensures for precision and lack of bias of the results (24). Statistical experimental design is highly dependent on the type of mathematical model that the statistician wants to use to describe the data and because of this, the planning of an experiment is an essential step in inductive modelling. The way the experiment will be planned will influence the further steps in the model building process. In this way, before planning the experiments the scientist has to gather as much information:

- Rigorous definition of the objective(s) of the work. Without this, it is impossible to design experiments that will contribute to the solution of the problem at hand.
- Selection of the variables of interest in the study. Given that food is a complex biological material in most of the situations, the number of factors that can affect food phenomena can be numerous. A preliminary selection of the most important factors, based on literature, work objectives criteria will help to construct the experimental design.
- If working with continuous variables, the range covered by the study has to be selected. What are the interesting values for the variables? How much will be the response(s) varying? Are the changes in the response measurable?
- Analysis of the expected associated uncertainty and variability of the experiment. What are the sources of uncontrolled variability? Which other factors can contribute to the uncertainty in the experiment? Can those factors be controlled or not?
- Preliminary study of the structure of the model that will be built. Is one devising a linear or a non-linear model? What are the dependencies between the responses and the factors? Can one separate the different levels of the model: For example a modelling step that is concerned with the primary covariate (e.g. time) and another modelling step concerned with the secondary environmental factors in the study (e.g. temperature).

- Planning of the final report design before the experiment is carried out, in order to identify weaknesses in the experimental design.
- Perform trial or preliminary calculations to determine whether the experiment will fulfil the objectives.

The research team will have to spend a reasonable amount of time discussing these aspects of the experiments in order to devise an appropriate experimental design that will contribute to the research work. The main issues that a statistical experimental design will have to deal with are (for a thoroughly description see chapter 50 by Schrevens and Portier):

a) Randomisation to eliminate bias coming from uncertainty in the parameter estimation and prediction.
b) Replication to allow for the estimation of the residual variance and to test the significance of the factors under study.
c) Blocking of the experiments, considering the available experimental units and randomised assignment of the experimental blocks to each of the experimental days. This will:
   - Avoid bias coming from time variation.
   - In the case that random effects are important in the experiment (uncontrollable known factors that affect variability) will help to the estimation of the random effects variance component (26).
d) Factorial treatment structure that will allow studying the effect of different factors in the experiment. It has been demonstrated that experiments that try each of the factors one-at-a-time spend considerable experimental resources compared with factorial designs (26).

a. Experimental design for linear model building

Experimental design is a subjective methodology that depends on the type of model that data is expected to follow. The simplest kind of relationship between a response and a series of factors is to assume a linear relationship, which is an assumption that one can hold in a narrow interval of study (24). The development of experimental design started with the work from Fisher and developed in the context of statistical analysis of laboratory and pilot plant experiments with the ideas from Box and in the design and analysis of industrial scale experiments with the work of Taguchi (26). For a more concise focus on experimental design for product development and optimisation, please refer to chapter 50 (Schrevens and Portier).

Factorial designs

Factorial designs are the most used experimental designs for laboratory and food pilot plant studies when working with linear models. Several different options are available (24):

TABLE 144.1
Example of a Full 2^k Factorial Design with Two Replications to Study the Influence of Pasteurising Temperature (− = 60°C, + = 90°C) and pH (− = 3.0, + = 7.0) in the Shelf Life of a Food Product. The Experiment Had Two Experimental Units That Could Be Used Each Day to Treat the Samples. Blocks Are Not Randomised

Repetition	Block	Unit	Temp	pH
1	1	1	+	+
		2	−	+
	2	1	+	−
		2	−	−
2	3	1	+	+
		2	−	+
	4	1	+	−
		2	−	−

i) When the relationship between the response and the variables is linear and one is happy to explore the main effect and the interaction between the different variables in the response there are several alternatives:
   a) When comparing two different treatments with a single factor randomised block designs can be used to elucidate if the treatment produces a significant effect.
   b) When the objective of the study is to screen the effect of several factors 2^k full factorial designs can be used to help to select the most important variables and their interactions. See Table 144.1 for an example of implementation.
   c) If the number of factors to screen is big and one is not able to perform a full factorial design a 2^{k-p} fractional factorial design may be applied, but some of the interactions in the model will be confounded and the design resolution will decrease. The loss in the ability to estimate further level effects (e.g. two or three factor interactions), will be compensated by the reduction in the experimental runs. Once the fractional design is analysed it would be possible to enhance the design resolution the number by several methods (e.g. via foldover) (24, 27).
ii) In some cases, factors can have more than two levels and sometimes it might be that the effect of the factor in the response is not simply linear. A possible empirical model in this situation is to use polynomial models of different

degrees to model the curvature of the response of the form

$$y = b_0 + b_1x_1 + b_2x_2 + ... + b_kx_k + b_{12}x_1x_2 + ... + b_{nn}x_n^2 \quad (144.1)$$

This models, still fall under the domain of linear regression therefore facilitating parameter estimation, study of effects and ANOVA analysis. They are of special interest if the objective of the study is to find optimum points (maximum or minimum) of the response in the experimental range. In this case, 3^k full factorial designs or 3^{k-p} fractional designs with response surface methodology can be used to estimate the effects of the factors and their interactions in the response (27, 28).

Factorial designs make for the most part of the experimental design in food and agricultural sciences, and they are widely used in empirical modelling, optimisation and response surface analysis of food phenomena. There are, however, some other alternatives.

Latin square designs

Latin square designs are used when the factors of interest have more than one level and when the experimenter is interested in estimating only the main effects, as illustrated in Table 144.2.

Central composite designs

Sometimes the object of the study is to map the effect of changing continuous variables at and around a point of interest. In this case, central composite designs can be a valuable alternative to the 3k-p design (27). A typical central composite design can be observed in Figure 144.1. The analysis of these designs uses the same linear models and ANOVA tables as the conventional factorial designs.

TABLE 144.2
Example of a Latin Square Design for the Analysis of the Effect of the Use of Three Different Sweeteners (Fructose = F, Glucose = G and Aspartame = A) in the Texture of Ice Cream. The Experimenter Can Use One Lot at Each of the Three Ice Cream Factories Available, Is Mostly Interested in the Effect of the Three Sweeteners and Wants to Avoid Bias in the Estimation of the Effects from the Different Plants and the Ice Cream Processing Lines

	Plants		
Processing Lines	**Factory A**	**Factory B**	**Factory C**
1	F	G	A
2	A	F	G
3	G	A	F

Mixture designs

Mixture designs are suitable in the food formulation studies that require more than one ingredient, since the proportion of each ingredient in the mixture depends on the other ingredients, and the sum of all ingredients must complete 100% of the composition of the product (29, 30). An example of a simplex lattice design is shown in Figure 144.2. In the same way as central composite designs, the analysis of these experiments involves ANOVA tables and response surface methodology.

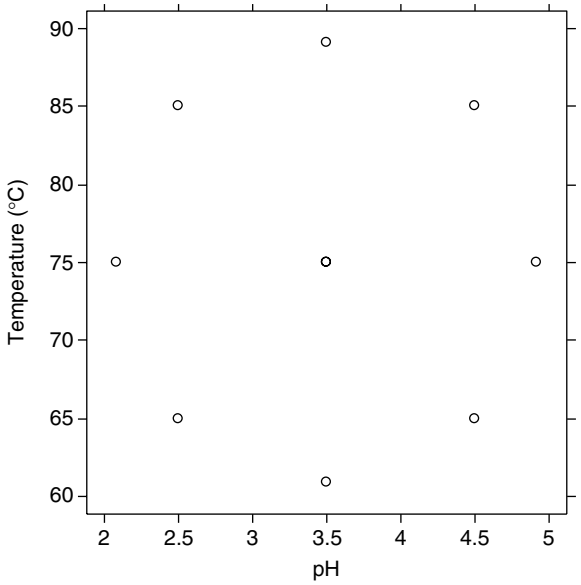

FIGURE 144.1 Example of a central composite design to study the effect of pasteurising temperature and product pH on the shelf life of a pasteurised product at around the 75°C and pH 3.5 region. The design is composed of a 22 full factorial design (cube points) plus the star points. The central point is repeated.

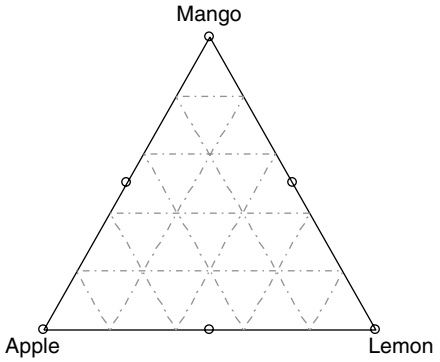

FIGURE 144.2 Example of a simplex lattice design to study the sensorial acceptance of a mixture of mango, apple and lemon in chutney. Each of the points in the graph represents a combination of mango, apple and lemon that complete the mixture.

b. *Experimental designs for linear and non-linear model building: optimal experimental designs*

The application of a design strategy to optimise certain criteria in an experiment (i.e. precision of the prediction, error associated to the estimates) has been extensively studied in applied statistics (31, 32, 33) and several algorithms exist to design different optimal experiments in a single run or sequentially (34).

It is not the purpose of this section to explain the details of the design of optimal experimental designs, as there is specialised literature on it (35, 36, 37) and the reader may find some additional material in chapter 48 (Cunha et al.), but it is well worthwhile to comment and rephrase some of the particular aspects of these designs:

- Optimum experimental designs were introduced first for the design of experiments considering polynomial response surface models over regular regions.
- One of the strengths they had is the development of algorithms for non-standard applications (e.g. constrained experimental domain) and the ease of extension to non-linear models.
- In linear and non-linear model regression, the Fisher information matrix contains the variance and co-variances of the parameter estimates.
- Under usual regression assumptions (see Section "Least Squares Estimation") the Fisher information matrix D is proportional to $X \cdot XT$, where X is the Jacobian matrix of the model, with $X \equiv \lfloor f_{ij} \rfloor$ and $f_{ij} = \partial \eta_i / \partial \theta_j$ (the derivative of the expectation function h evaluated at the i-th design point and the j-th parameter).
- Optimal designs of linear models yield exact designs, but given that for non-linear models $X \cdot XT$ is a Taylor approximation of the information matrix, the designs produced for non-linear models are only locally optimal.
- Another "problem" of the structure of the Fisher information matrix in non-linear models is that the D depends on the actual values of the parameters that are to be estimated. In this way, to design the optimal experiments with non-linear models preliminary estimates of the parameters are needed.
- An optimal design produces a scalar from the information matrix and searches to optimise the scalar to produce the set of experimental points. The most usual experimental designs are:
  - A-optimal designs search to minimise the maximum value of the trace of the Fisher information matrix, looking to minimise the biggest variance associated to one of the parameters in the model.
  - D-optimal designs search the maximisation of the determinant of Δ, with the result of minimising the generalised variance of the parameter estimates. This results with more precise parameter estimates.
  - E-optimal designs search to minimise the ratio of the smallest to the biggest eigenvalue of Δ, with the result of maximising orthogonality and minimising correlation between parameter estimates.

Depending on which one is the objective of the experiment a particular criteria will be chosen to design the experiment.

Example 1. D-optimal design for the Bigelow model under isothermal conditions

A research laboratory is in charge to estimate the thermal stability of different strains of *C. Botulinum* spores. The two properties that characterise the thermal stability of the spores are the D_{121} value (the time in minutes necessary to reduce a certain population one decimal log fold — from 100% to 10%) and the z value (the slope in °C of the thermal death curve). Both parameters are related to the normalised population η (population at any time divided by the initial population at time zero) of colony forming units (cfu) by the Bigelow model (2) where

$$\eta = 10^{\frac{t10^{\frac{T-121}{z}}}{D_{121}}} \qquad (144.2)$$

The following considerations were taken to produce a D-optimal design:

a) Initial estimates of D_{121} and z (1 min and 10°C respectively) were obtained from literature. It is expected that this value will be close to the particular value of each of the strains.
b) The reasonable limits of temperature (110°C to 140°C) and time (from 0 min to 120 min) were assumed as the most appropriate.
c) A number of sampling points equal to the number of parameters to estimate were selected. This type of experiment (two design points) is the minimum set of points necessary to estimate D_{121} and z.

The Jacobian matrix of this experiment is

$$X = \begin{bmatrix} \frac{\partial \eta_1}{\partial D_{121}} & \frac{\partial \eta_1}{\partial z} \\ \frac{\partial \eta_2}{\partial D_{121}} & \frac{\partial \eta_2}{\partial z} \end{bmatrix} \qquad (144.3)$$

Where η_1 and η_2 stand for the remaining spores at the design times 1 and 2 respectively. After solving the partial

TABLE 144.3
Example of D-optimal Design with the Bigelow Model to Estimate the Thermal Destruction Parameters of *C. Botulinum* Spores

	Temperature	Sampling Time
Sample 1	110°C	328 s
Sample 2	140°C	26 s

derivatives in respect to the two parameters, the determinant of Δ is

$$|\Delta| = |X \cdot X^T| = \frac{\eta_1 \ln(\eta_1)\eta_2 \ln(\eta_2)\ln 10}{D_{121}z^2}(T_2 - T_1) \quad (144.4)$$

T_1 and T_2 stand for the temperature of the experimental points 1 and 2 respectively. Looking to the determinant function it can be seen that for given values of D_{121} and z the determinant will be maximised the bigger $T_2 - T_1$, η_1, $\ln(\eta_1)$, η_2 and $\ln(\eta_2)$. Therefore, the experimental points should be each at one of the extreme temperatures in the experimental range. At each of the selected temperatures, the optimal times that maximise the |Δ| correspond to

$$t_1 = \frac{D_{121}10^{\frac{T_1-121}{z}}}{\ln 10} = \frac{D_{T_1}}{\ln 10} \quad (144.5)$$

$$t_2 = \frac{D_{121}10^{\frac{T_2-121}{z}}}{\ln 10} = \frac{D_{T_2}}{\ln 10} \quad (144.6)$$

Using the initial estimates obtained from literature the D-optimal design proposed for this is presented in Table 144.3.

Optimal design in food research

Three research groups in special have applied different optimal designs in food research:

- The group from Oliveira and collaborators have studied the application of D-optimal design on the parameter estimation of food quality, shelf life and mass transfer phenomena in isothermal and non-isothermal experiments (38, 39, 40, 41, 42).
- Nicolai et al. have studied the application of optimal design criteria (A, D and E-optimal) on the design of an experimental set-up to measure thermal properties in non-isothermal experiments (43, 44, 45).
- Finally, Van Impe et al. have proposed the utilization of optimal designs (E-optimal) in the area of parameter estimation of predictive microbiology models (10, 46, 47).

2. Parameter Estimation

This involves the estimation of the unknown parameters of the model from the experimental data. Maximum likelihood, least squares, and Bayesian estimation are the most common ones. The least squares method is widely used nowadays in the food research area in most of the model based estimation methods.

Least squares parameter estimation

For most of the mathematical models describing responses in general science and engineering the maximum likelihood estimates can be found by minimising the residual sum of squares. It is of worth to point out the assumptions used when estimating parameters from a model using least squares (38, 48), previously developed in chapter 48 (Cunha et al.):

a) The expectation function is correct.
b) The response obtained corresponds to the expectation function plus a disturbance.
c) The disturbance in the measurement of the response is independent of the expectation function.
d) Each disturbance has a normal distribution associated.
e) Each disturbance has zero mean.
f) The disturbances have equal variances.
g) The disturbances are independently distributed.

Example 2. Kinetics of thermal degradation of peroxidase during drying

The kinetics of thermal degradation of the enzyme horseradish peroxidase in maltodextrin dextrose equivalent 40 during a drying process was investigated (38).

Looking to the shape of the kinetic curve, the logistic model was identified as the most appropriate to provide a simple description of the situation. In this way:

$$\frac{P}{P_0} = A + \frac{(B - A)}{1 + e^{\frac{xmid - time}{scal}}} + \varepsilon \quad (144.7)$$

Where P/P_0 is the normalised peroxidase activity, time is the drying time, A is the horizontal asymptote at small times (with a fixed value of 1), *B* is the horizontal asymptote at high times, *xmid* is the time at the inflection point of the logistic curve, *scal* a numeric scale parameter on the time and ε a normally distributed error residual.

Figure 144.3 shows that the expectation function seems to describe the data adequately and the residual analysis seems to agree with the assumptions of least squares nonlinear regression (independently normally distributed with a constant variance and no significant autocorrelations). Table 144.4 shows the parameter estimations with their standard errors and regression statistics.

Figure 144.4 shows the bi-variate joint confidence regions of the regression parameters, which are another way of examining the precision of the parameters and the

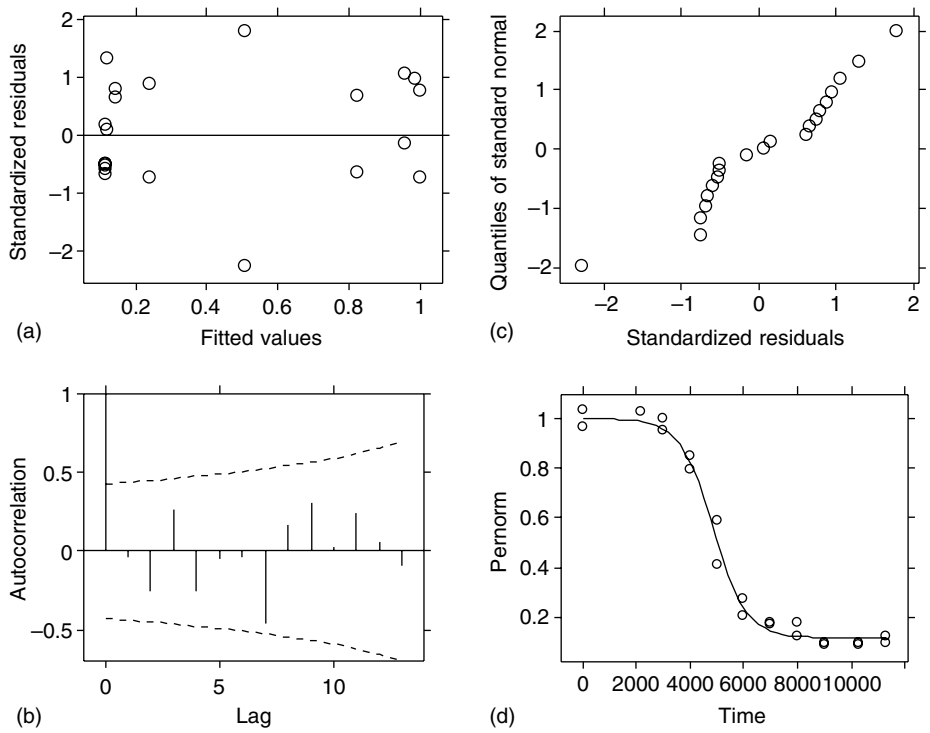

FIGURE 144.3 Diagnostic plots of the regression of the peroxidase data with the logistic model. (a) Standardised residuals vs. fitted values to study if the variance of the residuals is constant. (b) Autocorrelation of the residuals vs. the lags, to help see if there are interdependencies on the residuals. (c) Quantile-quantile plot of the residuals to examine normality. (d) Prediction of the peroxidase data with the logistic model.

TABLE 144.4
Nonlinear Regression Summary of the Peroxidase Data with the Logistic Model

Parameter	Estimate	Std. Error
A	1	Fixed
B	0.12	0.02
xmid	4860	74
scal	620	64
Residual Standard Error	0.04	
Residual Sum of Squares	0.03	

All parameters significant at 95% confidence.

tau-profile (31) that shows the negligible influence of the curvature in the error associated to the parameters of the fit. Table 144.5 compares the fit of the logistic model with the parameter A fixed against a model that has the parameter A estimated (to check if there was a problem in the estimation of the initial enzymatic activity). As those two models are nested, a likelihood ratio test (31) can help to ascertain the necessity of an additional parameter or not. The results of the analysis show that the addition of one more parameter to the model does not improve significantly the fit.

3. Model Assessment

The assessment of the model fit is a statistical analysis of the applicability of the model through analysis of the error term and the expectation functions. Model assessment is usually performed by examining the prediction of the model and by testing that the previous assumptions done in the model building have been fulfilled, generally by making residual diagnostic plots.

4. Model Validation

Model validation can be performed using k-fold validation, bootstrap techniques or external data. Given that the availability of experimental data k-fold and bootstrap are the most common techniques used (24).

5. Model Maintenance

Once models are fit and validated, they can be applied. However, modelling itself is a dynamic activity and models rarely have a long life. As new data and new theories are developed, new models will arise to compete with the previously developed ones. The new models can be compared and selected or discarded using model discrimination criteria like the Akaike and Bayesian information criteria or the likelihood-ratio tests (24) or new experiments can be devised to discriminate between the two models (35) to improve the precision of the forecasts.

B. Deductive Modeling

Deductive modelling uses the *theoretician approach*, with deductive modelling techniques to build a mathematical

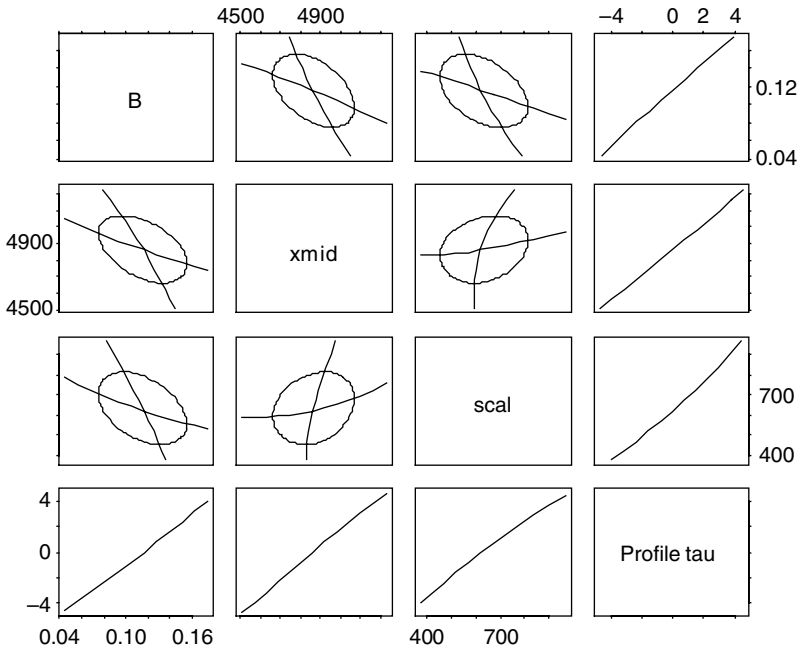

FIGURE 144.4 90% confidence bi-variate regions and tau profiles of the peroxidase non-linear regression (31).

TABLE 144.5
Log-Likelihood Ratio Test to the Addition of the Parameter A to the Fit

Model	RSQ	df	Sum. SQ	F value	Pr (>F)

Logistic fit A	0.032	1.00	0.002	0.798	0.384

model from the first principles that govern the phenomena under study. In this way, the food problem is decomposed in a series of components that make a conceptual unit on themselves. Each of the components can then be studied separately and then they can be coupled to describe the integrated behaviour under the study.

For each of the components of the model, the identification process then involves the tasks of:

- Stating the main assumptions that will help to model the problem.
- Identifying the fluxes that govern the phenomena under study.
- Determining the governing equation(s) of the phenomena under study.
- Defining the conditions (initial and/or boundary) that control the particular solution of the governing equation.
- Defining a solution of the problem defined in steps 1–4 or implementing an approximation of the solution using simplification or a numerical scheme.

In deductive modelling the process of estimation and validation becomes more a *calibration* of the *true* model to the particular situation and weights less in the overall model building compared to the model identification task. There is a certain expectation that once the model has been built and validated in a simple system it can be used in different scenarios without much difficulty and that the same explanative behaviour will hold for the new situation (21). Table 144.6 summarises some principles used in deductive modelling of food phenomena.

Example 3. Deductive modelling: Water absorption of breakfast cereals

The water absorption of an extruded cereal product during the storage and consumption dictates the shelf life of the product, given the consumer expectations for a crispy product. Unfortunately, the home conditions vary during the day and extra care has to be taken to build a model that can describe dynamic changes "at home." In order to study this a spherical breakfast cereals were placed under dynamic atmospheric conditions and their weight gain or loss recorded (49).

A typical experiment of water absorption can be seen in Figure 144.5. It seems evident the model to be developed must be very responsive to the changes in relative humidity of the air.

The assumptions to build the model were:

- Water will arrive from the air surrounding the cereal. This implies that the water influx from the atmosphere will define the transport.

- If one considers that the surface of the cereal is in constant equilibrium with the surrounding air and that the main obstacle to the water transport is actually the diffusion of liquid water from the surface of the cereal to the dry core.

TABLE 144.6
Some General Laws Used in Deductive Modelling of Food Phenomena

Fluxes	Law/Equations	Example of Food Phenomena
Heat transfer	Fourier's 1st and 2nd	Sterilisation of solids, refrigeration, freezing, etc.
Mass transfer	Fick's 1st and 2nd	Drying, acidification
Mass transfer	Maxwell	Multi-component mass transfer in food phenomena
Pressure	Darcy's	Transfer of water and gases in porous inert foods
Momentum transfer	Navier-Stokes	Convective flows in food fluids or air fluxes in food systems
Momentum transfer	State equations, mechanical equilibrium equations	Rheology, texture, deformation and fracture of food materials
Chemical species	Zero, First-order, second and n-order reaction	Shelf life of foods, chemical reaction kinetics in foodstuffs, quality prediction
Thermodynamic fluxes	Luikov's	Transfer phenomena in porous media

- A typical volume differential was considered and an effective diffusion coefficient was defined including all the different water transport mechanisms inside the core of the cereal (liquid water diffusion, water vapour transmission by convection and conduction, transport by pressure differentials, etc.).

Under those assumptions, Fick's second law can be proposed as the one that will govern the flow of water from a soaked surface to the core of a spherical breakfast cereal:

$$\frac{dX}{dt} = \frac{1}{r^2}\frac{1}{\partial r}\left(r^2 D_{eff}\frac{\partial X}{\partial r}\right) \qquad (144.8)$$

Where X is the moisture content in dry basis, r is the radius of the cereal, and D is the apparent diffusion coefficient, if the following initial and boundary conditions are considered:

- Constant initial water content in the cereal as the initial condition

$$@\ t = 0,\ X = 0 \qquad (144.9)$$

- Symmetry of the spherical diffusion front from the centre.

$$t > 0,\ r = 0,\ \frac{\partial X}{\partial r} = 0 \qquad (144.10)$$

- Constant flux surface equilibrium through the water sorption isotherm equation of the breakfast cereal (16)

$$t > 0,\ r = R,\ -D_{eff} A\frac{\partial X}{\partial r} = K_g A(P_V - P_{V\infty}) \qquad (144.11)$$

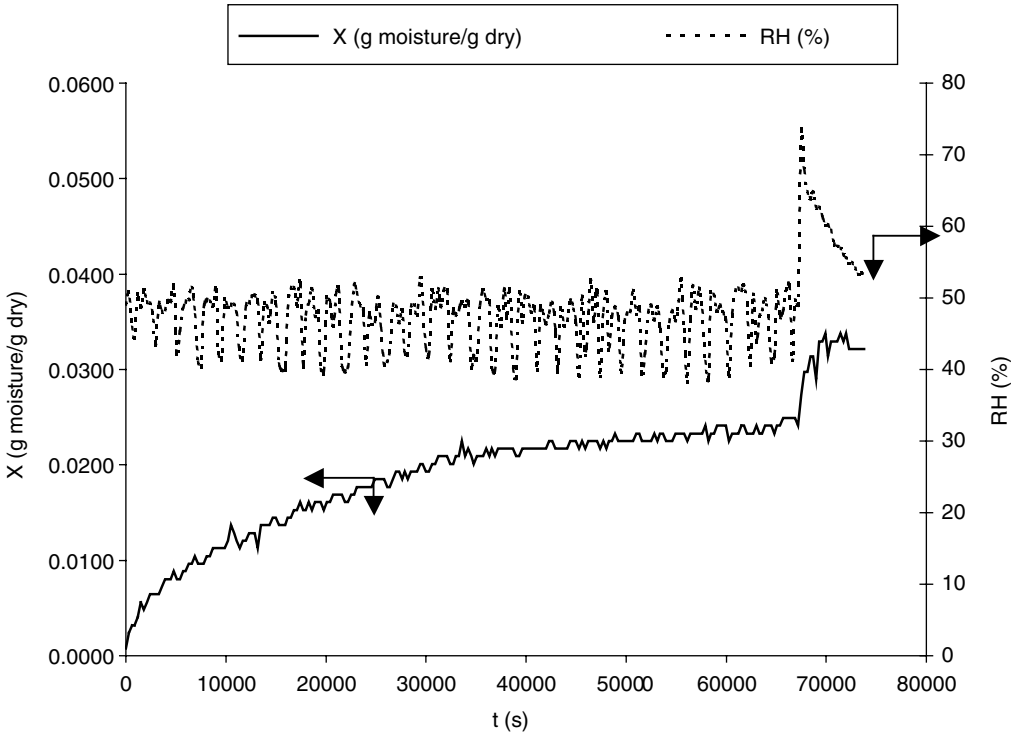

FIGURE 144.5 Plot illustrating the effect of change in relative humidity on equilibrium moisture content.

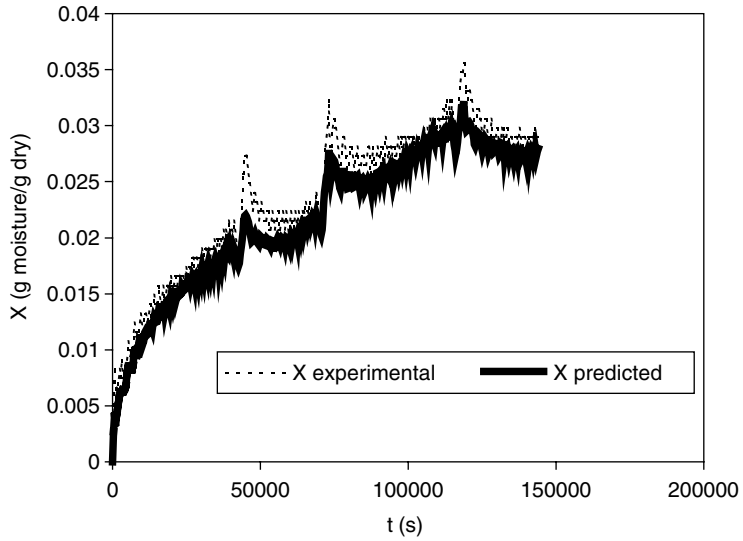

FIGURE 144.6 Prediction of the moisture intake of the breakfast cereals with the model.

where A is the area of the cereal, K_g is the external mass transfer coefficient, P_v is the vapour pressure of the atmosphere surrounding the extruded cereal and P_v is the vapour pressure in the surface of the breakfast cereal that is found from the sorption isotherm equation. The sorption isotherm equation can be described using the GAB model,

$$a_w = \frac{\left(\frac{M_0 C}{X} - C + 2\right) \pm \sqrt{\left(C - 2 - \frac{M_0 C}{X}\right)^2 - 4(1 - C)}}{2(1 - C)kappa} \tag{144.12}$$

with Mo, C and kappa as unknown parameters and with a temperature dependence that follows:

$$\ln\left(\frac{a_{w2}}{a_{w1}}\right) = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{144.13}$$

Considering the governing equation and the initial and boundary conditions, an approximation to solve the problem can be built using the method of the lines and a standard ODE solver. If there is no further information from other experiments (i.e. breakfast cereal sorption isotherms), in order to calibrate the model to the particular breakfast cereal the diffusion coefficient and the sorption isotherm parameters have to be estimated from the experimental data. Particular care has to be taken with (50):

- The numerical stability of the scheme that can greatly affect the simulation and the estimated parameters.
- The convergence towards a minimum, ensuring that local minima are avoided.
- The stability of the solution for all the experiments.

Figure 144.6 shows one of the experiments with the model prediction and Table 144.7 shows the parameters found using a least squares method. Both the diffusion and the sorption isotherm parameters are within physical constraints and Figure 144.6 shows the ability of our model to predict a dynamic situation with variation of the outer relative humidity of the air surrounding the cereal.

This mathematical model can then be used to study the water absorption of breakfast cereals under different scenarios of relative humidity and to help predict the shelf life of the breakfast cereals.

TABLE 144.7
Parameters Estimated from the Diffusion Model of Water in Breakfast Cereals

Parameter	Value	95% Confidence Interval
D_{eff} (m^2/s)	1.0633×10^{-10}	1.0616×10^{-10} to 1.0651×10^{-10}
E_a (kJ/(mol K))	6.527×10^4	6.244×10^4 to 6.271×10^4
K_g (kg/m^2Pa s)	3.120×10^{-8}	3.116×10^{-8} to 3.124×10^{-8}
M_o (g water/ g dry)	1.350×10^{-2}	1.348×10^{-2} to 1.352×10^{-2}
C	20.34	20.32 to 20.36
kappa	1.199	1.198 to 1.201

$R^2 = 0.9982$.

C. Eclectic Modelling

The form and the complexity of the mathematical model depend on the purpose of the particular application. A typical example of this is the study of drying of foods:

- Several competing fundamental theories have been developed and models developed from those theories (e.g. 15) co-exist with empirical models (e.g. 16).
- Despite the fact that the theories developed seem to explain thoughtfully many of the interactions in drying systems, it does not seem that empirical models will stop being developed by researchers for particular applications where model building techniques "accommodate."

- In the same way the applied work in empirical drying modelling does not seem to stop new fundamental developments in the area of drying that extend the knowledge on the process.

The co-existence of those two methodologies in several R&D fields seems to indicate that there are areas where one technique or the other can present certain benefits, and certain problems (e.g. optimisation of drying processes) where the two approaches present different solutions that compete in their applicability. In this way inductive and deductive modelling can be complemented in an "eclectic" way to develop:

- Apply the theoretical knowledge to identify model constructions for a particular problem.
- Use powerful inductive statistical techniques to estimate parameters (least squares, likelihood, Bayesian estimation).
- Use inductive validation combined with knowledge based experimental design to compare the model to the experimental data and to demonstrate the domains of applicability of fundamentally based models.
- Use deductive knowledge and statistical criteria to be able to benchmark several different theories and establish the limits and applicability of their models to the particular food phenomena of interest.
- Employ statistical techniques of simulation to apply the fundamental model in new situations.

The statistical procedures to fit a simple empirical model do not differ greatly from the fitting of a complex system of partial differential equations (50) and deductive model building techniques would benefit from the possibility of creating procedures by which different model theories can be compared. In the same way inductive modelling could benefit from the application of knowledge based models to enhance the applicability of the models generated from experimental data.

V. FUTURE PERSPECTIVES

The field of mathematical modelling is in constant advance and there are some topics that will present the opportunity for developing:

a) In the area of inductive modelling:
   - Accurate model formulations for reaction networks present an opportunity to improve the knowledge of complex food phenomena with possible extensions to metabolic studies of biological phenomena in food (51).
   - Multiphysics and the interactions between different transport phenomena (e.g. heat, mass, momentum) may lead to the understanding of complex food problems like (e.g. grain checking, material formation during food processing, influence of rheological properties on food phenomena, etc.) (18).

b) In the areas of estimation and model application:
   - Advances in the integration of system modelling and the development of hybrid simulation can provide the tools for the integrated study of whole food processing systems (52).
   - Bayesian modelling techniques (53) and mixed modelling can help in the estimation of variability in food processes and to integrate food modelling with quantitative risk assessment (17). The Bayesian approach to include previous expertise and experience in the modelling and parameter inference procedure has the potential of producing a fruitful interaction between advance statistics and food technology/engineering. Example 4 provides an illustrative example on an application to build a model that can be used in further risk analysis of the microbiological risks associated with deli shops.

Example 4. Modelling the kinetics of microbial growth in vacuum packaged cooked chicken in deli premises accounting for the uncertainty between premises.

Four sandwich premises (A, B, C and D) where tested where the log of the total viable count (TVC) was measured in chicken pieces (used as an ingredient for ready-made sandwiches) during a working day. The data showing the microbial growth can be seen in Figure 144.7.

Primary modelling

It can be seen that there is a general functional relationship that can describe the growth, with a significant variability between premises. In order to propose a model that could describe in a reasonable way the phenomena, a non-linear mixed effects model was proposed, where the Gompertz model was used to describe the growth of the TVC with time:

$$\log(TVC_{i,j}) = Asym \cdot e^{-b2 \cdot b3^{time}} + \varepsilon_{i,j} \qquad (144.14)$$

where each measurement of the TVC at the premise i in time j is associated to a normal distributed error $\varepsilon_{i,j}$ The fit of a Gompertz model to each individual premise can be seen in Figure 144.8 that serves to validate the model application to model the kinetics of the phenomena. Once this primary model is achieved, one can try to start modelling the variation between premises.

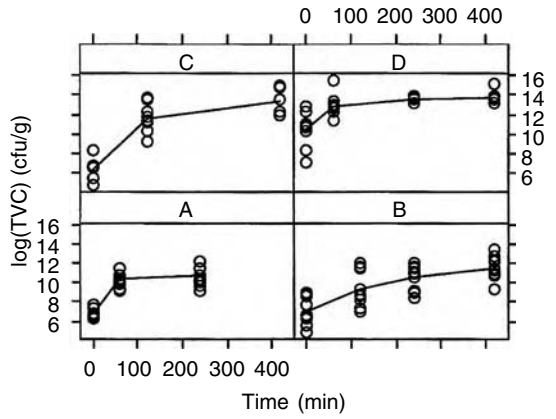

FIGURE 144.7 Growth of total viable count (TVC) in cooked chicken at four sandwich premises.

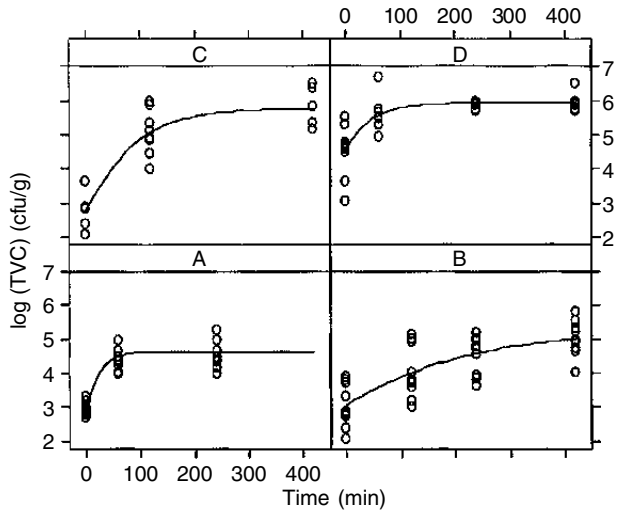

FIGURE 144.8 Individual fit of the Gompertz model to the kinetic data in each of the premises.

Secondary modelling

In order to model the variance of the Gompertz model parameters with the premise variation *Asym*, *b*2 and *b*3 were modelled as unknown parameters which had an associated fixed effect (the behaviour of the "average" premise) and a random effect (the variation between premises) in the form of a random distribution that changes between premises *i*.

$$Asym_i \sim Asym + N(0, \sigma_{Asym}) \quad (144.15)$$

$$b2_i \sim b2 + N(0, \sigma_{b2}) \quad (144.16)$$

$$b3_i \sim b3 + N(0, \sigma_{b3}) \quad (144.17)$$

Mixed effect models convey a hierarchical structure of the error in a model that intuitively suits many food related problems. Using this non-linear mixed effect model, the parameters were estimated via maximum likelihood estimation using the library NLME (54) and the average premise parameters together with the variability between premises can be seen in Table 144.8.

TABLE 144.8
Results of the Model Regression

Parameter	Low 95%	Estimate	High 95%
Average Premises Parameter			
Asym	4.898	5.405	5.911

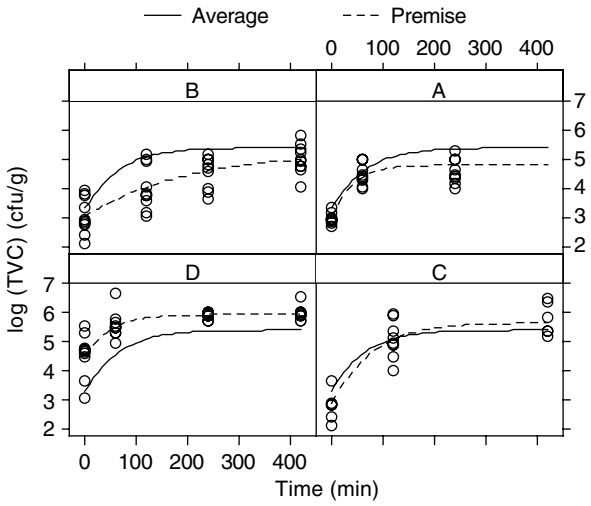

FIGURE 144.9 Fit of the NLME Gompertz model to the data. The continuous line shows the average premises population kinetics and the dotted one the best linear unbiased predictions (BLUP) of the model for the particular premise.

The fit of the model to the experimental data, together with the average behaviour, can be seen in Figure 144.9 showing the agreement with the model. The parameters from Table 144.8 can then be used in stochastic simulations to perform uncertainty analysis of risk assessment on the microbial growth in the sandwiches.

VI. CONCLUSIONS

Model building is an exciting research and development field in food technology and engineering that offers powerful tools to solve complex problems. The main aspects where model building is applied in the food

technology and engineering domain have been outlined. Simple examples have shown the different steps in the building of models from different approaches. This prolific field of food technology and engineering enjoys a healthy development sustained by the new demands of industry and research, and provides exciting tools to investigate food related phenomena.

CONTENTS

INTRODUCTION

The purpose of this chapter is to present an overview of major types of engineered wastewater treatment systems that are used by different industries in Canada, with examples of actual systems that have been operated in a diversity of applications ranging from treating food processing and pulp and paper industry wastes to toxic landfill leachates. Regardless of the actual wastewater treatment application, these engineered systems typically combine different physical, chemical and biological unit operations which are selected and matched according to the ultimate treatment

objectives of the treatment system. At the heart of the processes are the biological reactors which employ aerobic and/or anaerobic bacteria to remove a wide variety of soluble substances that may be present in the wastewaters, such as organic matter (biological oxygen demand, BOD_5) and nutrients (typically ammonia and phosphate).

Examples of aerobic engineered biological treatment systems used in Canada and elsewhere include large field-size aerobic stabilization lagoons which typically employ mechanical surface aeration, conventional activated sludge treatment systems, aerobic biofilters (e.g. Acticontact Process), sequencing batch reactors (SBRs), trickling filters and rotating biological contactors (RBCs). Each of these systems requires mechanical aeration to provide needed oxygen to drive the aerobic microbial biodegradation processes. For some applications, anaerobic biological treatment systems such as the upward flow anaerobic sludge blanket reactor (UASB Process) can also be found in Canadian industrial and municipal applications.

The biological treatment unit operations of a wastewater treatment system form what is called the secondary treatment system. To achieve cost-effective and efficient wastewater treatment requires secondary treatment systems to operate in conjunction with other non-biological wastewater treatment unit operations referred to as pre-treatment, primary treatment and tertiary treatment. Pretreatment (e.g. screening, grit removal chambers, comminution (grinders), pH neutralization) and primary treatment (gravity clarification, dissolves air flotation) unit operations are typically located ahead of the secondary treatment system, where they are first to treat the incoming raw wastewater by physical and chemical means. Tertiary (polishing) unit operations are located downstream of the secondary treatment system and are designed to polish the final effluent before final discharge. Examples of unit operations that are used for tertiary treatment include residual phosphate precipitation and removal; break point chlorination for residual ammonia removal, disinfection and dechlorination; and polishing to remove trace metals (e.g. metal precipitation, activated carbon). The pre-treatment steps are designed to remove solid materials such as grit and sand, leaves, rags, bottles, and other large debris. The equipment used in primary treatment on the other hand is employed to remove settleable solids and floatable materials (e.g. fats, oils and grease).

TABLE 145.1
Final Effluent Discharge Compliance Limits for a Large Meat Processing Plant in Ontario, Canada

Parameter	C of A Discharge Limit
Carbonaceous BOD_5 (mg/L)	7.5 mg/L ($t \geq 5°C$); 10.0 mg/L ($t < 5°C$)
TSS (mg/L)	10 mg/L
Ammonia and ammonium (as N) (mg/L)	3 mg/L
Unionized ammonia (as N)	0.02 mg/L
Total phosphate (as P)	0.4 TP (monthly average)
Residual chlorine	0.002 mg/L
Dissolved oxygen	$\geq$ 4 mg/L
Acute toxicity (96 h rainbow trout assay)	Non-toxic (i.e. $\geq$ 50% survival in 100% effluent)

The choice of treatment technologies that will be selected for a particular application will be determined by the treatment objectives of the facility, which are commonly mandated by government regulations through strict, enforceable industrial discharge permits such as Certificates of Approval in Ontario, Canada. Such permits impose very strict final discharge standards which the discharger must meet or else face potential costly fines and/or imprisonment. Table 145.1 presents an example of the tight discharge compliance limits that one meat processing plant in Ontario must currently meet.

This chapter has been written in two parts. The first part presents a description and an analysis of case studies performed during 1990. The second part discusses some current thoughts on new approaches, techniques and methodologies.

PART I. Biological Wastewater Treatment: Case Studies

I. APPLICABILITY OF BIOLOGICAL TREATMENTS FOR THE DETOXIFICATION AND DEGRADATION OF ENVIRONMENTAL AND FOOD PROCESSING POLLUTANTS

Increased awareness and concern over the quality of the environment have led the Federal and Provincial governments in Canada to pass stringent regulations and guidelines on the release or disposal of pesticides, industrial wastes and other pollutants into the natural environment. Failure to comply with such regulations can result in the levy of high fines, costly plant shut down or even jail sentences for responsible offenders. In response to the needs of industry to meet the regulations, there has been a tremendous effort over the past several decades to develop new and improved waste treatment processes that are both efficient and cost effective and which are capable of consistently meeting tight effluent discharge quality criteria. Increased industrial and government funding has sparked fundamental research in the fields of microbial ecology, metabolism, genetics and bioengineering, which in turn has led the way to the development and recent introduction of some novel biological treatment processes for man made synthetic chemicals (xenobiotic) wastes.

A variety of aerobic and anaerobic biological waste treatment processes have been employed for years in Canada for the treatment of domestic wastes such as sewage, food processing wastes and the like. With the widespread manufacture and use of novel xenobiotic substances, many of which have been found to be very recalcitrant to conventional microbiological treatments, came the understanding that the existing biological approaches and processes would have to be refined significantly for the treatment of industrial wastes, landfill leachates and other materials containing hazardous compounds such as dioxins (1).

Many microorganisms have the ability to degrade organic pollutants. Effective treatment in any biological treatment process will be absolutely dependent on the ability to provide the "correct" type(s) of microorganisms in the treatment system and to maintain the treatment microorganism(s) in a satisfactory or optimal physiological state (i.e. environment) to allow their metabolic well being. The latter will be determined by a whole host of chemical, physical, nutritional and biological factors which affect microbial growth, survival and metabolic activity. Failure in the past to understand these fundamental ecological principles has slowed the successful development of biological processes for hazardous waste treatment.

When a natural organic substance is introduced into an environment which is favorable for microorganisms, the substance will eventually become biodegraded. This is not necessarily the case for xenobiotic substances, many of which are highly resistant to biodegradation (e.g. PCBs, dioxins, PHAs). With over 1,200 chemical substances being added annually to the U.S. EPA's list of 60,000 industrial chemicals in 1985 (2) (The Chemical References Complete Index of EPA can be found in http://www.epa.gov/enviro/html/emci/chemref/complete_index.html), the capability of microorganisms to modify and degrade both natural and xenobiotic substances in the environment has been an important topic for research since the 1960s. It is now well recognized that as a group, microorganisms have an enormous capacity to biodegrade natural organic substances, given favorable environmental conditions (3, 4, 5, 6). This is attested by the fact that in the ecosphere, accumulations of natural organic compounds do not exist except where environmental conditions have been adverse to microbial survival (e.g. sites of fossil fuel deposits). In soils or aquatic ecosystems, such adverse conditions may include extremes of pH, salinity, temperatures, or low water availability in soil systems, as a few examples. For a particular waste problem, the operating performance of a biological process (i.e. efficiency, kinetics of biodegradation and detoxification, stability, control of undesirable microorganisms, etc.) will be dictated to a large part by how well these factors are understood (and controlled) by the designers and operators of the system.

The fate of xenobiotic chemicals following their introduction into a natural ecosystem is much more complex than the situation for natural compounds. Such molecules may undergo complete or partial biodegradation or may be entirely recalcitrant to microbiological attack. It is therefore important to distinguish among these possible mechanisms of removal when considering the feasibility of biological treatments.

The major objectives of biological treatment as pointed out by Aitken and Irvine (7) are as follows:

1. Reduction of a substantial fraction of the organic load, to a point where overall treatment costs are

reduced, minimizing the need for more expensive treatment such as activated carbon.
2. Removal of target compounds to specified levels, e.g. for wastes containing low percentages of xenobiotics, the objective is the removal of these compounds.
3. Attainment of a final toxicity standard. The major objectives are to reduce the concentration of priority pollutants in the waste to meet the allowable standards set by the regulatory agencies, as well as the reduction of surrogate parameters such as BOD and COD to acceptable levels. A ratio of BOD to COD will indicate whether the leachate is biodegradable (if less than 1.0) or not.

II. BIOLOGICAL TREATMENT PROCESSES FOR WASTEWATER

Basic biological treatment processes involve the use of microorganisms in a closed environment (a tank, or a man-made lagoon or basin) to remove (biodegrade, bind, entrap, incorporate) the organic matter in the wastewater. Such systems may be anaerobic (with no air included in the treatment), or aerobic (with air to oxidize the organics) as shown in Figure 145.1.

There are numerous types of engineered biological treatment systems which differ in their reactors and equipment designs (e.g. activated sludge treatment (AST), rotating biological contactors (RBCs), sequencing batch reactors (SBRs) and upflow anaerobic sludge blanket (UASB)) and in their operating principles (e.g. aerobic vs. anaerobic). Biological treatment may take place in an open or closed system or even in situ (i.e. right in the ground in contaminated sites). The advantages and disadvantages of several types of systems will be discussed here, as well as factors or guidelines governing the selection of the best process for a particular waste treatment problem.

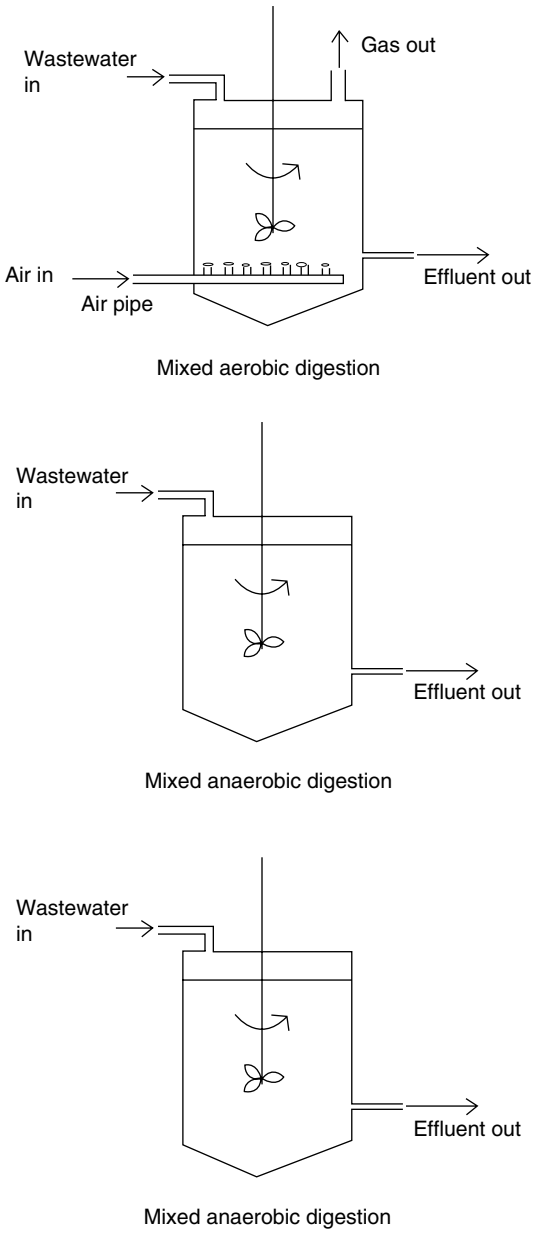

FIGURE 145.1 Basic biological treatment processes.

A. Aerobic Biological Treatment Processes

In aerobic microbiological processes oxygen consuming bacteria metabolize dissolved organic compounds and convert them into carbon dioxide and settleable solids (i.e. microbial biomass). Organic matter may also be removed from such systems by adsorption to, or entrapment within, the microbial biomass, and by incorporation into the microbial biomass itself. For an aerobic process, the rate at which biodegradation occurs is often limited by the rate at which oxygen can be dissolved in the wastewater. The oxygen transfer rate is often the critical parameter limiting the operation of aerobic waste treatment systems. Energy for aeration is also a major operating cost for such treatment systems.

Various types of mechanical aeration technologies are employed for increasing oxygen transfer into wastewater including various types of floating and fixed surface aerators and fine and coarse bubble diffusers fed by mechanical blowers. Figure 145.2 shows an aerial photograph of the activated sludge aeration basin used to treat meat processing wastewater at Canada's largest meat rendering plant, the Rothsay plant owned by Maple Leaf Foods Ltd. in Dundas Ontario. This system has 3 types of aerators in the aeration basin shown: 2 fixed surface aerators, 4 floating surface aerators and an underwater course bubble diffuser. This particular wastewater plant will be taken out of service in late 2005, when a completely new upgraded activated plant comes on line.

FIGURE 145.2 An aerial photograph of the activated sludge aeration basin in Canada.

Oxygen transfer to such systems can also be increased by a number of ways including pumping pure oxygen instead of air into the system (e.g. UnOx process such as is used at several Canadian pulp mills), altering the temperature, adding hydrogen peroxide to the culture, or by increasing the hydrostatic or the back pressure of the system.

1. Aeration Stabilization Basin

Aerobic stabilization basins or lagoons (ASBs) have been used successfully for the detoxification of some industrial pollutants and for organic matter (BOD_5) removal. This type of wastewater treatment technology is widely used in the Canadian pulp and paper industry, where large sections of land are readily available to accommodate these enormous, but simple-to-operate and effective systems. One such system which has been the focus of considerable research is the ASB belonging to the Domtar (formerly E.B. Eddy Forest Products Ltd.) pulp and paper mill in Espanola, Ontario (8). This kraft mill converts approximately 4×10^6 kg of wood chips a day to 1×10^6 kg of kraft pulp. Approximately 68,130 L/min of wastewater containing organic pollutants (BOD_5) and toxic substances (e.g. chlorinated lignin breakdown products, and resin acids) are sent to the mill's waste treatment facility for detoxification and BOD and total suspended solids reduction. Suspended solids (mostly cellulosic fibres and inorganic matter) in the kraft effluent are first removed by gravity in one of two parallel 7.19×10^7 L settling basins. At any one time, only one of the settling basins is operational, since the settling basins must be taken off line annually and de-sludged. The second settling basin therefore becomes operational when the other basin is taken off line for de-sludging. The effluent treatment system consists of two settling basins for primary treatment (each has a volume of 45,000 M^3; one of these is normally on-line, and the other empty), a 2-cell biological aeration lagoon (cascade arrangement) and a final settling basin (Quiescent Polishing zone) for removal of biological solids before final discharge. The capacities of Cell 1 and Cell 2 are 3.03×10^8 L and 3.78×10^8 L , respectively. The 2 aeration cells have a 40 acre surface area and are aerated by twenty two 75 hp mechanical surface aerators, 12 in Cell 1 and 10 in Cell 2. The hydraulic retention time in the system is normally kept between 6–8 days. From the aerobic basin, the treated effluent is sent to quiescent basin with a 12 hour retention time for final polishing (i.e. gravity settling of any remaining suspended solids), and it then is piped to the receiving environment (Spanish River). The entire treatment system is lined with a PVC liner to prevent untreated effluent from escaping into the ground water. In addition, a 2.27×10^8 L emergency spill diversion basin has been constructed as an added precaution. The efficiency of the system and the quality of the treated effluent is monitored closely for pH, conductivity, toxicity towards fish (LC_{50} trout minnow test) and water fleas (*Daphnia magna* 48 h bioassay), BOD, TOC and other physical, chemical and aesthetic parameters. According to two extensive published studies in the scientific literature (9, 8), the quality of the Epanola mill's effluent is within the original design requirements, having a BOD of below 4×10^6 kg/d and being non-toxic to fish.

2. Continuous Flow Activated Sludge Process

Activated sludge treatment (AST) systems are widely used throughout the world for the treatment of municipal and industrial wastewaters. These systems are designed as high rate systems which are able to treat a much larger quantity of wastewater in a much smaller footprint than is possible with aeration stabilization lagoons. This is made possible by the design of these systems which allow them to carry a much higher microbial biomass concentration that is the case with ASBs activated sludge systems typically consist of a mechanically aerated basin or tank followed by a secondary clarifier which separates treated effluent from the floc-forming microbial biomass (Figure 145.3). Most of the latter is returned to the aeration basin as RAS (return activated sludge), except for a fraction that must be wasted in order to maintain an optimal biomass concentration in the system (termed WAS, waste activated sludge). An example of an activated sludge system from a large meat processing plant is shown in Figure 145.2. Such systems are used in many other industries including pulp and paper, petrochemical and food processing.

As with all types of biological treatment systems, it is critical to provide the microorganisms in an AST with a favorable environment to effect the required wastewater treatment objective. For example, in 1986, CANVIRO Consultants of Ontario conducted a study with the Ontario

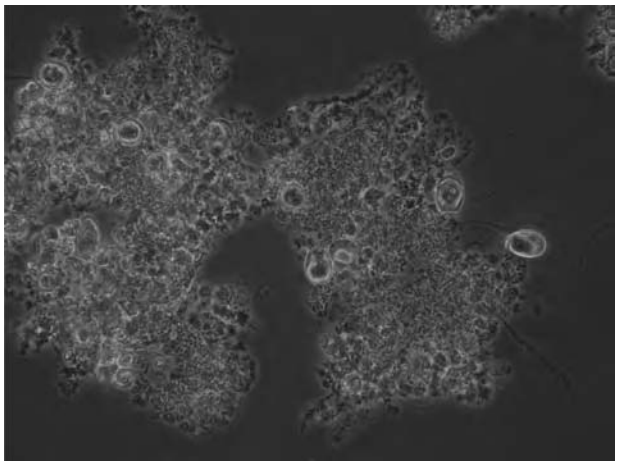

FIGURE 145.3 The floc-forming microbial biomass.

Petroleum Association (OPA), the Ontario Ministry of Environment (MOE) and Environment Canada to determine the relationship between biological treatment process operating conditions and the ability of the process to effect trace contaminant removal (10). The biological treatment (activated sludge system) was carried out at two preselected refineries in Ontario: one at Sarnia (Esso) and the other at Trafalgar (Petro-Canada).

Petro-Canada's Trafalgar Refinery has the capacity to process 1.012×10^7 L of crude oil per day. Major refinery processes at Petro-Canada's Refinery include distillation, reforming, alkylation, desulfurization and blending of crude to produce a variety of petroleum products. Process wastewater treatment involves oil/water separation in API (American Petroleum Institute) separators, equalization, further oil and solids removal in induced air flotation (LAF) separators and in-house biological treatment (aeration tanks-clarifiers-aerobic digester). All tanks are covered and air is supplied by a diffuse air system. There was no nutrient addition to the aeration tanks at the time of sampling in 1988. The activated sludge plant has an average design flow capacity of 6,019 m^3/day.

3. Rotating Biological Contactor (RBC)

An RBC bioreactor consists of a slow rotating disk assembly semi-submerged in an engineered tank or a pond. Several disks are typically attached to the support rotor. The disk is designed to provide a very large surface area for the attachment of microorganisms which grow to form an extensive biofilm on the disk (see Figure 145.4). The slow turning of the disks will enable microorganisms to utilize air oxygen (when the part of rotating disk is in the air) and to consume, bind or entrap the organics in the wastewater (when the part of rotating disk is submerged). A report presented at the HAZMAT Canada '87 Conference showed that the rotating biological disk has been successfully demonstrated for the destruction of phenolics in five

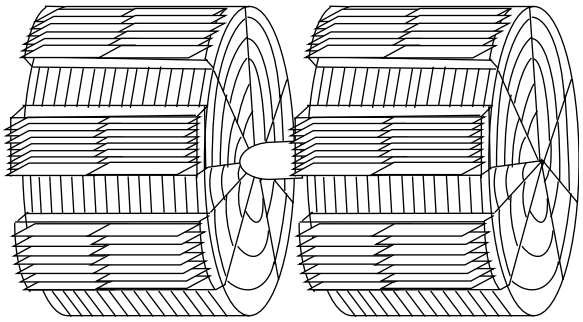

FIGURE 145.4 A rotating biological contactor (RBC) bioreactor.

waste streams, including streams from spray dried resin production, phenol-formaldehyde resin condensate, fibreglass insulation manufacture, pulp and paper mill effluents, and landfill leachates (11).

a. Peel county landfill (Ontario)

In the early 1990s, RBC technology was selected for treatment of chemically contaminated landfill leachate from the Brittania Road landfill site in Peel County, Ontario, following a promising pilot trial of this technology. At the time the landfill had been receiving a mixture of industrial and municipal wastes with a COD of 15000 to 19000 mg/L. According to information we received from the RBC vendor (CMS Rotordisk Inc.), 92% removal of COD was achieved in the pilot study. The decision was made to install a full scale system, designed to treat 2000 m^3 of leachate per month at a loading of 133 kg BOD/day. The total disk surface area for fixed film formation for this system is 11520 m^2.

RBC technology has been used in many other applications world-wide. For example, in Iran, an RBC application for treating bakers yeast wastewater achieved 94.9% and 84% removal efficiencies in COD and BOD in the wastewater, respectively (12). In another example, a rotating biological contactor with volume 14.26 M^3 L was used successfully for treating winery wastewater with maximum COD removal efficiencies up to 95% in South Africa (13).

4. Sequencing Batch Reactor

A sequencing batch reactor (SBR) is a biological reactor quite similar to AST except that all events (aerobic treatment and solids separation) take place in a single tank (i.e. no separate clarifier). SBRs operated in a cyclic batch mode (each cycle consists of 5 discrete events): fill (add wastewater to a tank), react (aeration of the wastewater with stirring to permit thorough mixing of the settled microorganism sludge with the wastewater), settle (an anoxic period in which the mixed liquor and suspended solids (biomass) are allowed to separate by gravity sedimentation), draw

(removal of the clarified supernatant water from the tank), and idle (a period of resting until the next batch of wastewater is ready for treatment) as shown in Figure 145.5. In a two-tank system, one tank is completing "react," "settle," "draw," and "idle" while the other tank is "filling." The SBR is one of several innovative and alternative biological waste treatment systems that has been evaluated by the EPA (14) and the Office of Technology Assessment (15).

A full scale SBR serving the Niagara Falls area (including the nearby industrial belt of St. Catherine in Ontario) has been built and operated at Niagara Falls, New York, since June 6, 1984. The treatment plant typically receives 10,000 m^3 of wastewater each month. Approximately 50% of this leachate is pumped from both active and inactive landfills on the CECOS site; approximately 30% is pumped as part of a remedial groundwater program from an unrelated facility bordering the CECOS site; the remaining 20% is received in bulk or drums from various industries in a 640 km radius. The SBR system uses a two-phase operation: phase 1 is dedicated to oxidation-reduction reactions, acid neutralization, heavy metals precipitation (lime) and de-watering; phase 2 is dedicated to pH adjustment (with HCl), biological degradation, carbon adsorption and batch discharge. The covered SBR (1890 m^3) was situated in the phase 2 operation between the equalization and neutralization basins, and the activated carbon columns. Flow through the SBR averaged 220 m^3/day, giving an 8- to 9-day retention time, and representing 90% of the wastewater processed at the Niagara Falls site. The management at CECOS chose SBR over other aerobic treatment designs because of its simplicity (all the actions in one tank) and its effectiveness in leachate treatment as shown in the pilot studies. They considered anaerobic processes to be more prone to shocks, and it would take the anaerobes a much longer time to recover from shock. Operation of an SBR at CECOS Intl. during the winter months showed a reduction as high as 50% in biodegradation rates. An SBR experiment to simulate cold weather operation showed that a reactor maintained between 5 and 6°C had a TOC value of 800, compared with 1600 for the influent, and 400 for the reactor that was maintained between 21 to 25°C (16). A senior official of CECOS suggested that longer retention time of the wastewater should be maintained for better treatability. Furthermore, if financially possible, each site should have two SBRs to provide more flexibility, such that while one SBR is operating in the reaction step, the other one is discharging treated effluent.

In the early 1990s, there were over seventy-five SBR plants operating in the United States (one in California

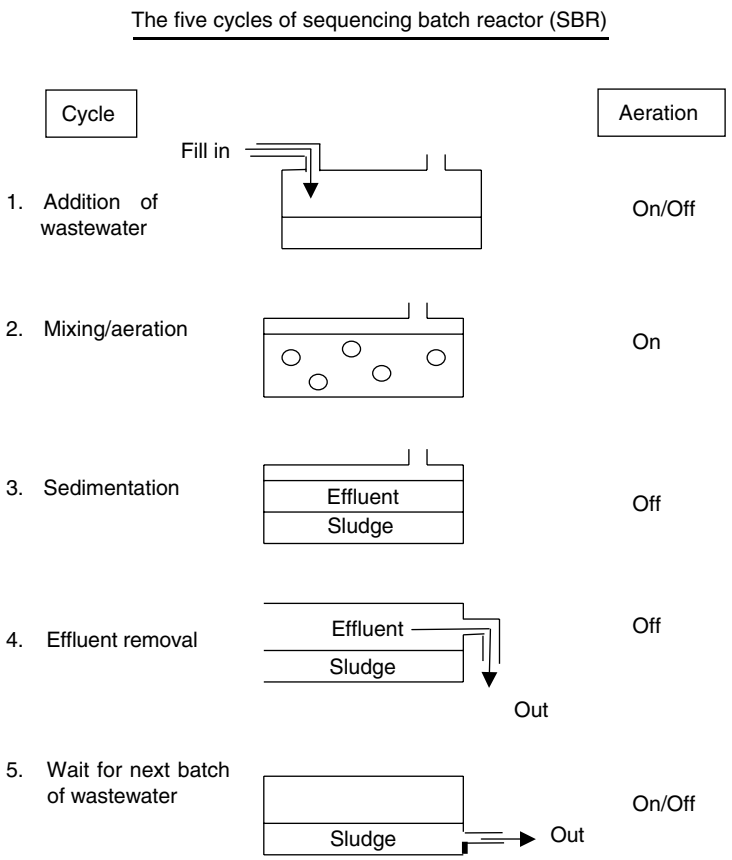

FIGURE 145.5 The five cycles of sequencing batch reactor (SBR).

that treated 1.89×10^7 L per day, and one in Oklahoma City that treated 9.46×10^7 L per day). At this same time in Canada, there was an SBR in operation in Quebec City for the treatment of slaughterhouse wastes. While in Greece, a sequencing batch reactor was operating for the treatment of landfill leachate and domestic sewage. This system was reported to have removal efficiencies of 95% for BOD_5 and 50% for nitrogen (17). Lin and Cheng (18) successfully treated municipal sewage waste with a sequencing batch reactor in Taiwan for removing 93.6%, 91.8% and 53.3% of COD, BOD and ammonia in the wastewater, respectively. On the other hand, a 60 L sequencing batch reactor in Korea removed 97–98%, 96% and 80% of BOD, nitrogen and phosphorus in dairy industry wastewater, respectively (19).

5. Acticontact System

Biofilters such as the acticontact biofilter that was installed in 1995 at the E.B. Eddy Forest Products Ltd. (presently Domtar Inc.) fine paper mill in Ottawa, Canada, are a relatively new technology for high rate aerobic treatment of wastewaters. The E.B. Eddy biofilter was selected after an extensive 10-month pilot trial showed that the system offered many advantages over other treatment technologies that the mill had considered, including limited available space for installation, proximity to neighbouring commercial and governmental buildings, low operating costs and need to meet stringent discharge limits (20, 21). The Acticontact is an upflow aerobic biofilter, in which effluent and air are fed into the bottom of a rectangular concrete tank that is filled with a porous, pebble-like man-made support material called Actilite. The Actilite provides a large surface area for the attachment of large numbers of biofilm-forming microorganisms.

While flowing upwards through and around the Actilite bed, BOD substances in the wastewater are removed and decomposed by the bacteria in the biofilm. The Acticontact can take exceedingly high BOD loadings (3 to 17 allowable BOD loading (kg BOD/m^3/d) compared to 0.6 of activated sludge process). The treatment system is able to consistently meet the BOD discharge limit of the mill, achieving 70–80% BOD reduction across the filter bed with a hydraulic retention time of only 22 min. (21).

B. Anaerobic Biological Treatment Processes

Anaerobic treatment processes are based on microbial biodegradation of organic waste in the absence of oxygen. In these processes, various bacterial species closely interact to effect total mineralization of organic compounds, such as the fermentative, acetogen and methanogen bacteria, etc., as illustrated in Figure 145.6.

1. Halifax, N.S. (Anaerobic Digester)

An anaerobic digester that removed organic-waste from the Halifax-area landfill site leachate could provide an energy-efficient model for other Canadian municipalities to follow (22). This system, the first of its kind in Canada, was officially opened in June, 1987, at the new Regional Landfill Leachate Treatment Plant near Sackville, Nova Scotia. It was designed by the National Research Council and Porter Dillon Ltd., and built by the Metropolitan Authority of Halifax-Dartmouth and the County of Halifax at a cost of $3.5 million. In the early 1990s this system was reported to process over 4500 liters per hour of highly concentrated waste liquid (the leachate is 200 times the strength of normal sewage). At this landfill site, more than 1 million tons of solid waste has been deposited to a maximum depth of 17 m. The site was operated by the Metropolitan Authority and received approximately 1×10^6 kg of refuse per working day. At that time, the site contained about 145 hectares of which 30 hectares are cleared. The daily cover material and liner is excavated from on-site glacial till material with a permeability of 10–6 cm/s or less. The base of the fill is underlain by a herring-bone pattern of leachate collector pipes through which leachate is collected and pumped into the

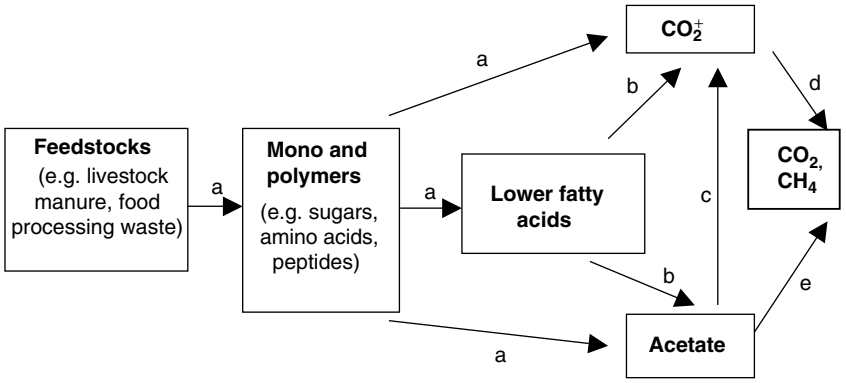

FIGURE 145.6 Flow diagram of degradation of organic wastes by anaerobic biological treatment processes.

closed-system biomass reactor. The leachate is at present treated in two anaerobic lagoons following which it is discharged to a series of four siltation ponds, and then into a swamp adjacent to the Sackville River. The treatment system consists of four stages including a pre-treatment stage, high rate anaerobic-reactors to reduce organic strength, sludge handling facilities and polishing lagoons. The pre-treatment system consists of an equalization tank with a volume of 50 m^3, a caustic feed system (heavy metals are removed by treatment with caustic soda; the high calcium concentration in the raw leachate discouraged the use of lime due to expected scaling problems) and rapid mix, flocculation and settling units. The anaerobic digester constitutes the primary treatment process. This system includes the following components:

a. The anaerobic digesters are fed on a semi-continuous basis by a specially designed feed station. A 1.5 m diameter closed vessel serves as the wetwell (covered and vented through scrubblers to the atmosphere) for the feed pumps.
b. Two upflow anaerobic reactors are used to achieve the reduction of COD in the leachate. The waste effluent is pumped upwards through a dense anaerobic bacterial suspension (i.e. termed the sludge blanket), and are biodegraded in the process. Upward flow anaerobic sludge blanket process (UASB) is an anaerobic bioreactor in which wastewater is introduced at the bottom of the reactor and forced upward to pass through a blanket of sludge (microorganisms). The organics in the wastewater are bioremediated by the microorganisms into carbon dioxide, water, methane and hydrogen gases as shown in Figure 145.7. The biogases can be collected and used as fuel to produce energy. The UASB reactor is designed as a gravity settler to maintain high concentrations of flocculent bacteria inside them. The treated liquid flows over an overflow weir at the top of the reactor, and is then discharged or recycled for more treatment. The concrete cylinders are 5.5 m in diameter and 8 m tall. The effective volume of each reactor amounts to 135 m^3. The bacteria which metabolize the organic waste produce water, carbon dioxide and methane as byproducts.
c. Reactor contents are re-circulated through a drawoff piping network to provide mixing and to maintain the temperature of the reactors at 35°C. The re-circulation ratio of the reactor's contents to influent is established initially at a ratio of 10:1. Duplicate heat exchangers have been provided and sized at capacities of 580,000 Kjoules/hr each, whereas re-circulation pumps have a rated capacity of 26.1 m^3/hr.
d. Methane gas produced during the fermentation is collected at the top of the anaerobic digester and is subsequently used as fuel for the boiler. At the initial and ultimate COD loads of 1,815 kg/d and 2,400 kg/d, respectively, and projected COD removal efficiencies of 95%, methane generation is estimated at 620 m^3/d under initial conditions and 820 m^3/d under

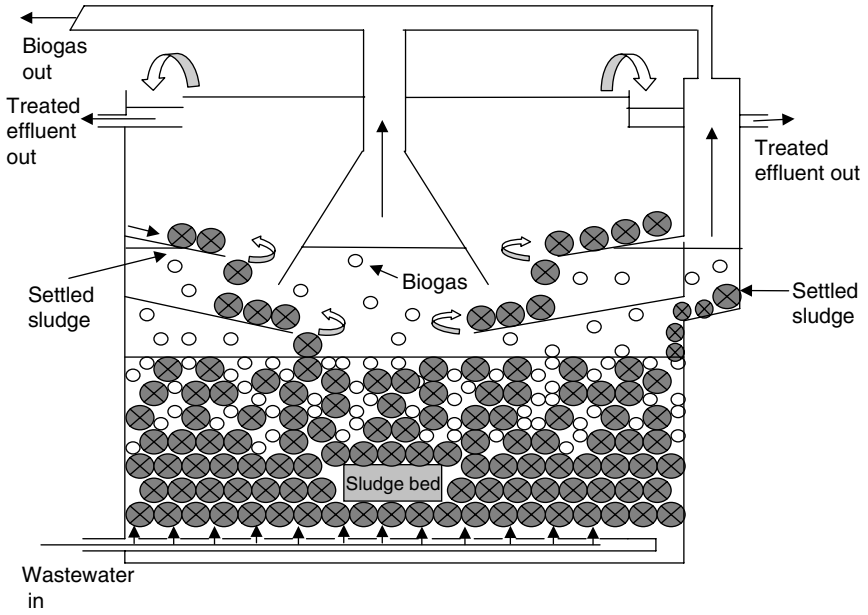

FIGURE 145.7 Upward flow anaerobic sludge blanket process.

ultimate conditions. This gas quantity converts to heating values of 938,000 Kjoules/hr, and 1.27 million Kjoules/hr, under present, and ultimate conditions, respectively. The energy derived from the gas is utilized as a priority to maintain the reactor contents at 35°C with excess gas directed to space heating. The sludge produced during the anaerobic digestion (consisting of microbial biomass, under graded insoluble, etc.) is periodically removed from the bottom of the digester. This material is then dried and returned to the landfill site. The combined sludge from the settling tank and anaerobic reactors are transferred to a covered thickener of 5.5 m diameter and 3 m sidewall depth. Supernatant overflows a perimeter V-notch weir in the thickener to a sump from which it is conveyed by submersible pumps to the equalization tank at the head of the treatment facilities. Thickened sludge is transferred to the dewatering equipment automatically in response to a level signal in the sludge vat of the vacuum filter. A skid mounted fully automated pre-coat vacuum filter system provides sludge dewatering. Dewatered sludge cake is dumped in the landfill, and filtrate from the operation is directed to the aerated lagoons. The final polishing step is carried out in aerated lagoons, which remove residual COD, BOD and ammonia, and precipitate dissolved and suspended solids. According to the information from the Metropolitan Authority of Halifax-Dartmouth and the County of Halifax, the reactor is currently removing 95 to 98% of the incoming waste and is producing enough methane to heat the building it is housed in.

2. Macmillan Bloedel (BIOPAQ)

Currently the (UASB) reactor has been successfully commercialized as a full-scale treatment system in Canada (e.g. the Macmillan Bloedel, Lake Utopia Paper, and Quesnel River Co.). The patented BIOPAQ system (Paques Lavalin, Toronto) is a biological treatment system which is based on the UASB process. The wastewater is pumped into the bioreactor through a number of nozzles that are evenly distributed at the bottom of the reactor. This incoming material then permeates up through the sludge layer, during which time the anaerobic bacteria digest the organics present in the waste, converting it to volatile organic acids, methane, hydrogen and carbon dioxide. Full scale BIOPAQ systems have been built for the pulp and paper, food, textile and petrochemical industries, and for treating domestic sewage.

Following the successful completion of an initial laboratory and pilot scale research, a 19 m^3 Upflow Anaerobic Sludge Bed Reactor was set up for operation under the dynamic mill conditions at Sturgeon Falls (23). The demonstration plant was constructed and was being operated by Paques Lavalin Ltd. There were three major component parts to this treatment system: an 18 m^3 pre-acidification/equalization tank, a 19 m^3 UASB reactor and an operation/control room. The average composition of the wastewater fed into the system was 35% spent sulfite liquor and 65% flotation-clarifier effluent. The two streams were combined, screened and then fed into the pre-acidification tank, where caustic soda (for pH control) and nutrients (required for biological growth) were added to the feed. After the first 8 months of operation, the results obtained showed that the biogas produced in the reactor contained 60–65% methane, 35–40% carbon dioxide and 1.5% hydrogen sulfide. The biogas production rate followed very closely to the volumetric loading rate (VLR) applied, indicating a healthy and acclimatized biomass. Preliminary results indicated net granular sludge growth, and the biomass was not overloaded. At a VLR up to 19 kg COD/m^3/d the plant consistently obtained 85% BOD removal or better. The projected capital cost for 1987 supply and installation of the proposed four reactor BIOPAQ package plant was $5.8 (Canadian) million or about $140 per kg BOD removed. The annual operating costs of the proposed system were estimated to be $0.5 million. The volume of biogas expected from the full-scale plant was estimated to have a value of $900,000/year.

The UASB bioreactor has been installed in many countries for treating different types of wastewaters from different industries, including foods (A. Pauss, Personal Communication). In the United States, an upflow anaerobic sludge blanket bioreactor achieved COD removals of 98% in the confectionery wastewater (24).

III. FOOD WASTEWATER TREATMENT IN HONG KONG

In Hong Kong, there are 12,694 food premises, including thousands of food production companies. By law, these premises (including restaurants) are required to have a basic grease trap (to separate wastewater from oil), and for food production companies they are required to have a wastewater treatment system to treat their food wastewater such that the effluent from the production plant will meet the requirement (such as COD, BOD, oil and grease, pH and suspended solids) of the Environmental Protection Department of Hong Kong. Most of the wastewater treatment systems of the food manufacturers in Hong Kong utilized aerobic systems, including the five government wastewater treatment centers (activated sludge ponds, although the Drainage Service Department is also exploring other pilot plant scale systems, such as the rotating biological contactors).

The followings are the reports of some of the newer development of biological treatment systems in Hong Kong.

1. Wastewater treatment in CFS (A large potato chip processing plant). The treatment plant is operated with physical, chemical and biological processes and it is designed by HKPC. The daily treatment capacity is about 175 cubic meter/day which is treated to comply with the HK discharge standard. All of the daily operation wastewaters are screened first, then collected and pumped to the equalization tank for further treatment. Chemicals are used to have coagulation and flocculation for the sedimentation of suspended solids, then followed by biological treatment process for organic removal. After the processing, the wastewater with sludge are pumped to have dewatering by filter press before deposed as solid waste. The percent of COD and BOD removal efficiency are more than 95%.
2. Immobilized cell bioreactor (a major fast food central kitchen). We had set up an immobilized cell bioreactor model (Figure 145.8) in the wastewater treatment center of a central kitchen of a large fast food chain restaurant (with over 200 branches) to treat their wastewater during 1997–1998. The bioreactor is made of polyvinyl chloride (PVC) with a rectangular working space which has base area of 0.35 m × 0.36 m and a height of 0.52 m. Plastic balls with high porosity which can increase the surface area for microbial attachment were used as the media for immobilization. Chemoheterotrophs were immobilized because of their ability to derive their energy form the oxidation of organic compounds in wastewater, and their ability to resist and recover quickly from organic loading shock and acid shock was noted in our preliminary finding. During the testing period from November 25th 1997 to February 9th 1998, the percent of COD and BOD removal efficiency in the wastewater were increased from 41% and 56% to 76% and 75%, respectively.
3. A counter-current process comprising a series of three batch immobilized cell reactors (R1, R2 and R3) was developed for removing and recovering copper from food industry effluents in Hong Kong. The ability of metal uptake by bacterial biosorbent has caught great attention due to its potential to provide an effective and economic means for removing heavy metals from food industry effluents. Cells of *Micrococcus* sp. were immobilized in 2% calcium alginate and 10% polyacrylamide gel beads. Each reactor consisted of immobilized cells with concentration at 100 grams dry cell per litre of beads. Six hours of reaction time was allowed for each reactor unit. The average copper concentration of the wastewater treated

TABLE 145.2
Removal Efficiencies of COD, Oil and Grease from the Food Catering Sewage of a Local Amusement Centre in Hong Kong

	Inlet (mg/L)	Outlet (mg/L)	Removal Efficiency
COD	1,100	410	30%–70%
	1,100	680	
	1540	490	
	700	370	
	1000	440	
	1000	470	
	900	280	
	1,660	680	
Oil and grease	360	95	70%–80%
	390	102	
	460	114	
	210	62	
	290	79	
	340	96	
	260	70	
	495	128	

with immobilized cells was 5.5 ± 4.8 mg/L. The average copper concentration recovered from the immobilized cells by desorption could be as high as 449 ± 77 mg/L and was ready to be reused. The results show that the immobilized cell system is a promising technology for removal and recovery of copper ions from metal-bearing industrial wastewater.

4. There was a brand new method for oil and water separation (Radio Frequency Technology) for treating the greasy food catering sewage from a local amusement centre in Hong Kong as the conventional greasy traps are incapable of removing those oil and grease that have already been emulsified in the wastewater. Therefore, a novel method with an emulsion breaking device (Figure 145.9) was developed to tackle those emulsified oil molecules. Radiating-wave frequencies (RF) can accelerate the emulsion-breaking process and extract the oil droplets from the emulsified liquid by the vibrating resonance generated from finely adjusting the radio frequency to a specific level, thus accelerating the "demulsification." Desirable effluent without any visible sheen could be obtained after passing through the RF oil interceptor. As shown in Table 145.2, it was found that COD removal efficiency ranged from 30–70% (wt) while oil and grease contents in sewage were reduced 70–80% (wt).

PART II. Biological Wastewater Treatment: Current Thoughts

IV. PRESENT NEW APPROACHES

Conventional biological treatment technologies including anaerobic contact, anaerobic fluidized bed and upflow anaerobic sludge blanket reactors were used frequently in the past. Recently, some newly advanced technologies and some re-modeled technologies were developed.

Using microorganisms for treatment of wastewater was extensively studied in the past. Recently, an ultrasound-assisted bioprocess for wastewater treatment for the food industry was developed in Germany for enhancing the biodegradation efficiency of the microorganisms (25). More than 100% increase of the maximum biological degradation rate has been achieved and the developed bioprocess reduces the overall energy by use of low-energy irradiation below the cavitation level.

Moreover, a fixed-film bioreactor system was designed to increase the efficiency of biological treatment systems for treating oil refinery wastewater (26). The system enhanced the treatment efficiency by (1) allowing greater organic loads, (2) minimizing production of sludge waste by-products, and (3) increasing process stability and resistance to shock loading. It was constructed with a highly porous polyurethane foam which can incubate very high concentration of microorganisms. The support frame which was built from cylindrical plastic pall rings formed a packed bed of "mixed-media" and can provide a high surface area-to-volume ratio. The bioreactor with 8-h hydraulic retention time demonstrated chemical oxygen demand removal rates of 85–90% and near one-third of the sludge waste compared to the traditional activated sludge process.

Another wastewater treatment system treated the wastewater from a food processing factory by bacteria immobilized onto a new type of carrier-ceramic carrier in an aerated system (27). This carrier allowed higher concentration of bacteria to be colonized (2.9×10^9 cfu/g of dry ceramic carrier). The system removed more than 87% of the influent COD when the hydraulic retention time was 30.17 h.

A multi-media-layering (MML) system was developed for food service wastewater treatment (28). The MML system consists of two units. One unit is composed of soil mixed with sawdust plus iron scraps and the other composed of soil mixed with (kenaf plus corncob) plus iron scraps. The mixture layers are arranged in a "brick like" pattern. Aeration significantly increased the efficiency of wastewater treatment in this system. The percentage removal of suspended solid, biological oxygen demand, chemical oxygen demand, total nitrogen, NH_4-nitrogen, total phosphorus and dissolved phosphorus was 71, 90, 70, 91, 76, 90 and 89 with a loading rate of 2301 $m^{-2}day^{-1}$.

V. CURRENT THOUGHTS

In recent years there have been significant advances in the design of wastewater treatment systems having improved performance and operational dependability. In large part, this progress has been driven by the needs of industrial and municipal wastewater discharges to meet ever increasingly stringent effluent discharge regulations that have been promulgated in North America and worldwide. Such regulations include the Ontario Municipal Industrial Strategy for Abatement (MISA) regulations and various United States federal regulations such as the '40 CFR (Code of Federal Regulations) Part 503 (1993) [Sewage Sludge Regulations], National Combined Sever Overflow Regulations (1994) and the Total Maximum Daily Load (TMDL) [2000] Section 303(d) of the Clean Water Act. The TDML is designed to protect ambient water quality, and it represents the maximal amount of a pollutant that a water body can receive and meet the water quality standards.

The net result of this research has been the development of novel high rate treatment systems such as the Acticontact biofilter, membrane bioreactors (MBR) and moving bed biological reactors (MBBR) which offer advantages over conventional treatment system technologies including smaller footprint and greater resilience to microbial upsets such as filamentous bulking. Similarly, for the treatment of contaminated soils and sediments, we have also seen the emergence of many different novel engineered systems such as *in situ* and *ex situ* bioremediation. Each of these systems strives to provide suitable environmental conditions to promote microbial activities which bring about the desired end-treatment result.

With the stricter regulations and the findings of recent research (29), many of the new treatment methods are now being developed to deal with the health and environmental concerns. Filtration is now regarded as a key component in wastewater treatment systems, as filtration is especially effective in improving the effectiveness of disinfection, particularly for ultraviolet (UV) disinfection

systems, because (1) the removal of large particles of suspended solids (which may harbor bacteria) enhances the reduction in coliform bacteria, and (2) the reduction of turbidity improves the transmittance of UV light (29).

Much research has also gone into the study of microbial ecology and into the mechanisms by which microorganisms are able to biodegrade complex xenobiotic substances, with the application of the knowledge gained to the development of improved and novel systems for bioremediation of heavily contaminated sites such as the Superfund sites. There are concerns that the current analytical techniques are inadequate for detecting all environmental microbial and chemical contaminants that may significantly affect health (30). Detection methods of constituent concentrations are becoming more sensitive, and the detection limit has expanded from milligrams per liter (mg/L) to nanograms per liter (ng/L), particularly in the area of pesticides and haloaromatics such as PCBs and dioxin.

From the results of the different types of waste treatment systems studied, it is clear that biological remediation is both technologically and economically feasible for the degradation and removal of chemicals and organics from wastewater and from landfill leachates.

146 Poultry Waste Management

Fatos Germirli Babuna, Serdar Dogruel, and Derin Orhon
Environmental Engineering Department, Istanbul Technical University

CONTENTS

Poultry processing is a typical agro-industry generating a strong wastewater in terms of organics, solids and nitrogen contents and significant amount of solid waste. Crude approaches in the past have often resulted in mixing of the two waste streams and which have resulted in serious treatment and disposal problems. Nowadays, poultry processing requires, like all other agro-industries, an integrated approach in waste management. This approach enables an in-depth look at the processes involved and provides a better perspective for critical issues such as water minimization, waste reclamation and recycling and optimization of treatment and disposal.

In-plant control or source based control of wastes; wastewater and solid waste management are integral parts of a sound waste management policy for the poultry processing industry. The level of in-plant control dictates the amount of wastewaters generated and pollutant loads of the effluents. Solid waste management practices such as the dry collection of wastes on the other hand, directly affect the pollutant loads of wastewaters.

I. SOURCES OF WASTES

Although subject to changes, the general process flow scheme together with the wastes originating from each process is briefly outlined below.

Receiving Area: This is the area in which the live birds are unloaded from the crates. Dirt, feathers and droppings are among the contaminants of receiving areas. Dry removal of solid wastes with subsequent washing operations is recommended for cleaning. In order to deal with fluctuations in delivery, it is sometimes necessary to keep the birds for a period of time in the receiving area. In such cases additional feces can be generated as solid waste.

Killing and Bleeding: Birds hanged from their feet are shocked with electricity. This procedure of stunning can be conducted in either an electrically charged stunning bath or by passing the birds through charged plates. Wastewater is generated when stunning is applied in baths. Then the throats of the birds are slit and blood must be collected in a storage bath as solid waste or by-product.

Scalding: Various types of scalding operations (spray, immersion, etc.) using hot water can be applied to carcasses for the easy removal of feathers. Scalding is one of the main sources of wastewater in poultry processing industry.

Defeathering: The plucked feathers can be transported with water or removed by dry processes. When water flume is applied, a subsequent screening must be performed for the separation of feathers from wastewater. Wastewater can be recycled and feathers can be directed towards a rendering facility or disposed as solid waste.

Evisceration: After removing heads and feet, the birds are spray washed with large amounts of water to reduce microbial contamination during and after evisceration. This produces a large amount of wastewater. Solid waste is generated when viscera is pulled out and sorted as edible

and inedible offal. Offal transport can be conducted by vacuum or water fluming. Water fluming results in additional wastewater.

Chilling: When water chillers are used wastewater with significant levels of organic pollutants is generated.

Filleting, Deboning, Portioning: Filleting, deboning and portioning operations can produce solid waste or by-products.

Area Washdown: Apart from the above mentioned wastewater sources, additional generation of wastewaters due to cleaning purposes should be taken into account.

The sources of wastes in poultry processing industry are summarized in Figure 146.1. However, it should be noted that the shown figure is subjected to variations. When handled as by-products and directed towards rendering facilities, the amounts of solid wastes can be reduced considerably. Similarly, when water usage for solids transportation is avoided throughout the operating steps, wastewater generation can be limited to a significant extent. Besides by-product processing usually done by rendering itself generates and contributes to wastewater loads (1).

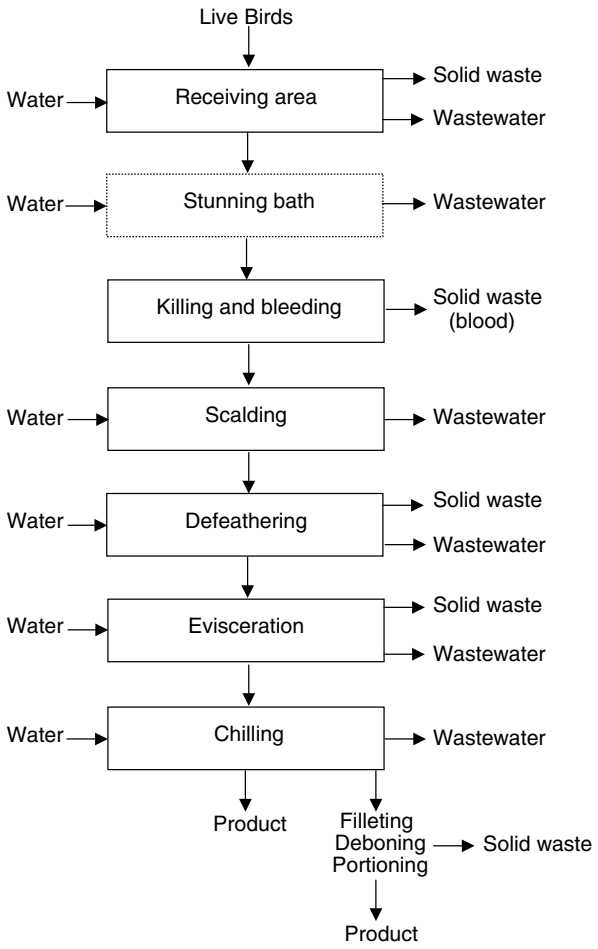

FIGURE 146.1 Sources of wastes.

II. IN-PLANT CONTROL

In-plant control alternatives applicable for poultry processing plants can be grouped under two main headings: i) water use reductions, ii) wastewater reclamation and recycle.

A. Water Use

The water usage varies in a wide range for poultry processing industry as given in Table 146.1.

It should be noted that the large plants generally use less water per bird than the smaller ones, as they are more likely to apply proper in-plant control measures. However, significant variations in water usages can be observed even in industries with same production levels. Table 146.2 tabulates the distribution of water use for a typical large poultry processing plant (1, 2). All the figures given in the table, especially the percentages can be very different for a smaller premise.

The amount of water used for a given plant is a certain value that is independent from the number of the birds processed, as almost all of the water is applied for cleaning operations or processes such as scalding. In this respect the utilization of plant capacity gains importance. The plants operating with full capacity are the most efficient ones in terms of water usage.

By-Products Rendering	5	0.9
Domestic (hand washing, etc.)	2	0.3
Total	100	17.0

Although the following recommendations for reducing the amount of water intake can be applicable to poultry processing plants with all sizes, more effective results can be obtained on large plants:

In order to identify the points where excessive water is used, all the water intakes can be monitored with water meters.
Cold water should be used for cleaning blood spillages. Hot water causes congealing of the blood, making cleaning more difficult and necessitating the use of more water than when cold water is supplied (2).
Dry transport of feathers and viscera should be preferred (1–4, 6).
Dry cleaning with shovels; scrappers or brooms should be conducted prior to washdown. Apart from reducing the water intake, the wastewater pollutant loads can also be significantly lowered with such an application (1–3, 6).
Usage of pressurized water should be applied wherever possible.
Good housekeeping and proper maintenance should be conducted. Leaks in piping should be avoided. Self-closing nozzles should be installed instead of valves to better control total water use.
Staff should be trained about water conservation techniques.

It should be noted that reducing the water intake lowers the amount of wastewater generated and concentrates the wastewater. Therefore it is suggested to check the treatability of wastewaters prior to applying such practices.

B. Wastewater Reclamation and Recycle

Wastewater recycle and reuse can be successfully conducted on poultry processing wastewaters. The important point in such applications is meeting the hygiene requirements. Stream segregation is the first step in wastewater reclamation. Depending on characterization of segregated streams, wastewaters with low pollutant contents can be reused directly or after being subjected to a proper treatment.

The following reclamation and reuse alternatives are recommended:

Streams having low contaminant loads can be reused in floor, vehicle and crate washing after being treated e.g. by membrane processes such ultrafiltration and reverse osmosis (1, 2). Feasibility of using such processes must be checked beforehand.
In plants where removed feathers are transported with water, this water can be reused in feather fluming and offal transport after passing through a screen (1, 2). In order to avoid cross contamination offal flume and feather transport water should be collected in different channels and screening of both wastewaters should be performed with separate screens (3).
Wastewater obtained from chillers can be used as make-up water for the scald tanks (3).
Wastewaters originating from chilling process can be recovered and reused again in chilling operations (3, 8). It is stated that fresh water supply in chilling can be reduced by 80% with recycling (7).
- ozonation (7)
- screening, ozonation, sand filtration, post-ozonation (7)
- screening, diatomaceous earth (DE) filtration, ozonation (7)
- UV-enhanced ozonation (8)

are the proposed treatment methods.

The feasibility of in-plant control applications must be evaluated by comparing the savings obtained on fresh water demand versus possibly elevated end of pipe wastewater treatment costs together with cost of treating reusable streams.

III. WASTEWATER MANAGEMENT

A. Wastewater Generation

Approximately 90% of the water input is converted into wastewater in poultry processing plants (1, 2). It is stated that 15.6 liters of wastewater generation per bird is observed for industries processing more than 10,000 birds/day, whereas for smaller premises a mean wastewater discharge of 19.0 liter/bird is obtained (1).

Table 146.3 outlines the amount of wastewater generated from different operations for a modern large (>10,000 birds/day) poultry abattoir where feather transport water is recycled, inedible offal is transported by use of water flume and efficient blood recovery and collection is applied (2).

B. Wastewater Characterization and Loads

As poultry processing wastewaters are contaminated with fat, viscera, blood, feathers, feces, etc., they can be characterized and distinguished from other industrial wastewaters by their high organic matter, oil and grease and solid contents. Concentrations of main pollutant parameters together

with volumetric wastewater loads for large and small size poultry processing effluents are outlined in Table 146.4. It is also stated in the literature that the oil and grease concentrations of these wastewaters can reach levels that might adversely affect the subsequent treatment steps (2, 9). Oil and grease might cause adverse effects in treatment units such as aeration tanks, settlers, etc.

Cleaning the bird manure and feathers with water results in the generation of wastewaters containing organic matter and solids in receiving areas. When the period of time for a bird to stay in the receiving area elongates, a proportional increase in wastewater pollutant loads is observed.

The killing and bleeding operation is one of the main sources of organic pollution in the poultry processing industry due to possible blood spillages. Proper blood collection and handling should be applied as part of a sound waste management strategy. In this context, it must be kept in mind that the organic matter content of the blood obtained from one bird is equal to 21,000 mg chemical oxygen demand, COD (2). The end-of-pipe wastewater strength in terms of organic matter can be elevated by 35 to 50% when blood is not collected as solid waste and mixed with other wastewaters sources (3). COD concentrations as high as 100,000 mg/l can be achieved in slaughter areas for small abattoirs with no or very poor blood collection facilities (1). The existence of some proteinaceous materials such as feathers, blood and animal tissues in poultry processing wastewaters is the main reason of getting high effluent total Kjehldal nitrogen (TKN) values (4, 10). In this respect minimizing the blood spillages might at least ease the TKN problem (4). Stunning the birds before slaughtering increases the blood recovery and reduces the organic pollutant loads as the blood spurting due to the birds' movements are minimized.

Pollutants such as blood, feathers, manure, dissolved greases, etc., are associated with the scalding tanks. The contaminants are concentrated at the bottom of the tank. Scalding tank sludges must be collected and separately disposed as solid waste. By doing so, wastewater pollutant loads can be reduced to a significant extent. As scalding tanks are usually continuously replenished with fresh water to maintain a previously set water quality, continuous wastewater is generated as overflows. Apart from this wastewater, the contents of scalding tank are discharged after every batch of operation creating intermittent wastewaters with shock pollutant loads. Wastewaters originating from scalding tanks contribute 4.0 to 15.5% of the total plant suspended solids (SS) and 0.4 to 10.9% of the total plant oil and grease (4).

Feathers that are plucked from the birds are transported either in dry form or by the use of flume in the subsequent defeathering operation. Dry transport does not generate wastewaters other than the ones produced from cleaning purposes. On the other hand when transportation with water is the preferred process, the wastewater originating from defeathering operation must be screened before being directed to drain in order to avoid clogging problems in the treatment system. The reuse of screened feather transport wastewater is recommended as mentioned in the wastewater reclamation and recycle discussion. Feathers exert high organic and TKN loads to wastewaters (4). The contact time of feathers with water is the determining factor in the TKN content of these wastewaters. Longer contact times results in elevated wastewater TKN concentrations (4). Feathers are valuable by-products as they contain protein. Therefore dry collection of feathers and processing them in rendering plants are proposed as part of a proper waste management.

After sorting the obtained viscera in the evisceration step, the offal is transported either by means of vacuum application or water fluming. Depending on the chosen offal transportation method, the amount and pollutant loads of wastewater produced from this operation vary significantly. Dry removal of evisceration wastes not only decreases the volume of wastewater generated, but also lowers the wastewater pollutant concentrations. A reduction that can be as high as 35% in organic strength has been reported in dry transportation of viscera (3). Data ranging from 14.8 liters wastewater production per bird (3), to 5 liter/bird as tabulated in Table 146.3 (2) on wastewater volumes can be found in literature. Microbial contamination is an important issue. Therefore apart from viscera flumes, plenty of fresh water is used for area and worker cleanups and bird washes. The wastewater generated from this source can be characterized with its high organic matter, suspended solids, oil and grease and bacteria (from intestinal tracts of birds) contents. Evisceration processes contribute at least

1/3 of the total wastewater load in terms of the mentioned pollutant parameters (4). It is recommended to use water spray for all sorts of bird washing processes, in order to minimize water use and wastewater generation.

Water chilling operations are the other source of wastewaters. The overflows of water giblet chillers contain significant levels of organic pollutants. However wastewaters originating from chilling processes have a great potential for reuse after being subjected to a proper pretreatment. More information about pretreatment alternatives applicable to chilling wastewaters can be found under the wastewater reclamation and recycle heading.

It was mentioned earlier that especially a significant amount of the solid wastes generated in poultry processing plants such as feathers, blood, offal, etc., can be handled as valuable by-products when they are directed towards rendering facilities. By-product processing can either take place on site or in a separate rendering plant. In this context the best waste management plan to follow for poultry processing plants without rendering facilities, is collecting all recoverable materials and sending them to rendering plants. In order to minimize the organic loads of effluents, it is recommended not to overcharge the cookers of the rendering plants. Otherwise cooker overflow wastewaters with very high COD concentrations (25,000 mg/l) can be obtained (2).

For large poultry plants processing more than 10,000 birds/day, COD and SS loads of 29 g/bird and 7 g/bird, respectively are given in the literature (1). 64,000 mgCOD/ bird and 14,000 mgSS/bird pollutant loads are reported for smaller premises (1). COD loads originating from different wastewater sources are tabulated in Table 146.5 (2). The figures are obtained from a modern large (>10,000 birds/day) poultry processing industry where blood is recovered and collected efficiently, inedible offal and feathers are transported with water and screened feather transport water is reused (2).

It should be kept in mind that different organic loads can be obtained for abattoirs in which feather and inedible offal transport is performed with dry methods. In such cases the COD load originating from washdown processes may constitute 60% of the total organic load (2). On the other hand, concentrations of organic matter differ in a wide range for segregated wastewater streams obtained from different sources. Values as high as 4000 mg/l of COD is reported in literature for giblet chiller effluents, whereas 250 mg/l of COD concentration is given for whole bird washing operations (7).

C. Treatment Alternatives

Two different approaches can be followed in dealing with the treatment of wastewaters originating from poultry processing industry. The first one involves collecting all wastewater sources in an equalization basin and subsequently treating them by the use of a previously determined treatment scheme. However, it is a well known fact that some wastewater sources contain high concentrations of certain contaminants in this industrial activity. Therefore, it is advantageous to handle wastewater streams separately and apply specific treatment alternatives defined for each of them. By doing so, pollutant loads discharged to end-of-pipe treatment facilities can be reduced, recovery of by-products together with water recovery and reuse applications ease (2, 6). This second approach covering stream segregation concept is of importance especially for new industrial installations.

The following treatment units can be adopted for wastewaters generated from poultry processing industry.

Primary Treatment: Primary treatment may consist of a screen and a primary sedimentation tank to reduce solids loads, an oil and grease removal facility such as dissolved air flotation (DAF) and an equalization unit to minimize the fluctuations in wastewater quality and quantity.

Secondary Treatment: The target of secondary treatment is the degradation of organic matter. The wastewaters respond well to biological processes such as

activated sludge
- conventional activated sludge
- step aeration activated sludge
- high-rate activated sludge
- extended aeration activated sludge
- contact stabilization
- sequencing batch reactors

trickling filter
- high rate trickling filter
- standard rate trickling filter

lagoons
- anaerobic lagoon
- aerobic lagoon
- anaerobic lagoon followed by an aerobic lagoon

biodisks (9, 11–13).

Current understanding of biological treatability covers biodegradability oriented fractionation of the COD parameter. Total COD consists of biodegradable and inert components; both subdivide into further fractions. The total

inert COD consists of soluble inert COD and particulate inert COD both by-passing the biological treatment without being affected from biochemical reactions. Apart from the soluble inert content of wastewater, the level of inert metabolic products generated within the biological treatment processes gain importance in meeting the effluent discharge limitations (14). Such a fractionation was performed on a small poultry processing industry located in a remote area where the wastewater only originated from scalding operations and cleaning processes. The results of this study can be used for better understanding of the nature of COD generated from this industry. According to the mentioned research, the total COD of the poultry processing effluent is around 90% biodegradable, with a practically negligible particulate inert and significant soluble inert portion; the latter together with soluble residual microbial products generation, is likely to impart a residual effluent COD concentration after passing through a biological treatment, not less than 12% of the influent total COD (10).

Tertiary Treatment: When the applied primary and secondary treatment is inadequate in achieving the required treated effluent quality; an additional advanced treatment step can be used.

On the other hand as the major part of poultry processing wastewaters generated from certain processes, such as killing and bleeding and defeathering, is proteinaceous in nature, the recovery of these dissolved and colloidal proteins is an important issue (1, 2). The recovered solids can be rendered and used as animal feed. The following protein recovery methods are the most used ones:

- application of cellulose based ion exchange resins (1)
- use of ultrafiltration (1)
- recovery of protein from generated activated sludge biomass (1)
- precipitation of protein by the use of coagulants before air flotation unit (2). Ferric chloride ($FeCl_3$), sodium hexametaphosphate or lignosulphonate are stated as the most effective coagulants (1, 2). A pH of approximately 4 must be adjusted prior to sodium hexametaphosphate applications (2).

IV. SOLID WASTE MANAGEMENT

The amount of solid wastes generated in poultry processing plants varies in the range of 0.2 to 0.4 kg/bird (2). Feathers, inedible offal, blood, feces and carcasses classified as unsuitable for human consumption are the main contributors of solid wastes for this industrial activity. Table 146.6 outlines the mass distribution of each solid waste source for a typical plant (2).

In small premises without a rendering facility, the majority of the solid wastes can be sold to a rendering plant and the rest must be directed to a solid waste disposal site. Another alternative is to transport all the generated solid wastes for waste disposal. Waste handling practices such as landfills and composting can be applied to solid wastes generated from poultry industries. Solid wastes can also be anaerobically digested (15–17). Poultry processing wastes can be applied as fertilizers in certain agricultural activities after being digested in an anaerobic unit (15). It is reported that compost produced from dissolved air flotation skimming of poultry processing plants can successfully be used in corn production fields (18). Feather composting is an applicable solid waste handling method (19). Feathers are almost made up of pure keratin that is not easily degradable by common enzymes (20, 21). Therefore although biodegradation of feathers can be achieved with native microbial populations, it is possible to accelerate this process by using isolated, target oriented cultures (19–24).

TABLE 146.6
Distribution of Solid Wastes

Source	Kg/Bird	%
Feathers	0.030	10.5
Inedible Offal	0.150	52.6
Blood	0.030	10.5
Unsuitable Carcasses	0.015	5.3
Others	0.060	21.1
Total	0.285	100

When solid wastes are subjected to a rendering process, they are converted to by-products. Protein recovered from wastewaters can be added to by-products to enrich the protein content (2). By doing so, the nitrogen content of the wastewater can be decreased to a level that does not require treatment specific to this pollutant parameter.

In order to improve the solid waste management in a poultry processing plant it is recommended to follow the items below:

Dry collection of solid wastes must be preferred whenever possible. A washing can be carried out subsequently. Such an application eases the solids by-product recovery and reduces wastewater pollutant loads.

Blood must be collected in a properly designed place for minimizing the spillages. This in turn eases the cleaning procedure in the bleeding area, and excess blood contamination of wastewater can be avoided. It must be noted that blood constitutes 6–8% of the bird's mass (2).

147 Waste Management in Meat Plant

Deng-Cheng Liu
Department of Animal Science, National Chung-Hsing University

CONTENTS

I. INTRODUCTION

In the meat industry, plant operators always hope to utilize all they can get from the livestock, but some non-meat wastes still exist and these are called co-products. Co-products can include blood and renderable offal tissues such as viscera, bone, fat trimmings and fine debris; and these materials play a dual role as both assets and liabilities in the meat industry. Thus, how to efficiently recover co-products or how to minimize the waste in a meat plant is an important work and the performances of these actions can create a huge income or minimize disposal cost in a meat plant.

Some unavoidable meat plant waste was being dropped into the bay near-shore or the river, and it was drifted out with the tide, causing unpleasant odors.

TABLE 147.1
The Yield of Wastewater from Different Slaughtering Methods (Skinned and Scalded) for Pork in Meat Plant

	Skinned Method		Scalded Method

Source: Adapted from Ref. 4.

Today, with environmental concerns, energy costs and increased volume have together made co-products handling major economic and management problems in the meat industry. Additionally, in many countries' regulations, the air and water effluents from meat plants must be as clean as or cleaner than the water and air entering the plant. It is estimated that there is a total return of 15.07% from co-products out of the total value of product sales in a beef cattle slaughter plant, with inedible offal return of 8.44% and the rendered products return of 1.73% (1).

Many non-meat products with origin from the meat industry enhance modern living. Hence, the use of processing techniques to transform the waste into valuable products that can be used for food, feed or fertilizer in the living environment, or create new products or increase incomes for the meat industry are still an important target in a meat plant. Hansen in 1983 estimated that at least an additional 181 thousand tons of protein would be recovered from meat industry wastes each year in the United States and the worth perhaps exceeded 400 million dollars (2).

II. PRODUCTION

Meat-processing waste consists of solid and liquid portions. Solids include manure, paunch manure, and large amounts of animal tissue. The liquid portion includes blood and other body fluids. In actual practice, most of the solids such as small animal tissue and paunch manure will be mixed with a greater amount of water used for carcass cleaning or rinsing of the equipment, and some blood, and they are discharged into the sewer. Therefore, the best functional filter system should be utilized to separate meat waste into solid and liquid fractions. The solid waste is generally transported to the rendering plant for feed or fertilizer manufacturing; and the liquid waste was sent to the wastewater treatment system.

TABLE 147.2
Percentage and Amount of Inedible Co-Products and Waste Based on Live Weight from Various Livestock Species

	Cattle	**Pigs**	**Sheep**
Inedible raw material %	5–17	6–15	6–22

Unaccounted items (stomach content, ahrink, etc.) kg	64	5	12

Source: Refs. 5, 6, 7, 8, 9.

The waste in the meat plant usually comes from slaughtering procedures. A traditional slaughtering method yields approximately one ton wastewater per pig, but only yields 40–50% of this amount in a modern system due to new policy or equipment used (Table 147.1). For example, an automatic spray system can be used for washing carcasses. In red meat plants such as beef, lamb and pork, solid waste includes almost all the inedible co-products and the productions were estimated (Table 147.2). According to a report published by American Meat Institute in 1995, it was reported that total numbers of cattle, sheep and pigs for slaughter in 1994 were 33.4, 5.7 and 85.4 million heads, respectively. Total inedible co-products (inedible tallow and grease, other inedible

products) production was approximately 3,732 thousand tons in the United States in 1994 (3).

III. COLLECTION AND ATTRIBUTES

Generally, meat slaughter and processing plants with rendering facilities must have two separate rendering units. The two units must be separated physically to prevent any inter-transfer of raw materials, products or contamination from inedible rendering area to the edible rendering area. Equipment used to handle, contain or process inedible co-products must be clearly marked "Inedible," and any edible product that comes in contact with any so-marked pan, truck or conveyors immediately is designated as being inedible. The use of the various inedible meat co-products has a profound effect upon the speed at which they must be handled and processed. Inedible co-products from animals as a whole present a heterogeneous collection of tissues, some of which may be subjected to various processing treatments in normal commercial practice. Therefore, each inedible co-product can be expected to exhibit different ways of collection. In addition, undesirable odor, flavor, texture and appearance can be quickly produced in inedible raw materials when these raw co-products are stored under unsuitable temperature treatments and as a result of microbial spoilage. It is usually considered that a temperature of 10°C is adequate to control pathogen proliferation during the collection and processing of inedible raw co-products.

A. BLOOD

Blood contains about 17 percent protein and may be used for meat food products. Thus, blood should be collected because it has high nitrogen content and can be utilized for human consumption. Every effort should be made towards this end, not only because of its enhanced value but also because of effluent problem; thereby reducing the BOD for wastewater with non-blood recovery to about 4480 mg/L (Table 147.3), and for whole blood it is about 200,000 mg/L (10). Small amounts of blood specially collected on the kill floor can also be turned into edible products like black pudding and protein supplements. A closed collection system should be established which requires approval by USDA-FSIS and allows for the disposal of blood from animals whose carcasses are condemned during post-mortem inspection (11). The bacterial quality of edible blood should be less than 2,000 total plate count organisms per milliliter. The blood used in livestock feed, fertilizer or industrial use is collected by an open method and supplied in the form of blood meal and the bacterial quality should be less than 2.5×10^5 organisms per ml of blood (12). It often contains flush water, has a high water content (as much as 85%) and low dry solids value, and is often haemolysed. Therefore, after collection all blood material should be refrigerated at 2°C to minimize bacterial count and maintain good hygiene.

The blood collection tank with refrigerator is shown as Figure 147.1.

B. ORGANS

It is generally considered that organs are necessarily of poor microbiological quality, with large bacterial loads and a high incidence of contamination with spoilage or pathogenic organisms. A putrid odor and flavor can be produced rapidly when these materials are exposed to improper treatment such as on the kill floor, or stored at a higher temperature (13). Thus, better control of organs handling are clearly necessary, but handling criteria which would be both commercially practicable and generally applicable are difficult to define because circumstances vary so greatly between individual plants. However, the end quality of organs is greatly affected by the manner in which the raw materials are collected, handled and held prior to further processing. The viscera collection is showed as Figure 147.2.

C. DEBONED RESIDUES

The bone yield of beef carcasses, pork carcasses and lamb carcasses is 15, 11 and 16%, respectively (14, 15). In recent years, labor has become more expensive, and as the red meat industry has attempted to salvage more of the adhering meat left on bones, new separating machines have been used. The amount of bone residues depends on the amount of separated red meat recovered from the bone materials. In general, with a requirement of good quality on separated red

FIGURE 147.2 The viscera were collected in an inedible co-product cart.

FIGURE 147.3 Deboning by hand and collecting bone residues in a cart for rendering.

meat, a larger amount of bone residue is obtained. The bone residue yield was from 21 to 80% by species, bone parts and machine types (16, 17, 18). The bone residues are used for meat and bone meals by rendering processes. An example of bone residues collection is showed in Figure 147.3.

FIGURE 147.4 The hog skins were collected by a peeling system and used for leather making.

FIGURE 147.5 The scalded and dehaired pigskin was collected in a cart for rendering.

D. Skin and Hair

Animal hide is about 4–11% of the weight of the live animal, and one of the most valuable co-products produced by that animal. Hides from cattle sheep and goats are obtained by the hide pulling technique, then preservation, fleshing, trimming, selection, grading, storage and shipping. Average weight of pigskin from a market weight hog is about 4.5 kg. Scalded and dehairing skins are usually obtained in most pork meat plants due to the usage of scalding and dehairing procedures. This heating causes the protein in skin to denature and results in 50% of the pigskins being unsuitable for upper shoe leather. Hogs also can be skinned with a peeling system (Figure 147.4) that pushes the skin and carcass apart and these skins are useful for leather production because it has received no heat treatment. The scalded and dehaired pigskin collection is showed as Figure 147.5.

Hair, a co-product of the slaughtering industry, may be used for making brushes or for fertilizer. Practically, hair is generally collected in a pork plant by the wet method that means hair was mixed with a large amount of

FIGURE 147.6 The pork fat tissues were collected in a carriage for rendering.

water and the wet yield will enlarge by 2.5–3.5%. Most hog hair is not suitable for brush making and is manufactured with other inedible co-products in the rendering plant and sold as meal products.

E. Fat Tissues

Fat tissues are co-products of the meat plant and come from two major sources, one from the preparation of meat for sale, and the other from the manufacture of processed meat products. Lard and tallow are the two major animal fat tissues. Lard is obtained from hog, while tallow is obtained mainly from cattle and sheep. Generally, lard production is limited to certain cut fat from pork. Examples of cutting fats are backfat, belly fat, ham fat, ham trimming fat, fat removed from loin, neck and shoulder and miscellaneous trimming fats (19).

The lard production per hog is approximate 10.1 lbs and total lard production in 1992 was 860 million pounds in the United States (20). The total tallow production in 1990 was 14,727 million pounds in USA; and a total of 4724 million pounds is inedible for factory use, soap and feed (21). The fat tissue collection is shown in Figure 147.6.

IV. SOLID WASTE TREATMENT AND MANAGEMENT

The largest amount of solid wastes comes from inedible co-products and a small amount is animal manure and tankage that comes from wastewater treatment in meat packing house. Most of the inedible co-products will be transported to the rendering plant or unit near the meat plant in a short time to obtain various co-products meals for animal feed or fertilizer in the field.

Rendering is an extraction technique that usually involves the heating or cooking of the raw material to liquefy the fat, and to break down membranes or other structures that may hold the fat. Rendering serves two purposes: (1) to separate fat and protein, and (2) to cook the animal tissue and kill the microorganisms.

Based on sanitary and safety reasons, premises should be situated so that the raw materials can be conveyed to them with minimum handling. They should be spacious, well lit and ventilated, with impervious walls and floors. Floors should be sloped to open channels leading through fat traps to the drains. Abundant amounts of steam, and hot and cold water should be supplied. In addition, a rendering plant for inedible co-products is best located outside the slaughterhouse. The secret in the production of high quality animal co-products lies in prompt treatment of the raw material. Animal wastes decompose quickly and depreciating markedly as a result; it should therefore be an axiom in slaughterhouse control that no raw material left untreated after a day's slaughtering.

A. Rendering Methods

Toady, there are four major methods of processing inedible co-products: wet rendering, dry rendering (batch), continuous dry rendering and continuous low temperature rendering.

1. Wet Rendering Method

The wet rendering method requires a batch pressure cooker (autoclave) in which pre-ground raw material is injected with live steam to a temperature of 140°C under pressure for 3–4 hours. After this time, the pressure is slowly released and the fat runs out into a receiver and is further purified by centrifugation to settle out the water. The proteinaceous solids or graves are emptied from the cooker and the fat removed by pressure and solvent extraction. They are then ground and dried.

2. Dry Rendering Method

This process involves the use of heat in the form of steam and water over a period of 1.5–2 hours at atmospheric pressure to drive off water indirectly from the fat in the cooker (22). The rest of the processes are the same as for the wet rendering process.

3. Continuous Dry Rendering Method

The continuous dry rendering system is similar to a batch dry rendering process. The big difference is that the flow of raw material into and out of the cooker is continuous. The cooker is usually horizontal, steam jacketed and equipped with a hollowed, steam-heated agitator. The duration of the cooking period depends on cooker volume, heat transfer capability and characteristics of the raw material. A screw press conveys and handles the raw material continuously. Remaining solids are pressed to remove

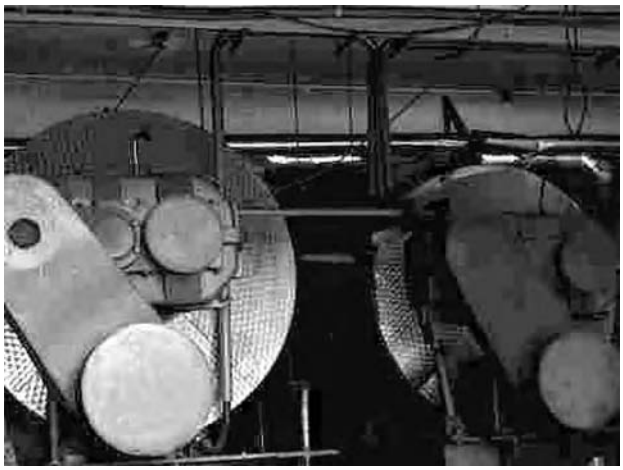

FIGURE 147.7 A dry rendering system usually used in a rendering unit in a meat plant.

FIGURE 147.8 Final rendered end products of meat and bone meal.

residual fat. Rendering processes of livestock by-products are shown in Figures 147.7, 147.8 and 147.9.

4. Continuous Low Temperature Rendering Method

This system is similar to the old wet batch processing but a significant difference is that the bulk of water is removed by mechanical methods made possible by the difference in density between fat, water and solids. The process involves mincing of the raw material, melting by live stem injection at 60–90°C, continuous separation of solids from the liquid fat in a decanter centrifuge, further heating, and centrifugation to remove the fines; and the tallow is used for manufacturing the final products. The solids (which contain about 40% water of the original material) are sent to a cooker/drier that is similar to the unit used in continuous dry rendering. The moisture of solid material is driven off by heat. High quality tallow will be produced in this system because of the relatively low temperature used in the processing.

FIGURE 147.9 A final rendered meat bone meal with package.

B. Use of Rendered Co-Products

1. Inedible Fats

A major use of inedible tallow and oil of animal origin is high-energy additive to livestock and poultry feed. Romans et al. in 1985 stated that inedible animal fat added to animal feed reduces the dust, improves color and palatability, and increases pelleting efficiency (9). An approved antioxidant needs to be added to prevent rancidity when the fat is kept in a storage tank.

Fatty acids and glycerol are obtained from animal inedible fats by a splitting technique that can be finished with the usage of high temperature, pressure and steam. Lard oil and neat's-foot oil are made from White A grease and White B grease, respectively, and can be used for delicate running machines, giving viscosity to mineral oil, and special leather oils, and making candles.

At present, the greatest utilization of inedible fats is still in soap making. Moreover, with environmental concerns, soap is biodegradable and has an advantage over the phosphate-based detergent for the water resources protection in lakes and streams. Additionally, new fat-based cleaning products with detergent-like traits have been developed and are helpful to get a large share of future cleaner markets.

2. Meat Meal, Meat and Bone Meal

Meat meal is used as a source of high quality protein, energy, B vitamins and minerals in animal feed. The bone content of meat meal supplies calcium and phosphorus, thus helps in providing necessary minerals to the animal's diet. It also supplies important B vitamins such as thiamin.

Some special bone meal is fed to poultry for bone growth and provides necessary calcium for eggshells, or

fed to those pregnant or lactating birds requiring higher level of minerals in the diet.

3. Blood Meal

Ockerman and Hansen in 2000 stated that dried whole blood (5–8% moisture) which has been steam-coagulated, dried and coarsely ground is called blood meal (23). If it has been finely ground, it is called blood flour. This product is about 75–83% protein, 1.2–1.6% fat and 3.8–5.6% ash. Blood meal is used in calf starter ration, swine and poultry feeds. It is less digestive than meat meal.

4. The Risk of Rendered Products

The production of end products from these wastes, e.g. bone meal, meat and bone meal, blood meal, poultry co-products meal, feather meal and the use of these for animal feed purposes may cause problem unless safe methods of treatment are employed. One of the problems in processing co-products used for feed is recontamination of the rendered product by incoming unprocessed material. The contaminated rendered product is then fed to animals. This is a special problem with *Salmonella* organisms in poultry feed. Another serious problem is a disease occurring in cattle in recent years (since 1985–86) and its common name is "mad cow disease" or bovine spongiform encephalopathy (BSE) (24).

BSE is defined as one of a group of neurodegenerative diseases categorized as transmissible spongiform encephalopathies (TSEs). The cause of BSE stems from unique self-replicating proteins called "prions" which unlike other infectious agents, contain no genetic material (25). They can survive high sterilization temperatures and remain in infected meat following cooking. The most common form of TSE is called scrapie and has been observed in goats and sheep. It was suspected that meat and bone meal made by rendering scrapie-infected sheep to be used in protein feed supplements for cattle could have been the cause of BSE. BSE was first identified in the United Kingdom in 1985.

V. WASTEWATER MANAGEMENT AND TREATMENT

Meat processing wastewater contains high concentrations of proteinaceous substance (15 kg/m^3) and fat (20 kg/m^3) (26). Therefore, parallel with the development and modification of resource-saving methods for the local purification, problems of cutting down raw material loss with wastewater, reducing specific volumes of unusable waste, exhaust gases and noxious substance escaped are put in the forefront. Fortunately, the technological progress for the management in meat plant can solve these problems. Water expenditures, raw material losses, the composition of wastewater and their loads can be determined for all operations in the meat production performed with water use. The composition of wastewater should also take into account not only their primary parameters [suspended substance (SS), chemical oxygen demand (COD), biochemical oxygen demand (BOD) and fat] to be controlled, but also the specificity of such water. The wastewater source and characteristics of meat plant are summarized in Table 147.4. In general, if BOD, SS and TKN are high in wastewater from a meat-processing plant, other parameters are generally relatively high also (27). BOD is proportional to water usage; as water usage increases, the BOD level in the wastewater from the plant also increases. Thus, paying greater attention to dry cleanup, and recovery of blood, meat scraps and paunch material in a meat plant will have lower sewer and water use bill.

TABLE 147.4
The Wastewater Load Characteristics Per Cubic Meter in Meat Plant

Items	SS kg/m^3	BOD kg/m^3	COD kg/m^3	TKN kg/m^3	NH_3 kg/m^3
Process water	1.20	3.00	4.50	0.35	—
Lairage	11.98	5.13	13.31	1.53	0.80
Total	13.18	8.13	17.81	1.88	0.80

Source: Adapted from Ref. 28.

A better wastewater treatment scheme for a meat plant should be designed based on the following requirements: (a) segregate blood from the wastewater system; (b) isolate solids from wastewater, wherever possible; (c) put flow equalization ahead of the biological treatment in the flow pattern; and (d) remove fat and grease before the biological treatment. The process flow schematic is shown in Figure 147.10 and briefly described below.

A. Preliminary Treatment

1. Sedimentation or Screening

The wastewater from slaughtering pigs has high solid and pig hair loadings comprised of approximately 1/3 of the total solids loading from the primary screening. A 0.5 mm wedge wire rotary screen is suggested in processing wastewater of meat works. A simple sedimentation can be performed to remove solids by gravity (Figure 147.11).

2. Equalization

An equalization tank with adequate mixing and aeration contents is designed to provide adequate blending capacity. It should handle variable volume with high loads associated with slaughtering period (7–8 hours/day), maintain constant and continuous effluent flow into biological treatment unit over 24 hour and maintain enough equalization tank volume (30% of total balancing).

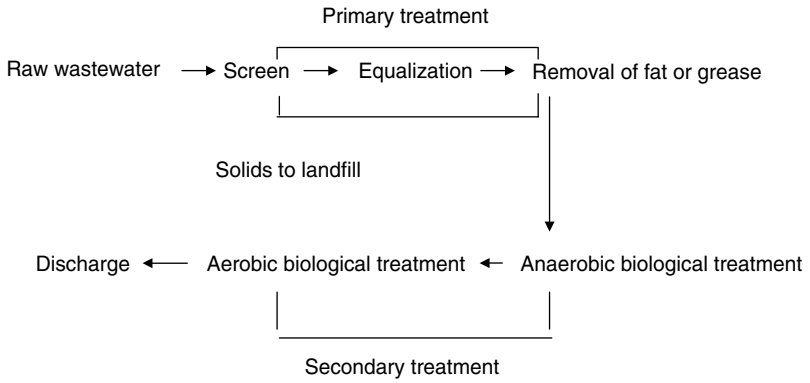

FIGURE 147.10 The schematic of wastewater processing in meat plant.

FIGURE 147.11 A simple and sedimentation and screening for meat plant wastewater.

3. Fat and Grease Removal

Fat and grease removal is done by centrifuges or dissolved by air flotation. Air flotation is a process in which air is dissolved in wastewater under pressure. The wastewater then is moved to a quiescent stage, and air bubbles come out of solution carrying solid with them as they rise to the surface. Air flotation has the advantages in that skimmings can be utilized as inedible grease.

B. Secondary Treatment

This step actually is a combination of anaerobic and aerobic biological treatments.

1. Anaerobic Biological Treatment

Anaerobic biological treatment is the most cost effective, efficient and popular unit process for meat industry and also is able to economically and effectively remove large quantities of organic matter by converting it into biogas, which contains 60–80% methane and 20–40% carbon dioxide. Methane is the major component of natural gas and can be burned to provide heat energy. This treatment can remove up to 82% of the applied BOD when operating properly. Therefore, it is an important part of the treatment process for wastewater containing a high concentration of

FIGURE 147.12 An activated sludge process in a meat plant wastewater system.

organic materials (29). The plug-flow digester or the fixed-firm and slide-blanket digester can be used to replace traditional anaerobic lagoon for economical reasons such as much shorter retention time, reduced area and less maintenance in this treatment (30, 31). The microbial flora balance is very important to keep this treatment stable and effectively operating; therefore, the wastewater should be at pH above 6.8 and temperature maintained around 35°C.

2. Aerobic Biological Treatment

This treatment is excellent in removing odor but needs artificial aeration (mechanically aerated lagoon) and its cost of electricity should be considered. The activated sludge includes aerobic microorganisms and few organic matters from the wastewater in an aerobic treatment (Figure 147.12) and needs to be recycled, meaning these microorganisms are removed by settling and fed back into the incoming wastewater. In this treatment, organic matter in meat plant wastewater is biologically converted primarily into carbon dioxide, water and more microorganisms. Different systems such as a trickling filter, rotary distribution

arms or rotating biological contactor usually are used to reach a high rate of mechanical aeration.

The wastewater is passed through the above primary and secondary treatments, and the solids are clarified by gravity. The final water usually is sufficiently low in BOD for approved discharge into rivers. Many municipalities further require that such water be lightly chlorinated to ensure its freedom from pathogens.

VI. DIMINUTION OF POLLUTION AND FLOW VOLUMES

With increasingly strict standards and restrictions being enforced on how waste can be disposed of, most meat processing plants are looking toward the challenge of improving their waste management practices, keeping cost to a minimum. There are alternatives to conventional processing operations that can significantly lower volumes of wastewater currently being discharged from meat plants. Re-use and recycling of water for less demanding operations within the plant have already been mentioned. Tighter antipollution laws are forcing a variety of innovative processing changes.

Good housekeeping and common sense are necessary for minimization of pollution and flow volumes in a meat plant. Good housekeeping is to avoid disposal of scraps or blood into floor drains and best utilize co-products in high quality products if possible. Two concepts of pollution and wastewater reduction are good housekeeping and water savings. Careful handling of waste and energy resource should be taught to employees and emphasized on a regular basis. A policy or program is composed and a team is needed to perform in the plant to reach the target of pollution and flow volumes reduction. At first, the performing team should consist of engineers, plant manager, maintenance staff and workers in the process. The second step of the program is to identify point of water use, gross spillage and collection of blood or scraps on the floor, etc. The third stage is to get information for decision making as economically and quickly as possible and avoid a large-scale change or measurement program. The last step of the program is to generate a list of possible solutions for each problem in the plant such as broom and shovel pickup, installation of catch troughs, installation of an automatic shutoff and curbing an area to divert water. Finally, the team needs to estimate the improving efficiency by these changes or install new equipment. Berthouex et al. in 1977 stated that increase of nozzles and change of location of shower on the top of the carcass can reduce the volume of water required to clean carcasses. Annual cost due to carcass shower reduction can be saved up to US $3,045 (32).

VII. CONCLUSION

At present, there has been increasing concerns on environmental pollution or large use of water leading to global water shortage and weather alteration in the next quarter century if this vital resource is not conserved and intelligently managed. Hence, how to save water and reduce wastewater flow volume or pollution is still an important responsibility for the managers of food plants. In a meat plant, significant amounts of blood and scrap are lost to the sewer. In addition, usage of more water and energy than needed to finish the given task also usually exists in the processes in meat plants. In consequence, good housekeeping practices and saving in water usage should be taught to all members of the plant. Recovery and upgrading of co-products also need to be developed as tactics to reduce pollution and increase profit.

Food Science and Technology

HANDBOOK OF FOOD SCIENCE, TECHNOLOGY, AND ENGINEERING

Volume 3

The **Handbook of Food Science, Technology, and Engineering, Four Volume Set** is a single source guide to the latest advances available in food science, technology, and engineering. It presents this information in a thorough, straightforward manner and contains contributions provided by international experts from industry, government, and academia.

Volume Three, Food Engineering and Food Processing is divided into nine parts to facilitate comprehension and accessibility. *Food Processing* discusses units of operation, while the following part, *Food Drying* presents topics that consider dehydrated vegetables, drying tropical fruits, drying pears, and freeze drying. *Thermal Processing* reviews principles and applications and explains heat transfer, temperature time, thermal processing of foods modeling, and the engineering aspects of deep-fat frying. *Freezing* reviews principles and covers the microwave and frozen foods, components, the quality and shelf life of meat, frozen storage, and frozen dough. *New Technology* details issues such as minimal processing food, MAP, ohmic and inductive heating, ultra sound and ultra light, irradiation, and nanotechnology. *Packaging* presents the new technologies that are available as well as discussions on plastics, paper, frozen foods, thermal processing, and edible films and coatings. *Ingredient Technology* focuses on five major concepts and products: spices, sweet flavors, emulsion, gums, and pectin. *Modeling* features Kinetics, experimental design, and model building. Finally, *Waste Management* describes water, poultry, and meat waste.

Each volume in the *Handbook of Food Science, Technology, and Engineering* series contains approximately 1000 pages of scientific and technical data, making it an authoritative reference that is unique in its depth and breadth of scope.

CONTENTS

Baking is a millennia–old process, and bakery products range in complexity from the simple ingredients of a plain pastry, to the numerous components of a cake. The term baking applies not only to the production of bread, but to all food products in which flour is the basic material, and to which heat is applied directly by radiation from the walls and/or top and bottom of an oven or heating appliance. More particularly, baking includes the production of items such as bread, cake, pastry, biscuits, crackers, cookies, and pies, where flour is the essential and principle ingredient for the base product; baking also includes the toppings, frostings, fillings, and so on that finish the baked product. Despite the fact that many differences in bakery products exist, both important issues of baking technology—baking materials/ingredients and techniques for combining and baking them, will be introduced in this chapter.

I. MATERIALS OF BAKING

A. Ingredients from Wheat

Wheat is one of the world's most important grains, with annual world production of 540~580 million tons. Wheat is the most valuable of all food grains and is widely used in all its stages, from whole to finely milled and sifted. In the bakery, wheat flour is the most important ingredient, which provides bulk and structure to most bakery products, including breads, cakes, cookies, and pastries. Wheat is unique among the cereals, in that its flour possesses the ability to form dough when mixed with water (1). The gluten in wheat dough has the ability to retain the gas produced during fermentation or by chemical leavening, and thus produce a leavened product (2). These characteristics of wheat flour dough or batters are responsible for the preference of bakery products with a light and soft texture.

All wheats belong to the genus *Triticum* of the *Gramineae* family, the 'grass' family. Common wheat (*Triticum aestivum*) and durum wheat (*T. durum*) are the two major wheat groups planted for food use now. For commercial purposes, common wheat is generally classified as hard or soft, red or white, spring or winter. Of these, hard and soft wheat flours are used in the baked goods that make up so many bakery products. Table 148.1 lists the top five wheat exporters in the world trade with the wheat classes produced in these areas. Hard wheat normally has high protein content and its flour is used primarily for yeast-leavened products, such as breads, bagels, croissants, English muffins, Danish sweet rolls, cinnamon rolls and bread type donuts (5). Soft wheat normally has low protein content and its flour is most suitable for making biscuits, muffins,

TABLE 148.1
Top Five Major Countries of Wheat Export (Marketing Year 2001–2002)[a] and Wheat Exports by Class[b]

Top Exporter	1000s Tons	Wheat Exports by Class
1. U.S.	26,139	Hard red spring (HRS)—21%
		Hard red winter (HRW)—44%
		Soft red winter (SRW)—17%
		White (Hard and Soft)—15%
		Durum—3%
2. Canada	16,758	Canada Western Red Spring (CWRS)
		Canada Western Amber Durum (CWAD)
		Canada Western Extra Strong (CWES)

pastries and cakes (6). The protein content of soft wheat flours ranges from 8% to 10%. The lower protein level produces a cell structure that provides good mouthfeel and a less chewy texture in chemically leavened baked goods.

Numerous bakery products are produced by using specific characteristics of flour that depend on the variety of wheat from which it is milled, the location in which the wheat is grown, and growing conditions. Both the quantity and the strength of the protein in the flour are important indicators of the flour's suitability for various baking applications. The "strength" of flour is generally defined as the capacity of the flour to make a tough, elastic dough, and a low-density loaf of bread has fine, uniform crumb structure (5). Flour contains two proteins of importance to yeast-leavened doughs—glutenin and gliadin. When these are mixed with water, gluten forms and contributes to the dough strength. This creates an elastic, extensible matrix; high-quality gluten entraps large amounts of the carbon dioxide produced by yeast fermentation. Strength of flour is dependent primarily, but not entirely, on the amount and type of protein present in the flour. Therefore, the high protein content of bread flours does not guarantee high-quality bread flour. Additionally, greater water absorption in bread flour results in better dough yield.

1. Wheat Flour Milling

The production of flour from wheat is derived from an ancient process used throughout the Middle Ages, that first separates the husks from the kernels by making use of the wind, which removes the lower density husk ("chaff"), followed by grinding of the kernels between two stone surfaces (7). Since those days, the milling process has developed considerably to enable it to cope with the demands of large industries, many of which require specialized flours. These needs are met by a sophisticated milling process from which various types of flours and by-products are obtained by the use of different types of rollers, sieves, and air classification systems. The separation of wheat components in the milling process relies on the knowledge of the distribution of the various components within the wheat kernel and their physical properties, including their size and shape. In order to produce flours that meet the requirements of the various applications, flour properties need to be correlated with the requirements of each of the end products. With progress of cereal chemistry, millers can benefit more and more from carefully choosing the proper recommended wheat, accompanied by an adequate milling operation.

The wheat kernel consists of three main parts: bran, germ and endosperm. Depending on its source, the wheat endosperm contains about 63 to 73% starch, and 7 to 20% protein (8–10). Flour milling is a complex process by which the interior endosperm of the wheat kernel (flour) is separated from the exterior shell (bran and shorts). In preparation for milling, the grain is thoroughly cleaned, then put through a tempering process where it is moistened and softened. Nowadays, various types of rollers and shaker sieves (e.g., plan sifters) are used to affect the separation. Roller milling is divided into two main categories, namely, "breaking" and "reduction." The breaking rollers are set to flake off the bran layers and germ, and crack the endosperm into coarse pieces. The coarse pieces of endosperm are then broken into smaller pieces by repeatedly shifting and roller reducing. Flour produced throughout the milling process is removed to storage bins for final processing, where it is enriched, graded, and either packaged or shipped in bulk. The remaining bran and germ are used for cereals, baking and animal feed. Figure 148.1 is the simplified scheme of wheat flour milling. Different grades or specific characteristics of flour can be extracted from one type of wheat, or combined from various flour streams that are derived from either a single type of wheat milling or blended wheat milling. For example, flour of medium strength can be achieved by milling and blending hard and soft wheat or blending hard wheat flour and soft wheat flour.

Flour extraction rates are usually used to express the portion of the endosperm that is separated into a particular

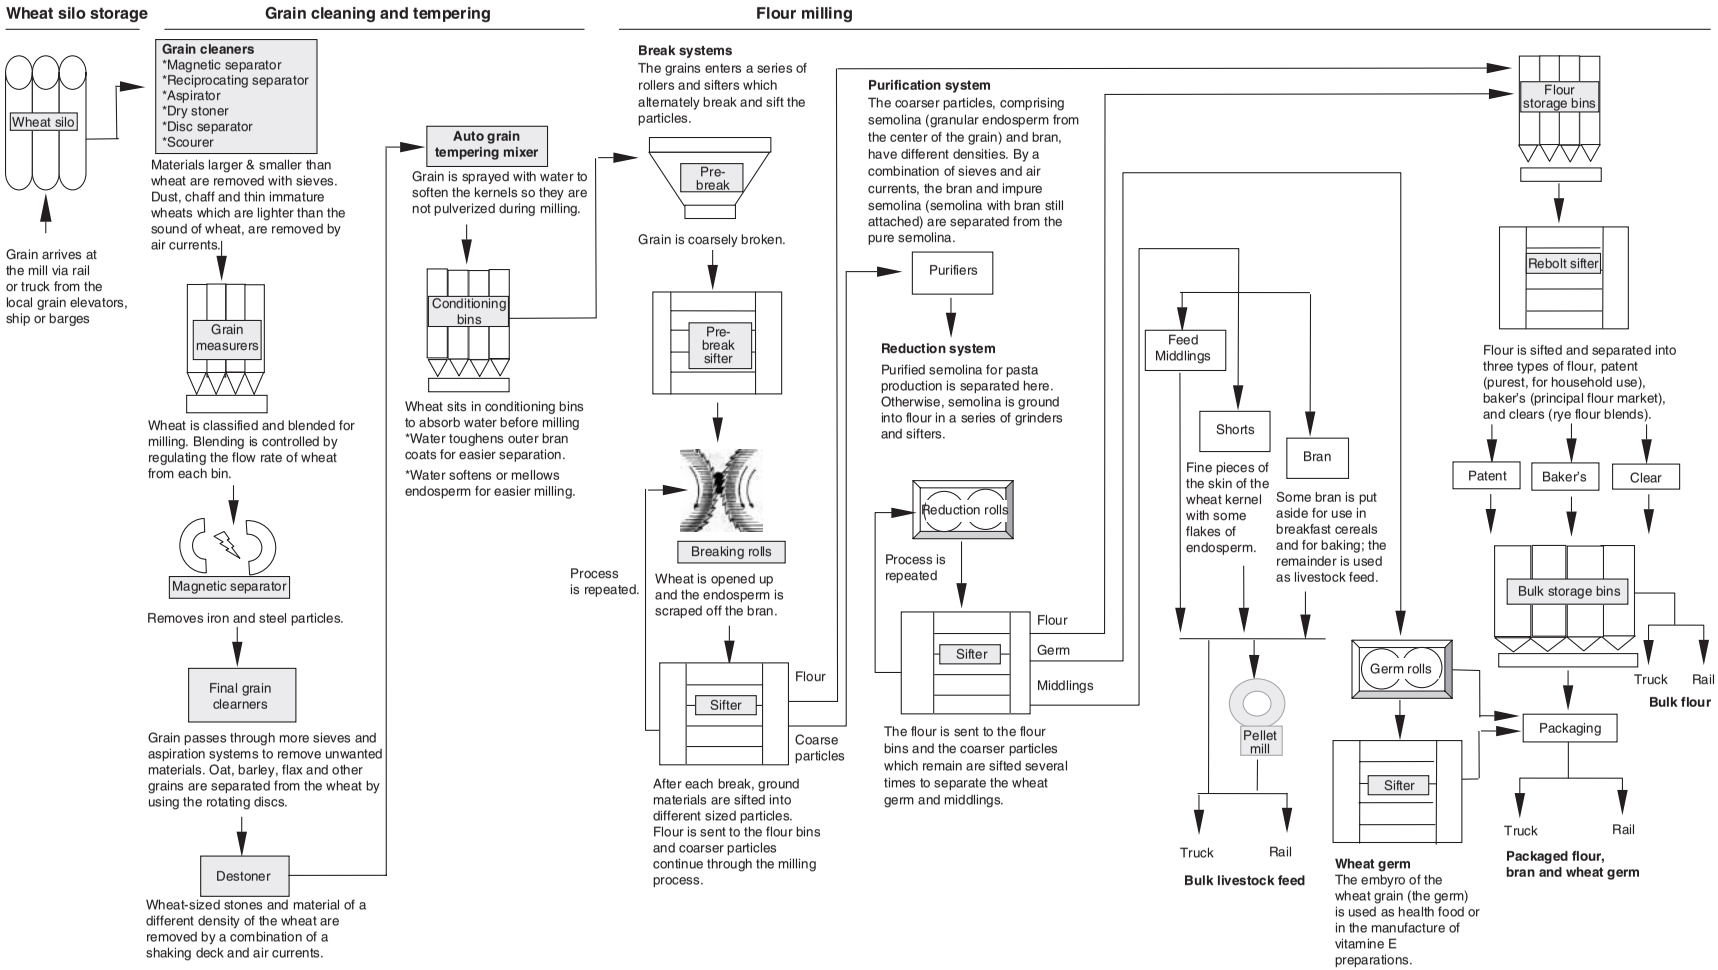

FIGURE 148.1 A simplified flow diagram of wheat flour milling.

grade of flour. Figure 148.2 shows the yields of wheat flour and by-products. The extraction rates are calculated as the percentage of flour obtained from clean, dry wheat. Table 148.2 lists the definitions of terms of milling products commonly used by millers and bakers. Ash content varies with the grade of flour, which depends on when the flour is obtained during milling. Patent flour is the "cut" of flour from the front of the mill and is considered very high quality. Clear flour is the portion of flour remaining after the patent flour has been taken off. Clear flour is further categorized as "first clear" and "second clear." Straight flour is all of the flour extracted from a blend of wheat. The differences in flour from patent to straight grade to clear flours are related to the level of bran and protein quantity or quality in the flour. Patent flour has the least bran and protein content, while second clear flour has the greatest bran and protein content. Commercially, many specialty flours for specific bakery products are usually blended with various flour streams from one or more varieties of wheat milling. For example, high-gluten flour is used in hard-crusted breads and in such specialty products as pizza dough and bagels.

Cake and pastry flours are made of soft wheat. Cake flour is a weak or low-gluten flour, with a lower ash content and smaller particle size, and sometimes is treated with chlorine to lower pH, which improves cake properties. Pastry flour is also a weak flour, but it is slightly stronger than cake flour with the same creamy white color as bread flour. Pastry flour is used for pie doughs, cookies, biscuits, and muffins.

Freshly milled flour is not most suitable for breadmaking, because gluten is somewhat weak and inelastic and the color may be yellowish. After milling, flour usually undergoes additional treatments that can affect performance, including bleaching and maturing. Flour will whiten and mature naturally due to oxidation, which changes its appearance and handling properties. Aging of flour this way is time-consuming. To speed it up, bleaching (maturing) often is done with chemicals. The US Code of Federal Regulations, Title 21, Part 137, Cereal Fours and Related Products, sets a number of requirements for products offered as "flour," in which flour may contain not more than 200 parts per million (ppm) of ascorbic acid as a dough conditioner. Chlorine, nitrosyl chloride, chlorine dioxide, acetone peroxides, benzoyl peroxide mixed with certain specific diluents, or oxides of nitrogen, may be used for bleaching or artificial aging, in quantities not more than sufficient to achieve such effects (12). In contrast to benzoyl peroxide, which only whitens the flour and has little

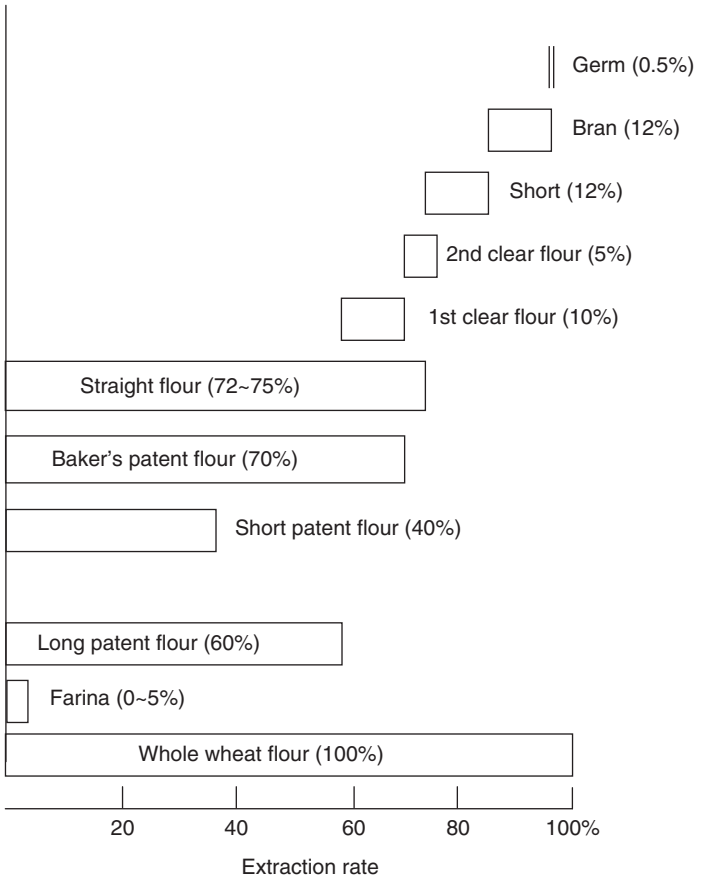

FIGURE 148.2 Milling flour stream of hard wheat and its by-products.

TABLE 148.2
Definition of Terms for Milling Products Commonly Used by Millers and Bakers[1]

Milling Products	Definition
Bleached flour	Flour is chemically treated to improve baking quality and color.
Bran	The broken seed coat of wheat, separated from the flour or meal by sifting or bolting, exclusive of any germ or most of endosperm.
Composite flour	A flour made by blending varying amounts of non-wheat flour with wheat flour and used for the production of baked goods that are traditionally made from wheat flour.
Dusting flour	Flour used on the bench and on machinery to prevent dough from sticking to equipment.
Farina	A very pure wheat endosperm, about the granulation of medium sizings; endosperm particles from hard wheat, in general can be used for breakfast cereal.
1st Clear flour	The portion of flour remaining after a "patent" cut of flour has been taken off. Clear flour is normally higher in ash and protein than patent and marketwise is secondary in value.
2nd Clear flour	The lower grade portion or division of "clear flour" from the tail-end reductions of the milling system, having a higher ash content and poorer color than those included in first clear.
Germ	The most viable portion of the wheat berry, i.e., the embryo extracted from the grain kernels.
Hard flour	This flour is strong in character, requiring prolonged fermentation to ripen, and has considerable fermentation tolerance and stability. Hard flour is produced from hard red winter, hard red spring, or hard white wheat.
Patent flour	The most highly refined flour that is cut off flour (combination of flour streams) from the front of the mill, lower in ash and protein, with good dress and color and marketwise considered highest in value. Short patent flour (SPF) is more highly refined than long patent flour (LPF); while, the SPF and LPF are all relative terms and are not constant from mill to mill.
Red dog	A low grade of flour, actually a mixture of endosperm and bran powder taken from the tail of the mill, which has high ash, high protein, poor dress and is dark in color.
Shorts	An inseparable mixture of bran, endosperm and germ, which remains after flour extraction (milling) has been completed; usually used for animal feed.
Short patent flour	Top-grade flour of any strength. The degree of extraction may vary from mill to mill, but is somewhere in the region of 40% of the total weight of the wheat from which it is milled.
Soft flour	The flour with a low percentage of weak gluten, milled from soft red winter or soft white wheat.
Straight flour	A flour milled from the entire contents of the endosperm available for milling, without division or addition of flour from other runs, excluding only the bran and germ; it is usually 72 to 75% of the wheat berry.
Strong flour	A flour that takes up a relatively large quantity of water and produces a dough that requires a relatively long mixing time for proper development. Usually a flour of high quality for bread-making.
Treated flour	Flour to which some supplement has been added, such as vitamins, calcium, iron, self-rising ingredients, etc.
Weak flour	That which (a) may contain an adequate quantity of gluten but is of inferior quality; (b) contains an inadequate amount of good quality gluten; or, (c) contains gluten that has been affected by proteolysis.

[1] From (11).

effect on its baking performance, bleaching with chlorine gas not only whitens flour, but also functions as a maturing agent. Chlorine modifies the starch and protein, permitting increased starch swelling and hydration while also weakening the gluten structure. Cake flour is usually treated with chlorine to pH values of 4.5–5.2, and cake flour treated with 1.75 oz chlorine/100 lb flour is recommended for optimum baking results (13). All varieties of refined wheat flour can be enriched with nutrients lost during milling off of the bran (e.g., thiamine: 2.9 mg/lb flour, riboflavin: 1.8 mg/lb flour, niacin: 24 mg/lb flour, folic acid: 0.7 mg/lb flour, and iron: 20 mg/lb flour), and it may contain added calcium in such quantity that the total calcium content is 960 mg/lb flour (12).

Commercially, many types of flour were designed for various applications, such as all-purpose flour (alternatively called household flour) for a wide range of applications. This flour is formulated to be slightly weaker than bread flour so that it can be used for pastries as well. Shelf-rising flour is a white flour in which baking powder and sometimes salt have been added. Whole-wheat flour is made by grinding the entire wheat kernel, including bran and germ. It is usually used for wheat bread or whole wheat bread making. The bran and germ are high in fat, which can cause whole-wheat flour to oxidize quickly. They also dilute gluten, so whole-wheat flour produces a denser loaf than bread made from wheat flour. In fact, using all whole-wheat flour results in a very heavy, whole wheat bread loaf; it is best to blend whole-wheat flour with regular wheat flour (50:50 to 20:80, w:w) to make a lighter-textured wheat bread loaf. Bran flour is flour to which bran flakes have been added. The bran may be coarse or fine, depending on specifications.

2. Other Wheat Products

Various types of wheat products beside wheat flour are also available for the making of bakery products. Wheat berries

(whole-wheat grains) or cracked wheat grains are often used for multigrain bread or used for topping of variety breads. Sold as individual ingredients, wheat bran and germ can boost the fiber and nutrients in bakery and cereal applications. Vital wheat gluten isolated from wheat has application in a variety of bakery items to modify the dough properties, resulting in the improvement of baked goods. Another wheat protein isolate, gliadin, can extend the freezer life of buttermilk biscuits and decrease fat absorption in cake donuts; it also provides excellent freeze/thaw stability in frozen doughs and can reduce the toughening of breads and pizza crusts brought on by microwave cooking. Germinating or sprouting the wheat kernel improves digestibility and increases bioavailability of protein, carbohydrates and vitamins. Sprouted wheat is subsequently toasted and used in breads to moisten the crumb and to lend a rich, malted flavor.

B. Ingredients from Other Grains

Products milled from other grains are occasionally used to add variety to baked goods. These include rye flour, corn meal, rice flour, soy flour, potato flour, oat flour and barley flour. In addition to flours, grains can be added in any shape, including whole grain, grit, flake or coarse meal. The term meal is used for products that are not as fine as finely ground flour. All of these products are normally used in combination with wheat flour because they do not form gluten. Table 148.3 is the proximate composition of grain and milled products commonly used in bakery products.

1. Rye

Next to wheat and wheat flour, rye is the most popular flour for bread-making. Although rye is the only other cereal grain with storage proteins capable of forming gluten, rye gluten is weak and inferior compared to wheat gluten. Therefore, bread made with 100% rye flour will be heavy and dense, such as pumpernickel and black bread.

Rye flour is milled much like wheat flour. Light rye extracted from the inner part of the kernel, with a very fine texture and a high percentage of starch but little protein, is correspondent to patent flour. Medium rye is a straight flour, milled from the whole rye grain after the bran has been removed. Dark rye is like the clear flour, which is milled from the part of the rye grain closest to the bran. Rye meal, or pumpernickel flour, is a dark coarse meal made from the entire rye grain. Rye blend is a mixture of rye flour (generally about 25~40%) and a strong wheat flour, such as clear flour, for making a lighter rye bread.

2. Corn

Corn flour, corn masa, corn meal and corn grits are just a few of the many specialty ingredients that can be obtained from corn, mainly from two varieties of yellow and white dent corn (15). Corn meal, or corn grits, comes in coarse and medium grinds for numerous baked goods, including: coatings for deep-fried foods; use in bread doughs; or as a sprinkle on bagels, bread sticks and pizza crust. Corn meal is also a popular ingredient in batter, baking and stuffing mixes. Corn flour, a finer form of corn meal found in pancakes, waffles and some baked goods, or for breading foods, may be yellow or white.

Corn masa, the traditional ingredient of Mexican tortillas, has been substituted by the more popular industrial corn flour, due to the ease of use, lower water requirement, and improved consistency in continuous processing. Masa is dough made from ground white corn or hominy (an old American Indian term for hulled and dried corn kernels

TABLE 148.3
Proximate Composition of Milled Products of Wheat and Rye Commonly Used in Bakery Products[1]

					Carbohydrate		
Grain/Milled Products		Water	Protein	Fat	Starch	Non-Starch Polysaccharide (NSP)	Ash
		g/per 100 g					
Wheat							
Wheat flour	Patent	12.8	11.8	1.8	65.2	22.1	1.6

Rye							
Rye flour	Whole	15.0	8.2	2.0	75.9	11.7	N

[1] From (14).

stripped of their bran and germ and soaked in limewater) (12). There are two kinds of masa: softer *masa molida* for tortillas; and coarser, thicker *masa preparada* for tamales. Masa dough can be made using three parts masa flour to one part lard and two parts water, with some salt.

3. Oat

Much like corn, most oats are used for animal feed. This nutritious cereal grain is both a source of high-quality protein and soluble fiber, β-(1→3,1→4)-glucan. In January 1997, the FDA declared that the β-glucan soluble fiber in whole oats is responsible for total and LDL blood-cholesterol-lowering, while helping to maintain good cholesterol (HDL) (13). To qualify for the health claim, the whole-oat-containing food must provide at least 0.75 grams of soluble fiber per serving. The amount of soluble fiber needed for a lowering effect on cholesterol levels is about 3 grams per day. Food products eligible to bear the health claim include oat bran and rolled oats, such as oatmeal, and whole-oat flour.

Oat ingredients come in a variety of forms. The oat kernel, commonly called a groat, is surrounded by an inedible husk, or hull, whose high adherence to the groat makes processing a bit more difficult than with other grains. Whole-oat groats are the whole grain with the tough outer hull removed. Steel-cut oats are groats cut into several smaller pieces. Steel-cut oats are used in thick soups and stews, and add bulk to sausages. Rolled oats, synonymous for oatmeal, are dehulled oats steamed and flattened between rollers, a process that allows them to be cooked quickly, or require no cooking at all, prior to consumption. Rolled oats can be cooked up as hot oatmeal cereal, or added to cold cereal, bread, cookies, muffins and even pancake mixes for flavor, texture and nutrition. They combine very well with other grains in these applications, but can be used as the only grain ingredient in baked and unbaked cookies to produce a chewy texture. In many baked-good formulas, rolled oats can replace up to one-third of the flour at an exchange of one part flour for four parts rolled oats. For a more direct substitution, whole-oat groats can be ground to make whole-oat flour or oatmeal flour, but oats do not contain gluten and will not rise if used alone in bakery applications.

4. Barley

Barley was a staple in the ancient city of Jericho as long ago as 8000 BC, and the Babylonians were brewing with it in 2500 BC (17). Though primarily used as an animal feed, and in the beer and whiskey-brewing industries, some food formulations also use barley. Many varieties of barley are grown, including naked, waxy, and non-waxy. Waxy hullless barley may have 6% to 9% soluble fiber, versus barley that is hulled, which has only 2% to 4% soluble fiber (18). Most forms of whole barley are a good source of protein, vitamin B, and dietary fiber. Whole barley flour is 13.5% dietary fiber, compared to whole wheat's 9% (Table 148.4). The kernels possess a pleasant, nutty taste, and include a protective husk that requires removal before human consumption. Hulled, or whole-grain barley, is simply the whole grain minus the outer hull. Barley flour, ground pearl barley, can be used in bread making.

For brewing, barley is converted to malt through controlled sprouting of the barley grain followed by drying. Malt is a source of the enzyme α-amylase, which hydrolyzes starch to fermentable sugars, such as dextrin and maltose. Malt can supplement flour for baked goods,

TABLE 148.4
Dietary Fiber Content of Grains and Milled Products Commonly Used in Bakery Products[1]

Grain/Milled Product	Moisture (g/100g edible portion)	Dietary Fiber (g/100g edible portion)		
		Total	Insoluble	Soluble
Barley	9.4	17.3	—	—

[1] From (19).

increasing the α-amylase content, and the dough's fermentation rate, and improving baking properties. The lack of gluten restricts its use in leavened bread to 10%, or appearance of loaf volume is affected. Extract and syrup forms of barley malt add flavor and color to various applications. Baked goods, such as rolls and bagels, often contain malt syrup at 1% to 3% of the flour weight. Barley flour has a 2.5-fold water-holding capacity compared to wheat, making it an ideal food thickener, binder, or ingredient in oriental noodles. Quick breads can contain up to 30% barley flour. Cakes, cookies, donuts, muffins, and pancakes can be made from 100% barley flour.

5. Rice

Rice is an ancient grain that has been a staple for centuries, and it provides ingredients with unique functional characteristics and health benefits. There are numerous varieties of rice and each possesses distinct flavor and texture characteristics. But overall, most rice grains are quite bland and soft, which is why rice tends to be the first solid food served to babies.

Parboiled rice is steam-treated long-grain white rice. It is more nutritious than long-grain white rice because it is processed prior to hulling, so the grain has the chance to absorb the bran's nutrients before the bran is discarded (20). Brown rice, on the other hand, is hulled (short-, medium- and long-grain) rice with its bran intact. As a result, it requires longer cooking times than polished rice.

Some rice components are sold as food ingredients, such as rice flour, pregelatinized rice flour, and rice bran. Beneficial health effects of rice bran are capturing the attention of the food industry (21). High in dietary fiber, rice bran boosts nutrition and adds texture to cookies or bread doughs. Besides, rice bran is a good source of oil, protein concentrates, protein isolates, and antioxidants (22). Rice flour is polished white rice finely ground to a silky consistency, and it often substitutes for wheat flour in wheat-free applications designed for consumers on gluten-free diets.

6. Soy

Soybeans have been utilized for centuries in Asia; however, worldwide consumption of soybeans has increased. Although soybeans are classified as legumes, their utilization is similar to grain. Human consumption of the whole bean remains low, but components of soybeans show great promise in the coming decade, particularly those derived from soy protein. Soy contains a class of phytochemicals that are referred to as isoflavones, which mimic the female sex hormone estrogen (hence the term phytoestrogen) and has effects on the prevention of post-menopausal syndromes (23). Defatted soy flour, generally by a hexane extraction, is one of the richest isoflavone sources, with levels as high as 2.0 mg per gram of soy protein. Soy concentrate that is aqueous-washed rather than alcohol-washed is another good source at 1.5 mg per gram. In comparison, soymilk can contain as little as 0.1 mg per gram.

Soy proteins are available in three major forms that are all derived from defatted soybean flakes: soy flours and grits; soy protein concentrate; and soy protein isolates. Defatted flours and grits range from 40% to 54% protein, 30% to 32% carbohydrate, 2.5% to 3.5% fiber, and up to 1% fat (24). Functionality of soy flours and grits is related to their capacity to bind water and absorb fat. These characteristics vary according to the particle size and the degree of heat treatment that the flour and grits undergo, resulting in protein denaturation. In general, lower heat treatment and smaller particle size means more functionality. As a general rule, up to 3% of wheat flour can be replaced by soy flour without any adjustments other than water addition, approximately a 1:1 to 1:1.5 ratio based on the weight of the soy flour.

C. Yeast and Chemical Leavening

Leavening is the production or incorporation of gases in a baked product to increase volume and to produce shape and texture. Leavening agents is a term used to indicate a source of gas that causes a dough or batter to rise or spring. These gases must be retained in the product until the structure is set enough by the coagulation of gluten and egg proteins and the gelatinization of starch to hold its shape. Unleavened medium- to high-moisture baked goods are dense and heavy, with virtually no cell structure. Three types of leavening agents, water, yeast and chemicals, can be used in bakery products (Table 148.5).

Hard wheat flour, as is used in bread, is usually leavened with yeast because of the protein content and gluten formation. However, soft wheat flours, used in products like cakes, are usually leavened with chemical leaveners because they do not contain the same level of gluten and cannot retain the gases generated by yeast. Most often, in each case, a yeast or chemical leavening system is used independently, but occasionally a combined system provides the desired result. For example, saltine crackers and pretzels undergo yeast fermentation, but the primary reason is to generate flavor and dough conditioning. The subsequent sheeting action removes much of the gas that is generated, and chemical leaveners are required to provide lift during the bake. Most formulations contain water, which when heated, forms steam and expands. However, water does not contribute significant amounts of leavening in most baked goods, except cream puffs and popovers, and most products require additional leavening, either with yeast or chemical leaveners. In general, chemical leavening is a faster, more convenient, and often more consistent method than yeast. In some frozen

TABLE 148.5
Major Leavening Gases Used in Leavening of Bakery Products

Leavening Gas	Source	Comments	Examples
Air	Mechanical mixing process	Nitrogen solubility in water is low. Forms nucleation sites during mixing.	Whipped egg whites entrap the air in angel food cakes. Beaten whole or fortified eggs incorporate the air into sponge cakes. Creaming of the shortening and sugar leaven the pound cakes.
Water vapor (H_2O)	Water as an ingredient	Because of high boiling point has a limited effect.	Moisture evaporation between the folded fat and dough layers leavens the puff pastry.
Ammonia (NH_3)	Ammonium bicarbonate Ammonium carbonate	Decomposes completely at about 60°C. No residual salts. Used in products that are baked to near dryness, such as cookies and crackers.	Cookies and crackers.
Carbon dioxide (CO_2)	Sodium bicarbonate (major) Potassium bicarbonate Sodium carbonate	Needs acids for appropriate leavening activity. CO_2 is produced faster, thus the products may be baked immediately after dough or batter preparation.	Most cakes and cookies. Cake doughnut.
	Yeast fermentation	CO_2 is produced slower during dough fermentation, thus reasonable fermentation time is required.	Breads, Chinese steamed breads, bread doughnut.

or refrigerated doughs, yeast and chemical leavenings complement each other.

1. Yeast

Yeast (*Saccharomyces cerevisae*) is the leavening agent in bread, dinner rolls, and similar products. Fermentation is the process by which yeast acts on sugars, which can be added sugar or sugar produced by hydrolyzing wheat starch with enzymes, and changes them into carbon dioxide gas and alcohol. This release of gas produces the leavening action in yeast products. The alcohol evaporates completely during and immediately after baking. Because yeast is a living organism, it is sensitive to temperatures (Figure 148.3). Yeast in dough is active between 0°C and 55°C. At temperature less than 20°C and over 40°C, the rate of growth is significantly reduced. Yeast can survive for a few weeks at temperatures as low as −20°C, but it gradually loses its fermentation capacity. The most favorable temperature for yeast to multiply is between 20°C and 27°C; optimum multiplication of yeast is achieved at around 26°C. The optimum temperature for fermentation lies between 27°C and 38°C; yeast ferments best at 35°C (25).

For the baking industry, yeast is available in two forms, fresh and dried. Depending on process, cost, and desired effect in the finished product, various forms of yeast may be used—compressed, fresh in cake or crumbled form, liquid cream yeast, or active dry yeast. The forms and properties of baker's yeast are summarized in Table 148.6.

Determining the correct yeast level is difficult because of variations in yeast activity and in the process. The conversion factors between the fresh yeasts and the dry yeasts are only guidelines and depend dry matter versus the viability. During processing, doughs are traditionally proofed, or allowed to ferment twice. This not only results in an increase in dough volume, but also develops characteristic fermented-yeast flavors. No-time doughs are only proofed once. The finished products are similar in quality to traditional doughs, but increased levels of dough conditioners and yeast are required. Frozen doughs require yeast that retains its activity through extended frozen storage conditions. Ice crystals formed in the frozen dough will disrupt yeast cell walls. Also, as the dough freezes, the amount of available water decreases, and the concentration of the solutes increases. The increase in osmotic pressure can destroy yeast cells. Therefore, yeast with a high osmotic tolerance is required for frozen dough.

Using yeast in bakery products is somewhat challenging, but it creates two main advantages: a distinctive flavor and dough conditioning. As yeast ferments, it forms a number of compounds, including organic acids, alcohols, aldehydes, esters and ketones. Some of these are volatilized during baking, some undergo further reaction, and most contribute to the flavor and odor of the product. Some of the compounds generated during fermentation act as dough conditioners and increase dough extensibility by relaxing the gluten. This is a function of time and pH; the longer the ferment, the more pronounced the effect.

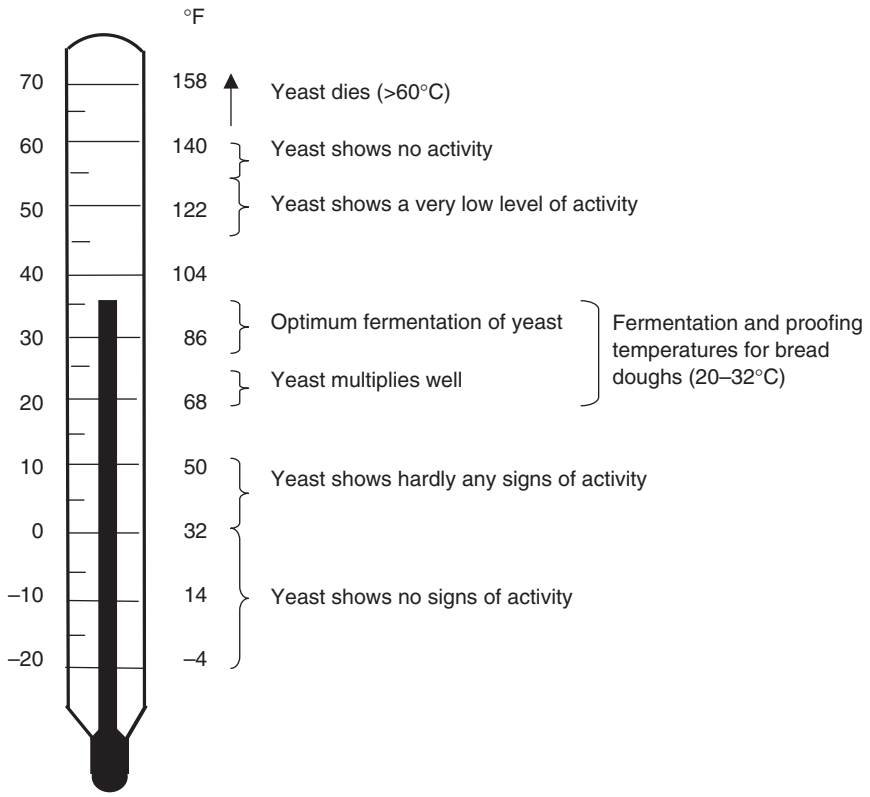

FIGURE 148.3 Effects of temperatures on yeast.

Using certain ingredients in excess—such as the salt that is added for flavor—may limit yeast growth. Extra nitrogen, as part of a dough improver, can be added to ensure optimum yeast growth. This produces the necessary carbon dioxide to yield oven spring, which is the sudden expansion of dough by about one-third its original volume during the early baking stages.

2. Chemical Leaveners

Chemical leavening systems produce CO_2 by one of two means: chemical decomposition through the application of heat, or a reaction of an acid with a base. Sodium bicarbonate (or baking soda) and ammonium bicarbonate are two major gas carriers in chemical leavening systems. For low-sodium applications, potassium bicarbonate may be used, but about 19% more is needed to gain the same effect as baking soda, because it has a greater molecular weight than sodium bicarbonate.

Sodium bicarbonate can be heat decomposed into CO_2, water, and washing soda (Na_2CO_3) as shown in Figure 148.4. Excess washing soda will react with shortening, giving a dark color and undesirable taste to the cake. Therefore, various acids are combined with sodium bicarbonate to accelerate the reaction for gas producing at lower temperature. Sodium bicarbonate is available in several grades differentiated by particle size, which affects the solubility of soda, and therefore, the reaction rate of gas production. Generally, Grade 1 is the standard powder grade. Use of the coarser Grades, 2 through 4, can reduce the tendency for pre-reaction and increase the system stability. Sodium bicarbonate also can be encapsulated with fat-based coatings to increase stability, particularly for refrigerated doughs. If the level of soda is too high in the finished product, it creates soapy off-notes. If the level is too low, it will allow the acidic flavors to come through. Excess levels also result in over-browning.

Ammonium bicarbonate decomposes into ammonia and carbon dioxide when exposed to temperatures above 40°C (104°F), and heat decomposition is complete at about 60°C (140°F), (Figure 148.4). Some gas is released at room temperature, but most is generated during baking. Acidic conditions accelerate the reaction at lower temperatures. The release of gas is rapid, resulting in fairly large cells. Ammonium bicarbonate not only increases the volume or height, but also tends to increase the spread in cookies. After decomposition, it forms ammonia gas, water and carbon dioxide without any residual salt. As it decomposes, it generates basic substances, so it does go through a temporary pH spike. Ammonium bicarbonate dissipates in low-moisture products that have a porous structure, such as cookies and crackers. In higher moisture products, water retains the ammonia, giving the product an undesirable flavor and odor. Ammonium bicarbonate

TABLE 148.6
Types of Baker's Yeast[1]

Yeast Type	Form	Storage Temperature	Shelf-Life	Moisture Content (%)	Gas Power (g Glucose Fermented/g Yeast Solid/hr)			Conversion Factor	Handling Requirements
					Straight Dough	Lean Dough	Sweet Dough		
Fresh compressed yeast	Cake crumbled	2–7°C/36–45°F	3–4 weeks	67–72	2.2–2.3	2.4–2.6	1.0–1.1	1	Weigh and add with other ingredients or disperse in water before mixing.
Fresh cream yeast	Liquid	1–4°C/35–39°F	10–14 days	80–82	—	—	—	1.5–1.8	Meter and add with other ingredients.
Dry active yeast	Granule	Room temperature	2–12 months	6–8	1.4–1.5	1.2–1.3	0.8–0.9	0.4–0.5	Must hydrate at 40–43°C (105–110°F) for 10–15 min before use.
Dry instant active yeast	Granule	Room temperature	1 year plus (depending on packaging)	4–6	1.6–1.8	1.8–2.0	0.8–0.9	0.33–0.4	Blend dry with other dry ingredients or delay addition in mixer.

can only be used in low-moisture applications, since the ammonia flavor persists at high moistures.

a. Acids

A number of leavening acids can be incorporated into the leavening system (Table 148.7). Natural acids such as lemon juice or sour milk can be used, but typically in a commercial operation, chemical leavening acids are added to provide consistent, controlled gas production. Acids commonly used include monocalcium phosphate (MCP), sodium acid pyrophosphate (SAPP), sodium aluminum phosphate (SALP), and dicalcium phosphate (DCP). Anhydrous monocalcium phosphate (AMCP) is sold with a coating that slows its rate of reaction. Other common leavening acids are sodium aluminum sulfate (SAS), monopotassium tartrate (cream of tartar), and glucono-delta-lactone (GDL).

Choosing the right acidulant(s) depends on the desired effect on the finished product, and on two other major characteristics: the reaction rate and the neutralizing value. The reaction rate is the rate at which the carbon dioxide is released in response to moisture or heat. This can be measured in several ways. The Dough Rate of Reaction (DRR) measures the rate of gas released during mixing and holding. The dough is held at a constant temperature, and the amount of gas is measured, converted to the percentage of sodium bicarbonate, and plotted against time. The reactivity of the acids, or DRR, is mainly a function of solubility in water at different temperatures. Solubility is influenced not only by chemical composition, but also by factors such as particle size, and any coatings or encapsulation techniques used. Dough temperature and rate of temperature change also affect solubility. Reaction rate may also be influenced by the addition of other ingredients, such as sugar and milk (due to calcium) that can slow the rate. Reaction rate affects the finished product's grain, volume and texture. The goal of the product developer is to balance the system so that none of the acid or base remains in the baked good. Residual soda causes a soapy flavor and yellowing of light-colored products. Excess phosphate causes metallic off-flavors and an unusual squeaky-teeth feeling.

The neutralizing value (NV) is the amount of sodium bicarbonate needed to completely neutralize 100 pounds of that acid. In most applications, the goal is to retain little or no sodium bicarbonate or leavening acid in the finished product. However, an excess is sometimes required to provide a specific pH-related effect, such as color or flavor modification in chocolate cakes.

Other ingredients also affect the pH of a product, so adding neutral proportions of leavening acids and bases does not guarantee a neutral pH in the finished product. Changing the pH can affect the speed and reactivity of the leavening system. The degree of flour bleaching can cause the dough to become puffy. Adding ingredients like fruit, buttermilk, or even high-fructose corn syrup and cocoa powder can significantly change the pH of the finished product and reduce its volume. Many ingredients contain organic acids, which will react very quickly with the bicarbonates.

Besides reacting with baking soda, leavening acids affect the structure, color, flavor, and pH of the finished product. Each acid produces a slightly different texture. Ions making up the acid salts influence the crumb structure and texture. Calcium and aluminum ions contribute to a fine grain, and also strengthen the structure of the batter and produce a spongy texture.

TABLE 148.7
Leavening Acids Commonly Used in Bakery Products

Chemical Name	Chemical Formula	Common Name or Abbreviation[1]	Rate at Room Temperature	Neutralizing Value[2] (NV)	Other Characteristics
Monocalcium phosphate monohydrate	$CaH_4(PO_4)_2 \cdot H_2O$	MCP	Very fast	80	Used in combination with slow acids to aid nucleation.
Monocalcium phosphate anhydrate	$CaH_4(PO_4)_2$	AMCP	Slow	83	Slow reacting at room temperature, reacts in oven.
Dicalcium phosphate dihydrate	$CaHPO_4 \cdot 2H_2O$	DCP*	None	33	Slightly alkaline at room temperature. A heat-triggered leavening agent but triggers too late (57–60°C) for most products. Used in frozen cake batters or high sugar baked products.
Dimagnesium phosphate	$MgHPO_4$	DMP*	None	40	The first heat-activated leavening agent (40.5–43.5°C) that does not contain sodium, yet reacts early in the baking process.
Sodium acid pyrophosphate	$Na_2H_2P_2O_7$	SAPP	Slow to fast	72	Wide range of reactivity release CO_2 in the oven, used in production of cake doughnuts. Slow acting: SAPP 21 and 26; used primarily in refrigerated biscuits and cake mixes. Medium acting: SAPP 28; commonly used for commercial baking powders. Fast acting: SAPP 37, 40, 43, and 45; used primarily in cakes and cake doughnuts.
Sodium aluminum sulfate	$Na_2SO_4 \cdot Al_2(SO_4)_3$	SAS*	Slow	100	Little reaction until heated, too slow to be used alone. Used in double-acting household type baking powder. May accelerate fat rancidity.
Sodium aluminum phosphate hydrate	$NaH_{14}Al_3(PO_4)_8 \cdot 4H_2O$	SALPH*	Medium	100	Temperature triggered.
Sodium aluminum phosphate anhydrous	$Na_3H_{15}Al_2(PO_4)_8$	SALPA*	Slow	110	Primarily temperature triggered.
Potassium acid tartrate	$KHC_4H_4O_6$	Cream of tartar	Medium fast	50	First leavening acid developed, relatively expensive.
Glucono-delta-lactone	$C_6H_{10}O_6$	GDL	Slow	55	Very expensive. Some uses in cake doughnuts.

[1] Heat-activated leavening agents are marked as *.
[2] Neutralizing value (NV) defined as parts (by weight) of sodium bicarbonate that 100 parts (by weight) of leavening acid will neutralize.
From (27).

b. Baking powder

Baking powders consist of one or more acids in combination with baking soda and a carrier such as starch. Three major types of baking powders are listed in Table 148.8. The starch physically separates the acid and base and prevents them from reacting during storage. The leavening reaction typically occurs over a period of time rather than all at once, but acids that react mostly at the batter or dough stage are generally categorized as "fast-acting," vs. those that function during baking, frying or griddle cooking and are categorized as "slow-acting." This gas cell nucleation also can occur by incorporating air during mixing. The better the dispersion of these nucleating cells, the finer the grain in the finished product. Often, leaveners are used in combination (or called double-acting) to achieve a specific effect. The initial gas release provides small gas cells that promote uniform expansion during baking. For example, cake doughnuts usually have a combination of a fast-acting SAPP, and a slower leavener such as SALP or GDL, to permit rapid expansion when the batter hits the hot fryer oil.

D. Fats and Oils

Nearly all baked products contain fat—often in significant quantities (10–50%, bakers, percentage). Fat's functionality is very versatile in baked products (Table 148.9). The major functions of fats in baked items are: (1) imparting shortening, richness, and tenderness to improve flavor and eating characteristics; (2) enhancing aeration for leavening and volume; (3) promoting desirable grain and texture qualities; (4) providing flakiness in pie crusts, Danish, and puff pastry; (5) providing lubrication to prevent the wheat gluten particles from adhering together to retard staling; (6) affecting moisture retention for shelf-life

TABLE 148.8
Types of Baking Powder

Type	Definition	Examples	Comments	Applications
Single-acting	Contains only one acid ingredient, either fast or slow.			
Fast-acting	Contains fast acting acids that release a large amount of the gas in a relatively short time during mixing, or while the batter is on the bench.	Cream of tartar Tartaric acid MCP	Increased batter aeration; greater volume; improved texture; most CO_2 released in mixer.	Pancake mixes, cookie mixes, angel food cakes, double-acting baking powder.
Slow-acting	Contains moderately slow acting acids that release a major proportion of the gas in the oven.	SAPP SALP SAS	Used in combination with others; improves tenderness and moistness of baked products.	Various types of donut mixes, refrigerated canned biscuits.
Double-acting	Contains two or more acid ingredients that must have a minimum of one fast and one slow acting, so that some of the gas is released during mixing and on the bench with the remaining gas being released in the oven starting at about 40–43°C (104–110°F).	MCP+SAS MCP+SAPP MCP+SAPP+SALP	Nucleation; late bake reserve; fast oven action; aluminum and calcium ions for batter viscosity and crumb resiliency.	Layer cakes, muffins, pancakes, refrigerated biscuits.

[a] ++: highly required functionality; +: required functionality; −: not required functionality.

improvement; and, (7) providing structure for cakes, icing, and fillings (28).

The functional performance and textural quality of fats, and fat-containing products are determined mainly by the balance between the solid and liquid phases (solid fat index, SFI) and the crystal structures of the solid fats. Table 148.10 is the SFI of fats commonly used in baking. The SFI influences how well air is incorporated, as well as the rheology, mouthfeel, shelf-life and other quality issues of many bakery products. The SFI depends on a number of factors, including the degree of hydrogenation and the type of fat. As the fat solidifies, it takes on one of three main crystal forms: alpha (α), beta prime (β'), and beta (β). Each affects hardness, texture, mouthfeel and stability. The β form is the most stable, but β' is generally preferred due to its smoothness and superior creaming properties. The factors that affect the formation of β' crystals include the amount of palmitic acid, the distribution and position of palmitic and stearic acids, the degree of hydrogenation, and the randomization of the fatty acids. Hydrogenation can increase β formation, while randomization of the fatty acids promotes β'. During storage, there is a tendency for the fat to be transformed into the most stable crystal form, which may or may not be desirable. Generally, fats in the α-form are characterized as waxy; fats in the β'-form are characterized as fine-grained with smooth texture; and the β-form crystals are termed coarse and grainy (30).

1. Fat and Oil Processing

Food fats and oils come from a number of different sources, either animal or vegetable. They can come from one source, or consist of a blend that creates a functional or cost benefit. Most food fats start out as refined/bleached/deodorized (RBD) oil. Figure 148.5 shows the typical sequence for fats and oils processing. To achieve improved functionality for bakery applications, solid fat index, melting curves, and crystal structure of fats should be focused. Altering a fat's functionality to meet

[1] From (29).

these needs requires further processing. Fractionation, hydrogenation, and/or interesterification are the processes most often used, but some specialty fats may require other modifications (30).

To increase stability and raise the melting point to accommodate most cookie and cracker applications, many RBD fats must undergo hydrogenation. Hydrogen atoms are added to the unsaturated bonds under high temperatures in the presence of a catalyst. Saturated, or single bonds, resist chemical reactions, including oxidation. As the chain length and the number of single bonds increase, so does the melt point. Hydrogenation may shift the location of the double bond, which slightly affects the melting point. It also promotes *trans* isomers through isomerization, a form where the hydrogen atoms are positioned on opposite sides of the carbon-carbon bond. These configurations also affect the melting point (31). *Trans* fatty acid formation during deodorization is influenced only by time and temperature. Generally, *trans* formation is negligible below 220°C; it becomes significantly between 220 and 240°C, and nearly exponential above 240°C (32).

Manufacturers can also use interesterification to alter properties of fats. This process rearranges the fatty acids on the triglyceride backbone with a catalyst or enzyme to change the fat's properties (33). The lower cost and broad functionalities produced with hydrogenation made this method less desirable, but since it doesn't create *trans* isomers, commercial interest in interesterification has increased significantly in the past several years.

The other processes essential for making oil-based ingredients for baked goods transforms them into a plastic shortening or margarine. Theses process include the use of scraped-surface heat transfer to mix; cooling and controlling crystallization; and incorporating air; making a pliable fat suitable for bakery products (34).

2. Types of Fat and Oil for Bakery Products

Many different fats are available to the baker. These fats have different properties that make them suitable for different purposes. Among the properties a baker must consider when selecting a fat for a specific use are its melting point, SFI (i.e., softness or hardness at different temperatures), flavor, and ability to form emulsions. In the selection process, bakers should take into consideration all of these issues, including functionality, cost, stability and health.

a. Butter

Butter (milk fat) has been legally defined as a food product made exclusively from milk or cream, or both, with or without common salt, and with or without additional coloring matter, and containing not less than 80% by weight of milk fat. The nonfat portion of butter is composed of approximately 16% water, 2.5% salt, and 1.5% milk solids. The soluble components in the fat or triglyceride portion are sterols, pigments, fat-soluble vitamins, and phosphatides or lecithin at approximately 0.2% (35). Butter has traditionally been used for its flavor contribution, but it usually is

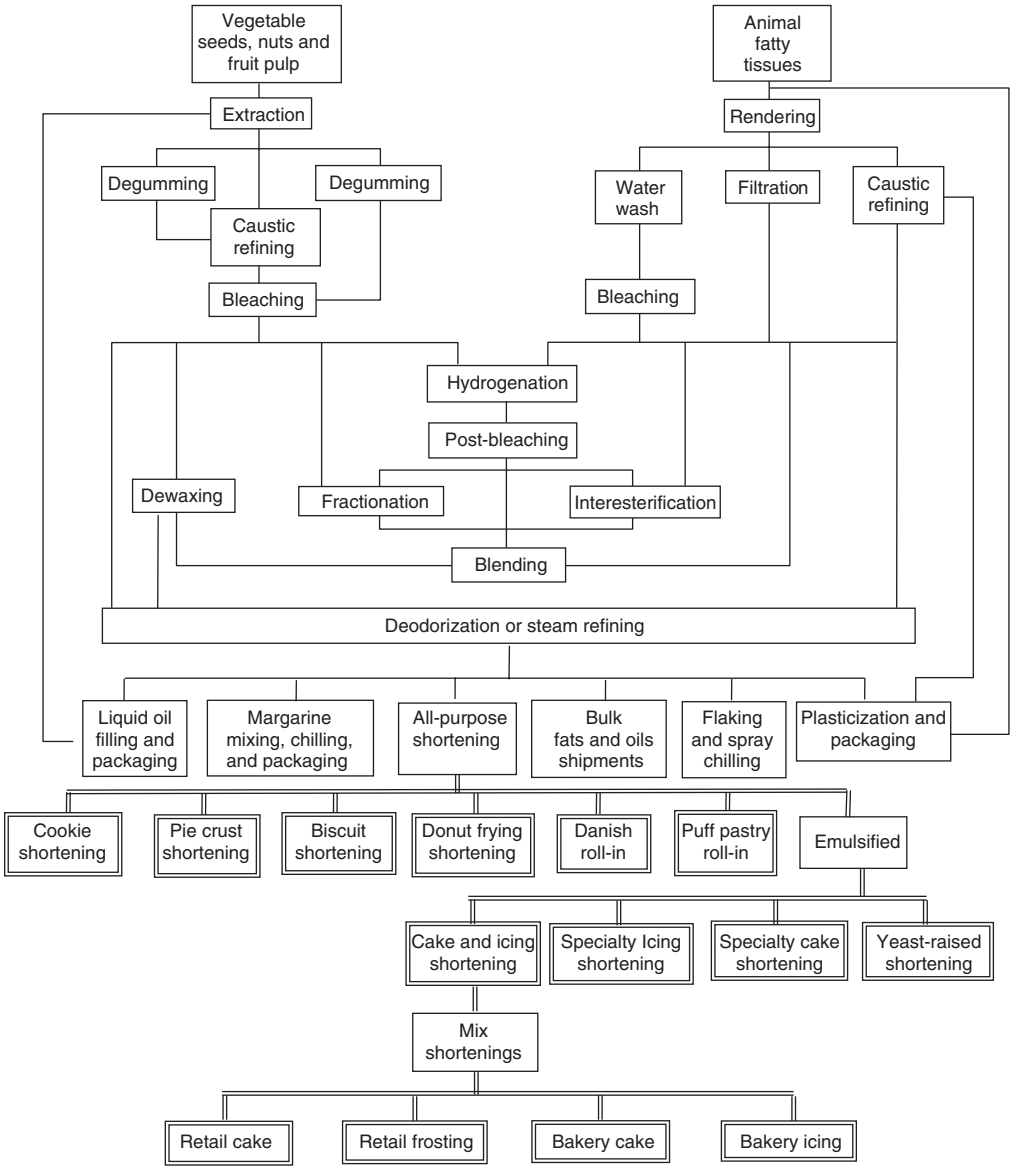

FIGURE 148.5 Flow sequence of fats and oils processing.

not the only source of fat in a product due to the expense. Butter is available salted and unsalted. Unsalted butter is more perishable, but it has a fresher, sweeter taste and is thus preferred in baking. While it can be substituted with margarine or straight vegetable shortening, butter offers an edge in mouthfeel and flavor that helps define a premium dessert. Butter also tends to provide a different end result than margarine, particularly when it is used in pastries and crusts. Both contain about the same amount of fat or oil, but the vegetable fat used in margarine tends to form in small globules or spheres, while the animal fat found in butter forms crystals. This crystal structure is layered flat, almost like shingles. Because of the physical shape of the fat crystals, butter tends to spread and layer more easily and uniformly, forming nice flaky layers with richer flavor notes. Butter is hard and brittle when cold, very soft at room temperature, and it melts easily. Consequently, dough made with butter is much harder to handle than shortenings.

b. Margarine

Margarine is manufactured from various hydrogenated animal and vegetable fats, plus flavoring ingredients, emulsifiers, coloring agents, and other ingredients. It contains 80–85% fat, 10–15% moisture, and about 5% salt, milk solid, and other components (36). Thus, it may be considered a sort of imitation butter consisting of shortening, water, and flavoring. There are two major categories of margarines for bakers: cake margarines (or baker's margarines) and pastry margarines. Cake margarines are soft and have good creaming ability, while, pastry margarines are tougher and more elastic and have a waxy texture that is especially formulated for dough that forms layers, such as Danish

dough and puff pastry. Puff pastry margarine, the toughest of margarines, is sometimes call puff pastry shortening. However, it has significant water content, which helps to give leavening power to the dough when it forms steam.

c. *Shortening*

Shortening was originally a baking term that described the function of a solid fat to give a "short" or tenderizing effect to baked products. Later, the word shortening was used to mean any of a group of solid fats, usually white and tasteless, that had been especially formulated for baking. Today, the term shortening has become virtually synonymous with fat, and includes many other edible fats or oils products designed for all prepared foods, not simply baking (34). Shortenings (or plastic fats) generally consist of nearly 100% fat; however, there are exceptions, such as roll-in shortening, which may contains moisture. Shortenings may be made from vegetable oils, animal fats, or both. During manufacturing, the fats are hydrogenated. Because shortenings are used for many purposes, manufacturers have formulated different kinds of fats with different properties. There are two main types: regular shortenings and emulsified shortenings (Figure 148.5).

Regular shortenings have a fairly tough, waxy texture, and small particles of the fat tend to hold their shape in a dough or batter. They can be manufactured to be of varying degree of hardness. Regular shortenings have a good creaming ability but melt, only at a high temperature. They are usually used for flaky products, such as piecrusts and biscuits. They are also used in many other pastries, breads, and products mixed by creaming, such as pound cakes, cookies, and quick breads.

Emulsified shortenings are soft shortenings that spread easily throughout a batter and quickly coat the particles of sugar and flour. Because they contain added emulsifying agents, they can hold a larger quantity of liquid and sugar than regular shortenings can. They are often used when the weight of sugar in a cake batter is greater than the weight of flour, and this results in a smoother and finer texture, as well as a moister cake. Such cakes are referred to as high-ratio cakes, and emulsified shortening is sometimes called high-ratio shortening. In addition, emulsified shortenings are often used in icings because they can hold more sugar and liquid without curdling.

Roll-in shortening is a harder fat than margarine and is used in sweet doughs. Puff-pastry margarine is harder, and is used to produce croissants and Danish doughs. Shortening for puff pastries is added to dough by a process called booking. A layer of semi-soft margarine is spread across the center of a piece of sweet dough. Each side is folded to the center, forming a book. The dough is retarded (refrigerated) to firm up the fat. After cooling, the dough is rolled out and the process is repeated several more times. The finished dough has between 45 and 60 layers.

Fluid shortenings have some characteristics of plastic shortenings, but are pumpable. Fluid shortenings that produce finished products identical to those made with plastic shortenings have been developed. Fluid shortenings are much more economical to transport, and reduce plant labor. In some applications, lower levels of fats can be used with fluid shortenings.

d. *Vegetable oils*

Vegetable oils used in baking come from a number of sources: canola, cocoa butter, coconut, corn, cottonseed, palm, palm kernel, peanut, safflower, soybean and sunflower. In many cases the primary considerations are price and availability, so soybean, or a blend based on soybean, typically has an edge.

Despite their notoriety, palm oil and the other tropical oils provide a number of positive functional attributes: They can be used as a source for solids to avoid hydrogenation of liquid oils. Palm oil promotes beta prime (β') crystallization. The high palmitic content increases the aeration of fat and sugar mixes. The absence of linolenic acid prevents flavor reversion, or the development of characteristic, often undesirable flavor notes that develop in most oils with time.

3. The Role of Fat in Bakery Products

Examining how the role of fat varies in different products is made clearer by dividing bakery products into the following general categories: yeast-raised products, including breads and rolls; laminated products, such as croissants and pastry; cakes; and cookies and crackers.

a. *Yeast-raised products*

Bread and rolls typically don't have much oil in the formulation, but fat is important both for organoleptic quality and processing. Although fat isn't required for aeration in yeast-raised products, it still is directly related to how well the dough rises. The small amount of fat in bread or roll dough will lubricate the cells so they can slide. This is important both for machining and for lubricity that directly affects product quality. When a dough is proofing, the cells must be able to slide easily to allow even distribution of the fermentation gasses. If the cells cannot move, the loaf will have an irregular shape and bulge in the areas where the gasses have concentrated. The lubricant qualities of the fat also work in the finished yeast-raised product to give a desirable soft texture and grain. If making a product without shortening, such as French bread, a hard crust will result. If making bread with shortening, the softer crumb associated with longer shelf-life will be obtained. As far as lubrication goes, most types of fat will work in yeast raised products because the usage levels are so low. In the Chinese National Standard (R.O.C), the fat content (on the baker's percentage, i.e., based on 100 g of wheat flour) of different types of breads is less than 4% for hearth bread

and roll, 4–10% for soft bread and roll, and more than 10% for sweet roll, based on CNS 3899 (37).

If a solid shortening is used in a bread or roll, it can make the product firmer than one made with oil. Following distribution during winter, or in cooler storage conditions, consumers may feel such a product and think it's stale. Sweet rolls or buns are a little different, because they have higher levels of both fat and sugar. Here, instead of oil, an emulsified plastic shortening may be better. Oil doesn't have anything that will solidify, so the bread stays soft. Because many breads and rolls are delicately flavored, the fat or oil selected also must possess and maintain as neutral a flavor as possible so it doesn't contribute off flavors to the finished product.

b. Laminated products

Laminated products, for example croissants, Danish and pastry, require two types of fat; in-dough fats that provide the function of giving lubricity and enhancing eating quality, and roll-in fats that create the flaky layers of products. Table 148.11 shows the typical formulas for croissant, Danish, and puff pastry doughs. The roll-in fat further enriches the dough to provide flakiness, tenderness and flavor. The fat's flavor, in particular, is critical because of the high fat content in these products. Between the in-dough and roll-in fats, for example, laminated products can have a fat content that ranges from 10 to 40%, based on dough weight. A good quality Danish, for example, will have at least 25% fat for the roll-in alone. At this high use level, many roll-in fats are margarines or other specially formulated fats incorporating rich, butter-like flavors.

The roll-in fat has to be able to be machined and keep its integrity through the machining process. The plasticity of a roll-in fat must be compatible with the dough. If the dough is soft and the roll-in fat is firm, machining will tear up the dough. On the other hand, if the fat is too soft, it will squeeze into the dough and layer integrity will be lost. If it mixes in, it won't create a distinct layer. To be both machinable and maintain integrity, a roll-in fat will have to have a wide plastic range. It should be smooth and workable over a wide range of temperatures and withstand make-up stresses. Such qualities are controlled by the SFI and its processing procedures. Basically, the solid fat profile, votating processing, and subsequent tempering of the product give those characteristics to the fat. Votated fats, which are produced by emulsifying fats with milk, enzyme products, and color with a votator, are soft and pliable over a broad temperature range.

TABLE 148.11
Typical Formula for Croissant, Danish, and Puff Pastry Doughs

Ingredient	Croissant	Danish Bread	Puff Pastry
	% (baker's percentage)		
Strong flour	70	75	100
Weak flour	30	25	
Milk solid	4	6	
Sugar	8	15	3
Salt	1	1.5	
Water	50	45	50
Egg	10	15	7
Yeast (Dry Instant)	1.5	2	—
Vinegar			2
Butter (Dough-fat)		12	
Shortening (Dough-fat)	5		15
Roll-in fat	45	50	85

Croissant dough is softer, therefore requiring a soft roll-in fat. Finished croissants also are a softer eating product, requiring fat with low solids. To maintain the desired softness, croissant roll-in fat also usually has an emulsifier to enhance the shelf-life of the finished product. It's not as chewy as Danish, nor as firm or with a waxy mouthfeel as puff pastry. Generally, the fat going into a croissant will be almost like a table-grade refrigerated margarine with about a 38.8°C (100°F) melting point. These margarines have low solids—they build just enough structure to give croissants the flake. If a shortening with higher solids is used, a very waxy mouthfeel similar to puff pastry will be obtained.

Danish dough is not as fragile as croissant dough, so the plastic texture of the roll-in fat should be slightly firmer. The finished rolls also are somewhat firmer than croissants with a slightly firmer texture. To meet the differences in both makeup and finished product, the roll-in fat for Danish will have a higher level of solids and a higher melting point than those used for croissants. Another noticeable difference between roll-in fats for the two products is that croissant fats are refrigerated margarines requiring the entire roll-in procedure to be conducted under cool conditions. Danish use roll-in fats that don't require refrigeration, so temperature will not be as critical during makeup.

Puff pastry is very different from both croissants and Danish. Here, the flake is very distinct and very crisp. This is achieved by using very little fat in the dough itself—typically not emulsified to avoid softening the flake. Normally, there will be a half percent fat used just to aid in sheeting. Some of the large operations use no fat in the dough at all, making it tough to sheet. With little in-dough fat, the structure of the finished puff will be largely dependent on the roll-in fat. Puff pastry roll-in fats are traditionally higher in melting point, thereby giving the product its distinct flakes and traditional waxy mouthfeel. While the tough puff pastry doughs can withstand machining with such higher solids fats, these fats still must be pliable so they can spread evenly and machine smoothly.

c. Cakes

Cakes are highly dependent on fat for proper aeration. Although the fat will contribute to crumb texture,

mouthfeel and lubricity as it does with other products, a cake simply would not be a cake if the fat didn't have the right aeration qualities. Many fat characteristics contribute to good aeration. This allows for even distribution of leavening gases and water vapor released during baking. The finished results include increased volume, lower specific gravity and a more desirable texture in the finished product. Proper aeration is a function of the solid fat crystals and requires that they be of the right type, size and shape. Many types of crystals exist; and the ones that form will depend on the temperature and rate of cooling when melted fat is plasticized. The most desirable crystal type for aeration is the beta form because of its small size, uniformity, and stability. The shortening having the correct amount of solids at the right melting range will be more critical for cake making.

An oil is not going to trap air in the same way as a solid shortening. Still, a shortening with too high a solids level can go to the other extreme and create a finished cake that is too firm. For some cakes, a liquid shortening with two to three times the level of emulsifier compared with a solid cake shortening can be used. Because of the fact that the fluid shortening is an oil base, a much more tender, moist product will result with about 20% more volume.

d. Cookies and crackers

Cookies and crackers have slightly altered priorities to the basic fat functions. Part of this is because they have lower moisture levels and depend more on the fat for tenderness and mouthfeel. Besides the fact that both have lower moisture levels, cookies and crackers are different products, and fat selection and application differ greatly with each (38). For example, cookies have relatively high levels of in-dough fat, while crackers do not. Nevertheless, crackers frequently have oil sprayed on topically after coming out of the oven to makeup the difference. Lower-moisture products like cookies also tend to have longer shelf-life than other bakery foods. With longer storage times comes the need for the fat itself to resist oxidative degradation.

Most crackers don't have much in-dough fat. Some do have in-dough fat levels as high as 20% based on flour weight; but for the most part, the fat in a cracker dough is at a low level and serves more of a functional purpose, much as it does in yeast-raised products. It smoothens and softens the dough to improve sheeting and cutting. On the other hand, most crackers with higher fat levels have that fat added after the bake as topical spray oil. This enhances the eating characteristics, or can be used to add to the concept when flavorings are added to the spray oil. But the advantages are not exclusively organoleptic. The oil, for example, protects the cracker from picking up too much moisture. Not all oils are suitable for spraying crackers. With many liquid oils, the finished product may appear too glossy and have an oily taste. Many liquid oils also do not possess the required oxidative stability. As a result, most cracker spray oils typically have a certain level of solids—either naturally occurring, or as the result of partial hydrogenation. Some spray oils, such as coconut oil, are solids that are melted prior to spraying. In general, the solids content, the stability, the taste imparted to the product, and the economics are the major concerns for selecting spray oil.

Shortenings have four primary functions in cookies: lubrication, aeration, eating quality, and spread. Lubrication is a function of the liquid oil fraction in the shortening. By coating sugar and flour particles, the oil reduces mixing time, the energy required for mixing, and smoothens the dough. The oils also help reduce gluten development so the finished product is tender. By coating the flour particles, liquid oil helps to increase mixing tolerance. Last, liquid oil's lubrication properties help prevent the dough from sticking to the baking surface. Oil can be used in place of shortening, if lubrication is the only function desired from the fat.

Aeration is the second major function of fats in cookie doughs and occurs primarily during creaming—usually the first stage of a multi-stage mixing profile. The entrapped air serves much as it does in a cake, providing a framework for the leavening gases and water vapor released during baking. The result is increased volume, uniform and fine grain, and tender crumb. Uniform aeration from batch to batch is critical because of its effect on dough density and weight control during forming or depositing.

Eating quality is the third function fats provide to cookies. Wide ranges of differences in eating quality are possible, depending on the selection of the shortening. Consequently, the target eating quality must be clearly defined (i.e., whether the product should be hard, soft, brittle, chewy, or tender) before product formulation and ingredient selection occur. Process requirements affected by texture, such as packaging or sandwiching, also should be established. Distribution also is a concern, since tenderness may have to give way to delivering cookies to consumers in one piece. In general, higher percentages of fat produce more tender cookies.

The fourth functional property of fats and oils is the effect on spread. Increasing the shortening level increases spread, and can do so quite significantly when using partially hydrogenated vegetable oil. This is not necessarily the case with lard, but lard does give a greater spread than vegetable shortening. Like cakes, cookies can be formulated with either a solid or a liquid fat. Solid shortenings are more frequently used, but a liquid shortening may help tenderize a product in a situation where adjusting other tenderizing ingredients is not desirable. While this replacement can be one-to-one in cakes, this is not usually the case with cookies. Because of the lubricity, one has to take a 15 to 20% reduction in fat when going from a solid shortening to oil in cookies.

When combining fats, especially in a filling or coating application, it's important to consider two issues: fat mobility and fat compatibility. When fat is in a liquid state

it travels, seeking equilibrium as long as there is physical contact. Thus, liquid fat can go from the filling to the cookie (or vice versa). If a filling has too high a liquid fat content, the surface of the cookie may become greasy. Combining incompatible fats may result in softening, changes in the crystal structure, and/or fat bloom. A phenomenon known as the eutectic effect occurs.

Fats and oils play a number of widely different roles in cookies and crackers, and they can be divided into dough fats for both cookies and crackers, filling fats, spray oils, and coating or confectionery fats based on their applications.

i. Dough fat

Dough fat is added to cookie dough for its effect on both the finished product and the process. Fat acts as a lubricant. It keeps the dough from sticking to the feeding and forming equipment. It facilitates mixing by lubricating the other ingredients. And it helps the cookies release from the baking surface without sticking. Depending on the product, the fat content of a full-fat product ranges from 20% to 70% (38). Fat helps control the texture of the finished product, its spread, and its appearance. In most cookies containing fat, a plastic (solid or semi-solid) shortening is first combined with the sugar in a creaming stage. This helps to entrap air, and contributes to the structure or grain of the finished product. It also influences the density of the dough. During creaming, the shortening coats the individual sugar particles. The critical point of this procedure is to be able to coat the sugar without any clumping of the shortening or the sugar. If sugar is not coated, then the melted sugar will recrystallize into little chunks.

Normally an all-purpose shortening for cookies has a 44°C (112°F) melt point, but a range from about 35–46°C (95–115°F) is also suitable, depending on the practical limitations. For example, if there were a high shortening level, a 39°C (102°F) shortening may be suitable to reduce the waxy mouthfeel. As a general rule, the more shortening, the more tender the mouthfeel of the finished product. A higher fat cookie will still be crispy without being hard. However, excess fat, particularly liquid, can result in a greasy, soggy cookie. The more fat in a cookie, the more it will spread.

Fat is particularly important in the texture of a low-moisture cookie. Most of these are baked to 2% to 3% moisture, and without the shortening effect the result is rather hard. Certain production techniques, or the addition of emulsifiers such as mono- and diglycerides, can improve the texture. Emulsifiers affect the dough and the finished product differently, depending on the system and the type of emulsifier used. The choice of emulsifier depends primarily on the effect required, in addition to the product characteristics such as moisture level. In a full-fat system, a distilled monoglyceride increases the tenderness of a cracker or cookie while keeping it crisp. In a low-fat application, the same general effect is obtained, but the emulsifier plays a much more important role. Emulsifiers, principally DATEM (diacetyl tartaric acid esters of mono- and diglycerides) will give a fat-sparing effect. They break the fat up into very fine particles. As with cookies, the purpose of fat in cracker dough is lubrication and texture modification. Traditionally the level used has been lower than in cookies (less than 10%). Because of this level and the lack of aeration, fairly good results can occur with the use of liquid shortenings, as well as solid ones.

ii. Filling fat

Approximately two-thirds of a crème filling consists of fats. In a typical sweet filling, the other third is mainly sugar. Savory versions also can be formulated using ingredients such as peanut butter and cheese powders. The key is to have sufficient fat to coat the dry material completely. The fat used must enhance eating quality, serve as an adhesive for the two halves of the sandwich, and function properly in the sandwiching operation. All of these depend on the solid fat index. Either liquid or plastic fat can be used for the crème depending on the result required. The crème, must remain plastic during the sandwiching operation. If the percent of solid fat is too high, the crème becomes brittle and dry and it will not stick to the base cake. If the percent of solid fat is too low, the crème will be too soft, causing a number of problems; for example, the crème will smear, and it will not hold the base cakes together. From an eating quality perspective, nearly all of the fat must be liquid over 33°C (92°F), or the filling will taste waxy rather than creamy. A fairly steep SFI also enhances mouthfeel by giving a cleaner, cooler melt. For both mouthfeel and processing, the standard SFI for filling fats is similar to that exhibited for coconut oil, at 33°C (92°F).

Some crèmes are aerated. The fat must have a fairly high level of solid fat during the mixing and processing step to incorporate air and maintain it during processing. Liquid fat does not retain air. Fats for crèmes also require a melt point and profile that give a rapid melt away in the mouth. The most effective way to aerate filling crèmes is by running them through a continuous scraped-surface heat exchanger prior to sandwiching. Aeration creates a softer crème, and that may affect the process. Because an aerated cream has increased exposure to air, the fat must have a high degree of oxidative stability.

iii. Spray oil

A coating of oil after baking improves the appearance of crackers. It also reduces the pasty mouthfeel generated by a product that consists mainly of flour. The level of spray oil depends on the equipment capabilities and the geometry of the cracker, as well as the desired organoleptic target. Products with a higher surface-to-volume ratio tend to require a higher level of spray oil. SFI plays a role in the fat selection, but with less importance than for a filling fat. The oil must be liquid during the spray operation, which

isn't too difficult, since this takes place at elevated temperatures.

Stability is important in spray oils. Because the oils are held and used at elevated temperatures, any reactions, including oxidative rancidity, occur more quickly. Spraying increases the exposure to air. The cracker will have a fairly high level of oil on the surface of the finished product, and this also increases the exposure to air. Traditionally, coconut oil was used as the preferred spray oil, but health concerns have changed this. Soybean and cottonseed oil have taken the place of coconut oil. Coconut oil has a unique melting characteristic, and it quickly goes from a solid to a liquid, giving it very good eating qualities. It's very stable, but the downside is that it is mostly saturated fat. Coconut oil is very bland. It has higher solids, so it offers a little dryness on the cracker. It has excellent stability because of the level of saturates. Some other the high-stability products, particularly soy oil, have also been used.

iv. Coating fat

Coating fats for cookies closely resemble those for confectionery, especially those used for chocolate or chocolate-like products. The model for coating fats in terms of the SFI is generally cocoa butter; that is, a steep curve with a melt temperature below 36.6°C (98°F). Cocoa butter is used in some high-end products and real chocolate chips, but in many cases, coatings and chips contain fats other than cocoa butter. Traditionally these were known as hard butters, but the fats and oils industry now uses a number of different terms to classify the types of fats used in coating and confectionery applications (32). Cocoa butter alternatives (CBA) are fats designed to replace some or all of the cocoa butter. Cocoa butter equivalents and extenders (CBE) comprise two different categories. The equivalents are completely compatible with cocoa butter and do not change the melting, processing, and rheological properties of the cocoa butter. The extenders can only be combined with cocoa butter to a limited extent, or they will change the properties. Cocoa butter replacers (CBR) have been engineered to replace or extend cocoa butter, and these are often labeled as "partial" or "complete" replacers depending on the level of compatibility. Often this term refers to only non-lauric fats, or those triglycerides that are low in lauric acid. Cocoa butter substitute (CBS) refers to a fat engineered to replace or extend cocoa butter. Some divide CBS into lauric and non-lauric classifications, and subdivide the categories into hydrogenated, fractionated, and/or interesterified fats.

E. Sweeteners

Sweeteners are one of the major ingredients in bakery products, because very few bakery products are made without some added sweetener. Besides providing the sweetness, sweeteners are also used as food for yeast and to develop crust color, enhance flavor and softness, and extend shelf-life in breads. In cakes, cookies, and other soft-wheat products, sugar helps cream air into the fat, maintain moisture, and contribute to spread of cookies. Granulation of sugars affects creaming, spreading of the cookies during baking, and surface texture of the cookies. As cookies are baked, undissolved sugar melts and the dough spreads on the cookie's baking surface. Coarse forms of granulated sugar dissolve less readily than fine granulations. A coarser granulation of sugar results in less spreading of the dough and more surface cracking of the baked cookie. Surface cracking results from the recrystallization of the sugar at the surface of the cookie. During the initial creaming mixing stage, sucrose particles are coated with a layer of fat. When the cookie dough piece warms in the oven, the fat layer melts away, allowing the water to migrate to the sugar and go into solution. As the sugar changes from solid to liquid, it causes the cookie to flow or spread. Table 148.12 shows the sweetness intensity of sweeteners commonly used for baking.

1. Nutritive Sweeteners

Nutritive sweeteners are based on carbohydrates. How a particular carbohydrate affects a formula is directly related to its chemical composition, physiochemical properties, and its physical form. Chemically, they can be mono- or disaccharides, or complex sugars such as oligosaccharides or dextrins. Physiochemical properties include sweetness, texture, solubility, mouthfeel, humectancy, and flavor. Physically, sweeteners can be solids in various granulations, or liquids.

From brown to white, to liquid, granulated, or powdered, there are many choices of sugars or sweeteners. The type of sweetener chosen depends on the degree of sweetness that is needed, the function of the sugars in the dough or batter being mixed, and the appearance or texture of the baked product. Sugars supply varying levels of sweetness, coloring/browning, moisture retention, and body/bulking, and assist in the creaming and aeration process of batters.

a. Sucrose (Regular refined sugars)

Sucrose (commonly called sugar), a non-reducing disaccharide (β-D-fructofuranosyl-α-D-glucopyranoside) refined from sugar cane or beets, provides a clean sweetness in baked goods with no off-flavors. It is used either alone or in combination with other complementary sweetening ingredients, and is still the most common sweetener in baked goods. Refined sugars in bakery are commonly classified by the size of the grains. The most commonly used are regular granulated sugar, also called fine granulated or table sugar, and confectioners' or powdered sugars. Granulated sugars are further classified into ultra fine, very fine, and sanding sugars, depending on the size of the grains. In general, finer granulations are better for mixing into doughs and batters

TABLE 148.12
The Sweetness Intensity of Sweeteners[1]

Type	Sweetener	Sweetness Intensity[2]	Type	Sweetener	Sweetness Intensity[1]
Solid sugar	Dextrose (Glucose)	0.75	*Sugar alcohol*	Sorbitol	0.5–0.7
	Fructose (Laevulose)	1.8		Mannitol	0.5–0.7
	Galactose (Cerebose)	0.3–0.6		Xylitol	1.0
	Sucrose	1.0		Maltitol	0.8–0.9
	Maltose	0.3–0.6		Lactitol	0.3–0.4
	Lactose (Milk sugar)	0.25		Isomalt	0.45–0.65
	Trehalose	0.45		Hydorgenated starch hydrolysates	0.25–0.75
	Molasses	—			
	Solid starch hydrolysates	—			
Liquid sugar	Liquid sucrose	—	*High-intensity sweeteners—Synthetic*	Saccharin	300–600
	Invert sugar	0.9–1.1		Cyclamate	30
	Liquid starch hydrolysates	0.45–0.75		Aspartame	160–220
	Glucose syrup, 42DE	0.5[3]		Alitame	2000
	HFCS 42%	0.92[3]		Acesulfame K	200
	HFCS 55%	1.0[3]		Sucralose	400–800
	HFCS 90%	1.6			
	Honey	1–1.2	*High-intensity sweeteners—Natural*	Glycyrrhizin	50–100
				Thaumatin	2000–3000
				Stevioside	200–300

[1] From (39) and (40).

[2] These values are only approximate and will vary depending on the individual tasting the sweeteners, concentration, temperature, and the product in which the ingredient is added.

[3] Based on solids.

because they dissolve more quickly. Coarse sugars are likely to leave undissolved grains, even after long mixing. These show up after baking as dark spots on crusts, irregular texture, and syrup spots. Also, fine sugars are better for creaming with fats, because they create a finer, more uniform air cell structure and better volume. Coarse sugar, on the other hand, can be used in syrups, where mixing properties are not a factor.

Confectioners' or powdered sugars are ground to a fine powder and mixed with a small amount of starch (about 3%) to prevent caking. They are also classified by coarseness of fineness. 10X being the finest, it gives the smoothest textures in icings. 6X is the standard confectioners' sugar. It is used in icing, toppings, and cream fillings. Coarser types (XXXX and XX) are used for dusting.

b. Invert sugar

Liquid sucrose is available, and is used primarily for yeast-leavened doughs. Invert sugar, made by boiling sucrose with a dilute acid, which breaks the sucrose into its constituent monomers, glucose and fructose, is still popular in bakery. At 75% solids, the invert syrup is as sweet as sucrose. Invert syrup is hydroscopic and resists crystallization, and is used where moisture absorption and retention are important, such as in fillings and icings. It is also brushed on Danish pastries after baking to help seal in moisture.

c. Fondant

Fondant is sugar syrup that is crystallized to a smooth, creamy white mass. When applied as icing, it sets up into a shiny, nonsticky coating. Because it is difficult to make in the bakeshop, fondant is almost always purchased already prepared, either in the ready-to-use moist form, or in the dry form, which requires only the addition of water. During the manufacture of fondant, part of the sucrose is changed to invert sugar to get the right amount of crystallization. This helps keep the sugar crystals very tiny, which makes a very smooth creaming icing with a good shine.

d. Brown sugar

Brown sugar is mostly sucrose (about 85 to 92%), but it also contains varying amounts of caramel, molasses, and other impurities, which give it its characteristic flavor. Basically, brown sugar is regular cane sugar that has not been completely refined. However, it can also be made by adding measured amounts of these impurities to refined white sugar. Its effects on crust and crumb color are related to the darkness of the sugar—the more molasses, the darker the color. It also has softening capabilities due to its solubility and the presence of the molasses, which contains reducing sugars.

e. Molasses

Molasses is the concentrated sugar cane juice, containing larger amounts of sucrose and other sugars (including invert

sugar). It also contains acids, moisture, and other constituents that give it its flavor and color. Darker grades are stronger in flavor and contain less sugar than lighter grades. Its main function in cookies is flavor, but molasses also adds humectancy due to the presence of reducing sugars glucose and fructose. Its natural acids may react with the leavening system when combined with sodium bicarbonate (baking soda) and also affect the spread of cookies.

f. Fructose

Crystalline fructose (β-D-fructofuranose) is another sweetener that may be used. It has sweetness synergy with other sweeteners, including sucrose, that may allow cost savings. Because it is a reducing sugar it can contribute too much color development if not used wisely. Fructose is sweeter than sucrose, on a weight basis, and lowers water activity (Aw) more effectively. It is more expensive than sucrose and is normally used only in bar fillings where low Aw is critical.

g. Starch hydrolysates

Starch hydrolysates, liquid or dried, are also becoming popular because of their diverse properties and reasonable price. Glucose syrup (also known as corn syrup and high fructose corn syrup (HFCS)) is the most common product realized by bakers. The syrups are made from starch via either acid or enzyme hydrolysis. Corn starch is the most common starting material for syrup production, as it can be completely hydrolyzed to glucose. Typical hydrolysis forms a mixture of maltodextrins, polysaccharides, maltose, dextrins and dextrose (i.e., glucose). Degree of hydrolysis is measured in dextrose equivalents, or DE. Glucose syrup generally come in 24, 36, and 42 DE. The lower the DE, the less sweet and more starch-like the syrup, and the higher the DE, the sweeter and thinner the syrup. Enzyme-converted syrups tend to have a cleaner flavor, and are sweeter and remain free-flowing slightly above ambient temperature as compared to acid-hydrolyzed syrups. Corn syrup, especially the lower DE forms, can help control crystallization, an important formulation consideration for icings and glazes. All corn syrups are hydroscopic, which helps retain moisture, thus extending shelf-life.

HFCS is produced from glucose syrup, in which some glucose is isomerized to fructose by the enzyme glucose isomerase. HFCS varies in fructose content from 42% to 90%. The 42% product is the most often used, because the balance of fructose/glucose most closely resembles sucrose. Different types of corn syrup and other sweeteners have different sweetness values, viscosity, and ability to lower Aw. Blending sweeteners—in particular, corn syrup and HFCS—will not exceed the solubility limits of the sweeteners and helps prevent sugar crystallization.

Corn sweeteners with a high level of monosaccharides depress the freezing point of products. This makes it possible to maintain a soft, chewable texture for fruit pieces in fillings used in products that are consumed in the frozen state. Corn syrup will also influence dough viscosity, cookie texture, and finished color. It is possible to obtain excessive flour starch gelatinization by the addition of corn sweeteners, because sucrose will increase the starch gelatinization temperature more than glucose or fructose. If that is the case, where cookie height increases, spread decreases, and the internal texture changes, then the water level should be decreased to rebalance the formula.

The effects of corn syrup will vary based on the type of syrup used; however, the DE cannot be solely used for selection criteria due to varied processing techniques which produce different sugar profiles of syrup. A high-maltose corn syrup, for example, may have a DE of 48, but will have a functional performance that is very different from that of a 48 DE acid-converted corn syrup.

Corn syrup is available as solids by evaporating the moisture in the syrup, but this is not the best form to use for baked goods, especially for the water limited products, i.e., cookies. Replacing solid sweeteners with an equivalent amount of liquid sweeteners, even on a dry solids basis, may not produce the right dough characteristics. Besides, water is limited in cookie systems and, as a result, dissolving the sweetener solids in water will extend the amount of liquids in the system, making doughs stickier.

Adding corn sweeteners adds fructose and dextrose (both reducing sugars) to the formula, which will contribute to browning. Fructose, lactose, maltose, and dextrose (glucose) are all reducing sugars, so they react with amino acids when heated, forming Maillard reaction compounds that give a brown color and characteristic baked flavors and aromas.

h. Honey

Honey is a natural sugar syrup consisting largely of the simple sugars glucose and fructose, in addition to other compounds that give it its flavor. It contains 41% fructose, 34% dextrose, 2% sucrose, and 18% moisture. Honey varies widely in flavor and color based on the nectar source. Honey has some great functional properties as a sweetener, but due to its high cost it is primarily used for flavoring. Composed mostly of invert sugars, it acts as a humectant. Its reducing sugars promote browning and increase spread. To lower cost, it is often found in blends with HFCS and invert sugar syrups, which can be used as a replacement when combined with honey flavors. Honey also is available in free-flowing powders, flakes, granules, and crystals.

Sometimes honey is used as the sweetening agent in cakes. Actually, the use of honey influences more than simply the sweetness of the cake, because of its liquid content and acidity. Because honey is a liquid, it does not provide crystals to aid in formation of a foam during creaming of the fat; thus honey-containing cakes tend to be a bit coarser than those made with only granular sugar. The acidity is quite variable between different honeys; between 1/12 and 1/2 teaspoon of soda may be needed to neutralize

a cup of honey, but the batter is permitted to remain more acidic in most cases. Honey promotes rapid browning because of the abundance of reducing sugars it adds to the batter. Reducing sugars are very susceptible to Maillard browning reactions. The high fructose content of honey is noteworthy in its effect on browning.

i. Malt syrup

Malt syrup, also called malt extract, is used primarily in yeast breads. It serves as food for the yeast and adds flavor and crust color to the breads. Malt is extracted from barley that has been sprouted (malted) and then dried and ground. There are two basic types of malt syrup, diastatic and non-diastatic. Diastatic malt is produced with high, medium, or low diastase content. It is used when dough fermentation times are short, because diastase in malt breaks down starch into sugars that can be a powerful food for yeast. It should not be used when fermentation times are long, because too much starch will be broken down by the enzyme, resulting in a sticky dough and crumb.

Non-diastatic malt is processed at high temperatures, which destroy the enzymes and give the syrup a darker color and stronger flavor. It is used because it contains fermentable sugar and contributes flavor, crust color, and keeping qualities to breads.

2. Alternative Sweeteners

a. Sugar alcohols

Polyols or sugar alcohols, such as sorbitol, maltitol, and isomalt, are produced by hydrogenation of selected sugars, whereby the reducing aldehyde or ketone chemical function is converted into a non-reducing alcohol group. They can be added to replace solids lost when sugar is removed, and used for sweetener for calorie-reduced or sugar-free baked goods. Because many of these products have humectant properties, it will soften the texture and hold on moisture in baked products (39). The sugar alcohols most often considered when designing sugar-free compound coatings are maltitol, mannitol, xylitol, lactitol, isomalt, and erythritol.

Maltitol is the most commonly used polyol in cookies. With 3.0 calories per gram, the organoleptic and technical properties of crystalline maltitol are similar to sucrose, making it effective in baked cookies or crème fillings. Maltitol is noncariogenic and has 0.9 times the sweetness of sucrose, as well as good water solubility (175 g/100 g H_2O). Maltitol has worked extremely well in chocolate and compound-coating applications, both in chocolate-confection applications and in enrobed products, such as nutritional bars.

Mannitol was used in most of the original formulations 10 to 20 years ago, but was eliminated from most general use due to its high cooling effect with very low heat of solution (−28.9 cal/g) and laxation potential (i.e., low laxation threshold, 20 g/day). Mannitol is permitted by FDA at 2% to 5% levels in most foods.

Sorbitol syrup, with 0.6 times the sweetness of sucrose and 2.6 calories per gram, also can be used in both liquid and crystalline forms in baked foods (e.g., cookies) at a maximum of 30%. Sorbitol causes small rise in blood sugar and is widely used as sweetening agent for diabetics. Sorbitol has high solubility (235 g/100 g H_2O at 25°C) and low heat of solution (−26.5 cal/g).

The FDA permits the use of xylitol in baked foods according to Good Manufacturing Practice (GMP). Xylitol is non-cariogenic and has equal sweetness to sucrose. Although xylitol causes a small rise in blood sugar, it also is widely used as sweetening agent for diabetics. Xylitol has high solubility of 200 g/100 g H_2O at 25°C and very low heat of solution (−36.6 cal/g).

Lactitol monohydrate is a sugar alcohol derived from lactose, and is 30−40% as sweet as sucrose. Lactitol the solubility of 140 g/100 g H_2O at 25°C, heat of solution of −13.9 cal/g, and a low degree of hygroscopicity.

Erythritol is produced from glucose by a fermentation process. With a calorie value very close to zero, it is approximately 70% as sweet as sucrose, and is an excellent ingredient for sweetening crème fillings. In some cases, sugar alcohols, such as sorbitol and manitol, take the place of sugar or corn syrup. These are not metabolized the same way as other sugars, and, therefore, provide fewer calories than the sweeteners they replace. However, because they pass through the gut, they can cause digestive problems (diarrhea) if consumed at a high level. Erythritol has solubility of 61 g/100 g H_2O at 25°C and very low heat of solution (−42.9 cal/g).

b. High intensity sweeteners

High intensity sweeteners can also be used to formulate lower-calorie or sugar-free bakery products. However, the formula must be adjusted. Using artificial, or high-intensity sweeteners in place of traditional nutritive sweeteners presents two major problems in preservation and Aw control.

Acesulfame potassium, or acesulfame K, was discovered in 1967 and approved by the FDA in 1989 for use in tabletop sweeteners, chewing gum, dry mixes, and potential baking applications. It is a high-intensity, non-caloric sweetener approximately 200 times sweeter than sugar, and remains stable in the baking process. It has good stability in aqueous media, but has some bitter aftertaste.

Another heat-stable sweetener is sucralose, trichlorogalactosucrose. It has good stability and is 600 times sweeter than sucrose. It was been approved by Canada in 1991 for use in baking.

Aspartame, a synthetic (nutritive) sweetener that combines the amino acids aspartic acid and phenylalanine, was discovered in 1965. It provides 200 times more sweetening than sucrose and imparts 4 kcal/g. It degrades with the heat of baking (41). Encapsulated aspartame is relatively heat

stable and is an option for baking. But change can still occur during storage of the baked goods when the aspartame is no longer protected. Aspartame could be used to make crèmes and fruit purees for filled cookies.

Cyclamate was discovered in 1937 and approved for food use in Canada. It is a non-nutritive sweetener, 30–60 times sweeter than sucrose. It has good heat stability.

Saccharin was discovered in 1879. It is a non-nutritive sweetener, 300–400 times sweeter than sucrose. Saccharin has good heat and pH stability and can be used as a tabletop sweetener in dry beverage blends, soft drinks, canned fruits, gelatin desserts, cooked and instant puddings, jams, jellies, and baked foods.

F. Dairy Products

Next to water, milk is the most important liquid in the bakeshop. Fresh milk, containing 88–91% water, fulfills the function of gluten development. In addition, milk contributes to the texture, flavor, crust color, keeping quality, and nutritional value of baked products. It is probable that bakers use more nonfat dry milk than any other milk-based product. Table 148.13 shows the composition of milk and milk derivatives. Functional characteristics of milk proteins are summarized in Table 148.14.

1. Fresh Liquid Milk

Whole milk is fresh milk as it comes from the cow with nothing removed and nothing added (except when fortified with vitamin D, calcium, folate, or other micronutrients). It contains 3.5% fat (known as milk fat or butterfat), 8.5% nonfat milk solids, and 88% water. Skim or nonfat milk has had most or all of the fat removed. Its fat content is 0.5% or less.

2. Cream

Various types of fresh cream, primarily differing in fat content, are available. Whipping cream has a fat content of 30~40%, such as light whipping cream (30 to 35%) and heavy whipping cream (36~40%). Ultrapasteurized cream will keep longer than regular pasteurized cream, but it will not whip as well. It often contains vegetable gums or other stabilizers to partially compensate for this decreased whipping ability. Light cream, also called table cream or coffee cream, contains 16 to 22% fat, usually about 18%. Half-and-half has a fat content of 10 to 20%, too low for it to be called cream.

3. Fermented Milk Products

Buttermilk, sour cream, and yogurt are fermented milk products. Buttermilk is fresh, liquid milk, usually skim milk, that has been cultured or soured by bacteria. It is usually called cultured buttermilk to distinguish it from the original buttermilk, which was the liquid left after butter making. Buttermilk is generally used in recipes calling for sour milk. When buttermilk is used in place of regular milk in baked goods such as cakes or muffins, the acidity must be neutralized by adding baking soda to the formula. Then, because the soda and acid together release carbon dioxide, this extra leavening power must be compensated for by reducing the baking powder as follows: add 15 g baking soda and subtract 30 g baking powder for each liter (1 kg) of buttermilk.

Sour cream has been cultured or fermented by adding lactic acid bacteria. This makes it thick and slightly tangy in flavor. It has about 18% fat.

Yogurt is milk (whole or low fat) cultured by special bacteria. It has a custard-like consistency. Most yogurt has additional milk solids added, and some of it is flavored and sweetened.

4. Evaporated and Condensed Milk

Evaporated milk is milk, either whole or skim, with about 60% of the water removed. It is then sterilized and canned. Evaporated milk has a somewhat "cooked" flavor.

Condensed milk is whole milk that has about 60% of the water removed and is heavily sweetened with sugar. It is available canned and in bulk.

5. Dried Milk Products

Dried milk is often used because of its convenience and low cost. Dried whole milk is whole milk that has been dried to powder. It has poor keeping qualities, because it still contains the original butterfat which can become rancid. Therefore, it should be purchased in small quantities and always stored in a cool place. Nonfat dry milk (NFDM), also known as nonfat milk solids, is skim milk that has been dried to a powder. It is available in regular form, and in an instant form which dissolves in water more easily. Milk solids, typically used at a level of 5% to 12% in bread, also add flavor and tenderness, and contribute to crust color.

NFDM contains about 52% lactose, which is a reducing sugar, and contributes to Maillard browning. Bakers use high-heat NFDM almost exclusively because of its effect on loaf volume. High-heat NFDM has typically been treated to 87.7°C (190°F) for 30 minutes to denature the milk proteins. This increases their water-binding capacity and gives a finished loaf with good volume. Low-heat NFDM, on the other hand, has less heat treatment and produces a slack dough with low volume.

6. Whey Products

Whey ingredients are often substituted for milk solids, primarily for cost savings. Dry sweet whey is very economical, and contains a lower level of protein and a higher level of lactose than NFDM. A whey protein concentrate of 34% has roughly the same levels of protein and lactose as NFDM, and thus can be substituted for NFDM on a 1:1 basis in most bakery formulations. Products with higher

TABLE 148.14
Functional Characteristics of Milk Proteins

Functionality	Casein or Caseinate	Whey Protein
Hydration, water binding	Very high, minimum at pH 4.6.	Water-binding capacity increases with denaturation of the protein.
Solubility	Insoluble at pH 4.6.	Soluble at all pH levels. If denatured, insoluble at pH 5.
Viscosity	High at or above pH 6.	Low for native protein. Higher if denatured.
Gelation	No thermal gelation except in the presence of Ca^{2+}. Micelles gel with rennin.	Heat gelation at 70°C or higher, influenced by pH and salts.
Emulsifying ability	Excellent at neutral and basic pH.	Good, except at pH 4–5, if heat denatured.
Foam formation	Good overrun, κ-casein best, followed by β- and as γ-caseins. Poor foam stability.	Good overrun, β-Lactoglobulin better than α-lactalbumin.
Flavor binding	Good.	Retention varies with degree of denaturation.

levels of whey protein concentrate are also available, which add increased nutrition and functionality, such as dough softening. Major physical and chemical differences in milk proteins is summarized in Table 148.15.

7. Cheese

Two types of cheese are used in the bakery, primarily for the production of cheese fillings and cheesecakes. Baker's cheese is a soft, unaged cheese with a very low fat content. It is dry and pliable and can be kneaded somewhat like a dough. Cream cheese is also soft, unaged cheese, but it has a higher fat content at about 35%. It is used mainly in rich cheesecakes and in a few specialty products. Cream is more important in the production of fillings, toppings, dessert sauces, and cold desserts such as mousses and Bavarian creams.

G. Eggs

Eggs should be well understood by the baker, because they are used in large quantities in bakery products and are more

TABLE 148.15
Major Physical and Chemical Differences in Milk Proteins

Caseins	Whey Proteins
Strong hydrophobic regions	Both hydrophobic and hydrophilic regions
Little cystein content	Both cysteine and cystine present
Random coil structure	Globular structure with helical contents
Heat stable	Easily heat denatured and insolubilized
Precipitate in acidic conditions and insoluble at pH 4.6	Stable in mild acidic environment
Precipitated by di- and polyvalent ions	

TABLE 148.16
Average Composition of Fresh Liquid Eggs

	Whole Eggs	Whites	Yolks
Composition		%	
Water	73	86	49
Protein	13	12	17
Fat	12	—	32
Minerals and other components	2	2	2

TABLE 148.17
Functionalities of Eggs in Bakery Products

Function	Comments
Providing structure	Egg protein, like gluten protein, coagulates to give structure to baked product (e.g., high ratio cakes).
Emulsifying of fats and liquids	Egg yolks contain natural emulsifiers, which help produce smooth batters and contribute to volume and texture.
Leavening	Beaten eggs incorporate air in tiny cells or bubbles, which cause expanding when heated and aid in leavening.
Shortening action	The fat in egg yolks acts as a shortening, an important function in products that are low in other fats.
Moisture	Eggs are mostly water and this moisture must be calculated as part of the total liquid in a formula.
Flavor	Eggs brown easily and contribute to flavor.
Nutritional value	Eggs are nutritious.
Color	Yolks impart a yellow color to dough and batters. Eggs brown easily and contribute to crust colors.

expensive than many of the other high-volume ingredients, such as flour and sugar. For example, half or more of the ingredient cost of the average cake batter is for the eggs.

A whole egg primarily contains a yolk, a white, and a shell. In addition, it contains a membrane that lines the shell and forms an air cell at the large end, and two white strands called chalazae that hold the yolk centered. The yolk is composed primarily of lipids, in the form of phospholipids, triglycerides, and cholesterol. The white portion, or albumen, makes up 60% of the egg's weight and contains approximately 15% protein. Egg white is mostly water and protein, plus a small amount of sugar and inorganic ions. As eggs age, the thickness of the white decreases. The decreasing viscosity correlates with a reduced ability to coagulate and form strong protein networks. Table 148.16 shows the average composition of fresh liquid eggs.

Market forms of eggs are: fresh eggs or shell eggs, frozen eggs (whole eggs, whole eggs with extra yolks, whites, yolks), and dried eggs (whole, yolks, whites). Frozen eggs are usually made from pasteurized high-quality fresh eggs and are excellent for use in baking. To thaw, place them unopened in refrigerator for two days; or place in a defrosting tank containing running water at 10 to 15°C for about 6 hours. Stir well before using. Frozen yolks may contain a small amount of sugar (usually about 10%) to keep the components from separating while frozen. Dried eggs are sometimes used in the bakery, though less often than frozen eggs. The whites are frequently used for making meringue powders. Dried egg products are also used in commercial cake mixes. Dried eggs are incorporated in baked goods in two ways: by reconstituting them with water to make liquid eggs, or by mixing them with the dry ingredients and adding extra water to the liquid portion of the formula.

Most wholesale bakeries use frozen whole eggs to facilitate handling and extend ingredient shelf-life. Egg whites aid in air entrapment, while yolks emulsify and tenderize. Yolks also add a desirable golden color, which gives a rich appearance. Powdered eggs may also be used, but generally do not give the same volume to baked goods as fresh or frozen eggs. A starting level might be to add eggs at the same level as sugar in a sweet dough formulation. The functions of eggs in baking are summarized in Table 148.17.

H. Fruits and Nuts

1. Fruits

Nearly any kind of fresh fruit can be used in the production of desserts. In addition, a wide variety of dried, frozen, canned, and processed fruit products are important ingredients in bakery products. Table 148.18 shows the most important fruit products used in bakery products. Each form of fruit offers its own advantages: fresh and frozen fruits undergo minimal processing; syrup-packed

TABLE 148.18
Fruits Commonly Used in Bakery Products

Fresh	Canned and Frozen	Dried	Candied and Glace	Other Processed Fruits
Apples	Apples, *sliced*	Apricots	Cherries	Apricot glaze or coating
Apricots	Apricots, *halves*	Currants	Citron	Jams, jellies, and preserves
Bananas	Blueberries	Dates	Figs	Prepared pie fillings
Berries	Cherries, *both sour and sweet*	Figs	Fruitcake mix	
Grapes	Pineapple, *rings, chunks, nibs, crushed, juice*	Raisins, *light and dark*	Lemon peel	
Kiwis			Orange peel	
Lemons	Strawberries		Pineapple	
Limes				
Mangoes				
Nectarines				
Oranges				
Papayas				
Passion fruit				
Peaches				
Pears				
Pineapple				
Plums				
Rhubarb (actually not a fruit, but a stem)				

TABLE 148.19
Nut Products Used in Bakery Products

Nut Products	Composition	Applications
Almond paste	Two parts finely ground almonds and one part sugar, plus enough moisture to bring it to the proper consistency.	Cakes, pastries, cookies, and fillings.
Marzipan	A sweetened almond paste. Coarse sugar crystals and freshly blanched almonds ground together until perfectly smooth.	Cake decoration and confectionery work.
Kernel paste	A mass of ground apricot kernels and sugar. It has a strong almond-like flavor.	Used as almond paste but less expensive.
Macaroon paste	A mixture of almonds (or marzipan), sugar, egg whites, and sometimes ground rice or other coarsely-ground cereal, such as maize cones, blended together.	Used as almond paste.
Praline paste	Made from almonds and/or hazelnuts and caramelized sugar, all ground to a paste.	A flavoring for icings, fillings, pastries, and creams.

fruits can be used immediately or stored at ambient conditions; dehydrated fruits can be shipped economically.

2. Nuts

Most nuts are available in-shell, whole, halved, chopped or ground, raw, roasted, or further processed into nut butters. They add both flavor and texture to a finished bakery product. Table 148.19 shows the nut products and their properties commonly used in bakery products.

Nuts supply protein, vitamins, and minerals; in their natural states, they are low in sugar and sodium. They are usually low in unsaturated fats and high in fiber. They should be stored under cool, dry conditions. Temperatures just above freezing are recommended to keep the nuts' unsaturated fats from oxidizing and becoming rancid.

Low humidity limits water activity, thus slowing down oxidation as well as microbial growth.

Almonds, coconut, walnuts, peanuts, and pecans are the most important nuts in bakery products. Other nuts, such as hazelnuts, Brazil nuts, cashews, macadamia nuts, and chestnuts, can also be used. In addition, nut products, such as almond paste, marzipan, kernel paste, macaroon paste, and praline paste, are used in a variety of cakes, pastries, cookies, and fillings.

I. Chocolate and Cocoa

Cacao originated in Mexico, but the Spanish found that the cacao tree (*Theobroma cacao*) would grow in any tropical region within about 20 degrees of the equator. Cacao trees are cultivated today throughout South and Central America, the West and East Indies, and West Africa. West Africa produces nearly 70% of the world's output, pooling the resources of the Ivory Coast (by far the largest producer of cocoa today), Ghana, Nigeria, and Cameroon. Other sources include Indonesia, Brazil, Malaysia, and Ecuador. These trees grow about 20 ft. in height and are susceptible to many diseases, as well as damage from the sun and wind. The average cacao tree produces 20 to 30 pods per year, each yielding only about 2 oz. of dried beans. The pods are cut open on the ground and the beans are immediately fermented, then dried in the sun.

Chocolate and cocoa are derived from cocoa or cacao beans. When the beans are fermented, roasted, and ground, the resulting product is called chocolate liquor, which contains a white or yellowish fat called cocoa butter. The most common chocolate products used in bakery are cocoa, bitter chocolate, sweet chocolate, milk chocolate, cocoa butter, and white chocolate. Pure chocolate and its blends can be used to top or coat bakery products, or become an integral part of the product formula, such as chocolate-chip cookies. Bitter chocolate has a lower cocoa butter content and high chocolate liquor content compared to all other varieties, giving it a more intense flavor. Baking chocolate does not include any sugar, but may be flavored with vanilla.

The color of chocolate cake depends on the color of the cocoa or chocolate used, as well as on certain other variables. The color of cocoa and chocolate is influenced by the variety of the cacao beans from which they are produced, including the extent of roasting of the beans, the addition of alkali, and oxidation. As would be anticipated, the deeper the roast, the darker the color of the resulting chocolate or cocoa. On the basis of processing, natural-processed cocoas and chocolates range between pH 5.1 and 6.2, but Dutch-processed products range between pH 6.0 and 7.8. Using cocoa powder in baked-product applications can also convey chocolate flavor. Cocoa powder is the powder remaining after most of the cocoa butter is removed from chocolate liquor, but it can have a wide range (0% to 24%) of cocoa butter content.

Oxidation of a cacao polyphenol to form a phlobaphene is another factor determining the color of cocoa and chocolate. The phlobaphene is responsible for the reddish color seen in cocoa and chocolate to varying degrees, depending on the extent of oxidation (42). The darker the chocolate, the higher the level of flavonols, such as procyanidins, catechins, and epicatechins. The presence of oxygen also influences the shelf-life of cocoa and chocolate, because of the potential for oxidative rancidity of the fat in these products. The major fatty acids in cocoa butter are stearic acid (35%), oleic acid (35%), palmitic acid (25%), and linoleic acid (3%). Cocoa powder ranks highest in antioxidant content, followed by dark chocolate and milk chocolate.

The pH of chocolate or cocoa-containing cakes differs as a result of the cocoa or chocolate, as well as the presence of leavening ingredients. For a desirable flavor, the pH of the batter should be no higher than 7.9. Chocolate-containing cakes range in color from a definite brown at a pH between 6.0 and 7.0, to mahogany between pH 7.0 and 7.5, with increasing redness above 7.5.

Chocolate coatings offer product designers a more economical and flexible option. Chocolate coatings contain added vegetable fat, either in the form of lauric hard butters (from oils such as coconut and palm seed), or non-lauric (domestic) hard butters (from sources such as soybean and cottonseed oils). The type of fat used will have a direct effect on flavor stability, tempering requirements, cocoa butter content, and the total amount of fat contained in the product. Rather than using chocolate, many coated baked products and nutritional bars opt for a compound coating, which is less expensive and sometimes easier to use. Compound coatings use hard vegetable or "tropical" fats in place of cocoa butter.

Chocolate and compound coating differ greatly in preparation for application to the final product. Chocolate contains cocoa butter, which is polymorphic in nature. Cocoa butter requires tempering to obtain the stable V (or beta) crystal form to maintain the proper gloss and snap of a good coating. To properly temper it, the chocolate mass must be cooled below its setting point, then re-warmed to a temperature higher than the melting point of the unstable beta-prime crystals, but lower than the melting point of the stable beta crystals. This is 31–32°C for milk chocolate (because of the milk protein), and 32–33°C for semi-sweet chocolate. The stable seed crystals are allowed to grow and mature, producing a more stable, compact structure that gives the best gloss and shelf life. Compound coatings, on the other hand, are simply cooled to 3–6°C above the melting point of the coating.

Title 21 of the US Code of Federal Regulations (CFR), part 163, states the industry has "specified requirements for specific standardized cacao products" (43). Standards are defined for: cacao nibs, chocolate liquor, breakfast cocoa, cocoa, low-fat cocoa, cocoa with diacetyl sodium sulfosuccinate for manufacturing, sweet chocolate, milk chocolate,

buttermilk chocolate, skim-milk chocolate, mixed dairy-product chocolates, sweet cocoa and vegetable-fat coating, sweet chocolate and vegetable-fat coating, and mild chocolate and vegetable-fat coating. These definitions include specific required ingredients, optional ingredients, and labeling requirements for certain exceptions.

Milk chocolate must contain at least 12% milk solids and not less than 10% chocolate liquor. As stated in the standard of identity, a sweet or dark chocolate must contain at least 15% chocolate liquor and less than 12% milk solids. German chocolate (not a standardized name), a sweet chocolate often used in baking, originated with an English immigrant, Samuel German, who marketed the product in Massachusetts. Bittersweet, or semi-sweet, chocolate is the darkest eating variety, and must contain at least 35% chocolate liquor. In January 2003, the FDA published the final rule (21 CFR, section 163.124) for white chocolate, which contains no chocolate solids other than cocoa butter. It must contain at least 20% cocoa butter, at least 14% total milk solids, and no more than 55% nutritive carbohydrate sweetener.

J. Salt, Spices, and Flavorings

1. Salt

Salt plays a very important role in baking. It is more than just a seasoning or flavor enhancer. It also has functions of (1) strengthening gluten structure and making it more stretchable, and (2) inhibiting the yeast growth for controlling fermentation in bread doughs. For these reasons, the quantity of salt in a bread formula must be very carefully controlled. If too much salt is used, fermentation and proofing are slowed down. If not enough salt is used, fermentation and proofing occur too rapidly.

2. Spices

Spices are plant or vegetable substances used to flavor foods. Plant parts used as spices include seeds, flower buds (such as cloves), roots (such as ginger), and bark (such as cinnamon). The most important spices in bakery products are allspice, anise, caraway, cardamom, cinnamon, cloves, ginger, mace, nutmeg, poppy seeds, sesame seeds, and zest of lemon and orange.

3. Flavorings

Flavorings in general may be divided into two categories: natural and artificial. Natural flavorings are usually more expensive but have a superior flavor. Because flavorings and spices are used in small quantities, it is not much more expensive to use the best quality.

Extracts are flavorful oils and other substances dissolved in alcohol. These include vanilla, lemon, and bitter almond. Emulsions are flavorful oils mixed with water with the aid of emulsifiers such as vegetable gums. Lemon and orange are the most frequently used emulsions. Their flavor is strong.

Vanilla is one of the most important overall flavors used in both bakery products and ice cream. It also serves and performs as a flavor enhancer, especially in premium and super-premium products, where it is commonly used in conjunction with cocoa or chocolate liquor in ice cream to provide a richer, fuller taste. Pure bourbon vanilla from Madagascar, if made properly, is considered the finest vanilla available. It projects a very clean flavor, and it won't over-flavor as artificial flavorings can.

II. PRODUCTION OF BREADS AND YEAST-LEAVENED BAKERY FOODS

Bread is the most important article of food. It has been used for thousands of years since Egyptians used yeast to produce risen loaves in 3000 BC. Many revolutions in bread-making processes, accompanied with the improvements of baking ingredients, have been employed in making and baking; and as a result, from the first flat cake has come the perfect loaf.

Although the minimal ingredients of bread formula are flour, water, yeast, and salt, many other ingredients and additives are usually included in a typical bread formula for desirable bread products (44). These include sugar, shortening, nonfat dried milk (or a substitute), malt, dough strengtheners, crumb softeners, mold inhibitors (e.g., sodium propionate), and oxidants. Table 148.20 shows the functions of ingredients and additives usually used in breads.

Wheat flour contains primarily gluten and starch, with minor components of pentosans (primarily anabinoxylans) and flour lipids, all of which are important contributors to the characteristics of the process and final product. After mixing, hydrated gluten is the continuous phase of wheat flour dough (46–47). During baking, gluten is denatured, and protein crosslinking occurs via formation of disulfide bonds. The resulting network, combined with partially gelatinized starch granules, is most certainly responsible for the semi-rigid structure of baked products (48–49).

Physical and mechanical mixing, chemical reactions (including enzyme-catalyzed reactions), and thermal effects (baking time and temperature), are factors that influence the nature and properties of breads. The ingredients and mixing effects on the dough rheological properties, which results in the changes of bread quality and storage stability, is a very complex process so that it is still not understood well at the molecular level.

A. Types of Yeast Products

Although all yeast doughs are made according to essentially the same basic principles, using yeast to produce a soft and light bread made from flour of wheat or other cereals, by

TABLE 148.20
Functions of Major Ingredients Used in Breads

Ingredient	Function	Descriptions
Flour	Structure	1. Protein (gliadin and gluten)+ water forms viscoelastic material (gluten) to retain gas, which is formed by sugar fermentation and contributes to structure of dough and bread. 2. Starch + water + heat forms a viscous paste that sets gel after baking. During storage the starch crystallizes (retrogrades) and contributes to firmness (major part of staling) of breads. 3. Protein content for bread flour:11–13% (on 14% moisture basis).
Water	Hydration	1. Hydrates protein to form gluten. 2. Hydrates flour non-starch cell wall polysaccharide (pentosans) and mill-damaged starch granules. 3. Solvent, dispersing agent, and medium for chemical and biochemical reactions. 4. Aids dough mobility.
Yeast	Leavening	1. Produces CO_2 and ethanol by fermentation of fermentable sugars. 2. Conditions dough biochemically. 3. Forms flavor precursors. 4. Rate of fermentation is controlled by temperature, nutrient supply, water level, pH, sugar concentration, salt, and level and type of yeast.
Salt	Flavor enhancer	1. Helps control fermentation. 2. Toughens dough by interaction with gluten. 3. Extends required dough development (delayed addition in dough mixing decreases mixing time by 10–20%).
Mineral yeast food	Controls fermentation	1. Water conditioners—calcium salts. 2. Yeast conditioners—ammonium salts. 3. Dough conditioners—oxidizing agents.
Sugar	Energy source for yeast	1. Fermentable carbohydrates. 2. Flavor—residual sugars, fermentation by-products, Maillard-type compounds during baking. 3. Crust color—results of caramelization (sugars+heat) and nonenzymatic browning (reducing sugar+amino group of proteins, amino acids, etc.).
Shortening	Lubrication	1. Ease of gas cell expansion in doughs. 2. Lubricates slicing blades during bread slicing. 3. Extends shelf life. 4. Tenderizes crust.
Dairy products	Nutrition and crust color enhancement	1. Protein (high in lysine) and calcium. 2. Flavor enhancement. 3. Crust color (browning reaction and caramelization). 4. Buffering effect in doughs and liquid ferments.

[1] From (45).

addition of water and salt, it is useful to divide yeast products based on their formulations into the following categories: lean dough products, rich dough products, rolled-in yeast dough products, and specialty dough products.

1. Lean Dough Products

A lean dough is one that is low in fat and sugar, and can be subdivided into three types based on the fat and sugar contents, or inclusion of other grains.

- Hard-crusted breads and rolls, including French and Italian breads, Kaiser rolls and other hard rolls, and pizza. These are the leanest of all bread products.
- Soft breads and rolls, including white and whole wheat breads and dinner rolls. These have a higher fat and sugar content, and sometimes also contain eggs and milk solids. Because they are slightly richer, they generally have soft crust.
- Bread made with other grains, including rye breads. Many varieties of rye breads are produced, with light or dark flours or with pumpernickel flour, and with various flavorings, especially molasses and caraway seeds.

2. Rich Dough Products

There is no exact dividing line between rich and lean doughs, but in general rich doughs are those that contain higher proportions of fat, sugar, and sometimes eggs.

- Non-sweet breads and rolls, including rich dinner rolls and brioches. These have a high fat

content, but their sugar content is low enough to allow them to be served as dinner breads.
- Sweet rolls or buns, including coffee cakes and many breakfast and tea rolls. These have high fat and sugar content and usually contain eggs. They generally have a sweet filling or topping.

3. Rolled-in Yeast Dough Products

Rolled-in doughs are those in which a fat is incorporated into the dough in many layers by using a rolling and folding procedure. The alternating layers of fat and dough give the baked product a flaky texture. Two major types of breads are non-sweet rolled-in dough (e.g., croissants), and sweet rolled-in doughs (e.g., Danish pastry).

4. Special Dough Products

There are also numerous yeast-leavened breads available in bakeshops, such as fried bread (e.g., bread doughnut), and steam bread. The differences between theses are the ways of heating.

B. Steps in Yeast Dough Production

There are nine basic steps in the production of yeast breads. These steps are generally applied to all yeast products, with some variations depending on the particular product.

(1) Scaling ingredients
(2) Mixing
(3) Fermentation
(4) Punching
(5) Makeup [dividing (scaling), rounding, benching (bench proofing, or intermediate proofing), sheeting, molding, and panning]
(6) Proofing
(7) Baking
(8) Cooling
(9) Packaging and storing.

First, all ingredients must be weighed accurately. Special care must be taken when measuring spices and other ingredients used in very small quantities. This is particularly important with salt, which affects the rate of fermentation. During the mixing of yeast doughs, the three main purposes are (1) to combine all ingredients into an uniform, smooth dough, (2) to distribute the yeast evenly throughout the dough, and (3) to develop the gluten.

Three principal mixing methods are used for yeast doughs: the straight dough method, the modified straight dough method, and the sponge-and-dough method (also called sponge method). The processes and comparison of these methods will be discussed later.

The first two purposes of mixing, combing the ingredients into dough, and distributing the yeast, are accomplished during the first part of mixing. The remaining time is necessary to develop the gluten. For gluten development, the flour proteins must first absorb water, then the gluten forms long, elastic strands after the dough is mixed or kneaded. Properly developed dough results in the desirable viscoelastic properties. As the dough is leavened, the gluten strands capture the gases in cells as a result of rising. Rich doughs are generally undermixed slightly, because a greater tenderness is desired for these products. Overmixing is a common error in bread-making. Gluten that is developed too long has stretched nearly as far as it can and loses its elasticity. It then tears instead of stretching, and molding is more difficult. Overmixed and undermixed doughs have poor texture and volume.

Fermentation is the process by which yeast acts on the sugars and starches in the dough to produce carbon dioxide (CO_2) and alcohol. Gluten becomes smoother and more elastic during fermentation, so that it can stretch farther and hold more gas. An under-fermented dough (young dough) will not develop proper volume and the texture will be coarse. A dough that ferments too long or at too high a temperature will become sticky, hard to work, and slightly sour. An over-fermented dough is called an old dough. Dough with weak gluten, such as rye doughs and rich doughs, are usually under-fermented, or "taken to the bench young." Doughs that are to be made into rolls and loaves requiring a great deal of makeup time should be slightly under-fermented to prevent the dough from being too old by the time makeup is completed.

Punching is the procedure of deflating the dough by pulling it up on all sides, folding it over the center, and pressing it down. The dough is then turned upside-down in the container. The purposes of punching are (1) to expel carbon dioxide, (2) to redistribute the yeast for further growth, (3) to relax the gluten, and (4) to equalize the temperature throughout the dough.

In general, the procedure of dough makeup includes dividing (scaling), rounding, intermediate proofing, sheeting, molding, and panning. During dividing or scaling, the dough is divided into pieces of the same weight, according to the product being made. Approximately 10–13% weight loss due to evaporation of moisture from the dough in the oven (i.e., baking loss) should be considered when scaling. Actual baking loss depends on baking time, size of the unit, and whether it is baked in a pan or free standing. Dividing and scaling should be done rapidly and efficiently to avoid over-fermenting the dough.

After dividing and scaling, the dough pieces are shaped into smooth, round balls by stretching the gluten on the outside of the dough. This procedure, called rounding, can be done by hand or machines. Rounding simplifies the later shaping of the dough and also helps retain gases produced by the yeast.

Rounded dough pieces are usually allowed to rest for 10 to 20 minutes to relax the gluten. The relaxed gluten

makes shaping the dough easier. This procedure calls for benching, benching proofing, or intermediate proofing. The dough is shaped into desired shapes (e.g., loaves or rolls) and then placed in pans or on baking sheets. The procedures of sheeting, molding, and panning can be done by hand in a small operation, or by machines in large commercial bakeries.

Proper makeup is of critical importance to the finished, baked product. All gas bubbles should be expelled during molding. Numerous and even distribution of gas cells' nuclei should be created for good texture of baked breads. For both pan breads and hearth breads, the seam must be centered on the bottom to avoid splitting during baking. For units baked in pans, the pan size must be matched to the weight of the dough. Too little or too much dough will result in a poorly shaped loaf.

Proofing (also called final proofing) is a continuation of the process of yeast fermentation, which increases the volume of the shaped dough. Proofing temperature is generally higher than fermentation temperature. Under-proofing results in poor volume and dense texture. Over-proofing results in coarse texture and some loss of flavor. French bread is generally given a long proof to create its characteristic open texture. Its strong gluten withstands the extra stretching of a long proof. Rich doughs are slightly underproofed, because their weaker gluten structure does not withstand too much stretching.

Many changes take place in the dough during baking. The most important changes are (1) oven spring—the rapid rising in the oven due to production and expansion of trapped gases as a result of the oven heat, (2) coagulation of proteins and gelatinization of starches – resulting in a firm and shaped product, and (3) formation and browning of the crust.

For baking breads properly, the oven temperature and baking time must be carefully controlled. Following are the general rules for the baking, but they should be adjusted depending on actual operation conditions.

- Large units are baked at a lower temperature and for a longer time than small rolls spaced apart.
- Rich doughs and sweet doughs are baked at a lower temperature because their fat, sugar, and milk content make them brown faster.

French breads made with no added sugar and long fermentation times require very high temperatures to achieve the desired crust color. For example, lean breads are baked at 205 to 220°C (400 to 425°F). Some French breads are baked at 220 to 245°C (425 to 475°F). Rich breads are baked at 175 to 205°C (350 to 400°F).

Many yeast products are brushed with a liquid, called a wash, just before baking. The most common washes are water, starch paste, and egg wash. Water wash is used primarily for hard-crusted products, such as French bread. Like steam in the oven, the water helps keep the crust from drying too quickly and thus becoming too thick. Starch paste is used primarily for rye breads. In addition to keeping the crust from drying too quickly, the starch paste helps give a shine to the crust. Egg wash is used to give a shiny brown crust to soft breads and rolls, and to rich doughs and Danish.

C. Types of Dough-Making Processes

1. Straight Dough Method

The straight dough method is the simplest mixing method, consisting of only one step. All ingredients are mixed in one operation, and then given a bulk fermentation time (that is, up until molding and proofing) of 1 to $2^1/_2$ hours. This is called short fermentation straight dough. For rich sweet doughs, the straight dough method is modified to ensure even distribution of the fat and sugar. The fat, sugar, salt, milk solids, and flavorings are mixed first until well combined. Then, the flour and yeast are added and mixed to a smooth dough.

A no-time straight dough is made with a large quantity of yeast, taken from the mixer at a higher temperature (up to 32°C 90°F), and given only a few minutes rest before being scaled and made up. The dough is generally transferred to the dough divider within 10 to 20 minutes after mixing. All further processing is the same as for other doughs. Since no-time doughs are not subjected to bulk fermentation, they do not require degassing prior to dividing. However, since the fermentation process does not condition no-time doughs, this must be done through the addition of extra maturing (oxidizing) agents, such as 60–120 ppm ascorbic acid. Although shortening the dough processing time by eliminating the bulk fermentation period is a significant advantage to the baker, the lack of fermentation has an adverse effect on the flavor and shelf-life of the baked product. This process is usually used only in emergencies.

Long-fermentation doughs are fermented for 5 or 6 hours or longer, sometimes overnight, at a temperature of 24°C (75°F) or lower (retarded fermentation). Retarding means slowing down the fermentation or proof of yeast doughs by refrigeration. This may be done in regular refrigerators or in special retarders that maintain a high humidity. The amount of yeast should be adjusted depending on the fermentation temperature and time for good control of fermentation. The advantage of this method is that the long, slow fermentation greatly enhances the flavor of the product.

The major disadvantage of the straight dough method is that the fermentation is hard to control because of fluctuations in temperature and other factors. Doughs often become over-fermented. Therefore, the straight dough method is usually used in small-scale productions.

TABLE 148.21
Advantages and Disadvantages of Sponge-and-Dough and Straight Dough Methods

Ingredients	Sponge-and-Dough Method	Straight Dough Method
Ingredients		
Yeast level	Less	More
Processing		
Processing time (fermentation time)	Longer	Shorter
Labor, power, and equipment cost	Higher	Lower
Fermentation losses	Increased	Reduced
Scheduling flexibility	Inflexibile	Flexible
Correction of overfermented dough	Yes	No
Products		
Flavor	Stronger	Weaker
Staling	Slower	Faster

2. Sponge-and-Dough Method

The sponge-and-dough method involves a two-stage mixing method. First a sponge is made of water, flour, and yeast and is allowed to ferment. Then, the remaining ingredients are mixed in to form the dough. The finished dough may be given a short fermentation, or if the sponge has had a long fermentation, it may be scaled immediately, like a no-time dough. Table 148.21 shows the advantages and disadvantages of sponge-and-dough and straight dough methods.

3. Chorleywood Bread Process

The Chorleywood bread process (CBP) was introduced in 1961 by British Baking Industries Research Association (now part of the Flour Milling and Baking Research Association). It was discovered that the amount of mechanical work expended on the dough during mixing and development had an important effect on bread quality. The amount of work that gave the best results was independent of mixer design, as long as the work took place rapidly. The best results are obtained when a work input of 11Wh (Watt hours)/kg (40 J/g) is applied during a mixing period of two to four minutes. The optimum level of work input, 11 Wh/kg, is five to eight times the amount of work expended during mixing in the straight dough method. The high speed mixing provides the optimal development of the dough (mechanical dough development). The CBP creates cells by trapping air in the dough during mixing and dividing that air into gas bubbles by the mechanical mixing, action. Molding the dough after fermentation does not create the bubble structure. Intensive mixing causes a dough temperature rise of 14–15°C and a water-chilling unit is needed to cool down the dough temperature to 28–30°C. The CBP needs more yeast (double that of the straight dough method) to give the same dough volume increase in the final proof as the straight dough method. More water is also needed when making a dough using this method because of better hydration of flour during intensive mixing.

4. Sourdoughs

Before commercially prepared yeast was widely available, bread making was often started by mixing flour and water and letting this mixture stand until wild airborne yeasts settled on it and began to ferment it. This 'starter' was then used to leaven bread. A portion of the starter was saved, mixed with more flour and water, and set aside to leaven the next batch of bread. This process is still used today, although the sours are generally started with commercial yeast.

The sour is actually a kind of sponge, except that it is allowed to ferment until it becomes strongly acidic. It may be used in two ways: (1) as a sponge in the production of the bread dough, except that a portion is saved for the next bread production, and (2) added to a straight dough as flavoring, i.e., light sour or rye sour.

Microorganisms in sourdoughs consist of two different types: bacteria and yeast. The end products of bacterial fermentation are primarily organic acids; and yeasts produce mainly alcohol and carbon dioxide. The flavor comes from either the various organic acids produced by bacteria, which may or may not react with each other, or by the alcohol from yeast fermentation which forms flavorful esters during the baking process. The most desirable organic acids are produced by heterofermentative lactic acid bacteria. The kind of acid produced depends on the type and the temperature of the material fermented. Generally, lower fermentation temperatures favor the formation of desirable organic acids, such as acetic, citric, lactic, fumaric, malic, and others. Higher fermentation temperatures seem to favor the formation of butyric and slightly longer chain fatty acids, which tend to result in undesirable flavors. The famous San Francisco sour- dough contained a specific lactic acid bacterium (*L. sanfrancisco*), and a unique yeast strain, which thrives under high acid (low pH) conditions and is unable to ferment maltose.

III. PRODUCTION OF SOFT WHEAT PRODUCTS

The number and types of bakery products made from soft wheat are larger compared to hard wheat. Flour milled from soft wheat normally has low protein content and is most suitable for making crackers, cakes, cookies, and pastries.

A. Crackers

In general, crackers contain little or no sugar and moderate levels of fat (10% to 20%) (50–51). Cracker dough, a

hard dough, generally contains low levels of water (20% to 30%), so baking proceeds quickly. Both yeast-fermented and chemically leavened varieties are common. Usually, oils are sprayed and salts are dusted on the surface of baked crackers to improve appearance and eating characteristics. There are three major types of crackers: saltine (fermented), snack cracker (chemically leavened), and savory crackers.

Saltine crackers are produced from fermented dough and the sponge is fermented up to 19 hours. During sponge fermentation, both yeast and beneficial bacteria grow, causing the consistency of the sponge to change drastically. After fermentation, the sponge is mixed with other dough ingredients, and sodium bicarbonate is added to bring the acidic dough back to pH 7.0. The dough is allowed to relax for 4–6 hours. After relaxation/resting, the dough is laminated by multiple pairs of heavy steel sheeting rolls. The purposes of laminating the sheeted dough (6–8 layers) are (1) to repair a dough sheet with holes or tears, (2) to turn the folded dough through 90°C for more uniform stress in two directions, (3) to accomplish a significant amount of work on the gluten development to obtain the characteristic of saltine crackers—a delicate and layered structure, and (4) to introduce other materials, like fat, between layers of dough to create a characteristic flaky structure after baking (50).

Chemically leavened crackers are not fermented but are leavened by chemical leaveners, and are also called snack crackers. They have a final pH of about 6.5. After mixing and a 2–4 hour rest period, the dough is sheeted to form a continuous ribbon that is laminated with a light application of dusting flour between the layers. The remaining processes are the same for both fermented and chemically leavened crackers. Before baking, the dough sheet is continuously cut into crackers and rolled with docking pins. The docking pins press the dough together to facilitate steam release from the crackers and help keep the layers from separating. The high-temperature, short-time bake puffs the thin dough sheets into crackers by vaporizing internal water. Salting is done prior to baking. If oil is sprayed or seasoning applied to the crackers, this occurs after the bake. Low moisture content in the finished product is important for preserving the crisp and brittle, but tender, cracker texture. Most crackers contain approximately 2% moisture.

Flavored or savory crackers are well accepted in the worldwide market. The appropriate flavoring agents are added directly to the dough or to the surface of the crackers after baking. The formulation and process is basically similar to that of soda crackers, with adjustments made to compensate for the fat and moisture content of the cheese for cheese crackers.

Table 148.22 shows the comparison of parameters or property changes as the recipe becomes enriched with fat and sugar for crackers and cookies.

B. Cookies

The word "cookie" means "small cake," and that's more or less what a cookie is. In fact, some cookies are made from cake batter. For some products, such as certain kinds of brownies, it's difficult to to classify them as cakes or cookies. Most cookie formulas, however, call for less liquid than cake formulas do. Cookie doughs range from soft to very stiff, unlike the thinner batters for cakes. This difference in moisture content means some differences in mixing methods, although the basic procedures are much like those for cakes.

Generally, cookies are produced using soft wheat flour that has relatively weak gluten strength (e.g., pastry flour, a blend of soft red and soft white wheat). The cookies usually consist of high fat and sugar contents, and a low moisture content. Mixing weak gluten flour in two or even three stages can control minimal gluten development, usually a desired property of cookie dough. The weak gluten and the relatively high quantities of fat and sugar in the dough allow plasticity and cohesiveness without the formation of a strong gluten network. Water level and sugar concentration play a role in restricting gelatinization and irreversible swelling of starch in the flour: although internal baking temperatures do not reach a level where this change could occur. Shortening in

TABLE 148.22
The Comparison of Parameters or Property Changes as the Recipe Becomes Enriched with Fat and Sugar for Crackers and Cookies

			Short		
Parameter/Properties	**Crackers**	**Semisweet**	**High Fat**	**High Sugar**	**Soft**
Moisture in dough	30%	22%	9%	15%	11%
Moisture in biscuit	1–2%	1–2%	2–3%	2–3%	3+%
Temperature of dough	30–38°C	40–42°C	20°C	21°C	21°C

Baking time	3 min	5.5 min	15–25 min	7 min	12+ min
Oven band type	Wire	Wire	Steel	Steel	Steel

cookies coats the flour; particles and renders them less available to water.

In general, cookies are formulated with high levels of sugar and vegetable shortening, or butter, and low levels of water. Sugar or other sweeteners determine dough and product properties. Sucrose contributes sweetness and flavor, as well as surface color via caramelization. Granulated sugar has several effects on finished cookies. As sucrose content increases, it acts as a hardening agent, creating a crisp, firm texture. Granulation affects creaming, spreading of the cookies during baking, and surface texture of the cookies. As cookies are baked, undissolved sugar melts and the dough spreads on the cookie's baking surface. Coarse forms of granulated sugar dissolve less readily than fine granulations; a coarser granulation of sugar results in less spreading of the dough and more surface cracking of the baked cookie. Surface cracking results from the recrystallization of the sugar at the surface of the cookie. Chemical leaveners, such as sodium bicarbonate and ammonium bicarbonate, are the most common agents used to leaven cookies. Carbon dioxide generated during heating enhances the leavening action of steam and entrapped air. Leavening cookies produces an increase in total volume of the cookie, and an alteration of the width of the cookie in relation to its height, which is referred to as spread ratio. Spread can also be influenced by flour chlorination, by adding emulsifiers to the dough, or by adding certain enzymes.

Besides the moisture content, granulation and ash content of flour are also important for cookie making. Moisture content of flour should be between 12% and 14% in order to provide proper water absorption. The amount of water used for cookie dough making affects how the gluten develops in the dough, cookie spread during baking, moisture retention, and eating quality of finished-products. High ash content flour contains high percentages of pentosans, which are the components of cell wall material and have high water absorbing qualities. The soluble pentosan content is usually higher in soft white wheat than in soft red wheat. Extra water will be added into the cookie dough for desirable consistency when high pentosan content flour is used.

Cookies come in an infinite variety of shapes, sizes, flavors, and textures. Flour, sugar, shortening, and chemical leaveners are the primary functional ingredients of cookies. Varying the types and quantities of these ingredients yields different dough rheology and finished eating qualities. Table 148.23 lists the factors that contribute to the characteristics of cookie doughs and the finished products. Cookies are crisp if they are very low in moisture; while, soft cookies have a high moisture content in the dough and baked products. Moisture is necessary for chewiness, but other factors are also important. In other words, all chewy cookies are soft, but not all soft cookies are chewy. Spread is desirable in some cookies, while others must hold their shape. Table 148.24 lists the factors affecting the dough spread.

1. Commercially-Made Cookies

Commercially made cookies are commonly classified into three categories: rotary-molded, wire-cut, and cutting machine cookies, based on the way the dough is placed on the baking band.

Rotary-molded cookies are produced by forcing a dough into molds on a rotating roll. As the roll completes a half turn, the dough is extracted from the cavity and positioned on the baking oven band. The doughs are often

TABLE 148.23
Factors that Contribute to the Crispness, Softness, and Chewiness of Cookies

	Crispness	Softness	Chewiness
Ingredients			
Proportion of liquid in the mix	Low—a stiff dough	High—a soft dough	High
Sugar	High	Low Hygroscopic sweetener (i.e., honey, molasses, or corn syrup) usually used.	High
Fat	High	Low	Low
Egg			High
Processing			
Gluten development	Minimum	Minimum	Strong flour or gluten developed during mixing
Dough piece	Small size or thin shape	Large size or thick shape to retain more moisture	
Baking	Long enough to evaporate most of the moisture	Underbaking	
Storage	Tightly packed to prevent moisture absorption	Tightly covered or wrapped to prevent drying	

TABLE 148.24
Factors Affecting the Dough Spread

Increase Spread	Reduce Spread
Flour in the Formulation	
Weak flour	Strong flour
Coarse flour particles	Fine flour particles
	High flour water-absorption value
Sugar in the Formulation	
Coarse granulated sugar	Fine sugar or confectioners' sugar
High sugar content	Low level of sugar
Leavening in the Formulation	
High dough pH	Low dough pH
More ammonium or sodium bicarbonate	Less ammonium or sodium bicarbonate
Fat in the Formulation	
Soft doughs due to higher temperature	Cold doughs
Aeration in the Formulation	
Minimum mixing prior to dough standing	Over-mixing of dough
Creaming together with fat and sugar until light	Blending fat and sugar just to a paste
Dough Age and Dough Piece Weight	
A slack batter with a high liquid content	A stiff dough with a low liquid content
Very fresh dough	Old dough
High dough piece weight	Low dough piece weight
Oven Conditions	
Heavily greased pans or oven band	Flouring of pans or oven band
Cold oven band at time of deposition of dough pieces	Warm or hot oven band at time of deposition of dough pieces
Low oven temperature in first zone	High oven temperature in first zone

high in sugar and shortening, but low in moisture [up to 15% (on flour basis)]. The typical dough is crumbly, lumpy, and stiff, with virtually no elasticity. During baking, dough spread and rise are minimized. For a rotary-molded cookie, such as a sandwich-cookie base, dough is forced into molds on a rotating roll. As the roll turns, the baking band extracts the formed dough piece from the molds. To maintain the molded design of the cookie, rotary doughs contain very low levels of shortening and sugar to prevent excessive spread. Oils do not function well in this case, because they lack shortening's ability to hold dough together during the molding process.

Wire-cut cookies are produced by extruding relatively soft dough through an orifice, and then cutting it to size with a reciprocating wire. The doughs are relatively high in fat, sugar, and water [up to 40% (on flour basis)] so that they spread during baking. The spread is desirable, but it must be closely controlled to have the desired geometry after baking. Wire-cut cookies have more sugar and shortening than rotary-molded cookies. Relatively high amounts of water and eggs are used, so that the dough will hold together during the cutting process. Higher water content means that excessive mixing or handling of the dough can lead to over-development of gluten and decreased tenderness. A tender product is produced by incorporating shortening with the flour into the dough or batter prior to adding water. Any fat retards the adsorption of formula water by the flour, and thereby limits gluten protein development. Examples of wire cookies are the chocolate chip type and fig bars.

Cutting machine dough consists of slightly less fat and sugar but more water [up to 25% (flour basis)] than rotary molded dough. The dough is sent through multiple sheeting rolls and made into a continuous sheet. This method for cookie production is slowly being discontinued.

2. Hand-Made Cookies

a. Dough mixing methods

The cookie mixing methods for hand made or homemade cookies are very much like cake mixing methods. The major difference is that less liquid is usually incorporated, so that mixing is somewhat easier. Less liquid means that gluten will become less developed by the mixing. Also it is a little easier to gel a smooth, uniform mix. There are three basic cookie mixing methods: one-stage, creaming, and sponge. These methods are subject to many variations, due to differences in formulas. The general procedures are as follows.

The one-stage method is the counterpart of the two-stage cake mixing method. There is more liquid in cake batters, so it must be added in two or more stages in order to blend uniformly. Low moisture cookies, on the other hand, can be mixed all in one stage. Because all the ingredients are mixed at once, the baker has less control over the mixing with this method than with other methods.

Therefore, the one-stage method is not frequently used. It can be used when over-mixing is not a great problem, as with some chewy cookies.

The creaming method is nearly identical to the creaming method for cakes. Because cookies require less liquid, it is not necessary to add the liquid alternately with the flour. It can be added all at once. The amount of creaming during the creaming stage affects the texture of the cookie, the leavening, and the spread. Only a small amount of creaming is desired when the cookie must retain its shape and not spread too much. Also, if the cookie is very short (high in fat and low in gluten development), or if it is thin and delicate, too much creaming will make the cookie too crumbly.

The sponge method is similar to the egg-foam methods, for cakes. The procedure varies considerably, depending on the ingredients. Batches should be kept small because the batter is delicate.

b. Types and makeup methods

Cookies can be classified by makeup methods, and grouped into pressed (or bagged), dropped, rolled, molded, icebox, bar, and sheet types.

Pressed or bagged cookies are made from soft doughs. The dough must be soft enough to be forced through a pastry bag, but stiff enough to hold its shape. Like pressed cookies, dropped cookies are made from soft dough. Actually, this method can be considered the same as the pressed method, and many bakers use the term "drop" for both bagging out cookies, and for depositing dough with a spoon or scoop. Usually, a pastry bag is faster, and it gives better control over the shape and size of the cookies. However, using a scoop to drop cookies may be preferred when the dough contains pieces of fruit, nuts, or chocolate that would clog the pastry tube.

Cookies rolled and cut from stiff doughs are not made as often in bakeshops and food service operations as they are in homes, because they require excessive labor. Also, there are always scraps left over after cutting. The advantage of this method is that it allows the making of cookies in a great variety of shapes for different occasions.

Refrigerated dough can be molded into the desired shape. For some traditional cookies, special molds are used to flatten the dough, and at the same time stamp a design onto the cookie. The pieces may also be shaped by hand into crescents, fingers, or other shapes.

The icebox, or refrigerator, method is ideal for operations that wish to have freshly baked cookies on hand at all times. The rolls of dough may be made up in advance and stored. Cookies can be easily cut and baked as needed. This method is also used to make multicolored cookies in various designs, such as checkerboard and pinwheel cookies. This procedure is called the bar method, because the dough is baked in long, narrow strips, which are then cut crosswise into bars. Sheet cookies vary so much that it is nearly impossible to give a single procedure for all of them. Some of them are almost like sheet cakes, only denser and richer; they may even be iced like sheet cakes. Others consist of two or three layers added and baked in separate stages.

C. Cakes

Cakes owe their popularity not only to their richness and sweetness, but also to their versatility. Cakes can be presented in many forms, from simple sheet cakes in cafeterias, to elaborately decorated works of art for weddings and other important occasions.

Producing cake requires as much precision as producing breads, but for completely opposite reasons. Breads are lean products that require strong gluten development and careful control of yeast action during the long fermentation and proofing periods. Cakes, on the other hand, are high in both fat and sugar. The most important consideration is to create a structure that supports these ingredients, and yet keep it as light and delicate as possible. Therefore, good and well-balanced formulas, and in understanding of the basic mixing methods are essential for making good cakes.

1. Types of Cakes

Many types of cakes are made by hand at home, or on a commercial scale, such as sponge goods, Swiss rolls, fruit cakes, cupcakes, etc. Cakes are often classified into three categories: batter type, foam type, and chiffon type, based on their formulations and mixing method. Table 148.25 shows the classification of cakes. Foam cake, featuring a large quantity of foam, results from a light, airy batter, and a baked cake with a somewhat coarse texture with moderately large cells. Chiffon cake is a combination of the batter and foam types, including oil and egg yolk as liquid ingredients, an egg white foam, baking powder, sugar, and cake flour. Cakes can also be classified according to the ratio of sugar and liquid to flour weight. For example, high-ratio cakes, one kind of shortened cakes, generally have a sugar to flour ratio of 1:1 or greater, with the ratio of total liquid (water + egg, or milk + egg) to flour is 1.1:1, or greater.

All egg-foam cakes, such as sponge cakes, angel food cakes, and chiffon cakes, are similar in that they contain little or no shortening and depend on the air trapped in beaten eggs for most or all of their leavening. Egg-foam cakes have a spring texture and are tougher than shortened cakes. This makes them valuable for many kinds of desserts that require much handling to assemble. For example, many European-style cakes or tortes are made by cutting sponge cake layers horizontally into thinner layers and stacking them with a variety of rich fillings, creams, icings, and fruits. In addition, sponge layers in this kind of cake are usually moistened with flavored sugar syrup(s) to compensate for their lack of moisture. Sponge sheets for jelly rolls and other rolled cakes are

TABLE 148.25
Types of Cakes

Types	Major Ingredients	Mixing Method	Examples
Batter type	Flour, sugar, egg, milk		
(High-fat cakes)	Usually containing high fat If fat<0.6 flour (w/w), need baking soda or baking powder for leavening		
High ratio type	Sugar ≧ flour	Creaming method Two-stage method Flour-batter method	Yellow layer cake White layer cake Devil cake Butter cake Pond cake Marble cake
Foam type	Egg, flour, sugar		
(Low-fat cake)	No solid fat		
Meringue type	Using egg white for leavening	Angel food method	Angel food cakes
Sponge type	Using whole egg or the mixture of yolk and whole egg for leavening	Sponge method	Sponge cakes
Chiffon type	The combination of batter type and foam type	Chiffon method	Chiffon cakes

often made without any shortening so that they do not crack when rolled. Flour for egg-foam cakes must be very weak, in order to avoid making the cake tougher than necessary. Corn starch is sometimes added to cake flour for these cakes to weaken the flour further.

2. Cake Formula Balancing

It is possible to change cake formulas, either to improve them or to reduce costs. However, ingredients and quantities can be changed only within certain limits. A cake formula in which the ingredients fall within these limits is said to be in balance. Knowing these limits helps you not only to modify recipes, but also to judge untested recipes and to correct faults.

For the purpose of balancing cake formulas, cake ingredients have been classified into four groups: toughenes, tenderizers, driers, and moisteners, according to their functionalities (Table 148.26). The idea of formula balancing is that toughenes should balance tenderizers, and driers should balance moisteners. In other words, if the amount of toughenes increases in a formula, it must be compensated for by increasing the amount of tenderizers.

Many ingredients have more than one function, sometimes even opposite functions. For example, egg yolk contains protein, which is a toughener, but also contains fat, which is a tenderizer. The general rules for balancing cake formulas are listed in Table 148.27. A common practice in balancing a formula is to decide upon the sugar-flour ratio, then to balance the rest of the ingredients against this ratio (Table 148.28).

TABLE 148.26
Four Groups of Cake Ingredients According to Their Functionalities

Group	Functionality	Ingredients
Toughenes	Provide structure	Flour Eggs (whites and yolks)
Tenderizers	Provide softness or shortening of protein network	Sugar Fats (including butter, shortening, and cocoa butter) Chemical leaveners
Moisteners	Provide moisture or water	Water Liquid milk Syrups Liquid sugars Eggs
Driers	Absorb moisture	Flours Starches Cocoa Milk solids

TABLE 148.27
General Rules for Balancing Cake Formula

Cake Type	Original Formula	Balancing Rules
Creaming method cakes	Made with butter or regular shortening	Sugar ≦ Flour Fat = eggs Eggs + liquids (milk and water) = Flour
High-ratio cakes	Using emulsified shortening	Sugar > flour (110 to 160%) Eggs > shortening Liquid (water + water in milk and eggs) > Sugar

TABLE 148.28
Guidelines for Balancing the Cake Formula

Change Made	Balanced by
Increasing liquid (water or milk)	Reducing eggs and shortening.
Increasing eggs	Increasing shortening.
Adding extra milk solids as an enrichment	Adding an equal weight of water.
Adding cocoa	Adding equal or 75–100% of cocoa (w/w).
Adding cocoa or bitter chocolate	Increasing sugar (up to 180% of the flour (w/w)) in high-ratio cakes. Increasing sugar (up to 100% of the flour (w/w)) in creaming-method cakes.
Baking very large units of cakes	Adding less liquid because less water will evaporate during baking.
Adding liquid sugar (honey, corn syrup, etc.)	Reducing other liquids slightly.
Using large quantities of moist ingredients, such as applesauce or mashed bananas	Reducing the liquid.
Using extra-large additions of moist ingredients	Increasing flour and eggs.
Using creamed batters	Using less baking powder than two-stage batters.

3. Methods of Mixing

Cakes are made on all scales, from the small craft baker to the large scale, highly automated cake bakery. The need to incorporate air into the batter means that most small-scale batch cake mixers have a beater or whisk, and the mixing tool follows a planetary motion during beating. For large-scale production, a continuous mixer (batch fed with slurries) will be used, with air being metered into the batter during mixing.

Beside the selection of high-quality ingredients, a thorough understanding of mixing procedures and precise operation is essential for making a good quality cake. There are many mixing methods available for cake making, but each of these methods is used for particular types of formulas, as indicated in Table 148.25. Three main goals of mixing cake batters are (1) to combine all ingredients into a smooth, uniform batter, (2) to form and incorporate air cells in the batter, and (3) to develop the proper texture in the finished product. These three goals are closely related.

Two of the major ingredients in cakes, fat and water (including the water in milk and eggs), are by nature unmixable. The first purpose of cake mixing is to form a water-in-fat emulsion; that is, the water is held in tiny droplets surrounded by fat and other ingredients. Curdling occurs when the fat can no longer hold the water in emulsion. The mixture then changes to a fat-in-water mixture. To avoid causing curdling during mixing, the following rules should be followed: (1) use high-ratio shortening with emulsifiers, (2) keep temperature of ingredients and batter about 21° (70°F) for stable emulsion formation, (3) mix the first stage of the procedure slowly to form a good cell structure to hold the water, and (4) add the liquids gradually or in stages (that is, a little a time). The secondary purpose of mixing is to create numerous air cells in cake batters, which is important for cake texture and for leavening. A fine, smooth texture is the result of small, uniform air cells. Large or irregular air cells result in a coarse texture. In addition, air trapped in a mix helps to leaven a cake when the heat of the oven causes the air to expand. When no chemical leavener is used, this trapped air, in addition to steam, provides nearly all the leavening. Even when baking powder or soda is used, these air cells provide places to hold the gases released by the chemical leavener.

Correct ingredient temperature and mixing speed are necessary for good air cell formation. Cold fat (below 16°/60°F) is too hard to form good air cells, and fat that is too warm (above 24°/75°F) is too soft. Mixing speed should be moderate (medium speed). If mixing is done on high speed, friction warms the ingredients too much. Not as many air cells are formed, and those that do form tend to be more coarse and irregular. In the cases of egg-foam cakes (sponge, angel food, chiffon), air cells are formed by whipping eggs and sugar. For the best foaming, the egg and sugar mixture should be slightly warm (about 38°/100°F). Whipping may be done at high speed at first, but the final stages of whipping should be at medium speed, in order to retain air cells. Table 148.29 shows the guidelines for making meringues.

Both the uniform mixing of ingredients and the formation of air cells are important to a cake's texture. Another factor of mixing that affects texture is gluten development. For the most part, little gluten development is desirable in cakes when cake flour, which is low in gluten, is used. Some sponge cake formulas call for corn starch to replace part of the flour, so that there is even less gluten (the high percentage of eggs in sponge cakes provides much of the structure). On the other hand, some pound cake and fruit cake formulas need more gluten than other cakes, in order to give extra structure and support to

TABLE 148.29
Guidelines for Making Meringues

1. Fats prevent whites from foaming properly.	*All equipment is free of any trace of fat or grease. *Egg whites have no trace of yolks in them.
2. Egg whites foam better if they are at room temperature than if they are cold.	*Remove them from the cooler an hour before whipping.
3. Do not overbeat.	*Overbeaten meringues look dry and curdled *Overbeaten meringues are difficult to fold into other ingredients and have lost much of their ability to leaven cakes.
4. Sugar makes egg white foams more stable.	*Egg whites can hold only a limited amount of sugar (no more than equal to the amount of egg whites) without sacrificing some volume.
5. Mild acids help foaming.	*A small amount of cream of tartar (15 g/kg) or lemon juice is sometimes added to egg whites for whipping, in order to give them more volume and stability.

the weight of the fruit. Thus, some cake formulas call for part cake flour and part bread flour.

The large number of ingredients in cakes makes it possible to make cakes by a tremendous number of methods, including creaming method, sponge method, and chiffon method.

The creaming method, also called the conventional method, was a traditional and standard method for mixing high-fat cakes. Although the development of emulsified, or high-ratio, shortenings has led to the development of simpler mixing methods for shortened cakes containing greater amounts of sugar and liquid, the creaming method is still used for many types of butter cakes. Fat and sugar are first creamed together to produce a light, fluffy foam. Creaming should stop before the appearance of the fat foam changes toward a frothy or runny consistency. Eggs are thoroughly beaten in the creamed fat-sugar foam. Ideally, the air bubbles are uniform, small, and surrounded by fat. Sifted dry ingredients are usually divided into thirds; the first third is stirred in the egg-fat-sugar mixture, then the first half of the liquid is added. The sifted dry ingredients are stirred in alternately with the liquid. The amount of beating that is needed during these alternating additions varies, depending on the ratio of ingredients in the formula. Rich batters that are high in fat and sugar requires more mixing than do leaner formulas.

In the creaming method, flour is added at or near the end of the mixing procedure, so that there is very little gluten development in properly mixed batters. If the batter is mixed too long after the flour is added, the cakes are likely to be tough. In the two-stage method, the flour is added in the first step. But it is mixed with high-ratio shortening, which spreads well and coats the particles of flour with fat. This coating action limits gluten development. It is important to mix the flour and fat thoroughly for the best results. Also, high ratio cakes contain a high percentage of sugar, which is also a tenderizer.

Modified conventional method is similar to the conventional method, except that the egg white is added as a foam at the end of mixing. The yolks, dry ingredients, and liquids are mixed as in the conventional method. The whites are beaten into a foam in which the peaks just bend over, and this foam is then folded gently and efficiently into the batter just prior to baking. The modified conventional method produces a cake very similar to that made by the conventional method, although the egg white foam has the potential to produce a cake of very slightly larger volume.

The two-stage method was developed for use with modern high-ratio shortenings. High-ratio cakes contain a large percentage of sugar, more than 100% based on the weight of the flour. Also, they are made with more liquid than creaming method cakes, and the batter pours freely. The mixing method is a little simpler than the creaming method, and it produces a smooth batter that bakes up into a fine-grained, moist cake. It is called two-stage, because the liquids are added in two stages. The first step is blending the flour and other dry ingredients with shortening. When this mixture is smooth, the liquids (including eggs) are added in stages. Throughout this procedure, it is important to follow two rules: (1) mix at low speed and observe correct mixing times to develop proper texture, and (2) stop the machine and scrape down the sides of the bowl frequently during mixing to develop a smooth, well-mixed batter.

Although there are many types of sponge cakes, they all have one characteristic in common. They start with egg foam that contains yolks. These are usually whole-egg foams, but in some cases the base foam is yolk foam, and egg white foam is folded in at the end of procedure. In its simplest form, sponge cake batter is made in two basic steps: (1) egg and sugar are whipped to a thick foam, and (2) sifted flour is folded in. Additional ingredients, such as butter or liquid, complicate the procedure slightly.

Angel food cakes are based on egg white foams and contain no fat. For success in beating egg whites, guidelines in Table 148.29 should be followed.

Chiffon cakes and angel food cakes are both based on egg-white foams, but there are some differences in the mixing methods. In angel food cakes, a dry flour-sugar mixture is folded into the egg whites. In chiffon cakes, a

batter containing flour, egg yolks, vegetable oil, and water is folded into the whites. Egg whites for chiffon cakes should be whipped until they are a little firmer than those for angel food cakes, but do not over-whip them until they are dry. Chiffon cakes contain baking powder, so they do not depend on the egg foam for all their leavening.

For the muffin method, the liquid ingredients (including oil or melted fat) are combined, the dry ingredients are sifted together, and then the two mixtures are stirred together until blended sufficiently to develop the necessary gluten, resulting in a cake with coarse texture and limited keeping qualities.

In the pastry-blend method, the flour and fat are creamed (first step); sugar, baking powder, salt, and half the liquid are then added (second step); and the last half of the liquid and the egg are then combined (third step).

The single-stage method is a rapid mixing method in which all of the ingredients, with the possible exception of part of the liquid and the egg, are placed in a bowl and mixed together vigorously to disperse all of the ingredients and develop the gluten. Then the egg and any remaining liquid are added, and the total batter is beaten. Shortenings containing mono- and di- glycerides are important when this mixing method is used, because these emulsifiers help to trap air in the mixture and promote a finer texture. Even then, the single-stage (sometimes called the quick-mix) method is very likely to produce a cake with a somewhat coarse texture and limited keeping qualities.

4. Baking

Cakes undergo remarkable changes during baking. Oven temperatures cause expansion of the air and carbon dioxide already in the batter and generate steam from the liquid. The heat also generates additional carbon dioxide production and expansion. Pressures from these leavening agents expand the cells and hold them stretched, while the proteins are denaturing and coagulating, and the starch is gelatinizing. In addition, some moisture is evaporated. An appropriate amount of pressure must be altered greatly under detrimental conditions. An appropriate amount of pressure must be maintained in the cells until the structure of cell walls is set by permanent changes in proteins (coagulation) and carbohydrates (gelatinization).

Oven temperature has an influence on the quality of cakes. At too low a temperature the volume is poor, because some of the cells collapse while others become quite large with rather thick walls. As the temperature increases, the volume improves and so does the texture. However, if the oven temperature is too high, the crust sets while the interior is still fluid. The pressure generated within the fluid mass presses against the crust, causing it either to begin to hump or to peak, depending on the temperature. A higher temperature can be used for a cake that is high in fat and sugar, because these ingredients elevate the temperature at which the proteins in the crust coagulate. This allows a little more time for the crust to remain somewhat flexible and accommodate the pressures produced within the batter.

Using the right pan for baking is also important for making a good cake. The depth of batter in baking pans influences final outcome. Shallow pans enable the heat to penetrate to the center of the batter more quickly, resulting in a cake of optimal volume. The surface is flatter and lighter in color than that which is produced when the batter is baked in a deeper pan. A cake baked in a deep pan also has a greater tendency to crack in the center than does one baked in a shallow pan. Regardless of the depth of the pan, sufficient batter should be used to almost fill the pan when baking is completed. This usually means filling the pans about half full with the batter. Even the material of which the baking pans are made influences the quality of cakes. Heat penetration is the best if the baking pan is dark and/or dull, so that the heat is absorbed efficiently to promote rapid heating of the batter (52). However, this rapid heating causes the sides of the cake to set quickly before the interior has had time to generate much of its potential gas. Humping and cracking, because of the lack of uniform heating within the batter, can be a problem despite the fact that the total volume is increased. Shiny pans absorb heat more slowly because they reflect the heat, so that there is time for the heat to spread into the interior of the cake before the sides of the cake are set. This leads to a cake that has a gently rounded or flat surface, rather than one that is humped, and browning is more delicate and uniform as a consequence of the slower rate of baking. However, volume is reduced a little, and the cells are a bit coarser and the walls a little thicker. Table 148.30 shows the pan preparation for cake baking.

TABLE 148.30
Pan Preparation for Cake Making

Cake Type	Preferred Pan Type	Pan Preparation
High-fat cakes	Layer pans	Grease with a commercial pan greasing. Dust the greased pans with flour and tap out the excess.
Sheet cakes	Sheet pans	Line the pans with greased parchment.
Angel food cakes Chiffon cakes	Tube pans	Do not grease the pan.
Sponge cake		Layer with little on no fat, grease the bottoms but not the sides of the pans.

D. Pastries

The term "pastry" comes from the word "paste," meaning, in this case, a mixture of flour, liquid, and fat. In the bakeshop, pastry refers both to various pastes or doughs, and to the many products made from these doughs. Pastry, whether it is in the form of pie crust or puff pastry, is a simple baked product that contains few ingredients, yet requires some skill for successful results.

Pies are pastries that consist of two distinct components: a relatively thin crust portion that serves to contain the second component, the filling (53). Piecrust is a very simple product in terms of its ingredients: flour, fat, salt, and water. The same ingredients are used for preparing the multilayered puff pastry. The difference between these two forms of pastry is the fat. The fat differs in kind, amount, and method of incorporation into the dough. The fat usually selected for making puff pastry is butter, and it is used in a flour-to-fat ratio (on a volume basis) of 2:1; that is, twice as much flour as fat, which produces a very rich dough. Pastry for pies usually is made with shortening, but sometimes oil, lard, or butter is selected. Although the ratio of flour to pure fat may vary from one pie dough recipe to another, a volume ratio commonly used is 3:1. Skilled workers can make a satisfactory pastry with the leaner ratio of 4:1.

A good piecrust is both flaky and tender. Yet success or failure depends on how the shortening and flour are mixed, and how the gluten is developed. Ideally, the ratio of ingredients, together with the method of preparation, prevents the formation of a gluten network and results in baked crusts that have a friable texture and flaky structure. That texture and structure is largely a function of the critical mixing step during which fat is incorporated as small, but discrete particles.

There are two basic types of pie dough: flaky pie dough, and mealy pie dough. The difference between the two depends on how the fat is blended with the flour. For flaky dough, the fat is cut or rubbed into flour until the shortening particles are about the size of peas. When water is added, the flour absorbs it and develops some gluten. When the dough is rolled out, the lumps of fat and moistened flour are flattened and become flakes of dough separated by layers of fat. For mealy dough, the fat is blended into the flour more thoroughly, until the mixture looks like coarse corn meal. Compared to the flaky pie dough, the more complete coating of the flour with fat has several results. The crust is very "short" and tender because less gluten can develop. Less water is needed in the mix, because the flour won't absorb as much as in flaky dough. The baked dough is less likely to absorb moisture from the filling and become soggy. Mealy dough is used for bottom crusts, especially in baked fruit pies and soft or custard-type pies, because it resists sogginess. Flaky doughs are used for top crusts and sometimes for prebaked shells.

Puff pastry is one of the most remarkable products of the bakeshop. Although it includes no added leavening agent, it can rise to eight times its original thickness when baked. Puff pastry is a rolled-in dough, like Danish and croissant doughs. This means that it is made up of many layers of fat sandwiched between layers of dough. Unlike Danish dough, however, puff pastry contains no yeast. Steam is created when the moisture in the dough is heated, and is responsible for the spectacular rising power of puff pastry. Puff pastry, or puff dough, is one of the most difficult bakery products to make. Because it consists of over 1000 layers, many more than in Danish dough, the rolling-in procedure requires a great deal of time and care.

Butter is the preferred fat for rolling in because of its flavor and melt-in-the-mouth quality. Special puff pastry shortening is also available. This shortening is easier to work, because it is not as hard when refrigerated, and because it doesn't soften and melt at warm temperatures as easily as butter does. It is also less expensive than butter. However, it can be unpleasant to eat, because it tends to congeal and coat the inside of the mouth. The quantity of roll-in fat varies from 50 to 100% of the weight of the flour. If the lower quantity of fat is used, the dough should be left slightly thicker when rolled out. Puff pastry that is low in fat will not rise as high and may rise unevenly. This is because there is less fat between the dough layers, so that the layers are more likely to stick together.

IV. SHELF-LIFE OF BAKERY PRODUCTS

Bread begins to undergo deteriorative changes commencing with removal from the oven. One of the first changes is thought to be retrogradation (increasing crystallinity caused by crosslinkage of starch molecules) of amylose released from starch granules during gelatinization in the oven. The rather crystalline and firm character of the crumb that develops as bread is stored for a day or more may be the result of retrogradation within the starch granules, and probably involves changes in the physical configuration of amylopectin (perhaps some folding of the branches). This retrogradation is reversible upon reheating of the bread, but recurs when the warmed bread cools once again.

Moisture levels also are involved in the staling process. There is a reversal in the location of water; some of the water that migrated to starch from gluten during baking returns to the gluten proteins. Water also migrates from the center of the loaf toward the crust, causing the crust to gradually increase in leatheriness, while remaining rather soft. This migration occurs even when evaporation from the crust is prevented.

Storage temperature has an effect on staling. Refrigerator storage accelerates firming of the crumb compared with storage at a warm room temperature—the firmness after a day at 8°C being about the same as that after 6 days at 30°C. The advantage of refrigerator storage is only the inhibition of mold growth in breads made without preservatives. Freezer storage is effective in inhibiting the firming of the crumb.

A. The Mechanism of Staling

Bread staling has been a problem for thousands of years, and it is responsible for huge economic losses to both the baking industry and the consumer. In a market of approximately 20 billion pounds of bread produced annually, about 3% (600 million pounds) of them were returned as unsalable because of staling (54). Staling was defined as a term that indicates decreasing consumer acceptance of bakery products caused by changes in crumb, other than those resulting from the action of spoilage organisms (55). The most widely used indicator of staling is measurement of the increase in crumb, firmness, which is the attribute most commonly recognized by consumers. However, bread staling is a very complex process. Neither the bread system nor the staling process is understood well at the molecular level (56–59). To date, water migration and transitions in the starch fractions, and changing starch from an amorphous structure to a partially crystalline one (56) are thought to be the two most important factors controlling the changes in texture of breads during storage.

During baking of bread dough, the starch granules are generally gelatinized, but little else other than restricted swelling followed by collapse happens to them because of the limited amount of water present in the dough system (57). Thus, deformed wheat starch granules can be isolated from the crumb (58). The small amount of amylose that leaches from granules during baking in the limited moisture system of bread dough retrogrades upon cooling and rapidly becomes unextractable (60–61). Even if amylose does leach from granules, by the time bread has completely cooled, any interstitial amylose will have retrograded and is unlikely, therefore, to play a major role in subsequent staling events. Therefore, freshly baked and cooled bread is an elastic system containing swollen wheat starch granules that are still largely intact, but may be deformed.

Bread staling falls into two categories: crust slating and crumb staling (62). Crust staling is generally caused by moisture transfer from the crumb to the crust (63), resulting in a soft, leathery texture, and is generally less objectionable than is crumb staling (64). Crumb staling is more complex, more important, and less understood. The firmness of bread varies with position within a loaf, with maximum firmness occurring in the central portion of the crumb (65).

The major theories on the staling mechanism are reviewed in cursory way in Table 148.31. It summarizes the factors affecting bread staling during storage: (1) starch retrogradation, especially amylopectin retrogradation, which plays an important role, but which alone is not responsible for bread staling, (2) gluten proteins and gluten-starch interaction also play an important role, and (3) moisture migration is also involved in staling. Overall, it is probable that several factors play a role in the bread firming process, but the large volume of data that implicates amylopectin retrogradation as a key factor, and the information that gluten is also involved cannot be ignored. Table 148.32 shows the hypotheses conurning the effects flour components on the staling mechanism.

Bread staling is unquestionably a complex process. In addition to the effects of flour components, formulation, and the processing conditions (103), many other factors affect staling rate of bread during storage: storage temperature,

TABLE 148.31
Factors Affecting Staling Rate of Bread During Storage

Factors	Findings	References
Storage temperature	The rate of staling has a negative temperature coefficient.	(66)
	Bread staling is correlated with starch recrystallization at storage temperature with the maximal rate at 4°C	(67)
Moisture migration	Drying out of the bread does not explain staling, but may accelerate reactions leading to staling.	(68)
Moisture redistribution between crumb and crust	Moisture gradient forms in the loaf as baked bread begins to cool, and moisture migrates from crumb to crust.	(69–70)
Moisture redistribution among components	Transfer of moisture from starch to gluten during aging.	(71–72)
	Transfer of moisture from gluten to starch as the starch crystallizes. The decrease in water mobility in bread upon staling is due to incorporation of water molecules released from gluten into crystalline structure of starch that develops upon staling.	(72–79)
	Gluten undergoes a 1st-order transformation resulting in the release of water from gluten and absorption of this water by retrograding starch.	(80–82)
	Amylopectin crystallization in bread requires both microscopic and macroscopic redistribution of water, so that there is sufficient moisture present at the locus where crystallization take place to plasticize polymer chains, so that they are mobile enough for crystallization to occur and for incorporation into β-type crystal lattices (36 water molecules in the unit cell, compared with α-type which has only 8 water molecules in the unit cell).	(79, 83–84)

TABLE 148.32
Hypotheses Concerning the Effects of Flour Components on the Staling Mechanism

Component	Hypotheses	References
Starch	Gradual change in the starch components from amorphous to crystalline forms is important to the staling process.	(71, 85)
	Degree of crystallinity of bread crumb was inversely related to its firmness, so that starch crystallization and bread firming were separate processes.	(86)
Amylopectin	Amylopectin was the fraction of starch responsible for staling, because heating stale bread above 50°C can restore the loaf to its original freshness.	(87–91)
	Adding 5% retrograded waxy corn starch to bread formula decreased gelatinization and reduced the firming rate.	(92)
	Retrogradation of amylopecitn cannot be the only factor affecting firming.	(93)
Amylose	Amylose fraction was involved in staling of bread through 1 day only, and the role of amylose in bread staling may be merely one of diluting amylopectin.	(94)
	Reoroganization of intragranular amylose enhances the rigidity of starch granules during staling.	(95)
	Amylopectin retrogradation is part of the staling process, but is not solely responsible for the observed changes in texture.	(96)
	Amylose-amylopectin aggregation was responsible for the changes that occur during aging of bread crumb.	(97)
Protein	Starch-gluten interactions are somehow involved in the firming process.	(98–99) (100)
	The differences in molecular mobility in an aged bread are attributed to the role of gluten and/or redistribution of water in the amorphous regions of the bread.	
Pentosans	Water-soluble and –insoluble pentosans retard staling or have no effect on the staling rate.	(60–61)
	Arabinoxylan-fortified breads exhibited a greater rate of starch retrogradation, because of their higher moisture content, while having softer crumbs than did controls.	(101–102)
Lipid	Flour lipids have an effect on the antifirming action.	(102)

moisture migration, moisture redistribution between crumb and crust, and moisture redistribution among components (Table 148.31).

B. Antistaling Additives

Although the mechanism of bread staling is not well understood, baking industries throughout the world have tried to inhibit staling through the addition of ingredients such as enzymes, lipids, emulsifiers, sweeteners, and other chemicals. The addition of sweeteners to provide fermentable solids, influence crust color, improve crumb texture and softness, and increase shelf-life is well documented. For over twenty years, fructose/glucose syrups and corn syrups have shown the ability to retard staling through their ability to bind moisture. α-amylases from malted cereal, fungi, and bacteria, are the most commonly used enzymes for the retardation of bread staling. Numerous research projects have been conducted to understand its mechanisms (Table 148.33). Although the mechanism of the antistaling effect of α-amylases has been debated, it appears that starch hydrolysis products are involved in inhibition of staling. But the hydrolysis products must be of a unique type; perhaps either maltotriose and maltotetraose, or products larger than those present in traditional maltodextrin preparations.

In addition to α-amylase, lipases (specifically 1,3-specific lipases), lipoxygenases (111–112), nonstarch polysaccharide-modifying enzymes (such as endoxylanase, β-xylosidase, and α-L-arabinosidase) (113), and protease are also reported to have a crumb softening effect when enzymes are added. The major purpose of adding proteases to breads is to improve flavor profiles, flow characteristics, machining properties, gas retention, and mixing time (114–115). However, given evidence that protein has a significant role in the bread staling mechanism (98,105,116), it is likely that modification of the gluten network structure via enzyme-catalyzed proteolysis would have an effect on bread staling. It is also possible that liberation of water molecules concurrent with protein hydrolysis could enhance amylase activity (117).

Emulsifiers of various types are widely employed in the baking industry as dough strengtheners and/or crumb softeners (103). Table 148.34 lists that the emulsifiers can be

TABLE 148.33
Effects of α-amylase on Bread Staling

Mechanism	References
α-amylases produce a partially degraded amylopectin that is less prone to crystallize, and its ability to produce partially degraded amylose is responsible for rapid formation of a partially crystalline polymer network that resists later rearrangements.	(95, 104–105)
α-amylases produce low molecular-weight dextrins (DP 19–24) that interfered with the retrogradation of starch.	(17, 63, 106–107)
α-amylases produce maltooligosaccharides (DP 3–11) that disturb water structure and promote ordering and aggregation of starch molecules.	(108–109)
Maltotriose and maltotetraose were directly responsible for retarding retrogradation in bread, suggesting that these oligomers were of the right size to interfere with starch-gluten interactions.	(110)
Maltotriose and maltotetraose might hold water around starch molecules and inhibit starch-starch interactions.	
Maltooligosaccharides (DP 3–8) produced by α-amylases are not themselves responsible for antistaling, but their presence is simply correlated with a key modification of starch granules that is related to reduced staling, possibly by reducing gluten-starch interactions.	(99)

TABLE 148.34
Commonly Used Emulsifiers in Bakery[1]

	Functionality		
Emulsifier	Dough Strengthener	Dough Softener	Aeration Aid
Lecithin (LC) or Hydroxlyated lecithin (HLC)	×		
Mono- and diglyceride (MDG)		×	×
Acetylated MG (AMG)			×
Glycerol-lacto ester of fatty acid (LMG)			×
Diacetyl tartaric acid esters of MG and DG (DATEM)	×	×	
Succinylated MG (SMG)	×	×	
Ethoxylated MG/DG (EMG)	×		×
Stearoyl monoglyceride citrate (SMGC)	×		
Propylene glycol mono- and diester (PGMS)			×
Polyglycerol ester (PGE)	×		×
Sucrose ester (SUE)	×		
Sorbitan monostearate (SMS)			×
Polyoxyethylene sorbitan monostearate (Polysorbate 60, PS 60)	×		×
Polysorbate 65 (PS 65)			×
Lactylic ester of fatty acid (SLA)	×	×	×
Ca-stearoyl lactate (CSL)	×	×	
Na-stearoyl lactate (SSL)	×	×	×
Sodium stearoyl fumarate (SSF)	×	×	

[1] From (120).

used in bakery products based on their functionality. Monoglycerides (MG) are the most commonly used in baking to delay staling in bakery products. The mechanism of the antistaling effect of MG is still unknown, but it is concluded that reduction in crumb firmness is probably the result of the interactions of MG with amylose. The physical state of MG is an important factor in the amylose-MG complexation ability, which decreases in the descending order of MG physical states: α-type crystalline gel > β-type crystalline hydrate > nonhydrated powder (118). Diacetyl tartaric acid esters of monoglycerides (DATEM) were reported to be as effective as antistaling agents in bread as sodium stearoyl lactylate (SSL) or ethoxylated monoacylglycerols (EMG) over 5 days of storage (119).

In addition to enzymes and emulsifiers, ingredients including shortening, hydrocolloids (gums), and damaged or modified starches are also reported as having the ability to retard the staling in bakery products (62, 121).

The uses of hydrocolloids and modified starches are attributed to their great water holding ability, which inhibits the movement of moisture this retards staling because moisture redistribution is a requirement for staling to occur (122).

CONTENTS

I. HISTORY

Cacao trees (*Theobroma cacao*) originated in the Americas and have been cultivated for at least an estimated 4,000 years where they thrive under conditions of semishade, warmth, and high humidity. Chocolate was important in Mayan and Aztec mythology and used as currency. A crude, unsweetened foamy beverage called chocolatl was served only to the noble ruling class. Early Spanish explorers found this bitter liquid could be improved with the addition of sugar, and it soon became the rage of Spanish nobility. It then spread to Italy, Holland, France, and England.

C.J. Van Houten of Holland patented a cocoa press that was able to remove cocoa butter from the chocolate liquor to produce cocoa powder. This was in response to the difficulty people experienced in digesting the full fat chocolate beverage and dispersing the chocolate in water. Mr. Van Houten is also credited with alkalizing (Dutch process) cocoa, which gives a darker color and a less acid flavor. The pressing of chocolate liquor resulted in an "excess" of cocoa butter. It was found that a superior product could be made when warm water was replaced with cocoa butter. Fry and Son in 1847, and Cadbury in 1849, were among the first to sell solid eating chocolate. The basic formula of chocolate liquor, sugar, and cocoa butter continued until 1875, when Daniel Peter developed a method of adding condensed milk to chocolate liquor and sugar. Moisture was removed from the chocolate "milk crumb" and replaced with cocoa butter to maintain a smooth mouth feel. Thus milk chocolate was born.

II. CULTIVATION, HARVESTING, AND CURING

The commercial cultivation of cacao trees is generally within a 20° latitude of the equator with a rainfall of 45–100 inches (114–254 cm), and a temperature of 70–90°F (21–32°C). Major producing areas include Africa (Ghana, Nigeria, Ivory Coast); South America (Brazil, Ecuador, Venezuela); West Indies (Dominican Republic); Asia and Oceania (New Guinea, Malaysia, Indonesia).

The cacao tree will usually attain its full height in about ten years. Though trees may grow to be 40 feet (1200 cm), they are usually pruned to 15 to 25 feet (450–750 cm) to facilitate harvesting. Flower clusters appear only on the trunk and main branches. Approximately five to six months later, 20 to 30 fruit pods develop. The growth cycle is continuous, so a tree may bear leaves, blossoms, and pods simultaneously. However, the main fruiting seasons occur between October and February.

The ripe pods are elliptical in form, seven to ten inches (18–25 cm) in length, and three to five inches (8–13 cm) in diameter. The pods contain approximately 20–50 seeds surrounded by a mucilaginous pulp. Each dried cocoa bean weighs approximately 1 gram. When dried, the beans from each pod weigh between 1.5–2 ounces (42–56 g). While yields can vary greatly, the average tree produces 20–30 pods; so each tree's output is between two to three pounds (0.9–1.4 kg) of commercial cocoa beans.

The region where the cocoa beans are grown and the variety of the bean can greatly affect characteristics for flavor, color, hardness of butter, etc. There are three major types of cocoa beans: Forastero, which accounts for the majority of the beans; Criollo, the flavor beans; and Trinitario, which are basically a cross between Criollo and Forastero. The bulk beans are generally dark brown in color with a strong, bitter flavor. Flavor beans are lighter in color with a mild, nutty flavor. The beans are blended to produce the desired end product.

Mature cacao pods turn yellow, orange, or purple in color. The pods are split open and the beans and pulp scooped out and heaped into boxes or baskets for fermentation (anaerobic and aerobic). The beans are allowed to ferment for 3 to 6 days, depending upon the type of beans used, batch size, temperature, and aeration. Aeration (turning) of the beans promotes bacterial activity and ensures uniform fermentation. Fermentation and drying processes have major influences on the quality of the beans used in making chocolate.

The beans are subsequently dried (naturally or mechanically) to a moisture content of less than 8 percent to prevent mold growth, with the optimum being 6 to 6.5 percent.

Cocoa beans arriving in the Untied States are usually inspected and fumigated at the ports when received. Beans are inspected for mold, infestation, filth, degree of fermentation, and bean size. To maintain quality, they should be stored in cool, dry, and well ventilated warehouses.

A cleaning step is required to produce a wholesome product with minimal microbiological risks, as well as to remove extraneous materials. On a dry basis, the beans are approximately 87.1 percent nib (cotyledons), 12.0 percent shell, and 0.9 percent germ. The nib contains about 55 percent cocoa butter fat (1).

III. PROCESSING OF COCOA BEANS

Roasting serves to develop the flavor and aroma of the beans. There are several roasting methods, which include whole bean, nib, and chocolate liquor roasting. Roasting can take anywhere from 15 minutes to 2 hours. In whichever roasting method is used, the nibs are separated from the shell (winnowing). Depending upon the degree of roast, nib moisture is about 1.5 to 3 percent. Federal standards allow no more than 1.75 percent shell in the nib portion used for chocolate production. Cocoa bean shells have little commercial value. The germ portion is also removed, since it is hard and gritty.

After roasting, the nibs are ground to a liquid state, which is called chocolate liquor. The heat and friction from the grinding process will rupture the cell walls of the nibs to release the valuable cocoa butter. This liquor (containing approximately 55 percent cocoa butter) will solidify upon cooling.

In the initial stages, the processing for cocoa and chocolate are essentially the same. The beans are cleaned, roasted, and shelled. The manufacturing of cocoa and chocolate though, involve two separate processes. See Figure 149.1.

IV. MANUFACTURING OF COCOA POWDER

Cocoa cake and cocoa butter are produced from chocolate liquor by hydraulic pressing. The hot liquor is subjected to more than 6,000 PSI. The cocoa butter flows out, leaving the cocoa cake. This cocoa butter contains small amounts of cocoa powder, which are filtered out to maintain consistent color and flavor. The butter may be further refined, bleached, and deodorized (via steam distillation) to yield a very bland, clean tasting cocoa butter.

The cake is then ground to the desired degree of fineness — usually 95 to 99 percent will pass through a 200-mesh screen.

The cocoa cake will generally have a fat content ranging from 10 to 24 percent. Powders with less than 10 to12 percent cocoa butter are known as low fat cocoas. Medium fat cocoa contains 10 to 18 percent fat, while high fat or "breakfast cocoa" has 22 to 24 percent fat. Approximately 95 percent of the cocoa powders on the market today are

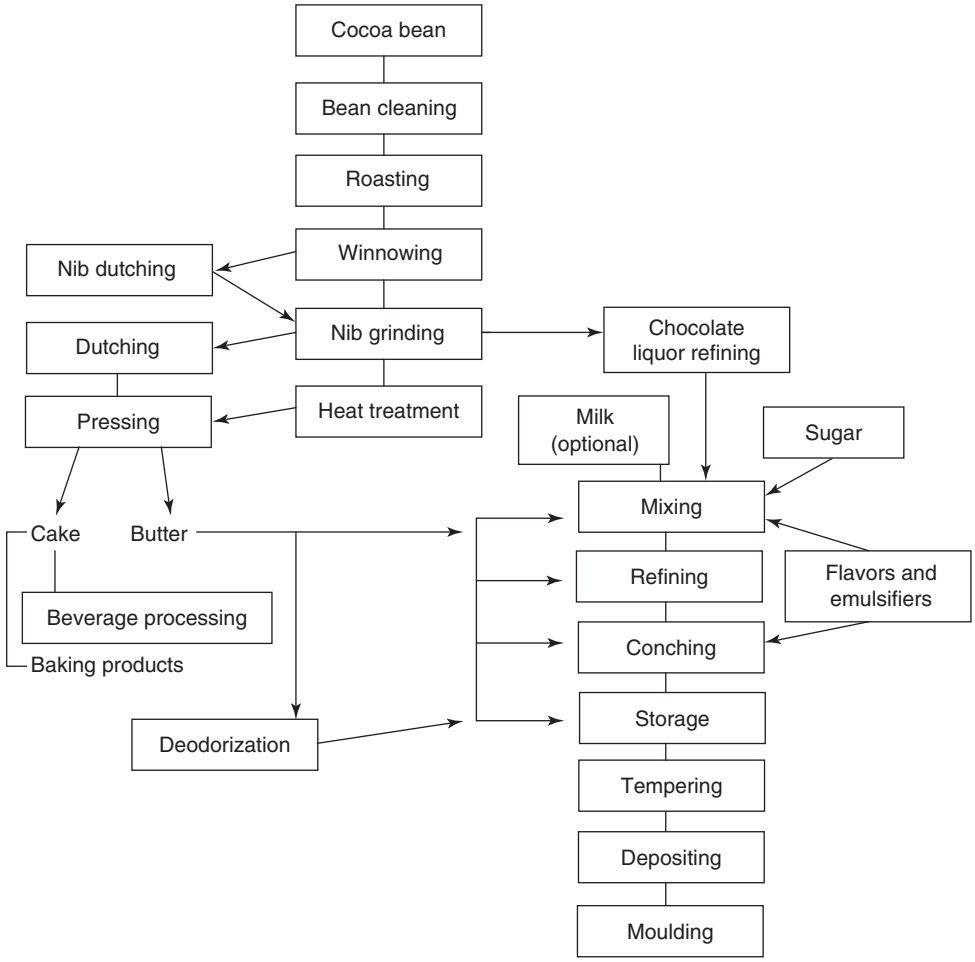

FIGURE 149.1 Typical chocolate production flow chart.

the medium fat variety. The FDA has established standards for various types of cocoas. See Table 149.1.

Cocoa powder not treated with alkali is often referred to as natural cocoa. The addition of alkali was first used by Van Houten in 1828; hence, it is also known as "Dutch" process cocoa.

The alkalization process raises the pH of the cocoa powder. The pH for fermented beans ranges between 5.2 and 5.6. Alkalized cocoas have a pH between 6.8 and 7.5. Black cocoas, used for color, may have a pH as high as 8.5 (3). FDA standards allow a maximum of 3.0 percent potassium carbonate per 100 pounds (45 kg) of nib weight equivalent. The purpose of alkalization is to neutralize the acidity of the cocoa, resulting in a milder, less astringent flavor and a range of colors (from light brown to red, and even black).

Various formulas, equipment, and processes are used to alkalize the nibs, liquor, or powder. This allows for a wide range of cocoa powders to be produced. As such, alkalized cocoa powders are in greater demand than natural cocoa powder. See Table 149.2.

V. MANUFACTURING OF CHOCOLATE

Dark, milk, and white chocolate involve certain basic operations: ingredient mixing, refining, conching, standardization of viscosity, and tempering. Like cocoa powders, the chocolate liquor (white chocolate uses cocoa butter only) may undergo alkalization prior to further processing. The FDA has issued standards of identity for milk, dark, and white chocolate. See Table 149.1.

A. Ingredient Mixing

The basic ingredients, including chocolate liquor, sugar, cocoa butter, milk products (for milk chocolate), emulsifiers, and flavors are blended together. The result is a paste with a rough texture and plastic consistency.

B. Refining

Refining serves to reduce the particle size of the mass, and thus increase the surface area, resulting in a smooth texture.

TABLE 149.1
U.S. Standard of Identity for Cacao Products Code of Federal Regulations (CFR), Title 21- Food and Drugs

21 CFR Reference	Product	Chocolate Liquor (%)	Milk Solids (%)	Comments
163.111	Chocolate Liquor	100	0	50–60% fat Optional ingredients 1. Other names: Unsweetened chocolate, bitter chocolate, baking chocolate, cooking chocolate.
163.112	Breakfast Cocoa		0	22% fat (min) Optional ingredients 1 with the exception of butter or milkfat.
163.113	Cocoa		0	10–22% fat Optional ingredients same as 163.112. Other name: Medium fat cocoa.
163.114	Lowfat Cocoa		0	Less than 10% fat Optional ingredients same as 163.112
163.123	Semisweet/Bittersweet Chocolate	35 (min)	12 (max)	Sweetened chocolate liquor, which may contain one or more specified optional ingredients 2. Traditional bittersweets 50% or more liquor.
163.123	Sweet Chocolate	15–35	12 (max)	Sweetened chocolate liquor, which may contain one or more specified optional ingredients 2.
163.124	White Chocolate	0	14 (min)	20% cacao fat (min) 3.5% milkfat (min) 55% nutritive carbohydrate sweetener (max)
163.130	Milk Chocolate	10 (min)	12 (min)	Sweetened chocolate liquor with dairy ingredient(s), which may contain one or more specified optional ingredients 2.
163.150	Sweet Cocoa and Vegetable Fat Coating		No limit	Same as 163.123, except: mixture of cocoa and chocolate liquor contains a minimum of 6.8% nonfat cacao solids; contains one or more optional ingredients 3.
163.153	Sweet Chocolate and Vegetable Fat Coating		12 (max)	Same as 163.123, except that it contains one or more optional ingredients 3 (except for cocoa).
163.155	Milk Chocolate and Vegetable Fat Coating		12 (min)	Same as 163.130, except that it contains one or more optional ingredients 3 (except for cocoa).

Optional Ingredients 1

- Optional alkalizing ingredients: ammonium, potassium, sodium bicarbonate, carbonate, or hydroxide, or magnesium carbonate or oxide.
- Optional neutralizing ingredients: phosphoric acid, citric acid, and L-tartaric acid.
- Spices, natural and artificial flavorings, ground or whole nut meats, ground coffee, dried malted cereal extract, and other seasonings that do not either singly or in combination impart a flavor that imitates the flavor of chocolate, milk, or butter.
- Other optional ingredients: Cocoa butter and cocoas, dairy butter or milkfat, salt.

When optional ingredients are added, it must be declared on the label.

Optional Ingredients 2

- Optional alkalizing ingredients: ammonium, potassium, sodium bicarbonate, carbonate, or hydroxide, or magnesium carbonate or oxide.
- Optional neutralizing ingredients: phosphoric acid, citric acid, and L-tartaric acid.
- Optional ingredients: cocoa butter, nutritive carbohydrate sweeteners.
- Spices, natural and artificial flavorings, ground or whole nut meats, ground coffee, dried malted cereal extract, salt, and other seasonings that do not either singly or in combination impart a flavor that imitates the flavor of chocolate, milk, or butter.
- Optional dairy ingredients: cream, milkfat, butter, milk (concentrated, evaporated, sweetened condensed, dried), skim milk (concentrated, evaporated, sweetened condensed, nonfat), concentrated or dried buttermilk, malted milk.
- Other optional ingredients: less than 1% emulsifying agents.

When optional ingredients are added, it must be declared on the label.

Optional Ingredients 3

- Cocoa, chocolate liquor.
- Safe and suitable vegetable derived fats, oils, or stearins other than cocoa butter (may be hydrogenated).
- Safe and suitable dairy-derived ingredients; bulking agents, formulation aids, humectants, and texturizers.

Optional Ingredients 4

- Optional dairy ingredients: cream, milkfat, butter, milk (Concentrated, evaporated, sweetened condensed, dried), skim milk (concentrated, evaporated, sweetened condensed, nonfat), concentrated or dried buttermilk, malted milk. Whey or whey products not to exceed 5%.
- Spices, natural and artificial flavorings, ground whole nut meats, ground coffee, dried malted cereal extract, salt, and other seasonings that do not either singly or in combination impart a flavor that imitates the flavor of chocolate, milk, or butter.
- Other optional ingredients: nutritive carbohydrate sweeteners, antioxidants, 1.5% or less emulsifying agents.

When optional ingredients are added, it must be declared on the label.

Steel rollers reduce the size of particles to 10–40 μ. The actual size will depend upon the product desired and type of chocolate, with dark chocolate generally having a smaller finished particle size. During this process the resulting mass often turns into a dry paste or powder.

The manufacture of milk chocolate is similar to that of dark chocolate. The method used to incorporate the milk ingredient plays an essential part in the process. Milk solids are introduced in the form of milk powder or milk crumb, where it is dry mixed with chocolate liquor and sugar.

Milk powder is produced by first concentrating liquid milk and drying it into a powder. The crumb process involves blending sweetened condensed milk and chocolate liquor. It is kneaded and dried. Crumb based chocolates have a unique caramelized flavor based on the Maillard reaction between milk protein and sugars (5,6).

The term "white chocolate" has been used loosely for a number of years. It is basically milk chocolate without the cocoa matter. Cocoa butter is used instead of chocolate liquor and mixed with sugar, milk solids (a white crumb can be made from cocoa butter), emulsifiers, and flavor.

It is important that a mild-flavored cocoa butter be used, since the flavor of white chocolate is quite delicate. White chocolate is also more prone to oxidative rancidity than milk and dark chocolate.

C. Conching

After refining, the mass is transferred to large shear mixers called conches. The machines get their name on the fact that the original equipment resembled a huge conch shell. This is the last manufacturing process where texture and flavor are affected. Time, temperature, moisture control, and shear manipulate the process. Some of the benefits of conching are (1):

- Improved rheology/reduction in viscosity—less cocoa butter needed
- Elimination of harsh volatiles for a mellower taste
- Removal of moisture (reduces lumping and graining)
- Improved mouthfeel (smoothes sharp particle edges).

During this process, additional cocoa butter, flavors, and emulsifier may be added. Conching times will vary depending upon the formulation and final product desired, but can vary from 10 to 12 hours to up to several days. Conching temperatures range from 120°F to 160°F (49–71°C), and sometimes up to 180°F (82°C). The higher conching temperatures give the final product a caramelized flavor that is different from a milk crumb caramelized flavor (7).

D. Viscosity

One of the final steps in manufacturing chocolate is to standardize the product for viscosity. The development of automatic moulding and enrobing equipment requires precise control over the fluidity or viscosity of the chocolate.

It should be noted that *free* moisture in chocolate will increase the viscosity of chocolate. Thus general moisture tests will not necessarily provide pertinent information. Minute amounts of water or steam from leaking equipment, improper storage (humid conditions), and rework can affect the overall performance of the chocolate.

Chocolate is a non-Newtonian liquid, in that its viscosity (internal friction of fluids) is affected by the presence of solids in suspension, as well as by temperature. Once chocolate starts to flow, its viscosity will decrease with an increase in the shear rate (8,9). Chocolate viscosity is still commonly referred to in terms of degrees MacMichael in the United States. In the remainder of the world viscosity is usually measured in centipoise.

The MacMichael viscometer is a single-speed rotational instrument. It works on the following principle: a metal cylinder is suspended on a torsion wire, which in turn, is immersed in a cup of chocolate at a given temperature. As the cup rotates the twisting of the wire is measured by a scale.

The main drawback of the MacMichael method is its inability to provide full information on the flow properties of different chocolates. A Brookfield viscometer can determine plastic viscosity and yield value accurately. Results using a Brookfield (measured in centepoise) can be converted to degrees MacMichael. Table 149.3 shows a range of chocolate viscosities and typical applications.

Viscosity alone will not indicate how the product will handle. Two terms that help to describe flow character are yield value and plastic value. Yield value (YV) is the force required to initiate the flow of chocolate. Plastic viscosity (PV) is the force required to maintain the flow of chocolate once it has started to move.

A high YV is important in maintaining decoration marks and the prevention of "feet" on enrobed goods. A low YV is desirable for moulded products to properly shake out air pockets (8,9).

Viscosity and rheology can be affected by several factors. Smaller particle size in a constant formula will give a higher viscosity. Lecithin exhibits both lipophilic and hydrophilic properties, and is thus an excellent emulsifier. The hydrophilic groups attach themselves to the water molecules on the surface of the sugar particles. This reduces friction, increasing particle mobility, and thus lowering viscosity (8). This reduction in viscosity can also decrease the need for more expensive cocoa butter by as much as 5 percent (9). In the United States, the addition of lecithin or other emulsifying agents is limited to one percent by weight.

E. Tempering

Tempering is the controlled cooling of melted chocolate with agitation that will promote the formation of small stable fat crystals throughout the chocolate. Besides agitation, time and temperature play a key role in the tempering process. Stable cocoa butter crystals will provide the following desired properties (11):

- Snap
- Good Gloss
- Proper texture
- Bloom resistance
- Contraction for demoulding
- Less permeable barrier (shelf life)

The cocoa butter used in chocolate manufacture will affect the physical properties of the chocolate. The origin of the bean will also affect its quality. Attributes affected include hardness, texture, mouthfeel, and melting point of the butter.

Cocoa butter is a polymorphic fat in which its crystals have different characteristics, melting points and stability. There are four major types, γ, α, β', and β, with β being the only stable form. The unstable forms will eventually recrystallize into the stable β form (12,13). See Table 149.4.

Tempering can be done manually or in an automatic tempering unit. There are many types of units available using various methods to achieve the same result: the formation of stable fat "seed" crystals. In general, chocolate tempering involves heating the chocolate to approximately 110 to115°F (43–46°C) to melt the fat crystals. It is then cooled down with agitation to between 80 to 84°F (27–29°C), and subsequently reheated to about 86 to 88°F (30–31°C) before moulding or coating. In general, dark chocolates are tempered about 1 to 2°F (0.5–1.0°C) higher than milk chocolate (11). However, exact temperatures and procedures will depend upon the tempering equipment and type of chocolate used.

During tempering, the viscosity of the chocolate increases in proportion to the increase in seeding; thus chocolate must be used fairly quickly, or carefully heated to remelt some of the seed to prevent overtempering and achieve a steady state of temper. Overtempered chocolate may cause problems such as dull finish, excessive air bubbles, and poor mould release because of reduced contraction of the chocolate. Undertempered chocolate will also have poor mould release and will have a tendency to 'finger print' and have premature blooming.

Once the desired pieces of chocolate are formed, the chocolate should be cooled gradually to prevent future problems. Initial cooling temperature should be approximately 65°F (18°C) with minimal air movement. This is necessary for the continued formation of stable crystals and to prevent case hardening or the formation of a "skin." Temperatures can gradually be decreased to about 45°F (7°C) with increasing air velocity. Final cooling temperature before packing should approach that of the room temperature (about 68°F or 20°C).

When sending product through a cooling tunnel, one must take into consideration the heat load of the product and adjust air temperatures and velocities accordingly. Small pieces of chocolate will set at a faster rate than large moulded blocks. It is also important that the temperature

TABLE 149.3
Chocolate Viscosities

Viscosity	°MacMichael	Used For
Very Thin	< 100°	Enrobing, Panning, Shell Moulding
Thin	100–125°	Solid Moulding, Enrobing, Panning
Medium	125–160°	Enrobing, Hand Dipping
Heavy	160–200°	Moulding, Hand Dipping, Depositing (Chips)

Source: Adapted from Ref. 9,10.

TABLE 149.4
Polymorphic Forms of Cocoa Butter

Form	Approximate Life	Crystallization Temperature (°F)	Melting Range (°F)
Gamma γ	Very Unstable	< 63 (< 17°C)	Up to 63 (17°C)
Alpha α	1 hour	From Gamma	70–75 (21–24°C)
Beta Prime β'	1 month	32–72 (0–22°C)	59–85 (15–30°C)
Beta β	Stable	72–92 (22–33°C)	68–95 (20–35°C)

Source: Adapted from Ref. 14.

on the discharge end be higher than the dew point to prevent condensation on the chocolate.

Although the chocolate may appear solid at this point, only about 70 to75 percent of the cocoa butter is crystallized. It will take about 48 hours for all of the cocoa butter to crystallize, so packing and storage conditions are still an important consideration (11).

VI. PRODUCTION METHODS

A. Enrobing

Enrobing is the mechanized form of hand dipping. The centers to be covered are placed on a conveyor belt, either by manual or mechanical means. The centers are then transferred to a wire belt, where the bottom is coated with a thin layer of chocolate. Not all products go through this prebottoming step; however it serves to reduce problems later on, especially with soft centers. The centers then pass over a cold table to set the chocolate, and then enter the main enrober.

Product entering the enrober should be between 70 to 75°F (21–24°C). Warmer centers may lead to possible bloom problems as the heat tries to escape from the interior of the enrobed product. Cold centers may also cause blooming and cracking of the coating shell due to expansion of the center mass as it warms. It is important that enrobing chocolate have the desired viscosity and rheological properties.

The prebottomed centers are then conveyed on a wire belt through a curtain of tempered chocolate, coating the tops, sides, and bottom as well. The excess coating is removed through the action of adjustable vibratory shakers and forced air blowers. The blowers will often leave a desired rippled decoration on top. Prior to transferring to the conveyor belt, the product passes over a rotating detailer rod. Its main purpose is to remove the trailing "tail" at the end of the enrobed piece. For maximum shelf life, it is important that the centers be completely covered, with no pinholes.

The product will now enter a cooling tunnel to allow the coating to harden. To avoid blooming problems, temperature changes should be gradual. Besides air temperature, attention should also be given to the relative humidity, since if the dew point is lower than the room temperature, moisture could condense on the product and cause sugar bloom during storage.

B. Moulding

Moulded chocolates are popular, since design details and uniformity can be controlled to a greater extent than with enrobed chocolates. The moulding process can be either done manually or mechanically. The main types of moulds include solid, shell, and hollow moulding.

Solid moulds range in size from small novelty items to the 10 pound (4.5 kg) blocks commonly used in industry. Tempered chocolate by itself, or mixed with inclusions such as nuts, raisins, crisp rice, etc., are deposited into metal or the more popular polycarbonate moulds that are the reverse image of the desired end product. The moulds are shaken to distribute the chocolate evenly and to remove air pockets. If necessary, the mould may be scraped to remove excess chocolate before entering the cooling area. After cooling, the hardened chocolate is inverted and the mould twisted or tapped to release the product.

It is important that the chocolate not be overtempered, since overtempered chocolate tends to increase in viscosity, and thus have difficulty flowing into the mould. Overtempered chocolate also exhibits little contraction, and thus may cause demoulding problems.

For solid moulding, a chocolate with a low plastic viscosity (PV) is desired for the proper release of entrapped air. If inclusions are added, a medium viscosity chocolate should keep the particulates in proper suspension.

Shell moulding is a fairly complex operation where a center confection is enclosed in a chocolate shell. Tempered chocolate is deposited in moulds, shaken, and then inverted so that the majority of the chocolate is removed, leaving a thin shell. The chocolate is then cooled and the center mass is deposited. The centers can range from fudges to semi liquid caramels to liqueurs. It is shaken to level out the center and cooled. The mould surface and shell rim are briefly warmed before the final deposit of chocolate is made. This allows for the complete adhesion between the shell rim and the bottom coat of chocolate. Excess chocolate is scraped off before being cooled. After sufficient cooling, the product is demoulded and packaged.

Recent developments in shell moulding equipment allow for the chocolate and filling to be produced in one depositing sequence that is commonly called a one shot line. It is possible to deposit a warm homogenous center mass, such as creme fondant, caramels, truffles and meltaways. Viscosity, tempering process, and nature of the fat phase of the chocolate and of the centers are extremely important.

Hollow moulding is most commonly associated with novelty items such as Easter eggs and rabbits, and Santa Clauses. Tempered chocolate is deposited in a two piece mould which is held together by hinges, clips or magnets. The closed mould is rapidly rotated on a spinner to distribute the chocolate evenly. After cooling, the moulds are opened and the product is removed. Chocolate used for this operation should have a low viscosity and yield value to provide a thin shell.

VII. CONFECTIONERY COATINGS

In the United States, chocolate must conform to a certain standard of identity. If it does not meet the specifications, it cannot legally be called chocolate. The FDA has established standard of identities for cacao products and other

commonly used cocoa-based products. They are listed in Table 149.1.

A. Compound Coatings (Vegetable Fat Coatings)

These are similar to real chocolate coatings, except that chocolate liquor and cocoa butter have been replaced with cocoa powder and less expensive vegetable fat, respectively. The ingredients are dry mixed and refined to a smooth texture, with conching kept to a minimum. White and pastel compound coatings consist of vegetable fat, sugar, and milk powder, with added flavors and colors.

The vegetable fats substituted for cocoa butter may be classified as lauric and nonlauric fats. Lauric fats are short-chained fatty acid glycerides that have physical properties similar to cocoa butter, but are incompatible with cocoa butter. Fractionated coconut and palm kernel oils are lauric fats that have good stability, texture, and flavor release. These oils do not need tempering and are less expensive than cocoa butter. However, when exposed to lipases, especially in the presence of moisture, the free fatty acids released will have a strong soapy taste (15).

The nonlauric fats are composed of longer chain fatty acids and include hydrogenated soy, palm, and cottonseed oils. Unlike lauric fats, the nonlauric fats can be blended with up to 25% cocoa butter and chocolate liquor for a stronger flavor. Due to texture differences, the nonlaurics are used primarily for covering baked goods where a less brittle (or snap) texture is desired. Nonlaurics fats are also susceptible to decomposition by lipases, however, the fatty acids liberated do not have a soapy flavor (15).

B. Sugar-Free Coatings

Sugar-free coatings have been available to the food industry for over 30 years. The original versions were difficult to manufacture and to handle. When compared to "real" chocolate, sensory properties were quite lacking. With the advent of technology and health issues, the quality and quantity of sugar-free coatings and their related products have increased tremendously.

According to the FDA, a sugar-free food contains less than 0.5 g of sugars per reference serving size (16). For most confections, the reference serving size is 40 g, so the 0.5 g/40 g equates to less than 1.25 percent allowed sugars. Sugars are considered to be mono- and disaccharides, and include glucose, sucrose, fructose, and lactose. Confections that are "no sugar added" generally have no added sucrose, but may contain another sugar such as lactose that is found in milk powder.

At the present time, there is no standard of identity for sugar-free chocolates in the U.S. Code of Federal Regulations. From a legal standpoint, this product cannot be called "chocolate." To minimize the sugar level, caseinates are often substituted for the milk, since milk contains sugars in the form of lactose.

The milk powder that is generally used for traditional chocolates can only be used for 'no sugar added' coatings, since the natural lactose sugar is over 50 percent of the non-fat dried milk. This does not meet the requirements of a sugar-free label. Sodium caseinate, and to a lesser extent calcium caseinate, are most commonly used as milk replacers. The total amount needed in the formulation will be less than the amount of milk solids found in standard chocolate, since the lactose and fat portion are removed. Sodium caseinate at a 4 to 9 percent level will be sufficient to replace a traditional milk chocolate containing 12 to 20 percent milk solids (17).

Sugar alcohols as a group have always been considered the key to making a good sugar-free coating. With the exception of xylitol, and in some instances maltitol, they are often combined with high intensity sweeteners such as aspartame, acesulfame K, and sucralose to achieve the same sweetness level as sugar-based coatings.

Aspartame and acesulfame K are approximately 200 times sweeter than sucrose, while sucralose is about 600 times sweeter. The duration of sweetness for sucrose and acesulfame K are similar, while aspartame and sucralose will have a longer sweet sensation. While all of these should be relatively stable in a coating environment, aspartame is more sensitive to heat and acidic conditions. Acesulfame K in high concentration can give a bitter aftertaste. Aspartame has the disadvantage of having to require a 'contains phenylalanine' warning label when used (17).

Most formulations using a high proportion of sugar alcohols will require a label statement of "excess consumption may have a laxative effect." If a sugar-free claim is made, it must also include a "not a reduced calorie food" statement, unless the caloric value is at least 25 percent less than the standard product.

While sugar-free coatings can generally be handled like traditional chocolate, there may be some differences based on formulation and manufacturing processes. Final enrobing/moulding temperatures may be one to two degrees higher or lower and with faster set-up times. They may also appear to be thicker with different flow characteristics.

VIII. CHOCOLATE BLOOM PROBLEMS

Blooming of chocolate is probably the most common problem encountered during chocolate storage. It is a defect which manifests itself as a grayish-white film on the surface of the product. In most instances, the eating quality is not affected; however, the appearance is not very appetizing. Bloom may occur anywhere from a few hours after production, to several months later (18). There are basically two types of bloom–sugar and fat.

A. Sugar Bloom

Sugar bloom occurs less frequently than fat bloom, and its appearance may look like fat bloom. Sugar bloom occurs when the surface of the chocolate is exposed to moisture or high humidity and then dries out. The surface film of water dissolves some of the sugar particles in the chocolate, which then recrystallize upon drying into a dull grayish-white haze. In general, sugar bloom feels dry to the touch and does not melt, as compared to fat bloom.

Sugar bloom commonly occurs when chocolate emerges from a cooling tunnel into a warm and humid room. It also may occur when product is brought out of cold conditions and subjected to warmer, humid conditions without proper packaging and time to gradually bring it up to room temperature.

B. Fat Bloom

Fat bloom is the visible accumulation of large cocoa butter crystals on the chocolate surface, which may give it a greasy surface texture that melts readily when touched. It may be accompanied by numerous mini cracks that gives it a dull grayish-white appearance. These changes are primarily due to the polymorphic nature of cocoa butter and the migration of liquid fat (19). See Table 149.5.

IX. STORAGE AND HANDLING

Like many other foods, chocolate flavor will change over time, resulting in a more balanced flavor profile. In general, most confections should be contained in a non-permeable barrier for protection from oxygen and moisture.

Ideally, chocolate should be stored at 65 to 68°F (18–20°C) and less than 50 percent relative humidity. Dark chocolate is less prone to moisture absorption during storage than milk chocolate (1,20,22). Chocolate should also be stored away from light. Since it is fat-based, it will readily absorb off-odors, so chocolate should be stored in an odor-free environment. Chocolate will also pick up odors from packaging materials and printing inks, as well as odors generated from the heat sealing or shrink-wrapping process. Advances in packaging technology now include water-based cold-seal adhesives, which not only eliminate the potential for heat-damaged chocolates, but are also low in odor, thus eliminating or reducing the possibility for the development of off-flavors or smells (22).

Properly stored, solid chocolate should have a shelf-life of one year of more. Chocolate can be frozen for even longer storage; however, care must be taken when bringing it back to room temperature from the frozen state to avoid condensation.

If chocolate is manufactured from clean beans under sanitary conditions, its microbial count should be low due to its low water activity (A_w) level. However, chocolates may become contaminated from some of the ingredients used and improper storage conditions.

Moisture can be introduced into the product during its manufacture (such as through equipment leaks or improperly dried equipment), or during storage under damp conditions. This may lead to mold and fermentation problems. Molds can survive under low moisture conditions to produce spores, enzymatic reactions, or toxins (such as aflatoxin in peanuts). Fermentation problems are not as common today as in the past, due to better controls on ingredient quality, pH, and A_w of the confection, as well as the use of preservatives such as potassium sorbate. An A_w of 0.68 or less is usually considered stable (20,23).

Rancidity is generally not a problem in milk and dark chocolate because of the natural antioxidant properties of undeodorized cocoa butter. Rancidity can be found on

TABLE 149.5
Some Factors Causing Chocolate Bloom

- Extreme water temperature used in cooling/heating.
- Cooling tunnels/rooms that are extremely cold.
- Cold moulds; warm to 75–80°F (24–27°C).
- Products removed from cold storage to room temperature, not done in steps to prevent condensation.
- Temperature fluctuations during storage.
- Storage temperature exceeding 88–90°F (31–32°C); ideally <68°F (<20°C).
- Too cold or hot center mass when enrobing; ideally 70–75°F (21–24°C).
- Formation of condensate in cooling tunnel.
- Improper formulation of centers that allow moisture or oils to migrate to the outer surface of the coating.
- Packaging/shrink-wrap of finished goods with heat can cause localized bloom.
- Undertempered chocolate.
- Placing chocolates in cold storage before fully solidified. Solidification takes 24–48 hours.
- Introduction of foreign fats (such as coconut oil) into the chocolate.
- Processing line equipment heaters that detemper chocolate.

Source: Ref. 11.

occasion in white chocolate and compound coatings, and is catalyzed in the presence of air, moisture, light, heat, and some metals. With oxidative rancidity, the fats or oils exposed to air produce objectionable flavors due to the formation of aldehydes and ketones. The addition of synthetic antioxidants will help inhibit this reaction, although some fats contain natural antioxidants as well (20).

Hydrolytic rancidity is also known as soapy rancidity, since the off-flavor produced has a soapy taste. Lipases hydrolyze the fat into glycerol and fatty acids. Lipases may be present in ingredients such as coconut, milk products, egg albumen, and cocoa. If possible, it is recommended that ingredients susceptible to hydrolytic rancidity be heat treated to inactivate the enzyme. Lipase activity will not always result in a soapy flavor. Fats containing lauric acid, even a trace amount, can also yield a soapy flavor. Coconut oil and palm kernel oil contain 40 to 50 percent lauric glycerides, while butter fat contains from 2 to 6 percent. Cocoa butter and palm oil do not contain lauric acid (20).

X. NUTRITONAL VALUE

Chocolate has also been noted recently to contain relatively high amounts of polyphenols, in particular the flavanols catechin and epicatechin. Polyphenols are found in the plant kingdom and exhibit antioxidant activity, which is thought to reduce the risk of some diseases of the human body. The levels found in chocolate and related products will depend upon cocoa bean variety, fermentation, and subsequent processing and formulation (24,25).

A food allergy is a reaction by the body's immune system to a substance, usually a protein, in food. An allergy to chocolate itself is uncommon; however, the addition of other ingredients may cause an allergic reaction. According to the National Institutes of Health, approximately seven million Americans (more children than adults) have a true food allergy. Eight food allergens account for 90 percent of all allergic reactions. These include milk, eggs, peanuts, tree nuts, soy, wheat, fish, and shellfish (26,27).

A common belief is that chocolate contains a lot of caffeine. Caffeine belongs to a class of alkaloid molecules known as methylxanthines. Caffeine is the primary alkaloid in coffee, while theobromine is the primary alkaloid in chocolate, and theophylline is the primary alkaloid in tea. Methylxanthines occur naturally in a number of plant species and they exhibit similar pharmacological properties. Methylxanthines are mild stimulants and possess mild diuretic properties (28,29). Table 149.6 shows the USDA nutrient content of several types of chocolate, and also a comparison of the caffeine content with coffee.

While chocolate is not a major source of dietary fat, it nevertheless does contain fat. The majority of the fat comes from cocoa butter and is composed mainly of three fatty acids: 30–37% of the monounsaturated fatty acid oleic acid (18:1), 32–37% of the saturated fatty acid stearic acid (18:0), and 23–30% of saturated fatty acid palmitic acid (16:0). It also contains 2–4% linoleic acid (31). While stearic acid is classified as a saturated fat, it does not appear to raise cholesterol levels the way other saturated fatty acids do (32).

Chocolate is often perceived to be a cause of dental caries. Dental caries occur when bacteria in the mouth metabolize fermentable carbohydrates, resulting in the formation of acids and a decrease in plaque pH, which then causes demineralization of the enamel. Thus the cariogenicity of a food is related to the total amount of fermentable carbohydrates. Unsweetened chocolate is not cariogenic, because it does not contain significant amounts of fermentable carbohydrates. The presence of fats, proteins, minerals, etc., can also modify cariogenicity. Studies have also shown that sweetened chocolate does not increase the incidence of dental caries (33).

Chocolate is one of the most popular flavors, enjoyed by millions of people in a variety of ways, from beverages, to main dishes, sauces, baked goods, and, of course, confections. Eaten in moderation it can be part of a healthful diet.

150 Mozzarella and Scamorza Cheese

Scott A. Rankin, Carol M. Chen, and Dean Sommer
University of Wisconsin-Madison

Arcangelo Esposito
Mozzarella Fresca

CONTENTS

I. INTRODUCTION

Mozzarella and scamorza cheeses originated in the southern regions of Italy, and are typical of a *pasta filata* or stretched curd variety. In fact, the term mozzarella is derived from the Italian verb *mozzare*, meaning to tear, indicative of the stretching process inherent in mozzarella manufacturing. Over the last few decades, mozzarella has experienced substantial growth, given its popularity and role as a topping for pizza. As an ingredient in pizza, as well as in other applications, mozzarella exhibits desirable functional attributes, such as stretching, melting, and browning. These and other critical attributes result from careful control of numerous manufacturing details, such as milk composition, acidification rate and extent, and stretching parameters. In the U.S., mozzarella represents approximately one-third of all natural cheeses and is consumed at a rate of about 9.5 pounds per capita [2]. Mozzarella is

typically manufactured from cow's milk; however, a cheese aficionado would certainly recognize a traditional mozzarella made from domesticated water buffalo milk, i.e., Mozzarella di Bufala.

Mozzarella is considered a fresh cheese and, as such, is known for a typically mild flavor and rubbery texture. Due to its high moisture, elevated pH, and lack of aging, and hence its propensity to support growth of pathogenic bacteria, mozzarella is made from pasteurized milk. In the U.S., mozzarella is generally manufactured according to one of four compositionally and functionally distinct products: whole, low moisture, part-skim, and low moisture part-skim (LMPS).

The word "scamorza" is derived from the manufacturing technique of cutting the melted cheese by hand. The Italian term "scamozzare" means to "behead," reflecting the cutting of the pear-shaped cheese during molding. For centuries, Italian cheese makers used sheep's milk, but as scamorza gained popularity as a semi-hard table cheese, the use of cow's milk became common. Scamorza was also used to preserve small quantities of butter. During the molding process, the cheese maker would include a small sphere of butter (about 10 oz) inside the hot cheese and seal it with the molten curd, thus protecting the butter from spoilage while sharing flavor with the ripening cheese. In the context of U.S. standards of identity, mozzarella and scamorza cheeses are compositionally identical. However, in the U.S., scamorza is somewhat of a rarity compared to mozzarella. Thus, the balance of this work will focus on mozzarella.

A great deal of research has been conducted on mozzarella, and several reviews can be found in the literature [28,41,34]. In general, researchers focused on manufacturing parameters and their impact on functional properties. Such parameters include milk source, milk composition, proteolytic activities, physical treatments, calcium status, and thermal treatments. Given the host of manufacturing complexities, functional properties, and continued positioning into demanding food service applications, mozzarella cheese continues to garner substantial research attention. This chapter will provide a brief overview of mozzarella from historical, manufacturing, and functional perspectives.

II. HISTORY

Mozzarella di Bufala has a springy texture and a pleasantly sour taste, with a faint mossy smell reminiscent of the humid grazing fields of southern Italy. It is porcelain-white in color, spherical in shape and, with a very thin, glossy, edible rind.

Northern Italy fronts the Alps and is bordered by Switzerland and Austria. Between the Alps and the Apennines (a north-south mountain range which traverses nearly the entire length of Italy) is the plain of Lombardy. The Lombardy region is considered the richest and most extensive agricultural area in Italy. Smaller agricultural plains, such as those of Tuscany, Campania, and Apulia, are scattered on either side of the Apennines. Origins of mozzarella begin in the Campania region in southern Italy, along the Mediterranean Sea.

Books by Plinius the Elder, and Lucius Junius Moderatus Columella date cheese technology to the Roman times in the 1st century A.D. The production of mozzarella is linked to that of the water buffalo. Plinius the Elder, in his writings on natural history, classified the water buffalo as a 'bubalus,' or an exotic animal, living in wet and swampy environments. Columella, in the book *De Re Rustica*, described a cheese that after curdling was warmed, cut, scalded in water, hand kneaded, and molded in the shape of a lump. Such descriptions give an indication of the historical presence of "spun" or "stretched" curd cheeses. The rearing of water buffalo in the marshy low lands in the Campania region dates back to the 12th century, but it was not until the 17th century that large scale processing of milk began. The first written records of mozzarella are from the Bishop's Archives in Capua (a city in southern Italy) in the 12th century, which describe a "mozza" or "provatura" as fresh cheese. Initially this cheese was consumed only within the southern region of Campania. The Stock Exchange of Naples and Capua in 1601 quoted water buffalo and its milk products, just like gold or wheat. In the 18th century, mozzarella's popularity spread beyond the Campania region; in particular to the much larger Lombardy region in the north.

At this time, the Bourbon's dominion strongly supported research toward a scientific approach to milk and cheese production. The Lombardy region was already known for its firm Grana-type and blue-veined Gorgonzola cheeses. The Bourbon's Royal Farm in Caserta supported studies to optimize milk production and improve production efficiency. As an artifact of this extensive cheese making, the region supported almost 8,000 free-ranging water buffalo. As production of buffalo and cow's milk mozzarella increased in the north, production decreased in the south. By the 19th century, most industrial cheese production was concentrated in northern Italy.

The reduction of the buffalo herd numbers continued through the mid-1950's. Due to promotional efforts by the northern Italian dairy industry, consumers' interest towards authentic water buffalo milk mozzarella increased. In 1979, the Italian government officially defined and recognized water buffalo milk mozzarella to protect the consumer from the common fraudulent practice of selling cow milk mozzarella at the higher price of water buffalo milk mozzarella.

Mozzarella gained a large section of the retail market several decades ago, and in 1993, became a "DOP" cheese protected and regulated by the "Consortium of Mozzarella di Bufala Campana." In Italy, the origin and the traditional technology are guaranteed by a legal standard of identity.

Only cheese made in specific areas with 100% water buffalo milk can be distributed with the consortium's logo.

In the United States at the turn of the 20th century, Italian immigrants built small cheese factories for the production of soft Italian cheeses, primarily because these high moisture cheeses would spoil during the long sea voyage. Initially, this mozzarella closely resembled the high moisture cow's milk mozzarella of northern Italy. However, changes in the manufacturing procedure altered mozzarella into a firmer, drier, cheese, better suited for transport and cooking saltier. Since the 1920s, the production of mozzarella in the U.S. has increased from less than 50,000 lbs to an estimated 2.8 billion pounds per year in 2002 [2,16]; the vast majority is low moisture, part-skim mozzarella. This change primarily occurred in the Midwestern United States as cheese makers worked toward manufacturing mozzarella with sufficient shelf life for transport to the metropolitan markets on the east coast.

III. DEVELOPMENT OF LOW MOISTURE, PART-SKIM MOZZARELLA

The first U.S. mozzarella manufacturing facilities (in upstate New York) made cheese from standardized milk with no or low levels of starter culture. The starter cultures selected were either an active *S. lactis* at 0.05% (now called *Lc. lactis* subsp. *lactis*), or *S. durans* at 0.50% (now called *Enterococcus faecium*) [10,34]. These cultures do not produce an abundance of acid under the conditions of the high moisture mozzarella protocol. The milk was set, cut (not cooked), drained, cut into small blocks, washed with cold water, and then bundled into cloth bags [33]. After storage at 40°F for 24 hours, these bundles were shipped on ice to stores in New York City markets. It was crucial that acid production up to this point be minimal, and it was not uncommon for acid development to require one to three days. The storekeeper or latticini operator then brought the cheese into a warm room to reactivate the acid fermentation and allow its pH to drop to about 5.3. At this point, the curd was stretched in hot water, molded, and brine salted for the customer.

In the textbook *Cheese Making*, originally published in 1918 [54], Professor J.L. Sammis of the University of Wisconsin-Madison described the manufacturing protocols of Italian cheeses of the time. The text outlines protocols for caciocavallo and provolone, but not mozzarella. These former cheeses are drier cheeses (28–38% and 37–45% moisture, respectively), and are made with one-third skim milk or whole milk, respectively [54]. Sammis describes adding starter (not specified, but presumably *S. thermophilus*) and rennet to milk, then cutting and raising the temperature to 125°F. Curd temperatures were maintained at 125°F for 4 to 5 hours in the summer, or 8 to 10 hours in the winter until the proper acidity was developed for stretching in hot water. In the 1930s the starter culture concept was further developed by Professor Sammis and Louis Rossini, a cheese maker at Stella Cheese Company of Campbellsport, Wisconsin. Sammis and Rossini found that the use of a ratio of *Lb. bulgaricus* (a rod shaped bacterium) in addition to *S. thermophilus* (a coc-cus shaped bacterium) enabled them to make cheese the same day the vat was set [16], greatly increasing production rates.

Italian immigrants in the Midwest also manufactured pasta filata cheeses and, as dairying increased, cheese makers looked to manufacture cheeses for the east coast markets. Of the "spun" Italian-type cheeses, the greatest demand was for mozzarella. Cheese makers found it difficult to maintain the quality of mozzarella manufactured using low acid producing mesophilic cultures. In the 1940s, cheese makers switched from the use of mesophilic to thermophilic cultures, facilitating the completion of mozzarella manufacturing in one day. It is unclear if this new mozzarella is a modified version of caciocavallo (higher moisture) or provolone (lower fat). To optimize acid development from the rod to cocci culture ratio, curd was cooked between 114–116°F. The higher cooking temperatures resulted in a cheese with a lower moisture content than that of the east coast mozzarella variety. Essentially, cheese makers were now manufacturing a low moisture mozzarella that could effectively be shipped long distances to reach new markets. It was noted that cheese made by this method was yellowish, drier, and frequently displayed a slight provolone flavor. This cheese was not considered a table cheese, but a cooking cheese, thus it was called 'pizza cheese,' until the USDA developed the Standards of Identity for Mozzarella in 1965.

A 1964 survey of randomly selected cheeses reported New York mozzarella to be part-skim (~56% moisture, <45% FDM [fat in the dry matter]) and Wisconsin mozzarella to be low moisture, part-skim (~48% moisture, <45% FDM; [50]). Italian Mozzarella di Bufala, by definition, has a minimum of 45% FDM. It is assumed that standardizing cheese milk to a lower fat content in both New York and Wisconsin was based on the higher value of the milk fat for butter making at the time, or to improve cheese shelf-life in the era of poor refrigeration.

IV. MANUFACTURING LMPS PASTA FILATA MOZZARELLA

Most mozzarella manufacturing operations vary in some fashion to accommodate differences in such factors as the production schedule, milk receipt, storage capacity, equipment design, and plant layout. However, there are several core unit operations that are common to most mozzarella manufacturers. A diagram of a typical commercial operation is found in Figure 150.1.

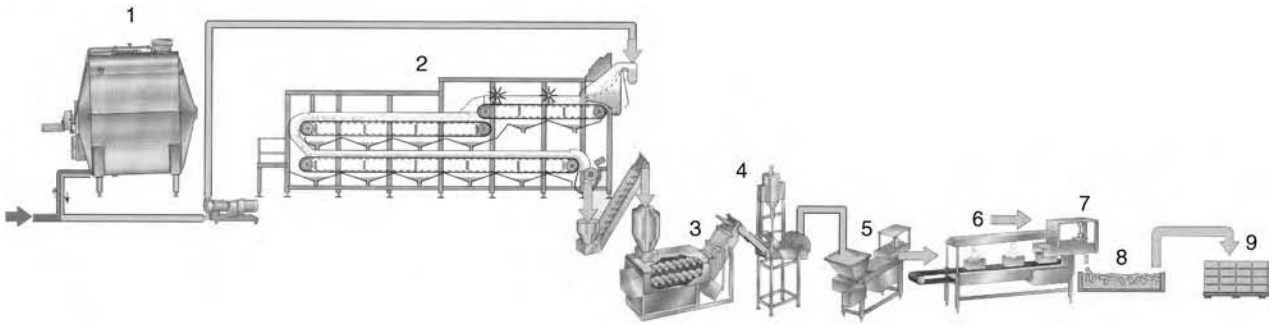

FIGURE 150.1 A typical process line for the commercial-scale manufacture of mozzarella cheese (Adapted from Tetrapak, 1995). 1. Cheese vat. 2. Cheddaring process. 3. Cooker/stretcher. 4. Salting. 5. Molding. 6. Hardening tunnel. 7. De-molder. 8. Brine tank. 9. Palletizing/storage.

A. Milk Quality

Although there is some basis for discussing the raising of water buffalo as a milk source, the vast majority of mozzarella produced is made from cow's milk; hence only this latter source will be addressed. Compositional data of typical cow breeds and water buffalo milks are described in Table 150.1.

In general, milk should be of top quality with low bacterial and somatic cell counts (SCC). As is typical of milk used in the manufacture of any cheese, pH also plays an important rule. Raw, fresh milk should have a pH no lower than 6.50. Milk with an alkaline pH is indicative of udder disease, and will dramatically influence cheese attributes, including the coagulation time and the final curd texture and flavor. The influence of the SCC on the composition of milk and suitability for cheese manufacture has been studied extensively [32,55]. Somatic cells are released from the blood to prevent or reduce udder infections (mastitis). Low numbers of somatic cells are always present in normal milk (i.e., $<$100,000/ml) from healthy animals in mid-lactation. Factors that increase SCC of bulk manufacturing milk include mastitis, advanced stage of lactation, lactation number, environmental stress, and poor nutrition. Milk with an SCC $>$750,000 in the U.S. is considered illegal, and hence is excluded from the commercial supply. An increased milk SCC is associated with marked changes in both the concentrations and state of milk constituents (e.g., degree of proteolysis), and leads to a deterioration of the rennet coagulation properties, curd syneresis, and a noticeable reduction in cheese yield. During cheese making, the curd is weak and subject to extensive shattering during cutting and stirring. This leads to a high quantity of fines, impaired whey drainage, and higher final cheese moisture contents [3,4,19,20,45,46,52,61,64].

TABLE 150.1
Effects of Species and Breed on Milk Composition (Adapted from [56])

Source	Lipid	Protein	Lactose	Ash
Buffalo	6.0	4.5	4.5	0.8
Cow	3.9	3.3	4.6	0.8
Jersey	5.1	3.8	5.0	0.8
Guernsey	4.9	3.9	5.0	0.8
Ayrshire	3.9	3.4	5.0	0.7
Holstein	3.5	3.3	4.6	0.7

B. Thermal Treatment

In certain countries, in an effort to preserve the delicate texture and endogenous microflora, some traditional mozzarella-type cheeses are made with little or no thermal treatment. However, because this practice cannot provide adequate assurance against the presence and outgrowth of microbial pathogens, by regulation, all milk in the U.S. must be adequately pasteurized for the manufacture of mozzarella. In practice, milk for mozzarella is standardized for milk fat (e.g., 2.0–2.4% for LMPS) and casein-to fat ratio (e.g., 1.04 for LMPS). Changes in total milkfat are achieved by centrifugal separation of cream. Casein-to-fat ratios may be manipulated by a number of approaches, including the addition of nonfat dry milk, condensed skim, or unfiltered skim milk. Typical pasteurization treatments are in the range of 163–165°F for 17–20 seconds, which is just above the legal minimum in the U.S. of 161°F for 15 seconds. Such heat treatments are considered sufficient, assuming good quality raw milk, to eliminate pathogens and reduce spoilage and competitive microflora, as well as inactivating several enzyme systems. In this temperature range, there is little change in the nutritive properties of the milk; however, it may develop a slight cooked flavor. Excessive heat treatment of milk is to be avoided, as it results in whey protein denaturation, weak textured curd, and greater moisture retention in the curd [65]. Heat treatment may also denature some enzymes. A notable exception is the enzyme plasmin, which is capable of retaining acti-vity even after significant heat treatments [44]. Plasmin is associated with elevated SCCs and effectively

degrades the casein proteins, resulting in a decrease in cheese yield, the development of off-flavors, and overall degradation of cheese rheological properties [18,58].

C. Curd Formation

The two main events responsible for the coagulation of milk proteins are acid development and rennet-driven proteolysis. In most cases, both processes contribute to the overall destabilization of the casein micelle; the activity of rennet is influenced by pH and setting temperature. The addition of calcium chloride is also a common practice. Each of these processes/practices is detailed below.

1. Calcium Addition

Because curd formation is partially a function of the state and availability of calcium in the milk system, calcium salts may also be directly added as a supplement to ensure adequate gel strength [56]. The level of calcium contributes to proper milk clotting activity; a common practice is to supplement milk at the rate of 3 grams of calcium chloride per 100 liters of milk. Calcium chloride will enhance the rennet properties, namely a reduction in gel time and increased curd firmness.

2. Acid Development

In native milk, the casein micelle is partially stabilized by the repelling effects of a substantially negative net charge. The isoelectric point of the micelle is approximately 4.6. Thus, as acid is produced in or added to milk (native pH 6.4–6.6), the negative charge and resulting repellent force is lessened [65], ultimately destabilizing the micelle and causing curd formation. Acid is introduced into cheese milk for mozzarella manufacture by one of two processes. In one method, milk may be directly acidified by the addition of a food-grade acidulant, such as acetic, lactic, or citric acid. To inhibit the localized destabilization of casein, cold (40°F) pasteurized milk is directly acidified to approximately pH 5.6. Rennet is added, and the acidified milk is heated to approximately 100°F, where it is held as it coagulates [34].

A more traditional method for the acidification of milk for cheese manufacturing is lactic fermentation. In this case, pasteurized milk is tempered to approximately 94°F, whereupon a commercial starter culture is added at the rate of 0.5–2%. The starter culture may be *Streptococcus salavarius* ssp. *thermophilus* only, or a blend of *S. thermophilus* and *Lactococcus delbrueckii* ssp. *bulgaricus.* Starter culture selection is dependent on the desired rate of acid production during the latter steps of cheese making. Detailed descriptions of the primary metabolic capabilities of these bacteria are available in the literature [59]. These bacteria convert lactose to lactic acid, lowering the pH, facilitating moisture loss from the curd, and altering the structure of proteins. In some procedures, mesophilic culture such as *Lactococcus* spp. are used in addition to the thermophilic cultures. In addition to lactic acid, these bacteria produce a caste of metabolites responsible for the pleasant "cultured" flavor and aroma typical of fermented milk products.

3. Rennet-Catalyzed Coagulation

Rennet is a generic term for a preparation containing the enzyme chymosin. Chymosin activities exist in numerous plant and animal sources, including calf stomach, porcine, goat, chicken, and the mold *Rhizomucor meihei* [17]. Due to improved supply volume, reduced costs, improved stability, and performance, the most commonly employed rennet preparations are manufactured using recombinant techniques and microbial expression systems. The primary purpose of chymosin is to enzymatically cleave the hydrophilic κ-casein molecule, thereby rendering the casein micelle unable to remain in aqueous suspension. Most rennet preparations, especially those extracted from plant and animal sources, exhibit several additional enzymatic activities that further catalyze the breakdown of cheese components, ultimately contributing to texture and flavor of the final cheese. Several descriptions of these enzymes and activities are available in the literature [13].

Although the fine detail of the micellar interaction varies, a result of either acid or rennet-catalyzed milk coagulation is that the casein micelles join together in a continuous matrix based on various molecular forces including electrostatic interactions involving calcium phosphate and interactions along protein regions of similar hydrophobicity. The result is a web-like protein structure comprised of open cells containing whey, fat globules, and bacteria. The firmness of the structure depends on the thickness of the chains of micelles, and the space between the chain cells [39]. The state of the milk proteins and their relative concentration to milk fat is also extremely important in order to yield a curd suitable for stretching. An excessive concentration of casein will give a hard, difficult-to-stretch curd. Conversely, higher milk fat levels will produce a soft and slippery curd that would be stretched at slightly lower temperatures to limit milk fat losses.

D. Cutting and Whey Removal

Once the proper gel strength is obtained, the coagulum is gently cut into approximately 1 to 1.5 cm cubes. Immediately, the curd begins to expel whey and shrink. The curd mass is left to rest or "heal" for approximately 5 minutes, and then is gently stirred to prevent clumping. If cultures have been added, the temperature of the curd is increased to approximately 106°F to facilitate acid production and whey expulsion. When an adequate acidity is developed, typically a curd pH of 5.9, the curd is separated from the whey. At this

point, the curd is either allowed to mat together, or it is gently stirred until the curd is ready for stretching (curd pH of 5.25). Prior to mixing, the curd may be pre-salted at a rate of up to 2% (salt to curd ratio). Pre-salting curd is done to reduce brining times by directly incorporating about 1/3 to 1/2 of the total salt.

E. Mixing and Molding

As a descriptor, the term "pasta filata" refers to the process of heating and stretching the curd mass, resulting in the visible alignment of protein fibers within the curd. In practice, the curd is added to hot water (155–165°F), where it warms to approximately 140°F. The heated curd is physically kneaded by an auger system (twin screw or single auger). Protein fibers align and entrap coalesced fat and moisture. The temperature at which the curd is mixed is important, because it influences the residual rennet activity, microbial populations, and the rate that the curd is transformed into a molten mass. All of these factors affect the rate of proteolysis during cheese ripening, thus impacting shelf-life and functional properties. The finished product will have visible fibers similar to cooked chicken breast meat, and a glossy, white appearance.

Next, the cheese mass is distributed into molds of desired shape and size, anywhere from single serving string cheese ropes to large blocks, typically either 6 or 20 pounds in size. The molded cheeses are chilled at ~60°F, then placed into a cold (35–45°F) brine solution. The brine solution typically contains approximately 22–24% sodium chloride salt (~90% saturated), and 0.1% calcium chloride to prevent net calcium loss and the resulting development of a slimy cheese surface due to resolubilized casein. The brine should also be adjusted to a pH of 5.3 to prevent surface defects. Residence time in the brine tank is determined by several factors, including cheese block size, temperature, and salt solution strength. Typical times are on the order of 4–8 hours with pre-salting (12 to 24 hours without) to achieve a final salt level in the range of 1.3–2.0%. Mozzarella is commonly vacuum packaged with plastic or laminant materials.

V. ALTERNATIVE MANUFACTURING PROCEDURES

To this point, the manufacturing procedures discussed dealt with low moisture, part-skim pasta filata mozzarella. The following section will discuss protocols for the production of whole milk mozzarella, as well as a non-pasta filata LMPS mozzarella. Whole milk mozzarella may be manufactured using starter cultures, organic acid, or a combination of the two.

A. Whole Milk Mozzarella with Starter Cultures

When a starter culture is employed to acidify milk in the manufacture of whole milk mozzarella, a relatively high level is used, approximately 2%. Starter culture selections range from solely *S. thermophilus*, to a one-to-one ratio of cocci-to-*Lb. bulgaricus* rods. The milk coagulum is set at 88°F, with a usage level of 1.15 oz/1000 lbs of double-strength milk coagulant. After a 30 minute setting time, the curd is cut into relatively large-sized pieces, allowed to heal, then minimally cooked. The large cutting size, mini-mal cooking temperatures, and short stir-out contribute to the high moisture retention of a whole milk mozzarella. When sufficient acidity is developed, the curd is separated from the whey, rinsed, molded, and brined.

B. Whole Milk Mozzarella with Direct Acidification

Typically, lactic or acetic acid may be used as the acidulant in a direct acid set whole milk mozzarella. At the time of acid addition, the milk should be cold (less than 40°F) to prevent localized clotting of milk proteins and facilitate thorough mixing of the acidulant. Sufficient acid is added to lower the milk pH from approximately 6.6 to 5.6. After thorough mixing, milk temperatures are raised to a setting temperature of 88°F. At this time, 0.25 oz per 1000 lbs of double-strength milk chymosin are added. The coagulum will be firm enough to cut in about 30 minutes. After which, the curd is healed, then gently agitated for approximately 10 minutes. A direct acidified whole milk mozzarella is not cooked. After sufficient curd firming, the curd is separated from the whey stretched, cooled, and brined. The manufacture of direct acidified whole milk mozzarella is a relatively short process, typically requiring an hour from addition of coagulant to chilling after mixing.

C. Non-pasta Filata Mozzarella

A non-pasta filata mozzarella is manufactured without the use of a mixer-molder or brine system. After stirring out, the curd is salted, hooped, and pressed. It is critical that the final cheese has similar composition and functionality to its pasta filata counterpart, meaning the curd should melt and stretch in a similar manner. To ensure similar functionality, strategies to control pH and limit proteolysis need to be incorporated into the non-pasta filata manufacturing schedule. The final pH of the cheese should fall within the range of 5.2 to 5.4 (never below a pH of 5.2). Acidity control may be accomplished by reducing the residual sugar content in the curd (wash treatments), or by reducing the initial lactose content of the milk (e.g., using ultrafiltered milk). Proteolysis is limited in a pasta filata mozzarella by use of the mixer molder. Internal cheese temperatures reached in the

mixer (135–145°F) inactivate residual milk coagulant and decrease starter culture populations. Limiting proteolysis in a non-pasta filata mozzarella may be accomplished by starter culture selection, or a reduction in milk coagulant levels. A non-pasta filata mozzarella manufacturing procedure includes the typical steps in the manufacture of any American-style cheese: setting, cutting, healing, cooking, stirring out, draining, salting, and pressing.

VI. MOZZARELLA FUNCTIONALITY

This section will address the functionality of mozzarella as it pertains to current usage and manufacturing practices. Mozzarella's clean mild flavor and melting characteristics make it well-suited for use as an ingredient in many prepared foods. Mozzarella manufacturers need to know how their cheese will function during high speed shredding or slicing (including the influences of flow agents). Cooking systems that differ from a traditional conduction oven have different affects on cheese (i.e., fast-cooking forced-air or microwave ovens). In addition, as mozzarella finds its way to different markets and food systems, it is more important to control the physical properties so the cheese has specific melt, stretch, cooked color, free oil release, and textural properties. Each of these attributes is addressed in the following text.

A. Shredding

Prior to usage in most cooking applications, block mozzarella is converted into shreds to facilitate uniform distribution and melting. Poor shredding properties were cited as a frequent problem among mozzarella cheese users [51]. Chen [6] identified favorable shred characteristics and textural attributes required for successful conversion of block mozzarella to shreds. Researchers evaluated shred size distribution (long shreds, short shreds, fines), shred dimension (length and width), and visual characteristics (straightness, roughness, wetness) to determine which shredded cheese attributes had the greatest impact on shredded cheese preference. The top three explanatory variables for shred preference were percentage of long shreds (from size distribution), shred thickness (from shred dimension measurements), and shred straightness (from shred character observations). Panelists preferred long, thick, and straight cheese shreds. The percentage of long shreds had the greatest impact on preference, with shred thickness and straightness being of secondary importance.

The most important textural factors in the conversion of block mozzarella to shreds are the cheese firmness and adhesiveness [6]. The relationship between these textural attributes and shred quality are valid, regardless of manufacturing style (pasta filata or non-pasta filata style), composition, or cheese age. Researchers found the firmer and less adhesive the cheese, the higher the quality of shreds. Commercial shredders (e.g., Urschel) use centrifugal force to direct cheese cubes onto stationery blades, thus converting cheese cubes into shreds. A firm textured cheese has less deformation, and blades are able to make cleaner cuts. In addition, a firm textured cheese cube maintains a uniform speed, and blades can cut shreds the length of the cube. On the other hand, as a soft textured cheese comes in contact with the blade, it deforms and bends around the blade, slowing the portion of the cheese cube in contact with the blade. The opposite side of the cheese cube is moving faster and has greater momentum. This momentum directs the cube away from the blade before the blade cuts a full cube length, producing shorter and thinner shreds. The other key textural property, adhesiveness, has similar effects. An adhesive cheese sticks to the blades, slowing the portion of the cheese cube in contact with the blade, and resulting in decreased shred quality (i.e., shorter shreds).

Manipulating the density and structure of the casein matrix can control mozzarella firmness. The more moisture or fat separating casein strands, the lower the protein concentration and the less firm the cheese [26,42]. The structure or strength of the casein matrix relates to the concentration of colloidal calcium phosphate associated with the casein strand [21,40]. Lawrence et al. [36] reported that curd and whey separation is critical. This point determines the basic structure of cheese, because it establishes the calcium content of the curd and the lowest pH that will be attained in the curd.

In general, as mozzarella ages it becomes more adhesive and less shreddable. Chen [6] reported a positive correlation between cheese adhesiveness and proteolysis. Limiting proteolysis can minimize the onset of adhesiveness that occurs during aging, thus maintaining the textural properties required for successful shredding.

B. Flow Agents

The use of flow agents is necessary in commercial shredding operations to ensure controlled distribution of shredded cheese into pouches and to prevent clumping. Flow agents change the shred surface characteristics, making them slide past packaging films and other shreds. This change in the shred surface characteristics affects cheese functionality. Chen and Muthukumarappan [9] investigated how flow agents affect the surface characteristics, melt, and textural attributes of melted mozzarella. The use of flow agents on shreds increased the quantity of blisters and thickness of skinning (a hardened, dehydrated layer of casein on the surface of baked cheese) by about 25%. The use of flow agents on shreds did not affect the cooked cheese color intensity. In addition, flow agents decrease

free oil release by approximately 25%. Flow agent particulates (cellulose or potato starch) adso-rb onto the shredded cheese surface and absorb water from the cheese. The overall water activity of the shreds does change with the use of flow agents. The use of cellulose increased melted cheese hardness by 20%, while the use of potato starch decreased melted cheese hardness by 20%. Panelists noted that melted cheese with potato starch had a slightly slippery mouthfeel. Overall, neither flow agent affected cheese flow rates or chewiness. Also, investigators noted that cellulose, at similar usage rates to potato starch, was visually more apparent on shred surfaces.

C. Cheese Browning

The browning of mozzarella during cooking is due to the Maillard reaction, a heat-induced reaction between sugars (residual lactose or galactose) and protein (free amino groups). The intensity of browning depends on the sugar content of the cheese and the ability of the cheese proteins to remain hydrated during cooking. Johnson and Olson [25] found a positive correlation between residual lactose and galactose levels and brown color intensity when mozzarella was heated. Because of the complex nature of mozzarella as a food product, there are additional factors that influence browning rate and degree. Jaeggi et al. [24] produced skim milk mozzarella with varying levels of a fat mimetic (acid-treated corn starch). These cheeses had higher levels of residual sugar and TCA soluble nitrogen (indicator of proteolysis), which makes for greater browning potential. However, as fat mimetic levels increased, cheese moisture increased, and the degree of browning decreased. The authors presumed that increased moisture helped protect the cheese proteins during cooking, by flashing off and minimizing the heat-induced browning reaction. Rudan and Barbano [53] reduced browning in fat-free and low-fat mozzarella by applying a protective oil coating to shreds prior to cooking. The protective layer prevented protein dehydration and scorching. Forced-air ovens blow hot air onto pizza surfaces, cooking them 2–3 times faster than conventional ovens. Mozzarella cooked in a forced-air oven is more vulnerable to dehydration and skinning.

Moisture protects cheese proteins during cooking. This knowledge can help explain, in part, the relationship between cheese aging and browning intensity. According to Alvarez [1], browning progressively decreased during aging. Oberg et al. [48] reported a relationship between increased cooked color and proteolysis, while Chen and Muthukumarappan [8] found more severe skinning with increased proteolysis. As mozzarella ages, proteolysis breaks casein into peptides and amino acids. With each peptide bond cleaved, two new ionic groups are generated and will compete for available water in the cheese. Creamer and Olson [12] proposed that water previously available for solvation of casein strands becomes tied up with new ionic groups. Due to proteolysis, less water is available to flash off during baking, leaving caseins more susceptible to dehydration and able to participate in heat-induced color reactions or skinning.

D. Melting Properties

During the heating of mozzarella, one can observe several distinct phases. These are described and quantified by a modified squeeze flow method [47]. When cheese is first placed into an oven, the cheese temperature quickly rises, but cheese shape does not change. As the cheese reaches a critical temperature called the softening point, it begins to flow. At this point, the cheese not only continues to rise in temperature, it also changes shape. The cheese matrix collapses, fusing into a semi-solid mass. Flow rate can be measured by calculating the slope of the best-fit line in a cheese height vs. time plot. Next, the melt profile reaches a third critical point called the complete melt point. After this point, cheese height changes are minimal, and cheese temperatures slowly approach the oven temperature.

A study by Chen and Muthukumarappan [8] characterized changes in melt profile attributes over time for pasta filata and non-pasta filata style mozzarella. At all ages, pasta filata mozzarella had lower softening and complete melt temperatures, and higher flow rates than non-pasta filata mozzarella. Softening temperatures decreased throughout aging with the most rapid decrease occurring between two and four weeks. Flow rate and complete melt temperatures were similar: decreasing rapidly during the first four weeks of aging, with relatively small changes between four and eight weeks, then steadily decreasing again between eight and twelve weeks. For all three melt profile descriptors, values changed the least between four and eight weeks. Changes in the melt profile are due to changes in casein-casein interactions within the cheese.

Technically, caseins do not melt, but interactions with each other result in an outcome referred to as melt. As cheese is heated, there is a more rapid relaxation of protein-protein bonds and a greater thermal motion of casein strands, which results in cheese becoming more liquid-like. Mozzarella melt properties are based on the number and strength of casein-casein interactions [40]. Casein-casein interactions may be hydrophobic (attractive forces between casein strands that pull together to keep away from water) or electrostatic [23]. In the pH range of a typical mozzarella (pH 5.15–5.40), we are primarily interested in electrostatic interactions. Electrostatic interaction is the attraction of unlike electric charges; charged calcium phosphate molecules act as a neutralizing bridge between negatively charged clusters on casein strands. To a degree, the higher the colloidal calcium phosphate

levels, the more numerous the casein-casein interactions. This results in a stiffer casein structure and a less meltable mozzarella. Electrostatic repulsion occurs after the solvation of the colloidal calcium phosphate; negatively charged clusters on casein strands push away from each other. The lower the concentrations of colloidal calcium phosphate, the more readily mozzarella melts.

When starter cultures are used in mozzarella manufacturing, a final pH of 5.25 indicates a colloidal calcium phosphate level that produces acceptable melting and stretching. In the case of direct acidified mozzarella, acidulants are added to the milk and there is a lower pH at the time of coagulant addition. In these situations, higher levels of colloidal calcium phosphate are lost into the whey, and sufficient demineralization for melting and stretching occurs at pH 5.6 [26]. At a given pH, the cheese with the least amount of colloidal calcium phosphate will have greater meltability [21].

E. Functionality Related to Melt

Softening and flow characteristics, along with composition and degree of proteolysis, influence the stretch, free oil release, and textural attributes (chewiness, hardness) of melted mozzarella.

Mozzarella's ability to form fibrous strands requires an appropriate flow rate, temperature, and an intact interconnecting casein network. Stretch is the result of casein-casein interactions that are broken and then quickly reformed at different locations in the casein network. When levels of intact casein strands are insufficient due to proteolysis, strands lack continuity and stretch is minimal. If casein-casein interactions are too strong, cheese is more likely to break than form strands. Scenarios include too high a colloidal calcium concentration (electrostatic interactions), or too low a stretching temperature. Stretch-ing occurs at a relatively high concentration of intact casein and within a narrow range of colloidal calcium phosphate [41].

End-user preferences and severe cooking conditions imposed by forced-air type ovens dictate the need for better control of free oil release in melted mozzarella. Free oil release is the separation of liquid fat from melted cheese. It depends on the manufacturing style, cheese composition, and melted cheese flow rates. Low-moisture, part-skim mozzarella manufactured using a non-pasta filata versus pasta filata protocol results in a 50% reduction in free oil release for cheese with similar composition, pH, and degree of proteolysis [7]. During the mixing (plasticizing) of a pasta filata style mozzarella, curd is heated in water to approximately 57°C (milk fat is completely melted and readily coalesces.) Kneading the curd aligns protein strands and entraps coalesced fat and moisture [27,29,60]. During subsequent softening and flow of pasta filata mozzarella, these larger pools of coalesced fat are more likely to leak from the casein matrix. Non-pasta filata mozzarella protocols (stirred curd, direct salted, and pressed) do not have a secondary heating step, resulting in a more continuous protein matrix with smaller pockets of fat and moisture [29]. This structure effectively traps fat during the softening and flow of mozzarella during cooking.

Compositional factors, such as salt content and percentage of fat in the dry matter (FDM), have been reported to affect free oil release. Kindstedt et al [31] proposed that salt (NaCl) influences mozzarella melting and free oil release. Investigators reported a decrease in meltability and free oil release as the concentration of salt increased in blocks of brined mozzarella. They proposed an exchange of sodium ions with casein-bound calcium ions within the casein network. Caseins are much stronger emulsifying agents when dissociated from calcium [57], thus reducing free oil release. The role of fat content on free oil release in melted cheese differs between studies. Investigators Breene et al. [5] and Kindstedt and Rippe [30] reported that cheeses with higher FDM yielded higher free oil levels (Breene et al. FDM 32–50, Kindstedt and Rippe FDM 36–47). A more recent study [9] reported no significant correlation between FDM (range 38 to 46) and free oil release for mozzarella. In the same study, investigators looking at cheddar found the higher FDM (range 50–53) resulted in increased free oil release.

To understand differences in these findings, one must consider how free oil is released during the softening and flow stages of melt, and how FDM affects the meltability of cheese. Thermal motion causes movement of casein strands and the eventual collapse of the casein matrix, allowing exposed fat to leak out and coalesce. Secondly, as temperatures rise, hydrophobic interactions between casein molecules increase. This, in turn, shrinks the casein network, pushes out water, and allows liquid fat to leak out [40]. Olson and Bogenrief [49] reported a biphasic relationship between FDM and meltability. Changes in FDM from 18 to 45% FDM had little effect on meltability, but above 45%, FDM caused a rapid increase in meltability (positive correlation). A FDM of 45% is critical. At this composition, the density of the casein network reaches a point where the solid to liquid ratio influences melt and the ability for casein to hold liquid fat. Both cheese structural elements (strength of casein-casein interactions) and protein density (number of casein-casein interactions) help explain levels of free oil release. Mozzarella can be found in a variety of foods (e.g., pizza, breaded appetizer, breads), each requiring specific functionality. Understanding the relationship between melt profiles and textural attributes enables controlled manufacture, where close tolerances of physical properties are to be expected. Melted cheese cohesiveness can be defined as the degree melted cheese holds together in a mass after chewing. In general, cohesiveness increases over time, with the most rapid changes occurring during the

first four weeks of aging [8]. Hardness and chewiness uniformly decrease over time. Melted cheese hardness correlates best to softening temperature; as softening temperature decreases, hardness decreases [8]. As cheese is heated, thermal energy is stored as movement in the protein, fat, and water molecules, while the cheese structural integrity is not changing. At the softening point, the cheese structure can hold no additional thermal energy and it begins to flow [40]. The amount of thermal energy the cheese is able to store relates to the strength of the casein matrix. Hardness is the force required to bite through melted cheese (rupture the casein matrix). Thus, it follows that the softening temperature (indicator of melted cheese structural strength) correlates well to melted cheese hardness. Melted cheese chewiness correlates best to flow rate; as flow rate increases, chewiness decreases [9]. As mozzarella flows, casein-casein interactions relax (break) and quickly reform [40]. In a mozzarella with greater flow, casein-casein interactions more readily relax, resulting in a more rapid movement of casein molecules past one another. Chewiness is defined as the length of time required to chew cheese before swallowing. As chewiness decreases, casein-casein interactions are more readily relaxing and, over time, not reforming.

VII. RELATED TOPICS

A. Composition

From a compositional standpoint, there are four main types of mozzarella cheese. Due to these compositional and resulting functional differences, there are slightly altered make procedures as well (see [34]). In the U.S., mozzarella cheeses are more precisely defined by standards of identity [62]. These regulations define final compositional requirements (Table 150.2), as well as certain manufacturing procedures. These regulations specify that mozzarella must be made from cow's milk, nonfat milk, cream, or the corresponding buffalo milk products. Cow and buffalo milk may not be blended. The procedure may also include rennet, vinegar (acetic acid), calcium chloride, coloring to mask natural yellow color, salt, and an antimycotic agent. If a product is made from buffalo milk, the label must include the phrase, "made with water buffalo milk."

B. Cheese Yield

The Van Slyke Formula [63], developed in the 1920s, is still a simple and reliable method for estimating cheese yield. Only milk composition (percentage of milk fat and milk casein) and cheese moisture are required in cheese yield calculations. The Van Slyke Formula was originally deve-loped for cheddar, but with a few modifications can readily be used for mozzarella. First, the percentage of fat recovery in the cheese needs to be adjusted. In addition to the fat losses that occur during the formation of curd, a significant amount of fat is lost during mixing and molding. In yield calculations for mozzarella, the value for percentage of fat recovery needs to be decreased from 93% (typical cheddar value) to 86% (mozzarella ranges from 84 to 88%). Secondly, the R-value is a correction factor that takes into account the solids—non-fat, non-casein, which contribute to cheese yield. It includes water soluble minerals, lactic acid, whey proteins, and other minor components. The R-value is dependent on the moisture content of the cheese, since moisture is the mechanism for conveying these contributing factors. Since the formula was originally written for cheddar at ~37% moisture, and a typical mozzarella contains ~48% moisture, this factor needs to be increased from 1.09 to 1.13.

$$\text{Cheese yield} = \frac{(\%\ \text{Milk fat} \times \text{Fat Recovery} + \%\ \text{Casein} \times \text{Casein Recovery}) \times \text{R}}{(100 - \%\ \text{Cheese Moisture})}$$

Assumptions: Fat Recovery (pasta filata style) = 86%
Casein Recovery = 96%
R value (solids non-fat, non-casein factor) = 1.13

TABLE 150.2
U.S. Compositional Standards of Identity for Mozzarella and Scamorza Cheese Types (U.S. CFR, 2003)

Type	Milkfat (% of solids)	Moisture (%)	Labeling Requirement
Mozzarella and Scamorza	≥45	≤60–>52	"mozzarella cheese" or "scamorza cheese"
Low-moisture	≥45	≤52–>45	"low-moisture mozzarella cheese" or "low-moisture scamorza cheese"
Part-skim	<45–≥30	≤60–>52	"part-skim mozzarella cheese" or "part-skim scamorza cheese"
Low-moisture part-skim	<45–≥30	≤52–>45	"low-moisture, part-skim mozzarella cheese" or "low-moisture, part-skim scamorza cheese"

Factors that affect the percentage of fat recovery include initial milk quality, cheese making equipment (vat type, stirring mechanisms), or mixer-molder parameters (type of mixing mechanisms, stretching temperature, finished mozzarella size—string cheese, 6 lb or 20 lb loaf). Factors that affect casein recovery include initial milk quality, milk pasteurization, or milk standardization methods [38].

C. Storage and Shelf Life

Mozzarella cheese will have optimal functional properties between 2 and 6 weeks of age, and a shelf life of up to 4 months. Due to its potentially high moisture and low salt content, there have been some concerns about the safety of mozzarella cheese. For the most part, these concerns are lessened by the regulatory requirement for pasteurized milk, the high temperatures in the mixing-molding operation, and overall improved plant hygiene conditions, especially on the brining and packaging side. An outbreak of *Salmonella javiana* linked to mozzarella cheese consumption prompted a series of studies that examined the microbial lethality achieved during mozzarella manufacturing [14,15,22,37]. Another study identified high levels of the spoilage organism, *Klebsiella pneumonia* in two production lots of mozzarella. This latter microbe is also very heat labile, suggesting that the contamination occurred as a matter of inadequate hygiene after the thermal processes [43]. There are several studies that document the ability of certain strains of Listeria to survive in brine tanks [35]. Other common contaminants include yeasts, molds, and coliform bacteria.

The characteristics of the spoilage of mozzarella cheese are not well described, but may include substantial increases in contaminant microbial counts (e.g., yeast, mold, and coliform), increases in free fatty acids, off-flavor development, curd softening, development of slimy surfaces, poor melt attributes, and visual mold outgrowth [11]. Due to the high enzymatic activities of cultured mozzarella, these products may become softer and whey off more readily that the acid set variety.

VIII. CONCLUSIONS

In spite of its ancient beginnings, understanding the physical, microbial and chemical properties of mozzarella cheeses certainly poses a daunting task. Additionally, the functionality of mozzarella cheeses are continually challenged, as the once simple, fresh cheese is currently expected to withstand rigorous marketing requirements, yet still deliver the desirable characteristics of flavor, melting, browning, and stretching. Although a wealth of knowledge has been generated over the last few decades, work continues to relate the manufacturing variables to the instrumental, chemical, and sensory attributes of significance to mozzarella cheese.

151 Processed Cheese

Marijana Carić and Spasenija Milanović
Faculty of Technology, University of Novi Sad

CONTENTS

I. INTRODUCTION

Processed cheese is manufactured by blending shredded natural cheeses of different types and degrees of maturity with emulsifying agents, adding water, and heating the blend under partial vacuum with constant agitation until a homogeneous mass is obtained. Besides natural cheeses, various other dairy and nondairy ingredients may be included in the blend.

While natural cheese varieties were known and appreciated as a valuable food component in ancient Roman times more than 2,000 years ago, processed cheese seems to be a brand-new product, originating in the 20th century, though based on natural cheeses. In Europe, the invention of processed cheese is connected to the year 1912 and a Swiss patent that claimed the introduction of citrate as an emulsifying and calcium-sequestering agent. The industrial production of processed cheese in Europe was then started. This invention was possibly connected to the Swiss national dish, fondue, in which cheese was heat-treated in the presence of wine, and in which tartrate from the wine had the emulsifying effect. Quite independently in 1917, the production of processed cheddar cheese by using the mixture of phosphates and citrates as emulsifying agents (developed by Kraft in Chicago), was started in the United States. Further progress in processed cheese production was the introduction of polyphosphates into the processing procedure.

The basic theory of processed cheese manufacture lies on the change of the state of casein from coarsely dispersed calcium paracaseinate in the raw cheese due to application of heat, agitation and particular salts as emulsifying/peptising agents, into a homogeneous, free flowing condition: the sol state.

In addition to the mentioned patents, there was numerous other research, which deserves attention and has contributed to the creation of completely new cheese-type products. In between, various research attempts targeted to produce long-life cheese by canning and pasteurization have failed. Such procedures were only successfully developed for soft cheese (Camembert), and later for semi-hard cheeses (Dutch cheeses), though were never suitable for hard cheeses. All attempts to pasteurize Emmentaler caused a breakdown of the cheese structure with separation of fat and water. On the other hand, proteolysis and lipolysis in natural hard cheeses always continued during storage, beyond the optimal flavor point, and most often in an accelerated degree. Decomposition of proteins and lipids results in a nutritionally defective product, unsuitable for consumption. This is the problem

if long storage of natural cheeses is expected, e.g., for export to overseas or to the Tropics. The best solution of the long storage problem for all native cheese varieties was the invention of processed cheese.

In addition, processed cheese manufacture enabled the usage of natural cheeses that were difficult or impossible to sell (such as cheeses with mechanical deformations and localized molds), as well as cheese trimmings, to obtain a product of better keeping quality.

The main advantages of processed cheese as compared to natural cheese varieties are:

- Economic advantages: usage of second class raw material (microbially adequate), reduced refrigeration costs during storage and transport, increased keeping quality, as well as adjustable and imaginative packaging.
- Great versatility of type and intensity in flavor: from mild to sharp native (natural) cheese flavor, specific flavoring, or spices of dairy or nondairy origin.
- Milk replacement: excellent source of nutritionally high-valued milk components for children or specific consumption groups.
- Suitability for home use, as well as for fast-food restaurants.

Processed cheese is grouped according to the following characteristics: composition, water content, and consistency. According to these criteria, there are four main groups: processed cheese blocks, processed cheese foods, processed cheese spreads, and processed cheese analogues (1–6) (Table 151.1). Additional subtypes are processed cheese slices and smoked processed cheese.

II. PRINCIPLES

The principles of cheese processing are rather simple, but require a skillful professional to control all the included ingredients, their concentrations in the blend, and processing parameters. Emulsifying agents, known in the processed cheese industry as "melting salts," are central to processed cheese production. They are used in the processing procedure to provide a uniform structure, also affecting the chemical, physical, and microbial quality of the product.

Emulsifying agents are not true emulsifiers according to chemical terminology — they are not necessarily surface-active compounds, although they help in emulsifying fat and stabilizing the emulsion. However, true emulsifiers may be included in commercially produced emulsifying agents that are mixtures of particular compounds. Most common components of the commercial salt mixtures are: phosphates, polyphosphates, and citrates, although compounds such as sodium potassium tartrate, complex sodium aluminum phosphate, or trihydroxyglutaric acid, could be used as well. Generally, polyphosphate application in the emulsifying agent blend results in processed cheese with superior structure and better keeping quality compared to other emulsifying salts as blend components.

The affinity, i.e., sequestering ability, of common emulsifiers for calcium increases in the following order: $NaH_2PO_4 < Na_2HPO_4 < Na_2H_2P_2O_7 < Na_3HP_2O_7 < Na_4P_2O_7 < Na_5P_3O_{10}$. The affinity of protein for the cations and anions of melting salts is determined by the valency of these ions (1,2).

The blend composition is a commercial secret, usually protected by the producer. The main types and roles of emulsifying agents, their characteristics, possible combinations, and commercial producers are listed elsewhere (1–3,6–8).

TABLE 151.1
Some Characteristics of Processed Cheese Types (1)

Type of Product	Ingredients	Cooking Temperature (°C)	Composition	pH
Processed cheese block	Natural cheese, emulsifiers, NaCl, coloring	71–80 80–85 74–85	Moisture and fat contents correspond to the legal limit for natural cheese	5.6–5.8 5.4–5.6 5.4–5.7
Processed cheese food	Same as above, plus optional food ingredients such as milk, skim milk, whey, cream, albumin, skim milk cheese; organic acids	79–85	≤44% moisture, < 23% fat	5.2–5.6
Processed cheese spread	Same as processed cheese food plus gums for water retention	88–91 85–98 90–95	≥44% and ≤60% moisture ≤55% moisture	5.2 5.7–5.9 5.8–6.0
Processed cheese analogue	Sodium caseinate, calcium caseinate, suitable vegetable proteins and fats (soyabean, coconut), emulsifying agent, salt, artificial flavor	As for processed cheese food	As for processed cheese food	

The essential role of emulsifying agents in the manufacture of processed cheese is to solubilize calcium paracaseinate, sequestering calcium and thus dispersing proteins. Calcium in the Ca-paracaseinate complex of natural cheese is removed by the ion-exchange properties of emulsifying agents, solubilizing the paracaseinate, usually as Na-caseinate. Chemically, this reaction could be observed as (Figure 151.1) (2).

Other beneficial effects provided by emulsifying agents are:

- hydrating and swelling of proteins;
- emulsifying fat and stabilizing the emulsion;
- controlling and stabilizing pH;
- forming an appropriate structure after cooling.

Rayan et al. (9) have researched the emulsification of fat during cheddar cheese processing using TEM (transmission electron microscopy). Figure 151.2A shows their findings after 10 minutes of processing. However, SEM (scanning electron microscopy) reveals large fat globules in processed cheese at the beginning of processing (Figure 151.2B).

The quantity of emulsifying agent permitted in the processed cheese blend prepared for processing is prescribed by government regulations, usually not higher than 3–4%. Since the effects of emulsifying agents are responsible for the unique features of processed cheese production, their correct application is of utmost importance for the quality of the final product.

III. MANUFACTURING

The general technological process for processed cheese manufacture consists of the following operations: natural cheese selection, formulation, blending, shredding, emulsifying agent addition, processing (thermal treatment), homogenization (optional), packaging, cooling, and storage (1,2,3). A flow chart of processed cheese manufacture is presented in Figure 151.3 (4).

A. Natural Cheese Selection

Processed cheese quality, particularly taste and flavor, depends on proper natural cheese selection. The most important criteria for cheese selection are: type, maturity, flavor, consistency and structure, nature and character of the additives, legal requirements, and the potential market (1–3,5). Processed cheeses manufactured from only one cheese variety of different degrees of maturity are very popular in some countries, such as: processed cheddar and mozzarella in the USA and Canada; cheddar in the UK and Australia; and Emmental in Western Europe. More frequently, processed cheeses are produced from a mix of various natural cheese types. The result is easier processing and a better flavor balance.

The selection and combination of native (natural) cheeses of proper maturity is of special importance for processed cheese production. Intact casein, present more in young cheese, has an emulsifying effect on milkfat and stabilizes the emulsion, forming a "long structure." This effect is not expressed by partially hydrolyzed protein, predominating in matured cheese ("short structure"). For example, high-fat spreadable processed cheese requires a larger proportion of young cheese in the blend with a correspondingly higher intact casein content (2,3,5,6). Proper selection of natural cheeses of good quality is not a guarantee for obtaining the desired high quality processed cheese, if the process parameters used are improper. However, some cheeses with incorrect physical characteristics can be successfully used in processed cheese manufacture, as it is possible to correct them by skillful blending. Natural cheeses with microbial defects (spore-forming, gas-producing, and pathogenic bacteria) should not be selected for processing.

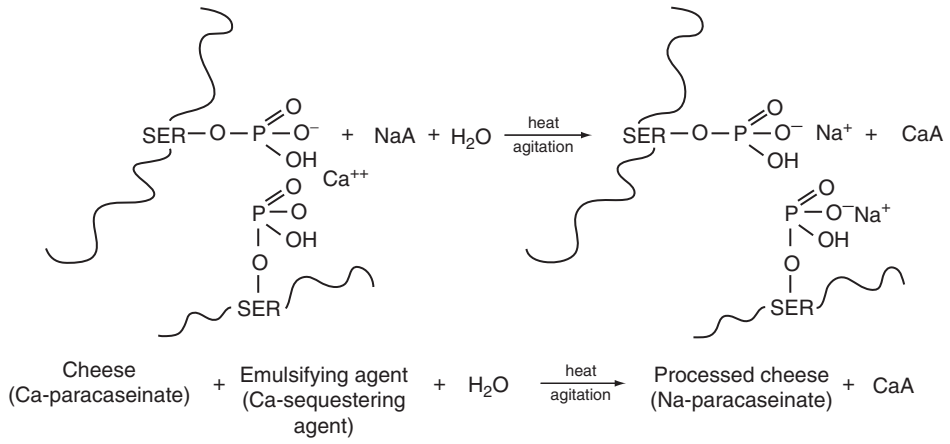

FIGURE 151.1 Chemical reaction during cheese processing (2).

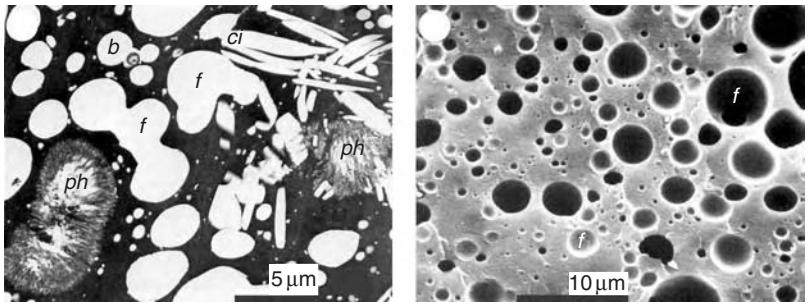

(A) (B)

FIGURE 151.2 Processed cheese microstructure: A. Transmission electron microscopy (TEM) of milkfat emulsification during cheese processing: f-fat; m-protein matrix; ci-crystalline sodium citrate; ph-calcium phosphate crystals; and b-bacterium; B. Scanning electron macroscopy (SEM) of processed cheese: f-large fat particles at the beginning of melting (9).

B. Formulation

Formulation of the ingredients is made in such a way as to yield a desired finished product composition. Formulation is conducted on the basis of fat and dry matter contents of the natural cheeses, including all blend components, added water, and condensate from live steam used during processing. If necessary, additional adjustments of fat and dry matter are possible before processing is completed (1,2).

C. Blending

Blending is influenced by the desired characteristics of the processed cheese type. Generally, in processed cheese spread manufacture the basic raw material in the blend is semi-mature cheese of shorter structure, i.e., approximately 50% semi-mature cheese, 20% mature cheese, and 30% young cheese (10). The recommended formulation for processed cheese block is 70–75% mild cheese and 25–30% semi-mature or mature cheese (6). In contrast, the blend for processed cheese slices must contain 30–40% young cheese, 50–60% mild cheese, and only 10% mature cheese (5,6).

There are some advantages and disadvantages of a high content of young cheese, as well as of a high content of extra-mature cheese, in blends for processed cheese manufacture (1–3). The main advantages if a high content of young cheese is used in the blend are: reduction of raw material costs, possibility of using cheeses with poor curing properties, formation of a stable emulsion with high water binding capacity, and production of a firm body with good slicing properties. The main disadvantages are: production of a tasteless cheese, an emulsifier-like off-flavor, excessive swelling, tendency to harden during storage, and the presence of small air bubbles developed due to the high viscosity of the blend.

A high content of extra-mature cheese in the blend has certain advantages: i.e., development of a full flavor, good flow, and high melting properties. However, there are certain disadvantages: sharp flavor development, low emulsion stability, and soft consistency.

Various other dairy and non-dairy ingredients are used in the production of different processed cheese types. Since the quality of the final product is influenced considerably by all the components present in the blend, the non-cheese components must also fulfill certain qualitative requirements. The most frequently used dairy ingredients are skim milk powder, casein, caseinates, various whey products (whey powder and whey protein concentrates — WPC), and milkfat products.

Skim milk powder improves the spreadability and stability of processed cheese and promotes the creaming properties. If used in quantities exceeding 12% of the total mass, it may adversely affect the consistency or may remain undissolved. Discoloration of processed cheese due to the Maillard reaction is excluded if total lactose content is not over 6% in the final product.

Although whey powder is the most common whey product used in processed cheeses (in concentrations up to 7%), whey protein products with lower mineral and lactose contents are preferable because they yield processed cheeses with better flavor characteristics. However, some other whey products could be successfully used in the processed cheese blend as well, such as: whey concentrate (2–4%), precipitated whey proteins (up to 25% with flavor correction), and native whey protein concentrates obtained by ultrafiltration (5–20%) (1–3,11). The addition of different protein concentrates (denaturated and undenaturated-ultrafiltered) to a processed cheese may lead to a product with particular functional characteristics. Control and manipulation of heating and pH conditions during protein concentrate processing may affect the inherent properties of the protein itself and alter the interactions of the protein with other components of the food system (12). The cheese may be made from 100% UF cheese, containing most and preferably all of the whey proteins from milk, or from a blend of UF and conventional cheese. This process was recently patented in the

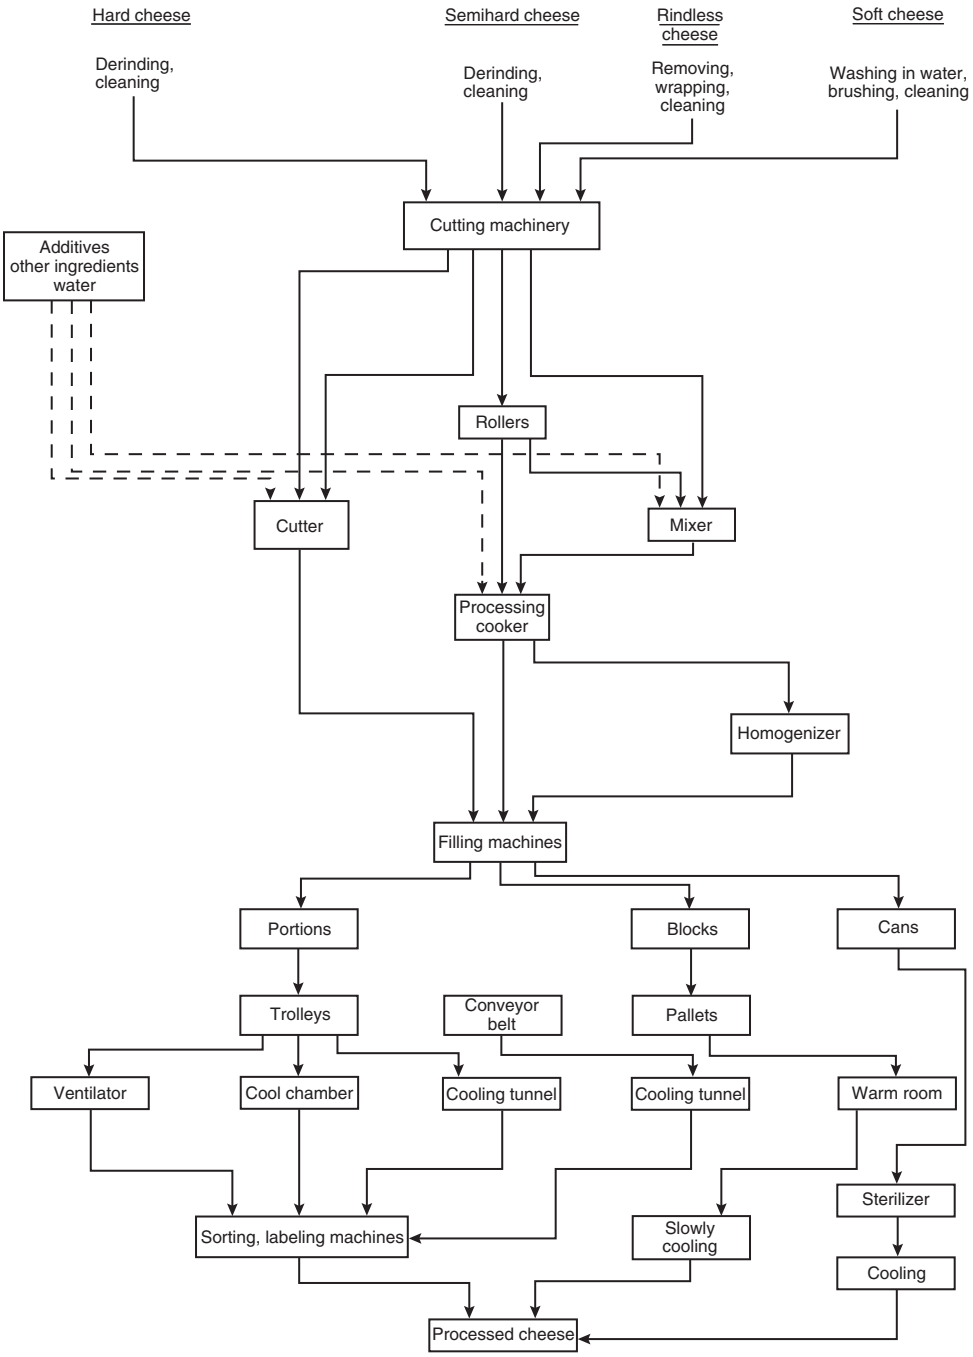

FIGURE 151.3 Flow chart of processed cheese manufacture (4).

USA (13). Generally, whey products incorporated in processed cheese blends promote both the nutritive and economic value of processed cheese.

If the blend contains milk protein coprecipitates, stability of the cheese emulsion and physical characteristics of the processed cheese are increased. Their emulsifying capacity is so high, that they reduce the amount of emulsifying salt added. This is particularly important for dietary and special food products, where limitation of the sodium content may be desirable. Milk protein coprecipitates should not exceed 5% in processed cheeses (1–3).

Butter, cream, and butter oil may be added as milkfat ingredients. All milkfat products used to adjust the fat content of the processed cheese to the desired level must be of high quality and free from off-flavors.

Cheese bases can also be used in processed cheese manufacture. Numerous procedures have been developed for producing economically favorable cheese or cheese

bases intended exclusively for processing. One of these processes for production of a cheese base by ultrafiltration (UF) and diafiltration of whole milk was developed and patented in Germany (14). The retentate (40% dry matter, 4.17% lactose) obtained after ultrafiltration was pasteurized, cooled to 30°C, inoculated with lactic starter, incubated at 25°C until the pH reached 5.2, and packed in plastic bags. The vacuum packaged cheese bases can be stored and later used in processed cheese production in combination with ripe cheese, in an 80:20 ratio.

The ultrafiltration application in preparing raw material for a processed cheese blend pays off the investment costs after only two years of operation.

In Germany, a kind of curd product, called Schmelzpack, is manufactured especially for processed cheese production. Containing 90–100% unhydrolysed casein, it can be blended with natural cheeses of diverse sources, types, and maturity. Good results with the use of chicken pepsin for the peptonization of curd for incorporation into processed cheese have also been reported (1,2,8).

The possibility of successful processed cheese manufacture from cheddar cheese and skim milk powder cheese base has also been investigated (15). Cheese base was produced from reconstituted skim milk powder after ultrafiltration, and was afterwards subjected to accelerated ripening by adding commercial proteolytic enzyme. Obtained processed cheeses were of good quality, if containing less than 40% cheese base.

Relatively new process to achieve the desired flavor in processed cheese is by addition of modified cheese flavors (enzymatically modified cheese — EMC). EMC is produced by inoculation and incubation of particular enzymes with specially designed media, followed by their heat inactivation. Flavor intensity of EMC is 10–30 times greater than the corresponding traditional cheese. The successful substitution of 15% ripe cheese in a processed cheese blend with a mixture of young cheese and whey powder by using cheddar or Parmesan cheese flavor (EMC), has been achieved (11). Headspace analysis showed that experimental processed cheese produced with EMC resulted in higher total aroma content than control samples. Thus, EMC application in processed cheese blends would be economically feasible, resulting in a product of excellent quality (1,2).

Investigations were carried out aimed at improving the economy of processed cheese manufacture by incorporating white cheese in the blend at different concentrations. The easy and rapid manufacture of white cheese makes it a suitable ingredient in processed cheese (16,17). White cheese in concentrations up to 33% blended well with mild and medium ripened cheddar cheese and resulted in an acceptable product. The presence of white cheese in processed cheese can be detected by transmission electron microscopy on the basis of the core-and-shell ultrastructure that is stable during storage (Figure 151.4) (17).

Another dairy-based product that could be included in the blend for processing is precooked cheese (or "rework"). Usually precooked cheese is used in processed the manufacture of cheese spreads to increase the creaming properties of the blend. It is used to improve the texture and stability of the finished product, especially when very young or very mature raw cheese is used for processing. The percentage used in the blend varies from 1 to 30%, depending on the quality of the rework, and the type of processed cheese desired. The presence of rework in processed cheese food has been detected by using electron microscopy (18). Some dairies produce precooked cheese that is stored in large containers.

Methods and composition for fat-free processed cheese manufacture have been patented recently in the USA (19). Processed cheese products with reduced calories and fat are produced by combining high moisture, fat-free, skim milk cheese with a fatty substance which is non-absorbable and non-digestable, and is lower in net caloric efficiency than butterfat, animal fat, or vegetable fat. A suitable fatty substance is a polyol polyester, such as a sucrose polyester.

The nondairy ingredients of the blend for processed cheese manufacture include spices, meat products, vegetables, fruit syrup, cocoa, honey, vanilla, hazelnut, coffee extract, and other components. Their quantities must be properly prescribed for blending. They all must be sterile and of the highest quality with typical flavor (1,2).

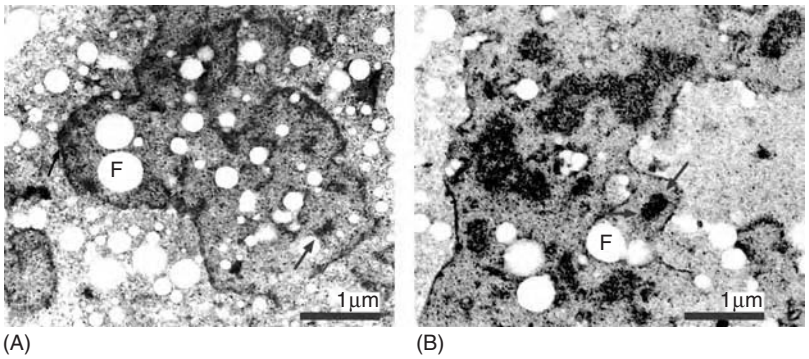

FIGURE 151.4 TEM of processed cheese made with white cheese: A. 16% white cheese; B. 8% white cheese; F-fat particles (18).

D. Shredding

Shredding includes grinding and milling of the components (primarily hard and semi-hard cheeses), enabling better contact between emulsifying agents and blend ingredients. Usually, cheese prepared in this operation is transferred directly to a processing cooker. However, different devices can be used for better blend mixing prior to thermal treatment. This operation can be performed in several ways: shredded cheese is mixed alone, or in combination with other ingredients (butter, milk powder, whey powder); cheese is mixed with water and other ingredients; and cheese is mixed with water, emulsifying agents and other ingredients (20).

E. Emulsifying Agent Addition

The last step in preparing the blend for processing is the addition of emulsifying agents. The type and role of emulsifying agents in processed cheese production is described earlier in the "Principles" section.

F. Processing

Processing involves heat treatment of the previously prepared blend with direct and indirect steam under partial vacuum. The product is constantly agitated when either the continuous or batch method is applied. If processing is carried out in a cooker discontinuously, the temperature reached is 71–95°C for 4–15 min, depending on various parameters (1–3,5). This thermal treatment also provides a pasteurization effect. In newly-developed cookers, it is also possible to reach temperatures up to 140°C. A processing cooker or kettle consists of 2 double-jacketed, round, stainless-steel vessels of various sizes (2–1001), fitted with corresponding lids, three-stage switchable stirring equipment, and fittings for direct steam and vacuum. Double jackets enable indirect steam heating as well. There are specially designed units, similar to cutters used in meat processing, where cutting is completed in the same unit prior to processing, by the aid of rapidly rotating knives with simultaneous heating and homogenization of the product. Two different cooker designs are presented in Figure 151.5.

The horizontal, tube-shaped processing unit, in addition to the most common round design, is also popular, particularly in the United States and Canada. This type of processing unit can process large quantities. It is constructed for batch operation, but also can be continuous. This installation is fitted with one or two mixing arms up to 4-m long. It is fed at one end and the final product is discharged at the opposite end within 4–6 minutes.

By continuous processing, the blend is sterilized at temperatures of 130–145°C for 2–3 s in a battery of stainless steel tubes (1,2,6). Continuous cheese cookers are not commonly used in the processed cheese industry, although they were developed as early as 1920. The main reason is the great versatility in processed cheese products; therefore changing over to a different product in the continuous process, which requires intermediate cleaning which cannot be considered economical. Review of the literature describes a continuous process for simultaneous melting, homogenization, and sterilization in processed cheese manufacture (1,2).

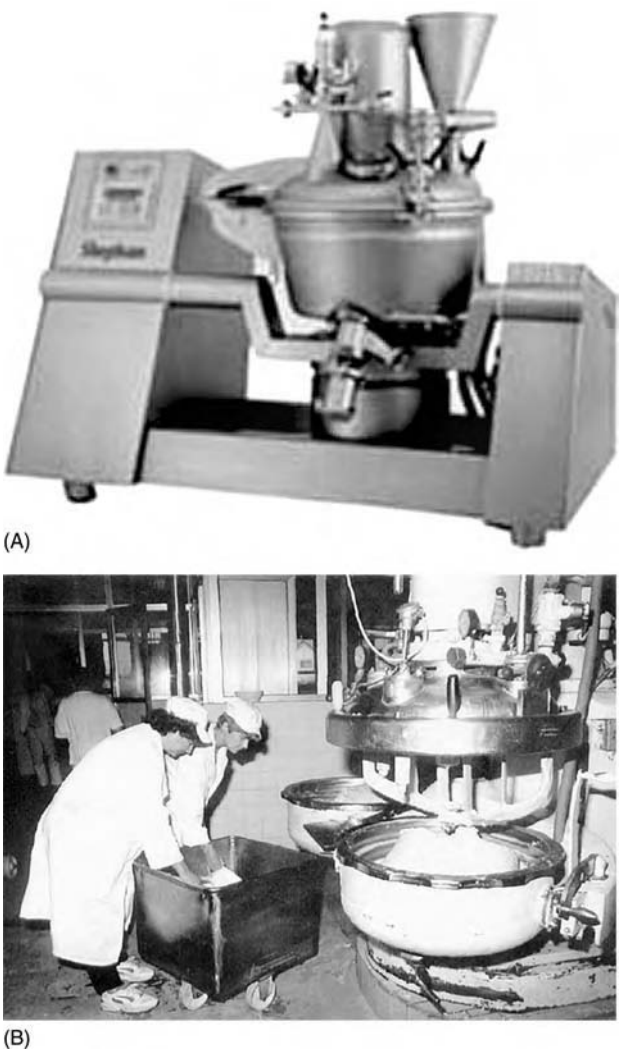

FIGURE 151.5 Equipment for processed cheese manufacture: A. Universal Stephan unit, UM/SK150; B. Voegele machine in Dairy "Mlekoprodukt," Zrenjanin, Serbia.

The most important manufacturing conditions, i.e., chemical, mechanical, and thermal parameters, that affect the processing, and thus the quality of the final product, are:

- temperature: heat induced by direct or indirect steam;
- processing duration: depending on size and construction of the cooker, quality of raw material and blend composition, mechanical treatment, emulsifying agent used, desired keeping quality, etc;

- agitation: slow, at lowest speed of 60–90 rpm for processed cheese block, or fast, at 120–150 rpm for processed cheese spreads;
- acidity (pH): a rather limited pH range; an increase of pH value and decrease of H^+ causes better peptization of casein, but can spoil keeping quality and flavor, whereas a decrease in pH value introduces thickening and solidifying of cheese structure. Higher pH values also favor more rapid product deterioration, in the event of post-pasteurization contamination (1,2).

A new method for processed cheese manufacture has been developed and patented in the USA (21). Processed cheese is made according to the following steps:

- thermal and mechanical treatment such as stirring the initial cheese fractionated into pieces at a temperature less than 60°C;
- cooling the mixture to a temperature less than 50°C;
- if required, mechanically treating the paste to complete the building up of the protein structure and stabilizing the emulsion; and
- forming the paste.

The first two steps are carried out by adding a mixture of emulsifying and chelating agents of calcium and sorbic acid (or a salt thereof) to the initial cheese product.

G. Homogenization

Homogenization improves the consistency, structure, appearance, and flavor of the processed cheese. It also improves the stability of the fat emulsion by decreasing the average fat globule size. It is recommended only for blends with high fat content, because homogenization involves unnecessary additional capital, operational, and maintenance costs. Certain additives or spices must be mixed after homogenization to retain their original form.

H. Packaging

Processed cheese is usually packed and wrapped in laminated foil; tubes, cups, cans, cardboard, or plastic containers; in sausage form; and occasionally in glass jars. Processed cheese in sausage form can be subjected to smoking. The continuous formation, slicing, and packing of cheese slices suitable for sandwiches, is used very often nowadays. Slices may also be obtained by mechanically slicing rectangular processed cheese blocks.

I. Cooling

The method and intensity of cooling depend on the processed cheese type. Processed cheese blocks are cooled slowly, while cooling of processed cheese spreads should be as fast as possible.

J. Storage

Processed cheese should be stored at a temperature range of 5 to 10°C. Sometimes, calcium diphosphate or calcium pyrophosphate crystals may be formed on the surface of processed cheese, at such temperatures, causing a gritty texture.

IV. QUALITY

The influence of blend composition, emulsifying agent type, process parameters, and equipment on the final processed cheese quality has been researched from the beginning of its production in the past century until now. Some data related to processed cheese quality are described, along with processing parameters, in the "Manufacture" section of this chapter. The typical composition of processed cheese is presented in Table 151.2 (3).

New trends in processed cheese technology that should be particularly emphasized are the developments of processed cheese analogues and low-fat processed cheese.

The possibility of substitution of one or more dairy components in processed cheese has been investigated around the world, most intensively in the USA. For example, the most popular processed cheese analogue variants with "mozzarella" cheese flavor and "American" cheese are suitable as toppings in various food industry products.

TABLE 151.2
Typical Processed Cheese Composition (3)

Component	Contents in 100 g of Processed Cheese	
	45% Fat in Total Solids	60% Fat in Total Solids
Water	51.3%	50.6%
Fat	23.6%	30.4%
Proteins	14.4%	13.2%
Natrium (Sodium ?)	1.26 mg	1.01 mg
Potassium	65.0 mg	108.0 mg
Calcium	547.0 mg	355.0 mg
Phosphor	944.0 mg	795.0 mg
Vitamin A	0.30 mg	—
Vitamin D	3.13 µg	—
Vitamin B_1	34.0 µg	40.0 µg
Vitamin B_2	0.38 mg	0.35 mg
Pantotenic Acid	0.52 mg	0.47 mg
Vitamin B_6	70.0 µg	80.0 µg
Biotin	3.60 µg	2.80 µg
Folic Acid	3.46 µg	3.40 µg
Vitamin B_{12}	0.25 µg	0.25 µg
Vitamin C	traces	traces
Energy value (kJ/kcal)	1178/282	1490/339
Utilization (kJ/kcal)	1125/268 (=95%)	1354/323 (=95%)

TABLE 151.3
Most Common Quality Defects in Processed Cheese (2)

Defect	Cause	Correction
	Flavor	
Moldy	Air contamination, moldy raw cheese	Use hermetically sealed foils, eliminate all moldy cheeses from the blend
Acid	Excess phosphates	Reduce emulsifier
Salty	Salty raw cheese or other components, too much emulsifier	Add younger cheese, unsalted cheese, or fresh curd to blend, decrease the quantity of emulsifier
Soapy	High pH value (>6.2)	Add young cheese (with lower pH value), use emulsifying agent with lower pH value
Burned with browning	Maillard reaction (lactose and amino acids); usually when very young cheese or whey products are present	Use processing temperatures < 90°C, cool processed cheese immediately after packaging, avoid large containers, store < 30°C, avoid high pH values in final product
	Texture (Body, Consistency)	
Too soft	High moisture, improper emulsifier, insufficient emulsifier, high pH, fast cooling, excess ripe cheese in blend, prolonged or slow processing	Reduce water content, use suitable emulsifier, increase emulsifier content, decrease pH, slow down agitation and cooling, increase proportion of young cheese in blend, reduce processing time, increase agitation speed
Too hard	Low moisture, improper or excess emulsifier, low pH, slow cooling, improper blend, excessively creamed or overcreamed reworked cheese	Increase water content, use proper emulsifier, decrease emulsifier content, increase pH, speed up cooling, change blend composition, avoid addition of creamed or overcreamed reworked cheese
Hard, with water separation	Collodial change in cheese structure (overcreaming), bacteriological action leading to reduced pH	Remove all factors that affect excess creaming, choose blend components carefully, keep processing temperatures >85°C
Inhomogeneous (grainy)	Unsuitable blend, improper emulsifier, insufficient or excess emulsifier, low pH, short processing time, low processing temperature, improper amount of added water, inadequate agitation, collodial or bacteriological changes caused by improper storage	Add younger cheese, use suitable emulsifier, correct emulsifier quantity, correct pH, prolong processing time, increase processing temperature >85°C, increase the amount of added water, continue agitation during processing and filling, proper cold storage
Sticky (adhering to lid foil)	Sticky foil, insufficiently impregnated, excessively high pH, processed mass left hot too long without agitation	Change aluminium foil, decrease water addition and add in two portions, increase proportions of ripe cheese or cause better creaming, keep pH < 6.0, continue agitation until packaging
	Appearance	
Holes (blown)	Bacteriological changes (growth of *Clostridia*, coliform, or propionic bacteria); physical changes (occluded air, CO_2 from emulsifier mixture), citrates, holes filled up with fluid from emulsifying agent having low solubility, chemical changes (hydrogen from reaction between processed cheese and aluminium foil)	Select cheese blend components, keep processing temperatures >95°C, use proper vacuum, preheat citrate emulsifier before processing, extend processing time, test porosity of aluminium foil and, if necessary, change it
Crystals	Calcium diphosphate and calcium monophosphate crystals (when phosphates are used in emulsifying agent), calcium crystals (when citrates are used in emulsifying agent), crystals due to undissolved emulsifying salt, large crystals due to excess emulsifier, lactose crystal formation caused by excess whey concentrates or low water content, light-colored, grainy precipitate of tyrosine (very mature cheese in blend)	Avoid monophosphates and diphosphates as emulsifying agent, or use in combination with higher phosphates and polyphosphates, exclude citrates from blend, distribute emulsifying agent, exclude sandy reworked cheese, use better emulsifying agent, increase processing time, add emulsifying agent in solution, use prescribed quantity of emulsifier, reduce level of whey products and increase water content, exclude raw cheese that contains tyrosine crystals

Processed cheese analogues are produced with similar processing parameters and identical equipment as conventional processed cheese. Blends for this processed cheese type can be tailored to obtain a final product of desirable chemical, physical, and nutritive characteristics, as well as lower costs. In processed cheese analogue manufacture, the essential ingredients are: milk proteins — casein, caseinates, whey proteins; vegetable proteins — soya (predominately), gluten, coconut, etc.; vegetable fats; flavorings; vitamins; minerals; emulsifying agents; and lactic/citric or other food-grade acid (for pH correction). The newly developed procedures for processed cheese analogue manufacture are mainly patented. The results of numerous investigations, as well as the composition of blends intended for processed cheese analogue manufacture, are summarized in publications by Caric´, Kalab (1) and Caric´ (2).

Investigations were also carried out aimed at developing processed cheese with a natural cheese appearance. The French cheese company, Fromageries Bel, has patented a process which includes the following steps: melting a blend of cheeses, casein, skim milk, butter, and emulsifying agent; agitating the mixture under an inert gas (N_2); defoaming of the obtained product; shaping; and rapid cooling. The final processed cheese has an open texture with visible eyes (aproximately 0.5 mm in diameter), similar to conventional cheeses (22,23).

Another modern trend in the processed cheese industry is the development of low-fat and low-sodium processed cheese products (1,2,24). Low-fat sliced processed cheese with natural or herbal flavor and 50% less fat has been developed. No significant natural or herbal flavor losses were noticed compared to full-fat processed cheese. The manufacture of virtually fat-free processed cheese, and virtually fat-free processed cheese analogues, have also been patented. Blends for virtually fat-free processed cheese (ca. 1.67% fat) consist of skim milk cheese, skim milk powder, whey, and buttermilk powder (25). Innovators found the body, texture, and eating properties of virtually fat-free processed cheese analogues to be identical to classic processed cheese (26).

Good quality processed cheese types (Table 151.1) should have typical flavor, shiny surfaces, homogeneous and smooth structure, uniform color, and no fermentation gas holes. The most common quality defects, their causes, and corrections are summarized in Table 151.3 (2).

Generally, causes of quality defects of processed cheese are unsuitable blend, irregular quality or quantity of emulsifying agent(s), or improper processing. Many of the listed quality defects originate from the natural cheeses used in the blend. Some of them can be avoided by adequate processing. Crystal formation (caused by emulsifying agent type and quantity), and discoloration (result of inadequate process parameters), are most the often visible physicochemical quality defects of processed cheese (1–3).

Processed cheese with minor defects can be recovered by reworking small quantities of it into subsequent batches. Processed cheese with more serious defects that cannot be corrected, such as presence of metal ions, excessive Maillard browning, microbial changes (presence of *Cl. botulinum*), should not be used for human consumption.

152 Yogurt

K.R. Nauth
Nauth Consulting Inc.

CONTENTS

I. INTRODUCTION

The first time fermented milk (yogurt) was consumed is not known. Fermented milk foods are the predecessors of cheese, which originated about the time dairy animals were first domesticated, 8–10,000 BC (1).

Belief in the healthful aspects of yogurt for human beings has been noted in many civilizations for centuries. Ilya Ilitch Metchnikoff was the Director of the Pasteur Institute. He received the Nobel Prize in medicine and physiology in 1908 for his classical work on phagocytes and phagocytosis, which formed a basis for the theory of

immunity. He is credited for his studies on consumption of fermented milk and longevity. Metchnikoff was not the first to promote curdled milks like yogurt. Hippocrates, in the 4th century B.C., in his "Application of Hygenic and Dietary Measures," spoke highly of yogurt (2). Leben, a fermented milk of the Middle East, is mentioned in the Book of Job (10:10), 1520 years before the birth of Christ (2).

In India, people have consumed yogurt called Dahi for thousands of years. A significant amount of milk produced in India is consumed as yogurt. A few years ago, Lassi, a sugared yogurt drink, was declared the state drink for the parliament in Punjab, a province in Northern India. In different countries, fermented milk is called by different names. However, the word "yogurt" is gaining popularity. In the developing countries, yogurt is an indigenous milk product. In the peri-urban and rural areas of Delhi, India, fresh raw milk is available from small local dairy farms with 40–50 buffaloes (3). Most households make their own yogurt from morning and evening milk. Raw milk is boiled and allowed to cool. When it feels warm to touch, it is inoculated from the previous day's fermentation. Some samples from these household fermentations have been examined in the author's laboratory. They contained mesophilic lactococci, including diacetyl producers, thermophilic cocci, thermophilic lactobacilli, yeast, and some coliforms.

In the past 30 years, annual per capita yogurt consumption in the United States has grown sixfold to 2.31 kg (Table 152.1). The consumption of fermented milk products (yogurt, sour cream, and buttermilk) in the United States is very low compared to other developed countries (Table 152.2). Actual consumption of yogurt and related products in the U.S.A. is a bit higher than reported. Many ethnic groups that consume large quantities of plain yogurt ferment their own. There are a number of adults who do not eat yogurt because they do not tolerate lactose in milk. Incidence of lactose intolerance in several ethnic groups is high (6). However, feeding trials with humans (7), and with rats (8), showed that yogurt containing viable microflora could be tolerated by individuals determined to be lactose intolerant. Other research workers demonstrated that the lactase (beta-galactosidase) activity of the yogurt culture remains in the intestinal tract after the culture has lysed, and continues to break down lactose (9). This activity can be detected in the duodenum and terminal ileum after consumption of viable yogurt (10).

* Adapted from ref. 5.

** For 1998, ref. 4.

Fermented milk products include yogurt, sour cream, and buttermilk.

The 2.9 billion dollar yogurt industry is growing at about 3 to 4 percent every year. The segment catering to kids under the age of 12 has shown huge gains. For example, Danimals, a yogurt product targeting children, has grown 137.9% (11). Excluding private labels, the top nine refrigerated yogurt brands are dominated by Yoplait and Dannon. In a recent consumer survey of 40 yogurts, the quality varied from flavor to flavor in a single brand (12). Many of the yogurts were characterized as astringent, thick, gummy, having jam and candy-like flavors, or as being chalky and slightly bitter. Fruit containing yogurts also contain large amounts of sugar. This is a huge problem for an estimated 16 million Americans with Type 2 diabetes, and another 20 to 30 million Americans with impaired glucose tolerance (13). Yogurt formulated for this segment of population can offer a big growth opportunity.

This brief chapter on yogurt is written to bring a clear understanding of this simple product, which is now becoming a vehicle for introducing probiotics and prebiotics believed to impart good health by maintaining a balanced and healthy gut. For a more extensive discussion on yogurt, see Tamine and Robinson (5).

II. DEFINITION OF YOGURT

Yogurt is an acid gel made from the fermentation of a standardized milk mix by *Streptococcus thermophilus* (ST) and *Lactobacillus delbrueckii* subsp. *bulgaricus* (LB) (14). The solid-not-fat component of milk may be raised to 12%

or higher to yield a custard-like gel. The fat in the product is adjusted to qualify for lowfat or fat-free yogurt.

A. Yogurt Description

Yogurt is the food produced by culturing one or more of the optional dairy ingredients with a characterizing bacterial culture that contains the lactic acid-producing bacteria, *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. One or more of the other optional ingredients specified below may also be added before the culturing process. All ingredients used are safe and suitable. Yogurt, before the addition of bulky flavors, contains not less than 3.25 percent milkfat, and not less than 8.25 percent milk solids-not-fat, and has a titratable acidity of not less than 0.9 percent, expressed as lactic acid. The food may be homogenized, and shall be pasteurized or ultra-pasteurized prior to the addition of the bacterial culture. Flavoring ingredients may be added after pasteurization or ultra-pasteurization. To extend the shelf-life of the food, yogurt may be heat-treated after culturing is completed to destroy viable microorganisms.

Optional Ingredients: Vitamins: (a) If added, vitamin A shall be present in such quantity that each 946 milliliters (quart) of the food contains not less than 2,000 International Units thereof, within limits of current good manufacturing practice. (b) If added, vitamin D shall be present in such quantity that each 946 milliliters (quart) of the food contains 400 International Units thereof, within limits of current good manufacturing practice. Optional dairy ingredients are cream, milk, partially skimmed milk, or skim milk, used alone or in combination.

Other optional ingredients include: (a) Concentrated skim milk, nonfat dry milk, buttermilk, whey, lactose, lactalbumins, lactoglobulins, or whey, modified by partial or complete removal of lactose and/or minerals, to increase the nonfat solids content of the food; provided, that the ratio of protein to total nonfat solids of the food, and the protein efficiency ratio of all protein present shall not be decreased as a result of adding such ingredients. (b) Nutritive carbohydrate sweeteners. Sugar (sucrose), beet or cane; invert sugar (in paste or syrup form); brown sugar; refiner's syrup; molasses (other than blackstrap); high fructose corn syrup; fructose; fructose syrup; maltose; maltose syrup, dried maltose syrup; malt extract, dried malt extract; malt syrup, dried malt syrup; honey; maple sugar; or any of the sweeteners listed in part 168 of this chapter, except table syrup. (c) Flavoring ingredients. (d) Color additives. (e) Stabilizers.

1. Lowfat Yogurt

Lowfat yogurt has a similar description as given earlier, except the milkfat of the product before addition of bulky flavors is not less than 0.5% and not more than 2% (14).

2. Nonfat Yogurt

Nonfat yogurt is the product as per the previous description of yogurt, except the milkfat content before the addition of bulky flavors is less than 0.5% (14).

B. National Yogurt Association (NYA) Criteria for Live and Active Culture Yogurt

According to the NYA (15), live and active culture yogurt is the food produced by culturing permitted dairy ingredients with a characterizing culture, in accordance with the FDA standards of identity for yogurt. In addition to the use of ST and LB, live and active culture yogurt may contain other safe and suitable food grade bacterial cultures.

Heat-treatment of live and active yogurt with the intent to kill the culture is not consistent with the maintenance of live and active cultures in the product. Producers of live and active culture yogurt should ensure proper practices of distribution, code dates, and product handling conducive to the maintenance and activity of the culture in the product.

Live and active culture yogurt must satisfy the following requirements (15):

1. The product must be fermented with both *Lb. delbrueckii* subsp. *bulgaricus* and *S. thermophilus.* The cultures must be active at the end of the stated shelf-life-as determined by the activity test described in item 3. Compliance with this requirement shall be determined by conducting an activity test on a representative sample of yogurt that has been stored at temperatures between 32 and 45°F for refrigerated cup yogurt. The activity test is carried out by pasteurizing 12% solids of nonfat dry milk (NFDM) at 92°C (198°F) for 7 min, cooling to 110°F, adding 3% inoculum of the material under test, and fermenting at 110°F for 4 h. The total organisms are to be enumerated in the test material both before and after fermentation by IDF methodology. The activity test is met if there is an increase of 1 log or more during fermentation. In the case of refrigerated cup yogurt, the total population of organisms in live and active culture yogurt must be at least 10^8 cfu/g at the time of manufacture. It is anticipated that if proper distribution practices and handling instructions are followed, the total organisms in refrigerated cup live and active culture yogurt at the time of consumption will be at least 10^7 cfu/g.

C. Frozen Yogurt

Frozen yogurt resembles ice cream in its physical state. Both soft-serve and hard-frozen yogurts are popular. These are available in nonfat and lowfat varieties. These products are not very acidic. The industry standards require minimum titratable acidity of 0.30%, with a minimum contribution of 0.15% as a consequence of fermentation by yogurt bacteria (15,16). Technology for production of frozen yogurt involves limited fermentation in a single mix, and arresting further acid development by rapid cooling; alternatively, using a standardization of titratable acidity to a desirable level by blending plain yogurt with ice cream mix containing fruit/syrup base, stabilizers, and sugar, and then freezing the mix in a conventional ice cream freezer. The mix is frozen at −6°C and hardened at−40°C. The finished product pH may vary between 5.5 and 6.0, depending on the consumer acceptance. Typical composition of nonfat hard-pack frozen yogurt may contain 0% fat, 13% milk-solid-nonfat, 13% sucrose, 6% corn syrup solids 36DE, and 2% maltodextrin 10DE, 1.2% stabilizer (16). For further discussion see references (5,16,18).

III. YOGURT STARTER ORGANISMS

For manufacture of legal yogurt in the United States, *Streptococcus thermophilus* and *Lactabacillus delbrueckii* subsp. *bulgaricus* must be added for basic fermentation of the yogurt mix. Additional optional organisms, preferably of human intestinal origin, may be incorporated in the yogurt either through the starter culture, or blended in after fermentation is complete (14,15). The optional organisms may be selected from a long list of candidates (Table 152.3). Some characteristics of organisms encountered in yogurts are listed in Table 152.4.

TABLE 152.3
Optional Cultures for Addition to Yogurt

Lactobacillus acidophilus
Lactobacillus rhamnosus
Lactobacillus reuteri
Lactobacillus casei
Lactobacillus gasseri

Adapted from reference 5, 20 and 21.

A. Streptococcus thermophilus

This organism is a Gram-positive, catalase negative anaerobic cocci, and it is largely used in the manufacture of hard cheese varieties, mozzarella and yogurt. It does not grow at 10°C, but grows well at 45°C. Most strains can survive 60°C for 30 min (22). It is very sensitive to antibiotics. Penicillin (0.005 Iu/ml) can interfere with milk acidification (20). It grows well in milk and ferments lactose and sucrose. Two percent sodium chloride may prevent growth of many strains. These streptococci possess a weak proteolytic system. It is often combined with the more proteolytic lactobacilli in starter cultures. Most ST grow more readily in milk than lactococci, and produce acid faster. These streptococci strains possess β-galactosidase (β-gal) and utilize only the glucose moiety of lactose, leaving galactose in the medium (23).

The proteolytic activities of nine strains of ST and nine strains of LB cultures incubated in pasteurized reconstituted NFDM at 42°C as single and mixed cultures were studied (24). Lactobacilli were highly proteolytic (61.0 to 144.6 μg of tyrosine/ml of milk), and ST were less proteolytic (2.4 to 14.8 μg of tyrosine/ml of milk). Mixed cultures, with the exception of one combination, liberated more tyrosine (92.6 to 419.9 μg/ml) than the sum of the individual cultures. Mixed cultures also produced more acid (lower pH). Of 81 combinations of LB and ST cultures, only one combination was less proteolytic (92.6 μg tyrosine/ml) than the corresponding LB strain in pure culture (125 μg tyrosine/ml). *Streptococcus thermophilus* requires fewer amino acids than lactococci and lactobacilli. Only glutamine and glutamic acid, along with sulfur amino acids, are essential for all of the strains that have been tested (25,26). Recently it was shown that ST possesses a branched-chain amino acid (leucine, isoleucine, and valine) biosynthesis pathway as an essential pathway for optimal growth in milk. This pathway is thought to play a role in maintaining the internal pH of the organism by converting acetolactate to amino acids (26). These organisms also have urease that produces ammonia from urea in milk to counter the acid effects. Dairy lactococci do not have this pathway (26).

B. Lactobacillus delbrueckii subsp. bulgaricus

These organisms are Gram-positive, catalase negative, anaerobic/aerotolerant homofermentative, and produce D-(−) lactate (1.8%), and hydrogen peroxide (27). These cultures have β-galactosidase activity. Only the glucose moiety of lactose is utilized and galactose is released in the medium (28). LB has a high level of protease activity in milk that reaches its maximum during the log phase; while ST produces highly active peptidase instead of protease (29,30). In a recent study (30), it was demonstrated that LB reached maximum protease activity between 4–8 h after incubation, and then declined rapidly. When grown singly in pasteurized reconstituted NFDM at 42°C, ST and LB were less proteolytic compared to the mixed culture growth (24).

C. Associative Growth of ST and LB

A symbiotic relationship exists between ST and LB in mixed cultures (31); carbon dioxide, formate, peptides, and numerous amino acids liberated from casein are involved. Associative growth of rod and coccus results in greater acid production and flavor development than the single culture growth (32,33). It has been established that numerous amino acids liberated from casein by proteases of LB stimulate growth of ST (34,35). In turn, ST produces CO_2 and formate which stimulates LB (35–38). During the early part of the incubation, ST grows faster and removes excess oxygen, as well as produce the stimulants noted above. After the growth of ST has slowed because of increasing concentrations of lactic acid, the more acid tolerant LB increases in number (29,39,22). For a one-to-one ratio of rod and coccus and inoculum level, time and temperature of incubation must be controlled and bulk starter should be cooled promptly.

D. Bifidobacteria

This Y-shape organism was isolated from infant stool in 1899 at the Pasteur Institute by Tissier (21). There are 24 species in this group. Nine of these are of human origin, and the other 15 come from animals (40). These Gram-positive organisms are strictly anaerobic. The degree of tolerance to oxygen depends on the species and the growth medium. It appears that the strains of *B. bifidus* are relatively aerotolerant (40). Optimum growth temperature for species of human origin is 36–38°C; no growth at 20°C. They do not tolerate heat; *B. bifidus* is inactivated at 60°C. Two moles of glucose are fermented by the fructose-6-phosphate phosphoketolase pathway to 2 moles of L (+) lactate and 3 moles of acetate. Some formic acid and ethanol may also be produced. Bifidobacteria of human origin synthesize several vitamins, thiamine (B1), riboflavin (B2), pyridoxine (B6), folic acid (B9), cyanocabalamine (B12), and nicotinic acid (P) (40).

It has been observed that the number of bifdobacteria falls significantly in the stools of adults and the elderly. The proportions of various species of bifidobacteria vary with the age of humans. It appears that *B. infantis* and *B. breve* are favored in breast-fed infants, and *B. adolescentis* predominates in bottle-fed infants and in adults (40). Allergic infants were reported to be colonized mainly by *B. adolescentis* species, with a lower mucous binding capacity than bifidobacteria from healthy infants (41). The Bifidobacteria population may be reduced after the administration of a Western diet. All strains of bifidobacteria do

not behave similarly. Morinaga Milk Industry Co, LTD claims that their *B. bifidum* (BB536) is hardier and superior to other strains (42).

E. Starter Culture Propagation

These days, yogurt manufacturing plants are large and highly automated. Trouble-free functioning of these operations requires predictable and dependable starter culture performance in the context of types of products and their sensory attributes. Following are some helpful hints.

1. Milk should be of good microbiological quality, free of antibiotics and inhibitors of bacterial origin.
2. Fresh milk, heat-treated at 90 to 95°C for 5 minutes, or 85°C for 30 minutes, tends to give a balanced growth with a 1:1 or 2:1 ratio for ST:LB. When cultures are propagated in reconstituted NFDM, STs tend to show abnormally large cells within a chain. More severe heat treatment, such as autoclaving of milk, is somewhat inhibitory to ST and favors the growth of LB, causing culture imbalance in favor of LB. It should be noted that ST first initiates growth, followed by LB (22). A low population of ST will delay the completion of starter or yogurt fermentation. The heat-treatment of 90°C for a few minutes generally inactivates bacteriophages present in the milk.
3. Many yogurt producers prefer to use skim and condensed skim milk over nonfat dry milk to raise solids in the growth medium. Handling of nonfat dry milk is labor intensive and invariably results in dusting of plant equipment and overhead fixtures. Under these conditions, keeping the plant clean is difficult and can result in higher incidence of yeast and mold. If nonfat dry milk is used, the area should be enclosed and isolated. The exhaust air should be filtered.
4. It is important to cool the starter when appropriate pH/% TA is attained. Higher acidity tends to reduce the ST count (22).
5. At any given time, the availability of phage-unrelated cultures suitable for specific yogurt attributes is rather small. These cultures should be handled carefully to grant them long life in the plant.
6. Monitor phage in the starter and in the environment on a regular basis.
7. Many of the defined cultures may contain up to six strains of lactobacilli. The culturing conditions should be carefully verified and controlled for uniform culture activity. If the starter contains probiotic cultures or other adjuncts, their numbers should be verified in the starter and the product.

The plants should work closely with the culture suppliers for phage monitoring and culture performance.

1. Bulk Starter Preparation

This is one of the key operations and should be attended to carefully by trained personnel dedicated to this duty. The starter tank valves, pipes, and hatch with gasket should be assembled and sterilized with live steam at low pressure (3 to 5 lbs). Keep the bottom valve open for the condensate to drain. Continue to steam the tank for 30 minutes after the surface temperature in the tank has reached ~99°C. Turn the steam off and close the bottom valve.

Skim milk with total solids raised to 10 to 12% is either pumped cold and heated to 90°C and held for 60 minutes, or the starter mix is heated to 90°C in a plate heat exchanger, and then held at that temperature in the tank for 60 minutes. Some plants prefer to use reconstituted nonfat dry milk at 10–12% TS for their bulk starter. In certain operations, where large amounts of starter are used for yogurt inoculation, yogurt base is used for starter culture preparation. This brings ease of operation, and eliminates yogurt composition variation. Cool the mix to 43°C. Close the chilled water valve early enough that the temperature does not fall below 43°C. For 500 gallons, thaw a can (350 ml) of frozen culture concentrate (10^{10} cfu/g) in 5 gallons of tepid water containing 100 ppm chlorine. Inoculate the tank and stir for five minutes. Turn off the agitator and let it incubate quiescently for 6–8 hours to reach 0.9% titratable acidity. Cool the starter to 5°C using slow agitation. Then turn off agitation. Turn on agitation for a few minutes before the starter is to be pumped. This rate of inoculation yields ~10^6 cfu/g of starter mix. For a healthy culture, it may take 8 to 10 hours to reach 0.9% acidity. Starter has 2–5 $\times$ 10^8 cfu/ml. Time to 0.9% titratable acidity also depends on the strain composition of the frozen culture concentrate.

It is advisable to make a Gram-strain of the fresh starter and run an activity test as described in section II. B., using 1% inoculum. Such data is invaluable in tracking the performance of culture(s), and in preventing failed yogurt fermentation.

IV. YOGURT MIX PREPARATION

Fermented milk products have a delicate flavor and aroma and require milk of good microbiological quality. A variety of yogurt mix can be formulated and standardized from whole milk, partially skimmed milk, condensed skim, nonfat dry milk, whey compositions, and cream. These mixes should be formulated to comply with regulations and meet consumer expectations. Clarified, fat-adjusted milk at 50°C should be blended with appropriate dry ingredients using

a powder funnel. It should be allowed to circulate for a few minutes. The solids content of separated milk or whole milk can also be raised to 12% and 15% respectively by evaporation. The increased solids content prevents whey separation and improves the texture.

A. Sweeteners

Sweeteners may be added to yogurt as part of the mix before fermentation, and/or through fruit preserved with sweeteners. Sucrose (sugar) is widely used in yogurt production. It provides a clean sweet taste which has no after taste or other odors. It complements flavors, and contributes to desirable flavor blends (17). It can be used in a dry, granulated, free-flowing, crystalline form, or as liquid syrup (67% sucrose). Inclusion of more than 5% sucrose in yogurt mix of 16 to 20% total solids may cause culture inhibition and lack of flavor development (5,16). Several corn syrup preparations and other sweeteners are also available (5,17). Non-nutritive sweeteners, such as Aspartame or Nutrasweet® are used in light products. These sweeteners have a lingering aftertaste (5) and have not faired well in consumer acceptance (12). Several newer sweeteners, Actilight®, Acesulfame-κ, Natren, Neohesperidine, and Thaumatin are available. These could be used alone or in combination. The choice of sweetner(s) is determined by availability, cost, and its legal status for use in yogurt (5).

B. Stabilizers

The set yogurt gel structure results from an acid-casein interaction, where casein micelles at or near their isoelectric point flocculate, and the colloidal calcium phosphate partially solubilizes as acidity increases. During the fermentation of milk, the pH gradually declines to around 4.5, and destabilized micelles aggregate into a 3-dimensional network in which whey is entrapped (43,44). Appearance of whey on the surface of yogurt gel is due to syneresis, separation of serum from curd. In yogurt, this defect is called wheying-off (45).

In stirred style yogurt, the 3-dimensional network is disturbed when fruit and flavors are mixed into the plain yogurt. The texture and physical properties of the yogurt depend on the fruit, stabilizer, and the rate of cooling (45).

Stabilizers are added to prevent surface appearance of whey, and to improve and maintain body, texture, viscosity, and mouthfeel. Yogurts with lower milk solids have a greater tendency to synerese. Numerous stabilizers are available on the market. Generally a combination of several stabilizers is included in the formulation to avoid defects that may result from the use of a single stabilizer. A partial list of stabilizers used in yogurt include:

1. Gelatin is a protein of animal origin. It is derived from the hydrolysis of collagen. Only high bloom gelatin should be used in yogurt making, due to improved gelatin/casein interactions, its higher melting point, and its higher stabilizing ability (5). The term "bloom" refers to the gel strength. It disperses in cold, but requires heat for activation. It is used at a 0.3 to 0.5% level. Microstructure of yogurt made with 0.5% gelatin under scanning electron microscopy did not show the gelatin, and the structure did not differ from that of a plain, unfortified yogurt. This yogurt was rated smooth in sensory evaluation (46).
2. Whey protein concentrates (WPC) are used at 1 to 2% of protein addition. In a study with skim milk yogurt fortified with dairy-based proteins, the yogurts made with casein-based products were coarser and inferior compared to those made with WPC at 1 to 1.5%. It was recommended that WPC should be used along with other stabilizers (47).
3. Gums are water soluble or dispersible polysaccharides and their derivatives. In general, they thicken or gel aqueous systems when used at low concentration. Gums are used to stabilize emulsion and prevent wheying-off. Food gums are tasteless, odorless, colorless, and non-toxic (48). All are essentially non-caloric and are classified as soluble fiber. These are used at 0.2 to 1.5%, depending on the application.

Locust bean gum is a seed gum. It has low cold water solubility. It is generally used where delayed viscosity development is needed. Dispersion of this gum, when heated to about 185°F and then allowed to cool, is high in viscosity. It works synergistically with carrageenan in some applications (48).

Guar gum is very similar to locust bean gum, but is more soluble in cold water. It hydrates readily at pH 6–9. Its solubility is not affected by pH in the 4.8 to 5.0 range. It does not cross-link well with carrageenan (48).

Carrageenan is derived from red seaweed. It is a mixture of various types, kappa, iota, and lambda. It may contain 60% of kappa form and 40% lambda. The kappa type forms a gel, whereas, lambda does not. The polymer is stable at pH above 7.0, and has a tendency to degrade slightly at pH 5–7, degrading rapidly below pH 5.0. The potassium salt of this gum is the best gel former, but the gels are brittle and prone to syneresis. This defect is prevented by the addition of a small amount of locust bean gum. It interacts with casein in milk, and promotes stabilization of the yogurt gel (48).

Xanthan is produced by microbial fermentation. It is readily soluble in cold and hot water. It is not affected by pH changes. A synergistic increase in viscosity results from interaction of xanthan with κ-carrageenan and locust

bean gum. These gels are prone to shear thinning. It also gives sheen to products, which may not be desirable in yogurt (48).

Protein, starch, modified starch, and tapioca-based starches can be used without affecting the flavor of yogurt. The stabilizer used in yogurt is generally a blend of stabilizers incorporated at 0.5 to 0.7% or less. The amount used also depends on the milk solids level (5). A recent consumer survey of marketplace yogurts has indicated that products are gummy, perhaps due to over-stabilization (12).

C. Fruit and Fruit Flavorings for Yogurt

The growth and popularity of yogurt is largely due to fruit and sugar. For fruit-containing yogurt, the primary component of yogurt taste is the perceived degree of sweetness. This attribute of yogurt is believed to be responsible for its spectacular growth popularity (49). In an earlier study, 79% of consumers preferred flavored yogurts (50). The surveys, done in the United Kingdom, indicated that 90% of yogurt sales were of fruit and flavored varieties (51).

Many fruit flavors, single or blended, are popular, and these may vary with the season. Fruit preparations are added to 10 to 20% in the final product. A fruit preserve consists of 55% sugar and 45% fruit (16). These are cooked until the final solids reach 65 to 68%. The pH of these preparations is adjusted to 3.0 to 3.5 with citric acid or other food-grade acid. The processed fruit, in most cases, is filled aseptically in totes and shipped to yogurt plants. Transfer of fruit to yogurt should be done through sterile equipment to avoid yeast and mold contamination. The blending and the filler areas are very crucial to the microbiological quality of the yogurt with respect to yeast and mold. These areas should have HEPA-filtered air to keep out airborne yeast, mold, and other contaminants. Cardboard boxes should not be brought into these areas. Also, high pressure water hoses should be avoided while fruit blending and packaging is going on.

D. Heat Treatment

The high solids mix is given a higher heat-treatment than the conventional pasteurization. Generally, milk is heat-treated at 85 to 95°C, and then held for 10 to 40 minutes. At these temperatures, bacteriophages and vegetative bacterial cells are inactivated, and the growth of starter bacteria improves. Up to 60°C, there is no effect on whey protein. At 60° to 100°C, the whey proteins interact with each other and κ-casein. This interaction decreases dissociation of α_s- and β-casein, and increases κ-casein dissociation (51). When skim milk was preheat-treated at 85°C for 30 min and 90°C for 2 min, whey protein denaturation was 76.5% and 55.0%, respectively (52). This heat-treatment and resulting interactions increase the water binding capacity of the protein system.

E. Homogenization

Homogenization of mix is carried out in two stages; the first stage is at 10–20 mega Pascal, and the second stage is at 3.5. It reduces the fat globule size to less than 3 μm, which gives a rich mouthfeel. This prevents creaming of the mix upon storage. Homogenization also improves gel strength upon fermentation, due to greater protein-protein interaction.

V. YOGURT MIX INOCULATION AND INCUBATION

The inoculation rate may vary from 0.5 to 6%, depending on the type of yogurt and system set up. For yogurt fermented in the cup (set style), small surges of mix, 20–100 gal, may be inoculated at 5% and packaged and then incubated at 43–45°C. Yogurt may reach pH of 4.7 to 4.8 in less than 2 hours, and is then sent out of the hot room. If more time is available, mix can be inoculated at 0.5 to 1.5%, which may take 6 to 10 hours to reach pH 4.4 to 4.5.

The inoculation rate may also vary from 0.5 to 6%, depending on the plant layout and equipment available. Two kinds of fruited yogurts are popular in the United States.

1. Set style, fruit-on-the-bottom. In this kind of yogurt, cups receive about 2 oz fruit preparation, followed by inoculated mix at ~44°C in the filler room. The cups are placed in cases, and pallets are moved to the hot room which is maintained at ~48°C. The pH of the product reaches 4.7 to 4.85 in ~100 min., then it is moved to the cooling tunnel. At the end of the tunnel, the temperature of the yogurt is 16 to 18°C. It is then moved to the cooler.
2. Stirred style or Swiss style yogurt. In this type of product, fully fermented, plain cooled yogurt at pH 4.3 to 4.4 is cooled to ~20°C, blended with the fruit preparation, and filled in the cups. The palletized product is placed in the cooler. The texture and physical properties of the yogurt depend on the fruit, stabilizer, and the rate of cooling (45).

A. Yogurt Fermentation

Yogurt fermentation is a homolactic fermentation. Glucose metabolism by ST, LB, and *Lb. acidophilus* proceeds by the EMP pathway. Lactose utilization in ST, LB, and bifidobacteria involves lactose transport into the cells via cytoplasmic proteins (permeases). This translocation of lactose takes place without chemical modification. This unphosphorylated lactose is hydrolysed by β-galactosidase to glucose and galactose. Glucose is catabolized and galactose is secreted from the cells (23,53). The lactose permease is an active transport system, and the energy is provided in the

form of a proton motive force developed by expulsion of protons. The excreted amount of galactose is proportional to the amount of lactose taken up. The current model for lactose transport in these bacteria is that a single transmembrane antiport permease simultaneously translocates lactose molecules into the cytoplasm, and galactose out of the cell. The energy generated through galactose efflux thus supports lactose uptake into these cells. The average lactose content of a yogurt mix of 13% milk solids-not-fat was about 8.5% (54). During fermentation it was reduced to about 5.75%. The initial galactose content of the mix was a trace, but increased to 1.20% during fermentation. Only a trace amount of glucose was noted (54). In commercial yogurts, lactose ranged from 3.31 to 4.74%, and galactose varied from 1.48 to 2.50% (54).

There are a number of inhibitors for yogurt cultures that can impede or slow down lactose fermentation. Some of these are listed here. For further details, refer to (53,27,20,5). These inhibitors are: heat-sensitive lactenins, lactoperoxidase/thiocyanate/hydrogen peroxide (LPS), agglutinins, mastitic milk, antibiotic residues, hydrogen peroxide, detergents and santizer residues, and bacteriophages. Many of the inhibitors mentioned here may be seasonal and sporadic, or accidental. Bacteriophages on the other hand are pernicious, and can be devastating if not managed properly.

B. Bacteriophages

Bacteriophages (phages) are viruses that can infect bacteria and destroy one or more components of the yogurt culture. Phages are differentiated into virulent (lytic) and temperate phages, which reflect different growth responses in the bacterial host. Phages that infect and lyse the host cell are called virulent phages; whereas those which do not necessarily lyse their bacterial hosts, but instead insert their genome into the host cell chromosome, are called temperate phages. The propagation of virulent phages in the bacterial cell is called the lytic or vegetative cycle of phage multiplication, and results in the release of new infectious phage progeny (55). Bacteriophages multiply much faster than the bacteria. A bacteriophage with a burst size of 100 can destroy a culture within a couple of generations. This can cause huge economic losses, and result in inferior yogurt. Due to explosive growth of yogurt and mozzarella cheese production, a greater incidence of phages against ST has been reported (29). It is also noted that phages for lactobacilli appear less frequently (29,56). Recent work has shown that ST phages are closely related, at both the genetic and morphological level, making differentiation difficult. Electron microscopy studies revealed that both temperate and lytic phages were nearly identical, having small isometric heads and long non-contractile tails (57,58). Some lysogenic strains were autolytic at 45°C (58). New strategies to develop phage-resistant strains include antisense RNA technology, and origin-conferred phage-encoded resistance (PER) (57).

Both lytic and temperate bacteriophages have been found in *Lactobacillus delbrueckii* subsp. *bulgaricus* and subsp. *lactis* (59,57). Strains of *Lactobacillus acidophilus* isolated from dairy products harbored temperate phages, and some produced bacteriocins. One induced phage lysed nine other dairy lactobacilli, including LB (60). Some of the LB were also sensitive to the bacteriocin produced by *Lb. acidophilus*.

Primary yogurt cultures, ST and LB, should be carefully chosen and evaluated with respect to phage and compatibility with other adjuncts. Since many of the organisms used in yogurt may harbor temperate phages, propagated starter culture, yogurt, and environment should be monitored for phages. Use of aseptic techniques for propagation and production by properly trained personnel, along with proper mix heat-treatment sufficient to kill phages, are essential to keep phages under control.

VI. FLAVOR OF YOGURT

Flavor of yogurt depends on the milk, its heat-treatment, the starter strains used, incubation temperature, and the balance of the organisms in the yogurt. Biochemically, flavor compounds of yogurt include, but are not limited to, lactic acid, acetic acid, formic acid, propionic acid, butyric acid, acetaldehyde, acetone, diacetyl, acetoin, and several other compounds. In milk, ST produces formic, acetic, propionic, butyric, isovaleric and caproic acid, diacetyl, acetone, and some acetaldehyde. Lactobacilli, on the other hand, produce large quantity of lactic acid, acetaldehyde, diacetyl, peptides, and amino acids. Many of the compounds are derived from lactose, and some from other components in milk (22). The flavor of yogurt can turn acidic and bitter during storage and through out shelf-life. Protein degradation can continue during cold storage of yogurt, and some peptides released may be bitter (22,61). Incubation temperature of yogurt below 30°C may also cause bitterness (61). It is again emphasized that the cultures used should be carefully selected to deliver quality attributes of yogurt through out shelf-life.

VII. NUTRITIONAL AND HEALTH ASPECTS OF YOGURT

Nutritional value of yogurt is derived from milk. The value of milk and its products was recognized long ago. An example is a reference to the Promised Land as a land "flowing with milk and honey" (62). Yogurt has higher nutrient density, at 13–18% milk solids, compared to milk, at 12.3%. In literature, a number of healthful benefits have been assigned against various disease states (16,19,62).

These disease states are: colitis, constipation, various kinds of diarrhea, gastric acidity, gastroenteritis, indigestion, intoxication (bacterial toxins), diabetes, hypercholesteremia, kidney and bladder disorders, lactose intolerance, liver and bile disorders, obesity, skin disorders, tuberculosis, vaginitis and urinary tract infections, cancer prevention, and prevention and treatment of *Helicobacter pylori* gastritis and irritable bowel syndrome. Yogurt is a good source of calcium. One 8 oz. serving will provide about 400 mg of calcium (62). It is recommended that milk and yogurt be consumed with oxalate rich foods, such as spinach and soy products. A diet of products rich in calcium decreases urinary oxalate and helps in the prevention of kidney stones (62).

In 1908, in explanation to his longevity-without-aging theory, Metchinkoff stated that lactic acid bacteria in sour milk displaced toxin producing bacteria, thus, promoting health. At about the same time (1899), Tisser isolated bifidobacteria from the stools of infants, and recommended administration of the same to infants suffering from diarrhea (63). Since that time, numerous studies on the use of lactic cultures in foods have continued throughout the centuries. These studies have yielded variable results with regard to the health benefits of probiotics. In the past few years, the use of probiotics in yogurt and fermented products has exploded.

A. Definition of Probiotics

Probiotics are a live microbial feed supplement which beneficially affects the host animal by improving its intestinal microbial balance (63). Considerable work is going on, where a combination of molecular biology techniques and phenotypical analysis are being used to deciphe the participation and the role played by the probiotics. This will certainly challenge our current concepts.

B. Benefits of Probiotics

Health benefits imparted by probiotic bacteria are strain-specific and not species or genus specific. The strains *Lactobacillus rhamnosus* GG (Valio), *Saccharomyces boulardii* (Biocodex), *Lactobacillus paracasei* Shirota (Yakult), and *Bifidobacterium* BB12 (Chr Hansen), have the strongest human health efficacy data against some or all of the following: lactose intolerance; rotaviral diarrhea, antibiotic-associated diarrhea, and the associated *Clostridium difficile* diarrhea; as well as some other bacterial diarrheas and infections. Travelers' diarrhea may also be alleviated in some people by *Lactobacillus* GG. It is not yet possible to relate probiotic intake to prevention of bowel cancer in humans. However, there is stronger evidence for effects on bladder cancer in the Japanese population using the Shirota strain (65). Probiotics may also help in atopic eczema, irritable bowel syndrome, inflammatory bowel disease, *Helicobacter pylori* infections, and, possibly, in arthritic conditions (65). For early evaluation and comparison of probiotics, in vitro laboratory tests and standards for good clinical tests must be followed. These are listed in Tables 152.5 and 152.6. Over the years, lots of studies have been done with different strains; but there are only a few strains for which peer-reviewed published evidence from human clinical trials is available. The evidence from these trials is presented in Table 152.7 (65). In a 15-month long study with human subjects consuming a probiotic milk product containing *Lb. rhamnosus* DR20, it was observed that the population of *Lactobacillus* and enteroccal content of the feces was transiently altered without markedly affecting biochemical or other bacteriological factors (66). Based on their work, the authors have proposed a new definition of probiot: "Probiotics contain microbial cells which transit the

TABLE 152.5
In Vitro Tests for Probiotic Bacteria as Indicators of Human Health

- Acid/pepsin (pH 2.0 for 105 min) and bile tolerance (physiological concentrations)
- Fast growth rate and active metabolism
- Acid production (rate of production, types of acids, and regio-specificity)
- Production of bacteriocins
- Immune response (local and systemic)
- Vitamin production (e.g., folate, B group)
- Colonization and adhesion ($CaCo_2$ and HT29 cells, mucus)
- Antibiotic sensitivity patterns
- Bile deconjugation
- Inhibition of pathogens (e.g., *Salmonella utyphimurium, Escherichia coli, Clostridium difficile, Clostridium perfringens, Candida albicans*)
- Fecal enzyme concentrations (e.g., β-glucuronidase)
- Safe history

TABLE 152.6
Standards for Good Clinical Trials on Probiotics

- Each strain identified by molecular methods, and properties fully documented
- Extrapolation of data from strains of the same species is not acceptable
- Double-blind, placebo-controlled randomized studies, with a "crossover" design where possible
- Adequate number of treatments to avoid "confounding" of data by other ingredients and organisms
- Study end-points should be unequivocally stated prior to commencement
- Currently acceptable statistical tests must be used
- Confirmation of findings by one or more independent research groups
- Publication in peer-reviewed journals of international standing
- Efficacy of the probiotic strain in different products should be assessed separately for each product against each health condition

gastrointestinal tract and which, in doing so, benefit the health of the consumer." This definition certainly calls into question some of the criteria set forth in Tables 152.5 and 152.6 for an organism to qualify as a probiotic.

It is generally agreed that *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptooccus thermophilus*, the yogurt bacteria, do not adhere to the mucosal surfaces of the intestinal tract during their transit through the gut (67,68,5). These organisms do not survive in the human gastrointestinal tract because of their low tolerance for bile salts (69,70). A combination of molecular methods has been used for the detection of lactic acid bacteria in the human gastrointestinal tract (41). *Lactobacillus delbrueckii* group was detected, but not *Streptococcus thermophilus* (41). Recent feeding trials with Gottingen minipigs appear to indicate that these yogurt organisms do survive the passage to the terminal ileum (71). The numbers detected (10^6 to 10^7 cfu/g of chyme) are considered to be high enough to be considered for potential probiotic status. It is believed that the gut is home to 400 to 500 species of organisms. Recent studies have indicated that the total microbiota of each adult individual had a unique pattern reflecting their differences in composition, which is partly dependent on the host genotype (41). What happens to the balance of these in different human beings, with different dietary habits and age, is not known. How the organisms get established in the gut in different segments is also not known. Lots of useful information is coming forth as this matter is studied more seriously.

C. Prebiotic

A prebiotic is defined as a non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, thereby improving the host health (18). The beneficial effects of the presence of bifidobacteria in the gut are dependent on their viability and metabolic activity. Their growth is stimulated by the presence of complex carbohydrates known as oligosaccharides. Some of these are considered as prebiotics (72). Fructo-oligosaccharides (FOS) are well-known prebiotics found in 36,000 plants (73). FOS may contain 2 to 8 units in a chain. Inulin, a type of FOS extracted from chicory root, has a DP (degree of polymerization) up to 60. FOS and inulin occur naturally in a variety of fruits, vegetables, and grains, especially chicory, Jerusalem artichoke, bananas, onion, garlic, asparagus, barley, wheat, and tomatoes (73). Recommended levels of prebiotics begin at 5 g/day (73), and may be as high as 15–20 g/day (18).

1. Benefits of Prebiotics

Prebiotic fermentation leads to health benefits, such as increased fecal biomass, and increased stool weight and/or frequency. Prebiotics are fermented by bifidobacteria with the production of short chain fatty acids (SCFA), mainly acetate, propionate, and butyrate, and hydrogen and carbon dioxide. Production of SCFA leads

to lower pH in the colon, which facilitates absorption of calcium, magnesium, and zinc (18,73). Lower pH also restricts pathogenic and other harmful bacteria, thus reducing or eliminating precarcinogenic activity (73).

2. Potential Prebiotics

Several materials are under study as prebiotics. These are: oligosaccharide (FOS Rafitilose P95), inulin, pyrodextrine, galacto-oligosaccharides, soy-oligosaccharides, xylo-oligosaccharides, isomalto-oligosaccharides, lactulose, transoligosaccharides, Rafitaline, HP, Frutafit EXL, and Fruitofit IQ (73,74). In a recent study of 54 strains of lactic acid bacteria, lactose-derived galacto-oligosaccharide utilization was linked to the presence of β-galactosidase in bifidobacteria studies (75).

3. Synbiotic

Synbiotic refers to a product in which a probiotic and prebiotic are combined. The synbiotic effect may be directed towards two different regions, both large and small intestines. The combination of pre- and probiotic in one product has been shown to confer benefits beyond those of either on its own (76).

4. Survival of Probiotics in Yogurt

It is known that bifidobacteria and lactobacilli are members of the human gut flora. Also, a large number of yogurt brands claim the addition of probiotics. For the probiotics to be effective, the organisms have to be alive (19). In market-bought samples, the fresh product had 10^6 to 10^7 cfu/g. Their numbers declined to less than $\leq 10^3$ cfu/g in some products (77,78). Some strategies to improve probiotics numbers in yogurt include reduction of regular ST and LB in the product, and the addition of cultured probiotics to yogurt (78,79). Since, the dietary probiotics appear to be transitory, feeding of prebiotics, inulin and FOS, may be sufficient to favor the growth of healthy organisms in the gut (80).

VIII. FUTURE TRENDS

The market for probiotic drinks is booming, and clinical work with probiotics continues to provide support for their benefits. Yakult from Japan, is the world's largest probiotic dairy beverage, followed by Actimel from Dannon (81). The dividing line between yogurt and cultured milks is becoming thinner. Probiotic strains may become the sole fermenting agents in yogurt and fermented milk (82,83). Biogaia and Farm Produce Marketing Ltd. have signed an agreement to market and sell drinkable yogurt with Biogaia's delivery system, Life Top™ straw. The straw will be attached to the side of the package and contain *Lactobacillus reuteri* (Reuteri TM) (84). Under the category of healthy and functional yogurts, new fruits and flavors are being offered (85). Some of these are:

- Yogurt containing fruit pieces and flavors like melon and pink grapefruit
- Yogurt with herbal extracts, including ginger and green tea extract
- Yogurt with passion fruit enhanced with elder flower extract
- Strawberry/rhubarb fitness yogurt, fortified with vitamins B, C and E

There is a growing interest in offering premium and indulgent yogurts as desserts (85). Some of the creations listed include:

- Bourbon Vanilla
- Pear and Butterscotch
- Goat yogurts containing mandarin and ginger, lemon and lime zest, and summer berries

We have come a long way in the development of yogurt into a respectable dairy product with noted health benefits. Producers and marketers of this product are making every effort to keep the yogurt category growing through product development and packaging innovations, while delivering a good-for-you flavorful product suited for all occasions of gastronomic indulgence.

ACKNOWLEDGMENT

153 Egg Biology

Gita Cherian
Oregon State University

CONTENTS

I. INTRODUCTION

The egg is both a biological and chemical entity. Eggs are unique in the sense that the nutrients are already in the egg, and are balanced in such a way as to support a new life upon incubation. The egg also provides a perfectly packaged, portion controlled, highly nutritious food containing vital nutrients essential for maintaining human health. This chapter describes, briefly, the formation, composition, and nutrient content of the egg, the egg's role as a functional food, nutrient modulation strategies, and also the uniqueness of egg in nutrition research.

II. PHYSIOLOGY OF EGG FORMATION

The ovary of an immature pullet has small-undifferentiated follicles that are not visible to the naked eye. At puberty, these follicles increase in size to form an array of small follicles (known as the ovarian stroma), as well as a hierarchy of large follicles that vary in size (1,2). Growth of follicles can be divided into a slow phase (months to years), a rapid phase increasing in protein content (2 month period), or a final phase (7 to 11 days before ovulation), when the majority of yellow yolk and lipids are deposited (1). During the final phase, a follicle will increase in size from 0.08 g to 16 g in weight. The production of eggs is orchestrated through the action of organs, such as the brain (endocrine), liver (lipoprotein), and skeletal system (calcium). Light stimulation causes the release of follicle stimulating hormone from the pituitary, causing an increase in the growth of ovarian follicles. Upon reaching sexual maturity, the ovum is released by the action of leutinizing hormone secreted by the pituitary gland. A list of major hormones and their role in egg production is listed in Table 153.1. The liver plays an active role in yolk lipid accretion, as it produces lipoproteins that contribute to egg yolk lipids. Yolk is deposited into follicles as they proceed through the hierarchy to become mature. Other nutrients, such as water, sugars, proteins, vitamins, and minerals are also deposited into the yolk from the hen's blood. Follicles are said to be "mature" when they are capable of producing progesterone, which is released from the largest follicle (3). Release of progesterone will trigger the ovulation process. Follicular maturation typically takes longer than 24 hours, and so the ovulatory cycle is set back slightly each day (4). The matured follicle is ovulated and drops from the ovary into the egg-laying tract as the pullet reaches laying age (around 20 weeks). The process of laying an egg takes approximately 25 hours from the time of ovulation until the egg is laid.

The avian oviduct is a tubular organ extending from the ovary to the cloaca. In laying hens, the oviduct is 40–80 cm long, consisting of five portions: infundibulum, magnum (albumen-secreting portion), isthmus, uterus, and vagina (1) (Figure 153.1). The oviduct ensures smooth passage of the egg and secretes extracellular matrix components to surround the egg albumen. The yolk enters the oviduct and is surrounded by two layers of thin white, and two layers of thick white. Initiation of calcification occurs in the shell gland (uterus). The egg stays in the uterus for about 21–26 hr to complete the process of calcification (5). The high rate of calcium secretion returns to basal level approximately 2 hr before expulsion of the egg. It takes approximately 2 grams of calcium to form an eggshell. Prior to calcification, the egg takes up water and pigments into the albumen from the tubular glands. Pigment deposition occurs in the last three to five hours the egg spends in the shell gland. It is believed that light colored eggs spend a shorter amount of time in the shell gland, and therefore have less shell deposition. The laying of an egg is known as oviposition, which occurs in sequences. Sequences are consecutive days of laying that are separated by a "pause"

TABLE 153.1
Major Hormones Involved in Egg Production[a]

Hormone	Location of Production	Function
Luteinizing Hormone	Anterior Pituitary	Ovarian hormone production
Follicle Stimulating Hormone	Anterior Pituitary	Early follicle development
Progesterone	Ovarian Follicle (Granulosa cells)	Oviduct growth. Initiate ovulation through feedback

[a] Reference 1,3.

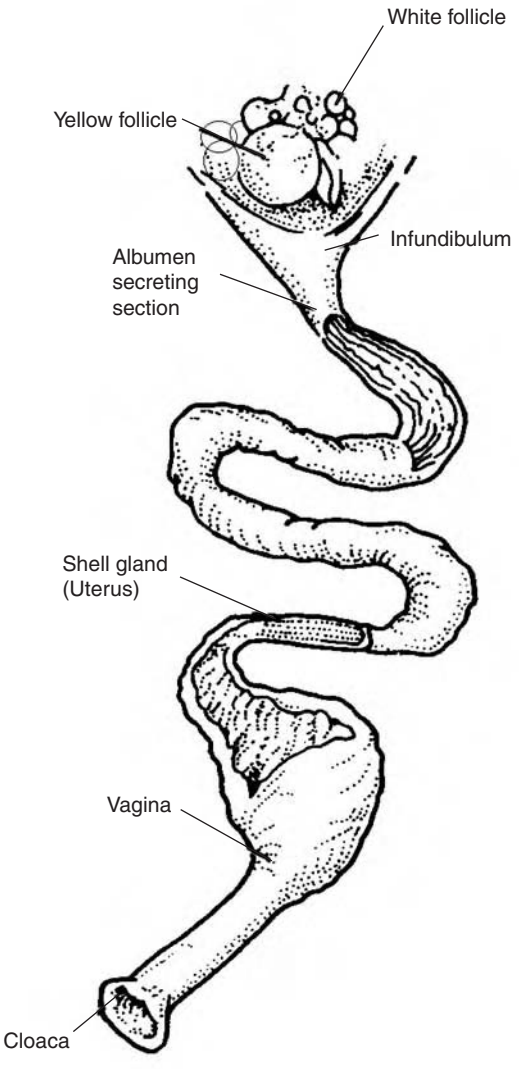

FIGURE 153.1 Oviduct of laying hens.

of 40 to 44 (or more) hours duration. Sequence length changes through the egg production year. The longest sequences are seen during the time of peak production at about 30 to 35 weeks of age (3,4).

III. EGG COMPOSITION

The egg is comprised of four main parts: yolk, egg white or albumen, shell membranes, and shell. The composition of eggs, reported decades ago, consisted of 58% white, 31% yolk, and 11% shell (6). Dietary manipulation of egg nutrients, strain of the bird, and genetic selection for egg size and production may lead to changes in egg components. Recently, there has been a tremendous interest in specialty eggs. The composition of such specialty eggs reveals a wide variation in egg components, such as yolk, white content, edible portion, and yolk:white ratio (7). A comparison of the egg components of supermarket eggs to those from hens fed special diets is shown in Table 153.2. In general, the shell contributes 9 to 11%, the yolk 25 to 33%, and the egg white 56 to 64% in chicken eggs (7). The total edible portion is 89 to 91%. Cooking leads to minor changes in egg nutrient content (8).

A. The Egg Yolk

The yolk is the first part of the egg to develop and comprises about 30–31% of the total weight. The yolk is comprised of 51–52% water, 16–17% protein, 31–33% fat including cholesterol, fat soluble vitamins, pigments, and some minerals.

1. Lipids

The lipids in eggs have attracted attention both at the scientific and consumer level, due to the link between high dietary fat consumption and coronary heart diseases. The fat in the egg is exclusively in the yolk, and comprises 5.5 to 6 g in an average 60 g egg. Almost all lipids are present as lipoprotein complexes associated with yolk. Trace levels of lipids have been observed in the whites. Yolk lipids are made mainly of triacylglycerol, phospholipid, and free cholesterol. Triacylglycerol and phospholipids are the major components of yolk lipids, comprising up to 65 and 32%, respectively (9). Fatty acids are the most prevalent components of triacylglycerol and phospholipids. Fatty acids may be of different chain lengths and degrees of saturation, as well as different configurations. The degree of unsaturation of fatty acids is of interest to researchers, because of its effect on health. Consequently, the most significant characteristic of dietary lipids is the content of different types of fatty acids. Fatty acids are classified into three families: saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids (PUFA).

TABLE 153.2
Comparison of Egg Components in Regular and Speciality Eggs

Egg Components	Control		Specialty Eggs			
Yolk	30.2^{b}	29.7^{b}	25.9^{c}	33.4^{a}	25.6^{c}	29.8^{b}
White	59.6^{b}	59.4^{b}	63.7^{a}	56.3^{c}	64.5^{a}	60.7^{b}
Shell	10.1^{ab}	10.8^{a}	10.3^{ab}	10.2^{ab}	9.9^{b}	9.5^{b}
Edible Portion	89.8^{ab}	89.2^{b}	89.7^{ab}	89.7^{ab}	90.1^{a}	90.5^{a}
Yolk: White	50.6^{b}	50.0^{b}	40.6^{d}	59.0^{a}	39.6^{d}	49.0^{c}
Total Lipids	25.1^{abc}	27.7^{a}	24.6^{bc}	26.2^{a}	22.9^{c}	25.9^{ab}

Different specialty eggs are collected from hens raised on a vegetarian diet or as free range. Reported as percentage of egg weight.

[a–d] within a row with no common superscripts indicates significantly different ($P < 0.05$), $n = 6$.

Adapted from Reference 7.

a. *Saturated fatty acids*

The predominant saturated fatty acids in eggs are palmitic (C16:0) and stearic (C18:0). The content of these two fatty acids in chicken eggs may range from 22 to 26% and 8 to 10%, respectively. There are also other minor amounts of C14 and C20. The total saturated fatty acids in eggs may constitute up to 30 to 35%.

b. *Monounsaturated fatty acids*

The monounsaturated fatty acids in eggs are constituted by C16:1, and C18:1, which constitutes to 42–46%. Oleic acid (C18:1) is the major monounsaturated fatty acid in chicken eggs. Oleic acid has been reported to be hypolipidemic, reducing both cholesterol and triacylglycerol without decreasing high density lipoprotein cholesterol in human patients (10). The content of egg monounsaturated fatty acids is affected by dietary lipids. Addition of high oleic acid sunflower seeds in feed has been reported to increase the content of oleic acid in eggs up to 3.2 g, compared with 1.9 g in regular egg (11). Recent studies reported a significant decrease in egg oleic acid when diets contained conjugated linoleic acids (CLA) (12,13,14).

c. *Omega-6 (n-6) and omega-3 (n-3) polyunsaturated fatty acids*

There are two families of PUFA in the egg, namely n-6 and n-3 fatty acids. The predominant n-6 PUFA in egg lipids is C18:2n-6 (linoleic acid). Other n-6 fatty acids in eggs may include C20:4n-6, C22:4n-6, and C22:5n-6. The content of long chain n-6 PUFA (LCPUFA) (>20-carbon) may vary from 1 to 2%, and is reflected by the type of laying hen diet (15). The content of n-3 fatty acids in eggs is contributed by α-linoleic acid (18:3n-3), eicosapentaenoic acid (20:5n-3), docosapentaenoic acid (22:5n-3), and docosahexaenoic acids (DHA, 22:6n-3). Among these, DHA is the major n-3 fatty acid in the egg. The α-linoleic content in regular eggs is under 1% of the total lipids. DHA may constitute

between 1 and 3%. The content of n-3 PUFA is a reflection of dietary fat. Addition of flax, fish oil, and marine algae in laying hen diet leads to significant increases in α-linoleic acid and DHA in eggs (15,16).

d. Sterols

The major sterol in yolk lipids is cholesterol, and is found in the free form. The cholesterol content may vary from 11–14 mg/g yolk or 200 to 220 mg/average egg. The cholesterol content of chicken eggs has received far more attention than any other component of eggs from the media, consumers, and health professionals, due to the reported role of serum cholesterol in cardiovascular diseases. Although diet has very little effect on egg cholesterol (17), other factors like egg weight, yolk size, and strain of bird may affect the cholesterol content (19). Most reported studies indicate an enhancement of high density lipoprotein ('good') cholesterol in humans by egg consumption (20).

e. Phospholipids

Phospholipids are an important component of egg yolk lipids and constitute 28 to 30%. The egg phospholipids are constituted by phosphatidyl choline, phosphatidyl ethanolamine, phosphatidyl serine, and sphingolipids (9). The amphipathic nature of phospholipids aids in their good emulsifying properties, and is widely used in the food, pharmaceutical, and cosmetic industries. Egg phospholipids are also rich in polyunsaturated fatty acids, such as DHA (22:6 n-3) and arachidonic acid (20:4–6), and are getting attention as a source of long chain PUFA for the infant formula industry, due to their role in central nervous system development (21).

2. Yolk Proteins

Egg proteins distributed in the yolk exist as lipoproteins. Low-density lipoprotein (LDL) is the major protein, and accounts for up to 65% of the total yolk proteins, and may contain up to 80–89% lipids. The high density lipoprotein exists as a complex with phosphoprotein as 'phosvitin.' About 80% of phosphorus in eggs is located in phosvitin, which is derived from vitellogenin formed in the liver (22). Other yolk proteins include livetin, a water-soluble, non-lipid glycoprotein, and riboflavin-binding protein, a hydrophilic phosphoglycoprotein.

3. Yolk Vitamins

The chicken egg is considered a good source of most vitamins, except vitamin C. Egg vitamins include both fat soluble and water soluble (Table 153.3) (23). Most fat-soluble vitamins are concentrated in the yolk. Although several factors, such as age, strain of bird, and age of bird are involved, diet is the most important factor, regulating egg vitamin content. Transfer efficiency of a vitamin depends on vitamin level in the diet, feed intake, rate of egg production, and egg weight. The transfer efficiency may vary between vitamins. For example, vitamin A has a transfer efficiency between 60 and 80%; riboflavin, pantothenic acid, and biotin have a transfer efficienies between 40–50%; vitamin E and vitamin D have a transfer efficiencies between 15–25%; and vitamin K, thiamin, and folacin have 5 to 10% transfer efficiencies (24).

TABLE 153.3
Vitamin Content of Eggs[a]

Nutrient	Whole Egg	White	Yolk
Vitamin A (IU)	317	—	323
Vitamin D (IU)	24.5	—	24.5
Vitamin E (mg)	0.70	—	0.70
Vitamin B12 (μg)	0.50	0.07	0.52
Biotin (μg)	9.98	2.34	7.58
Choline (mg)	215.1	0.42	215.9
Folic Acid (μg)	23	1	24
Inositol (mg)	5.39	1.38	3.95
Niacin (mg)	0.037	0.03	0.002
Pantothenic Acid	0.63	0.04	0.63
Pyridoxine (mg)	0.07	0.001	0.065
Riboflavin (mg)	0.25	0.15	0.106
Thiamine (mg)	0.03	0.002	0.028

[a] http:/www.aeb.org/food/nutrient.html (21).
Based on 59 g shell weight, with 50 g total liquid whole egg, 33.4 g white, and 16.6 g yolk.

4. Yolk Minerals

The egg yolk contains 1% minerals, and phosphorus is the most abundant mineral component. More than 60% of the total phosphorus in egg yolks is contained in phospholipids. The major inorganic components of egg white are sulfur, potassium, sodium, and chlorine (Table 153.4). Phosphorus, calcium, and magnesium are next in importance. Table 153.3 shows the content of major minerals in eggs (23).

5. Yolk Carbohydrates

The content of carbohydrates in egg yolk is about 1%. The majority of carbohydrates are oligosaccharides bound to protein. The remaining 30% are free carbohydrates in the form of glucose, and constitute to 0.8 and 0.7% in the whole egg, albumen, and yolk respectively. The total carbohydrate in the whole egg, white, and yolk constitute to 0.61, 0.34, and 0.30 g, respectively. Sialic acid is a functional carbohydrate in egg with pharmacological potential (25), due to its involvement in cell adhesion, receptor functions, and defense mechanisms.

6. Yolk Pigments

Several pigments are present in all parts of the egg. The yolk has the highest pigment content constituting 0.02%.

TABLE 153.4
Mineral Content (mg) of Egg Edible Portion[a]

Nutrient	Whole Egg	White	Yolk
Calcium	25	2	23
Chlorine	87.1	60.0	27.1
Copper	0.007	0.002	0.004
Iodine	0.024	0.001	0.022
Iron	0.72	0.01	0.59
Magnesium	5	4	1
Manganese	0.012	0.001	0.012
Phosphorus	89	4	81
Potassium	60	48	16
Sodium	63	55	7
Sulfur	82	56	25
Zinc	0.55	—	0.52

[a] Reported in mg (21). http:/www.aeb.org/food/nutrient.html. Based on 59 g shell weight, with 50 g total liquid whole egg, 33.4 g white, and 16.6 g yolk.

The yolk carotenes are classified as xanthophylls and carotenes. Leutin, zeaxanthin, and cryptoxanthin belong to the xanthophyll group, and β-carotene belongs to the carotene group. The yolk color is of aesthetic importance in some parts of the world, with preferences ranging from deep yellow to light-colored yolks. Feed containing yellow corn, canola, flax, or alfalfa produces medium yellow yolks, while feed containing wheat or barley produces lighter color yolks. Natural yellow-orange substances, such as marigold petals, are added to feeds to enhance the yolk color. The yolk pigments are attracting a lot of interest, due to their potential role in sight and antioxidant actions.

B. Egg White

1. Egg White Proteins

The protein value of whole egg protein is considered to be 100, and is used as a standard for measuring nutritional quality of other food proteins. Addition of two eggs in the diet provides 12 g of protein, which will meet 30% of recommended dietary allowance in the United States. Protein is the major component of egg white, which contains about 11% proteins consisting of more than 40 different kinds of proteins. Due to their functional and pharmacological properties, egg proteins are desirable ingredients in many baked foods and in the drug industry. Ovalbumin is the major protein, and constitutes up to 54% of total egg white proteins, serving as a major source of amino acids for the developing embryo. Ovotransferrin and ovomucoid constitute about 12 and 11% of proteins, respectively (22). Ovotransferrin is implicated in the transfer of iron to target cells, and could be used as a nutritional ingredient in iron-enriched food products. Other proteins include ovomucin, ovoglobulin, ovomacroglobulin, ovoglycoprotein, flavoprotein, ovoinhibitor, avidin, and cystatin. Egg white also contains enzymes, such as lysozyme, phosphatase, and catalase. Among these enzymes, lysozyme constitutes about 3.5% of egg white, and is widely used in the food industry due to its antibacterial properties.

C. Egg Shell

Egg shell is a complex compound composed of 95% minerals, of which calcium is more than 98%. Other inorganic components include phosphorus, magnesium, and trace amounts of iron and sulfur comprising less than 0.05%. Egg shell powder is considered to be a good source of highly bioactive calcium, and could be used as an ingredient for human consumption. Egg shell is composed of a thin film cuticle, a calcium carbonate layer, and two shell membranes. Egg shell membrane contains several bacteriolytic enzymes, such as lysozyme and N-acetyl glucosaminidase as well as other membrane proteins that have been thought to have beneficial effects in treating injuries. Carbohydrates in egg shell are composed of glycosaminoglycans that are anionic polysaccharides consisting of hyaluronic acid (48%) and galactosaminoglycan (52%) (27). These carbohydrates have wide application in the cosmetic, pharmaceutical, and food industries.

IV. EGGS AND HUMAN HEALTH

Although chicken eggs are a rich source of vital nutrients essential for maintaining human health, the per capita consumption of eggs has been declining steadily over the past four decades (Figure 153.2). Changing lifestyles, more choices of food products, and consumers' increasing health consciousness are some of the contributing factors. The egg, with its high source of fat and cholesterol, has been an easy target in the control of dietary fat intake. Due to its relatively high cholesterol content, the egg has been used as an exclusive source of dietary cholesterol in both

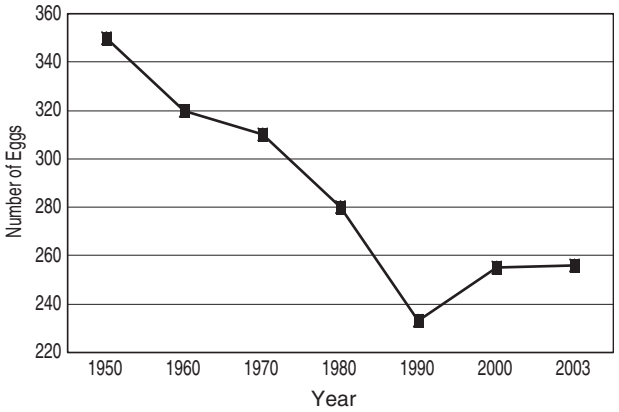

FIGURE 153.2 Shell egg consumption patterns in the U.S. during the last 50 years.

animal and human experiments, and has become the visual icon of high cholesterol. The results from some of the studies claimed cholesterol as a promoter of diet-related chronic diseases, resulting in damage to the egg's reputation as a nutritious food item. However, recent research has shed more insight into the beneficial health effects of eggs, and egg consumption has observed an increase since the late 1990s (Figure 153.2).

A. Egg Consumption, Blood Lipids, and Coronary Heart Disease

In a large prospective cohort study that evaluated the food consumption patterns of more than 100,000 people, Hu et al., 1999 (28) reported no overall association between egg consumption (up to one egg per day) and the risk of coronary heart disease. The authors speculated that the positive health effects associated with egg consumption were attributable to health-promoting nutrients, including PUFA, antioxidants, folates, and other B vitamins. However, an adverse effect of egg consumption on diabetic subjects was observed by these authors. The increased risk of coronary heart disease may be associated with abnormal cholesterol metabolism in diabetics (28). The effect of dietary egg cholesterol on the ratio of total cholesterol to high density lipoprotein (HDL) cholesterol was investigated by Weggemans et al., 2001 (20). After reviewing the data from 1974 through 1999, these authors concluded that egg cholesterol increases the ratio of total to high density lipoprotein cholesterol, thus adversely affecting the human cholesterol profile. Investigating the nutritional significance of eggs in American diets, Song and Kerver, 2000 (29) conducted a cross-sectional and population-based study (n = 27, 378) during 1988–1994. Nutrient intake, egg intake, and blood cholesterol concentrations of subjects were evaluated according to the frequency of egg consumption. These researchers reported no association between egg consumption and blood cholesterol concentration. In addition, consuming eggs contributed significantly to other nutrients, such as vitamin B6, saturated and PUFA, and vitamins A, E, and B12 (29).

V. HENS' EGGS AS FUNCTIONAL FOOD

Functional foods have been defined as foods that, by the virtue of the presence of physiologically active components, provide health benefits beyond basic nutrition. Consumers are highly interested in functional foods that prevent or ameliorate the disease progression process. The egg is a storehouse of several biologically active functional ingredients, like PUFA, carotenoids (leutin, zeaxanthin), cholines, sphingolipids, and antioxidant vitamins, providing new and exciting avenues for developing health-value-added egg and functional foods. The health-enhancing nutrients in eggs could also be modified through the hens' diet, making eggs an excellent choice as a functional food.

A. Eggs: Role in Sight

Age–related macular degeneration is a debilitating eye disorder of the elderly, resulting in irreversible blindness. Two carotenoids, leutin and zeaxanthin, accumulate in the macular region of the eye and have recently received attention for their potential role in delaying age–related macular degeneration (30). Leutin and zeaxanthin are able to absorb blue light striking the retina, which is thought to initiate degeneration of the retinal membranes. Egg yolk contains 292 and 213 μg of leutin and zeaxanthin, respectively; and they are more bio-available from this source than from plant sources of carotenoids. Eating eggs resulted in respective 50 and 114% increases in plasma leutin and zeaxanthin (30). Leutin and zeaxanthin also possess antioxidant properties and protect the PUFA-rich retinal membranes from phototoxic damage. In view of the potential role of these carotenoids in delaying macular degeneration, including eggs in the diets of the elderly should be reconsidered.

B. Eggs as Brain Food

Phospholipids are an important component of egg yolk lipoproteins, and also the major constituent in cell membranes of all living organisms. Phospholipids provide the necessary interface for nutrient transport, due to their amphipathic properties, and are rich in long chain PUFA, such as DHA (22:6n-3) and arachidonic acid (20:4n-6). Neural tissues, such as those in brain and retina, are highly concentrated, with DHA constituting over 50 and 70% of fatty acids in brain synaptosomal membranes and rod outer segments of retina, respectively DHA is involved in maintaining membrane fluidity, signal transduction, protein signaling, and gene expression (31). Accretion of DHA in the human brain is also high during periods of brain growth spurt, which starts during the third trimester of pregnancy and extend through the first 2 years of life (21). An average egg could provide over 300 mg of long chain PUFA, and could well be included in the diet of pregnant and nursing women as well as the diet of weaning toddlers. The content of egg DHA and arachidonic acid is highly dependant on dietary PUFA, and can be increased by feeding appropriate feed sources, which are discussed later in the nutrient modulation section.

C. Source of Choline

Chicken eggs are a rich source of choline (associated with phosphatidyl choline in phospholipids). Choline is responsible for the structural integrity and signaling function of phopholipid-rich cell membranes. One large egg contains about 300 mg of choline, which provides 60% of the recommended daily intake of choline for adults,

including pregnant and lactating women (32). Animal studies have found that choline plays an essential role in the development of brain function, memory and learning ability in mice (33).

D. Source of Sphingolipids

Sphingolipid content of eggs has been reported to be the highest of any food at 2250 umol/kg (34). Sphingolipids are critical for the maintenance of membrane structure and modulate the behavior of extracellular matrix proteins. Sphingolipids also function at the binding site for microorganisms, microbial toxins, and viruses. Inhibition of early stage colon cancer and a decrease in the proportion of adenocarcinoma have been reported in mice fed sphingolipids (35). An inverse correlation between tissue and plasma concentrations of sphingolipids and cholesterol in normal and pathological conditions has also been reported. Sphingolipids have been reported to alter cholesterol metabolism and, consequently, to affect cholesterol balance in the cell. A 30% reduction in plasma cholesterol in rats fed semipurified diets supplemented with a 1% mixture of sphingolipids and glycosphingolipids was reported (36). However, very little information is available on the health effects of egg sphingolipids. Further research in this area is warranted.

VI. EGG NUTRIENT MODULATION

Animal fats including egg lipids are important sources of many nutrients. In a typical Western diet, 58% of dietary fat, 74% of saturated fat and 100% of cholesterol are supplied through animal products such as eggs, meat and milk. Modern agriculture with its emphasis on production resulted in drastic changes in fatty acid content of food products resulting in an imbalance of polyunsaturated and saturated fatty acids, antioxidant vitamins and a wide ratio of n-6:n-3 fatty acids in the current food supply including eggs. The dietary recommendations set forth by health agencies include reduction in total fat intake to 30% of calories with an increase in monounsaturated fatty acids and PUFA to 15 and 10% of calories and a balance of PUFA to saturated fatty acids close to 1 (37). The food industry is encouraged to intensify the effort to develop and market products that would facilitate adherence to the dietary guidelines. The egg industry has been very responsive to these recommendations and dietary guidelines by producing and marketing eggs with more balanced PUFA containing both n-3 and n-6 fatty acids. Chickens are monogastric and the lipid nutrient composition of the diet alters the content of fatty acids and other fat-soluble vitamins and pigments in eggs. The enrichment of other minor nutrients through feed manipulation has also been reported. This section highlights some recent research in nutrient manipulation of chicken eggs.

A. Designing Egg Constituents

1. Omega-3 (n-3) Fatty Acids

The past decade witnessed a tremendous interest in the health benefits of the n-3 family of PUFA. Several studies have indicated that increased consumption of n-3 PUFA offers potential for reducing the risk of coronary heart disease, atherosclerosis, hypertension, and other cardiovascular diseases (37). These health-promoting effects of dietary n-3 fatty acids have invoked considerable efforts during recent years to create alternate sources by enriching chicken eggs with n-3 fatty acids (38). The technology has been focused on increasing the n-3 fatty acid content of eggs through incorporation of different oils or oil seeds in the hens' diet (37). Addition of ground flax seed has been used as a common practice in the production of n-3 PUFA-rich eggs (18,37). Eggs from hens fed diets containing 10 to 15% flax seed could provide up to 550–600 mg of n-3 PUFA, compared to 60 mg of n-3 PUFA in regular eggs (38). The amount of n-3 PUFA supplied from n-3 fatty acid modified eggs is equivalent to a 100 g serving of fish. Other oil seeds, such as canola seeds, contain 18:3 n-3 and also increase n-3 fatty acid content to a lesser extent (38). Other source of n-3 PUFA for fatty acid enrichment include marine oils and algae. A comparison of total n-3 fatty acids in eggs from hens fed different levels of flax oil (3.5%) or menhaden oil (3.5%) is depicted in Figure 153.3.

2. Conjugated Linoleic Acids

Conjugated linoleic acids (CLA) is the generic name for a group of positional and geometric conjugated dienomic isomers of linoleic acid. CLA has received considerable attention for its anticarcinogenic, antiatherogenic, hypocholesterolemic, immunomodulatory and body fat

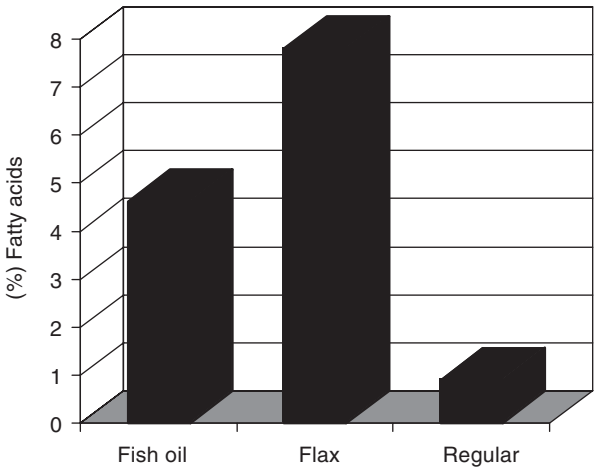

FIGURE 153.3 Omega-3 fatty acid content of eggs from hens fed 3.5% fish oil or flax oil, compared to regular eggs. (Adapted from Reference 52.)

reduction properties (40). Current intake of CLA is estimated to be several hundred milligrams/day (41). Based on animal data, it is estimated that approximately 3 g/day of CLA would be required to produce beneficial effects in humans (42). Humans do not have the ability to synthesize CLA, which be supplied through their diet. Dietary CLA is contributed by food products of ruminant origin, such as dairy products and beef (42). Poultry products contain relatively low CLA concentrations (less than 0.9 mg CLA/g of fat, respectively (43)). Increasing the concentration of CLA in poultry foods is a possible way for humans to increase their CLA intake and obtain the potential health-benefits. A significant incorporation of CLA in eggs by dietary manipulation has been reported (44,45). The diet-induced incorporation of CLA in eggs is dose-dependent. Diets containing 5% CLA resulted in about 15% CLA in egg lipids (46). From the research reported, consumption of an average chicken egg weighing 60 g could provide over one-third of the daily CLA recommendation (3 g) for an adult human (46). Cherian et al., 2002 (48) used menhaden fish oil (as a source of long chain n-3 PUFA) along with CLA in the diet of laying hens to produce n-3 PUFA-CLA rich eggs. Such eggs from hens fed a diet containing 1.0% fish oil and 2.0% CLA oil could provide over 300 mg of CLA along with 230 mg of n-3 fatty acids to the human diet.

3. Antioxidant Vitamins

a. Tocopherols, tocotrienols, retinols, and carotenes

In recent years, the term "antioxidant vitamins" (tocopherols, retinols, carotenes) has caught the attention of consumers. Both clinical and epidemiological studies have reported the protective effect of dietary antioxidants against the biggest health threats in the US, such as heart disease, cancer, and stroke. The Food and Nutrition Board of the National Academy of Sciences has increased the recommended daily amounts of certain antioxidant micronutrients. The consumption of health-enhancing antioxidant nutrients may benefit public health and reduce medical costs. Of the natural antioxidants, vitamin E has attracted much attention, due to its powerful antioxidant activity both in vivo and in vitro. In biological systems, vitamin E can function both as an intracellular and intercellular antioxidant, thus neutralizing free radicals and preventing oxidation. In addition to tocopherols, other tocols, such as tocotrienols and carotenoids also exhibit health benefits in certain diseases, such as cancer, coronary heart disease, and immune functions (49,50). Incorporation of tocols in the hens' diet has been reported to increase the vitamin E content of chicken eggs, providing a natural source of health-enhancing vitamins through food (51,52,53). Cherian et al., 1996, reported a total of 7 to 8 mg vitamin E per average egg from hens fed diets containing 400 μg/g of vitamin E (52). These results corroborate with the 400 μg/g of yolk tocopherols when hens' diets were supplemented with 800 mg/kg tocols (53). Enrichment of other minor tocols like tocotrienol and retinol alteration in eggs through diet has been reported (54).

Carotenoids constitute a group of lipid-soluble organic compounds. Carotenoids are of biological importance for their light-absorbing properties, antioxidant functions, and immunomodulatory functions. Carotenoids have been used for many years in the poultry industry as a means of pigmenting eggs and meat. Over the past few years, there has been tremendous interest in the role of carotenoids and other pigments, in particular lutein and zeaxanthin, in prevention of eye disorders. Feeding diets containing palm oil to laying hens resulted in a significant incorporation of carotenoids in eggs (54,55). Other natural products, like tomato byproducts, have been reported to increase carotenoid pigments in eggs (56). Marigold meals are used as premixes in pigmenting eggs, and contain natural yellow xanthophylls. As plant-derived natural forms of antioxidant nutrients are gaining popularity, and since poultry products contribute a major part of animal products in the western diet, altering the micronutrients and pigments in eggs and meat or further-processed poultry products may provide an alternate source of such health-promoting nutrients to consumers.

4. Vitamin D

Vitamin D is needed for normal bone formation. A deficiency of Vitamin D can lead to osteomalacia in adults and rickets in children. A less severe form of vitamin D deficiency can happen in elderly women leading to postmenopausal osteoporosis (57). Vitamin D deficiency may also occur in Europe in winter months due to restricted sun exposure (58) and because few foods are rich in vitamin D. One way to ease this problem is through fortification of eggs with vitamin D. A recent study by Mattila et al., 2004 reported up to 34 μg/100g of Vitamin D3 in vitamin D–enriched egg vs. 2.5 to 5.0 μg/100 g in control eggs (59).

5. Other Minor Nutrients

a. Selenium

Selenium (Se) is an essential component of several antioxidant enzymes such as Se-dependant GSH-Px, superoxide dismutase, and catalase. These enzymes are involved in providing cellular antioxidant protection against free radical damage produced during normal physiological processes at the cellular level. Evidence from epidemiologic, clinical and experimental studies have reported a chemopreventive potential of selenium (60). In particular, the results of recent clinical intervention trials have shown strong protective effects of selenium-enriched yeast for cancers of the lung, colon and prostate. The average intake of Selenium from food sources is reported to be between 50–70 μg/day. Levels of over 100–200 μg are

reported to have beneficial effects. With the knowledge of the effects of these selenocompounds as anticarcinogenic agents, it became of interest to investigate the most appropriate methods for delivery to the general population. One obvious approach was to investigate additional methods for expeditious ways to deliver these protective agents through the food system. When laying hens were fed high dietary levels of selenium, a significant deposition of selenium in eggs was observed (61,62). Additions of graded amounts of selenite up to 4 mg/kg diet resulted in a linear increase in the selenium content in eggs, reaching up to 30 µg of Se, which is about 50% of the daily requirement.

b. Folic acid

The term folate compounds encompasses a number of different water-soluble compounds, each based on the structure of folic acid. Folic acid does not naturally occur in appreciable amounts in foods. The recommended dietary allowance of folate is 400 mg/day (63). In 1998, the US enacted legislation requiring cereal fortification with folic acid. However, additional strategies may be needed to ensure that all segments of the population are consuming adequate folates. Eggs naturally contain 22 µg folate per large egg (Table 153.2), which provides 6% of the newly established adult daily requirements for folate (63). Recent studies by House et al., 2002, reported 41 µg/egg, providing 12.5% of the recommended dietary allowance of folate for adult humans (64).

B. Omega-3 Fatty Acid Modified Eggs and Human Health Effects

1. Effects on Blood Lipids and Blood Pressure

Several authors investigated the effects of n-3 fatty acid enriched eggs on human blood lipid parameters. In general, a significant increase in plasma n-3 fatty acids and platelet phospholipid n-3 fatty acids, as well as a decrease in platelet aggregation have been reported after the consumption of n-3 eggs (for review, see Reference 65). A reduction in systolic blood pressure was also noticed with the daily consumption of two n-3 PUFA modified eggs for four weeks (65).

2. Omega-3 Fatty Acid Eggs and Breast Milk Lipid Composition

In human infants, most DHA and arachidonic acid accumulates during the last intrauterine trimester and during early stages of life, suggesting that long chain PUFA may be indispensable for neural development of the newborn (21). During the early stages of life, infants consume n-6 and n-3 fatty acids both as C18:2n-6 and C18:3n-3 if fed on formula. Breast milk, however, reflects the mother's diet and because modern diets are low in PUFA, it is assumed that infants at present are receiving less long chain n-3 or n-6 fatty acids from breast milk. In view of the importance of n-3 PUFA for newborn infants, Cherian and Sim, 1996, used n-3 PUFA rich egg in the mothers' diet as a vehicle for supplying n-3 PUFA to nursing infants (66). Consuming two n-3 eggs as a part of their normal daily meal for six weeks resulted in a significant ($P < 0.05$) deposition of total n-3 fatty acids at 3.6%, compared with 1.9% for the pre-test milk, and a reduction in n-6:n-3 ratio (6.7 vs 3.0). The long chain n-3 PUFA comprised 1.2% compared with 0.4% in the pre-test milk ($P < 0.05$). Consuming n-3 eggs did not ($P > 0.05$) alter the C20:4n-6 or the total n-6 fatty acid content of breast milk. Infants nursed from women consuming n-3 eggs could have over 300 mg of long chain n-3 fatty acid, such as 20:5n-3, 22:5n-3, and DHA (66). Thus, a diet supplemented, with n-3 eggs for nursing women should provide an alternate way of increasing the dietary consumption of n-3 fatty acids.

3. Fatty Acid Modified Eggs: Alternate Food Uses

a. n-3 fatty acid eggs for infant formula enrichment

Although there has been a significant increase in breast-feeding in the last decade, infant formulas remain the major source of nutrition for many infants during the first 12 months of life. Fat sources in the formulas are derived from one or more vegetable oils, usually coconut, soy, safflower, or corn oil. All vegetable oils differ from human milk in such a way that they do not contain long chain n-3 or n-6 fatty acids. The ability for the in vivo formation of DHA from C18:3n-3 is also limited especially in premature infants. Therefore, optimal postnatal accretion may depend on the dietary supply of preformed DHA and other long chain PUFA to the newborn. One average n-3 fatty acid modified egg contains 6 g of lipids, with DHA constituting to about 2 to 4%, along with other long chain n-3 and n-6 PUFA. Thus, eggs enriched with LCPUFA would be a useful weaning food for infants fed formulas that do not have DHA (67). The fatty acid composition of the n-3 fatty acid enriched egg yolk lipids and breast milk lipids show similarities in their saturated, and monounsaturated fats, as well as PUFA (Table 153.5). Thus, egg oil, once extracted could be useful as a natural lipid source to be included in infant formula preparations (67). Agostoni et al., 1995 and Carlson et al., 1996, reported improved visual acuity and higher developmental quotients in term infants fed formulas containing egg phospholipids, when compared to term infants fed unsupplemented formulas (68,69). These results demonstrated the uniqueness of egg lipids in providing essential nutrients for the newborn.

VII. EGGS AS A UNIQUE MODEL FOR NUTRITION RESEARCH

In oviparous species, the developing embryo is absolutely dependent on nutrients stored in the egg yolk. Thus, the developing chick is in a nutritionally 'controlled' environment not influenced by maternal supply of nutrients

TABLE 153.5
Comparison of Fatty Acids in Human Breast Milk, n-3 Fatty Acid Enriched Egg Yolk and Commercial Infant Formula[a]

Fatty Acid (%)	Breast Milk	Egg Lipids	Commercial Formula
Total saturated fatty acids	38.3	34.2	52.8
Total monounsaturated fatty acids	45.0	38.4	19.6
Total long chain (>20-carbon) omega-6 fatty acids	1.1	1.4	0.0
Total long chain (>20-carbon) omega-3 fatty acids	1.1	3.3	0.0

[a] Adapted from Reference 67.

through the placenta as in mammals. This biologically self-contained model allows a close relationship between nutritive substances and their physiological utilization. Thus, the laying hen and the chick (avian model) can be useful models for studying the net transfer of nutrients from maternal sources and its effect on the progeny (70). In this model, chicks with severe deficiency or excess of a nutrient could be obtained through diet manipulation. Upon hatching, the newly hatched chick can be used to study the effect of maternal (yolk/laying hen) or neonatal (chick) dietary nutrients (excess or deficient) on metabolic effects and/or other behavioral changes in the progeny. Furthermore, as incubation takes only 21 days, the time span involved in raising multi-generation progeny with severe deficiency of a particular nutrient (e.g., essential fatty acids) can easily be reduced. The hatched chick, like newborn infants, must obtain the bulk of its nutrients from dietary supply.

A. Fertilized Eggs and Hatched Chicks for Infant Fatty Acid Nutrition Research

Because fat composition can be manipulated by diet, the egg is a unique research tool in studying the role of maternal dietary fatty acids on the lipid metabolism in the progeny. In mammals, the nervous system is the organ with the greatest concentration of lipids after adipose tissue. These lipids are structural and are high in long chain PUFA of the n-6 and n-3 series. DHA is the predominant n-3 fatty acid, and arachidonic acid is the major n-6 fatty acid in the central nervous system of mammals and avians. Deficiency of long chain PUFA has been reported to cause impaired visual acuity, abnormal electroretinogram, and reduction in intellectual performance. In the human brain, the last intrauterine trimester is the most active period of brain tissue growth and DHA accumulation. During prenatal life, the accretion of long chain PUFA in the human brain is of quadratic type, the increase being most rapid towards the end of gestation and continuing into early life, plateauing by two years of age, by which time 90% of human brain growth is completed (71). Considerable similarities exist between mammalian and avian species in the accretion of LCPUFA during embryonic development (72). The effect of maternal diets high or low in n-3 essential fatty acids on the PUFA metabolism of the brain tissue of developing progeny was investigated using laying hens, eggs, and hatched chicks (73). Regardless of dietary supply, an intense transfer of lipids, DHA, and arachidonic acid from maternal supply (yolk sac) resulted in a preferential incorporation of DHA and arachidonic acid in the chick (73). The changes in maternal dietary source of fat during development of brain tissue can affect the fatty acid composition of the progeny in mammals (74). Thus, despite the obvious developmental difference between mammals and avians, the subsequent usage and metabolism of PUFA is similar. This is evidenced by accretion and preferential uptake of long chain PUFA by the chick brain during the last week of incubation, suggesting that the egg and the hatched chick are unique research models in studying the effect of maternal diet on the metabolism of PUFA in the brain.

Considering the uniqueness of egg in offering several nutrients and other biologically active components that contribute to human health and the health and development of a new life during its 21-day incubation, eggs are nature's first and original functional food. Much work remains to be done before the nutritional significance of this biological and chemical entity will be fully known.

154 Ice Cream and Frozen Desserts

H.D. Goff
Department of Food Science, University of Guelph

R.W. Hartel
Department of Food Science, University of Wisconsin-Madison

CONTENTS

This chapter is focused on frozen desserts, dairy or non-dairy, that are characterized by being concomitantly whipped and frozen in a scraped surface freezer, and subsequently consumed in the frozen state. There are many product variations on this category, ice cream and lower fat versions being the most common, but also including sherbets and sorbets, frozen yogurt, soy-based frozen desserts, etc. Thus we begin with definitions and formulations of the major products within this category. However, there are many features of these products that are similar, hence many other aspects can be treated collectively. We will review the sources and functional roles of ingredients, mix manufacturing, including formulation calculations, the dynamic freezing process, including structure and structure formation, the static freezing (hardening) process, product storage and distribution, and finally, a review of shelf-life and quality aspects. Although we use "ice cream" in the generic sense throughout this chapter, all of these topics are relevant to all products within this category.

It is not possible to provide a complete coverage of all aspects of ice cream and frozen desserts in one chapter. However, various aspects are covered in numerous books (1,2), book chapters (3–8), and review papers (9–11).

I. FORMULATIONS AND INGREDIENTS

A. Product Definitions and Formulations

1. Ice Cream

The most common product within the category of frozen desserts is ice cream. The legal definition of ice cream is controlled by regulations and varies with jurisdiction, but it is generally a sweetened product containing milkfat and milk solids-not-fat (msnf), and is frozen while being whipped. The general composition of most ice cream products is shown in Table 154.1.

Some of the factors affecting the choice of composition include legal requirements, which must be met, the quality desired in the finished product (increasing fat and total solids are usually associated with increasing quality), and the cost to be borne by the consumer. Premium products usually command a higher price. There are no specific definitions of common industry-accepted terms, such as premium or super-premium ice cream, but a relationship between fat content, total solids content, air content, and cost (also affected by quality and proportion of inclusions and marketing issues) exists, as illustrated in Table 154.2.

Suggested formulations for a range of ice cream products are presented in Table 154.3. Several trends are evident. There is usually an inverse relationship between fat and total solids compared to msnf. As discussed in Section I.B.2, the lactose component of the msnf is quite insoluble and above its saturation level in ice cream, so with increasing lactose content in a decreasing quantity of water, the risk of lactose crystallization increases. There is also generally an inverse relationship between corn syrup solids (starch hydrolysate sweetener, sometimes referred to as "glucose solids") levels and total solids. The corn syrup solids will contribute to a firmer, chewier texture, which is more desirable when there are less solids present. Likewise, as total solids increases, there is less requirement for stabilizer. This is generally due to the fact that increasing stabilizer-in-water ratios lead to enhanced gumminess, which becomes undesirable at high levels. Also, a reduction in the water content means there are diminished problems associated with ice recrystallization. Additionally, as fat levels in a mix increase, there is generally less need for emulsifier in order to optimize the extent of partial coalescence of the fat. Further discussion on many of these aspects of formulations can be found in the appropriate sections of the chapter.

Soft-serve ice cream is very similar to its hard-frozen counterpart in composition, but is sold at a different point

TABLE 154.1
The General Composition of an Ice Cream Mix

Component	Range of Concentration
Milkfat	>10–16%
Milk solids-not-fat	9–12%
Proteins, lactose, minerals	
Sweeteners	
Sucrose	10–14%
Corn syrup solids	3–5%
Stabilizers	0–0.25%
Guar, locust bean gum (carob), carrageenan, carboxymethyl cellulose (cellulose gum), micro-crystalline cellulose (cellulose gel), sodium alginate, xanthan, gelatin	
Emulsifiers	0–0.25%
Mono- and di-glycerides, Polysorbate 80	
Water	55–64%

TABLE 154.2
Average Values for Fat and Total Solids Content, Overrun, and Cost among the Categories of Ice Cream

Component	Economy	Standard	Premium	Super-Premium
Fat content	Legal minimum, usually 10%	10–12%	12–15%	15–18%
Total solids	Legal minimum, usually 36%	36–38%	38–40%	>40%
Overrun	Legal maximum	~100%	60–90%	25–50%
Cost	Low	Average	Higher than average	High

TABLE 154.3
Suggested Mixes for Hard-Frozen Ice Cream Products

	Percent (%)						
Milk Fat	10.0	11.0	12.0	13.0	14.0	15.0	16.0
Milk Solids-not-fat	11.0	11.0	10.5	10.5	10.0	10.0	9.5
Sucrose	10.0	10.0	12.0	14.0	14.0	15.0	15.0
Corn Syrup Solids	5.0	5.0	4.0	3.0	3.0	—	—
Stabilizer *	0.35	0.35	0.30	0.30	0.25	0.20	0.15
Emulsifier *	0.15	0.15	0.15	0.14	0.13	0.12	0.10
Total Solids	36.5	37.5	38.95	40.94	41.38	40.32	40.75

*Highly variable depending on type; manufacturers' recommendations are usually followed.

in its production stage, and usually with a much lower overrun content. Suggested formulations are shown in Table 154.4 for soft-serve ice cream, but it should also be recognized that much of the soft-serve on the market today falls into the low-fat, or ice milk category, with fat contents typically around 4%. Generally, while the fat content is kept lower, the msnf content is generally higher than for hard-frozen products. Lactose crystallization is not a problem in these products, as they are consumed immediately after freezing. Corn syrup solids are often used, but can lead to an enhanced sensation of gumminess. Stabilizers are also generally used for viscosity enhancement and mouthfeel, but their function in ice recrystallization is no longer needed. Dryness and shape retention, however, are a big concern in soft-serve products, hence the emulsifier content is generally kept high.

2. Reduced Fat Products

Ice milk was the traditional lower fat ice cream product for many years; but this category has been reclassified by many regulatory jurisdictions to include three reduced fat categories: light ice cream, lowfat ice cream (the traditional ice milk), and non-fat ice cream. Light or "reduced fat" ice creams are usually in the range of 5–7.5% fat. Lower fat versions are usually in the range of 3–5% fat. It has generally been possible to produce lower fat products, as low as 4% fat, with traditional ingredients, but further fat reductions have generally involved the incorporation of fat-replacers. These are discussed further in Section I.B.1. Suggested formulations for light and low-fat ice creams are presented in Table 154.5.

3. Sherbet

Sherbet is usually taken to be a frozen dairy dessert made from a milk product, but containing a low (usually legally-defined maximum, e.g., 5%) level of milk solids, including milk fat, a high level of sweeteners (sugar and corn syrup solids, 30–35%), and added acidity (usually to greater than a legally defined minimum, e.g., 0.35%, expressed as lactic acid). Suggested formulations are given in Table 154.6. Because of the acidified nature of sherbets, they are most suited for typical acidic fruit flavors, e.g., citrus. The sugar and acid levels in fruits or fruit purees have to be considered in the final formulation, and are included in the numbers suggested above. Acidity is usually added in the form of citric or tartaric acid, and this level of acidity modifies the perception of sweetness that would otherwise be created by the high level of sugars. Acid should not be added to ice and sherbet mixes until just before freezing. Heating of some stabilizers in the presence of acid will reduce their effectiveness. Adding acid to a sherbet mix in which the milk solids have been included, may result in aggregation/precipitation

TABLE 154.4
Suggested Mixes for Soft-Frozen Ice Cream Products

	Percent (%)	
Milk Fat	10.0	10.0
Milk Solids-not-fat	12.6	12.0
Sucrose	13.0	10.0
Corn Syrup Solids	—	4.0
Stabilizer *	0.15	0.15
Emulsifier *	0.20	0.20
Total Solids	36.0	36.3

*Highly variable depending on type; manufacturers' recommendations are usually followed.

TABLE 154.5
Suggested Mixes for Low-Fat Ice Cream or Ice Milk Products (3–5% Fat) and Light Ice Cream Products (6–8% Fat)

	Percent (%)				
Milk Fat	3.0	4.0	5.0	6.0	8.0

Corn Syrup Solids	9.0	6.0
Stabilizer/emulsifier	0.3	0.3
Citric acid (50% sol.)	0.7	0.7
Water	63.5	64.0
Total	100.0	100.0

of the protein. Sherbet generally requires the addition of milk solids, and at least some fat (~0.5%) is desirable, as it tends to lubricate the dynamic freezer and provides a slightly more pleasant mouthfeel than non-fat products. In many multi-product manufacturing settings, ice cream mix is widely used as a source of milk solids, and the amount added will depend upon the level of milk solids desired. Overrun should be kept much lower in sherbet than that in ice cream, usually 30–35%.

4. Frozen Yogurt

Yogurt is a well-established dairy product, is generally perceived to be characterized by developed acidity (lactic acid) from fermentation of lactose by bacterial culture, and may or may not include live culture. The acidity destabilizes the casein micelles in the milk, and they, in turn, establish the typical acid gel. Frozen yogurt, therefore, should be much like the unfrozen version, and be also characterized by developed acidity from fermentation. The example formulation in Table 154.7 is typical of a more traditional frozen yogurt. However, in most legal jurisdictions, frozen yogurt is not standardized, so a wide range of products exists, including those in which the acidity is not developed by bacterial culture, but has been added in the form of citric acid.

To make a traditional frozen yogurt, as in Table 154.7, the processing occurs in two steps: the manufacture of a fermented yogurt-like ingredient, and the blending of this product with the rest of the ingredients. For example, 20% of the mix in Table 154.7, consisting of skim milk and skim milk powder, blended to give 12.5% msnf, is pasteurized at 85–90°C, cooled to 40 to 43°C, inoculated with a yogurt culture (typical of yogurt processing), and incubated as the yogurt portion. When the fermentation is complete (to the desired acidity), the "yogurt" is cooled. To make the "sweet" mix, the cream, sugar, stabilizer, and the balance of the skim milk powder and skim milk are combined, pasteurized, homogenized, cooled (typical for ice cream processing), and then blended with the "yogurt." The completed frozen yogurt mix is then aged and prepared for flavoring and freezing.

TABLE 154.7
Suggested Frozen Yogurt Formulation

Sugar	15.0
Stabilizer	0.35
Water	68.65
Total	100.0

5. Fruit Ices and Sorbets

"Ice" or "sorbet" is likewise typically not defined in legal regulations, but is generally taken to be much the same as sherbet, except that milk solids are not included. Sorbets are generally frozen in a swept surface freezer, while ices are generally frozen quiescently in molds. Both sorbets and ices are usually fruit-based, and ingredients include combinations of fruit and/or fruit juices, sugar, stabilizer, and water. Overrun is very low, as aeration is difficult to achieve without protein or emulsifier. To make water ice or sorbet mixes from the above suggested sherbet formulae, delete the fat and msnf.

B. Sources and Functional Roles of Ingredients

1. Fat

The fat component of frozen dairy dessert mixes increases the richness of flavor, produces a characteristic smooth texture by lubricating the palate, helps to give body, and aids in producing desirable melting properties (1,6). The fat content of a mix also aids in lubricating the freezer barrel while the ice cream is being manufactured. Limitations on excessive use of fat in a mix include cost, a hindered whipping ability, decreased consumption due to excessive richness, and high caloric value. Fat contributes 9 kCal/g to the diet, regardless of its source. During freezing of ice cream, the fat emulsion that exists in the mix will partially coalesce (destabilize) or churn as a result of emulsifier action, air incorporation, ice crystallization, and high shear forces of the blades (6,12). This partial churning is necessary to set up the structure and texture in ice cream, which is very similar to the structure in whipped cream (13). This process will be discussed in Section II.B.4. The fat content is an indicator of the perceived quality and/or value of the ice cream. Ice cream must have a minimum fat content of 10% in most legal jurisdictions. Premium ice creams generally have fat contents of 14 to 18%. It has become desirable, however, to create light ice creams, $<$10% fat, with the same perceived quality. In addition to

structure formation, fat contributes a considerable amount of flavor to ice cream, which is difficult to reproduce in lowfat ice creams. Fat content must be altered by at least 1% before any noticeable difference appears in the taste or texture (1). Several recent papers have examined the effect of source and quantity of milk fat on sensory and textural characteristics of ice cream (14–20).

Milkfat as a fat source for ice cream formulations is in widespread use in North America, Australia and New Zealand, and parts of Europe. The triglycerides in milkfat have a wide melting range, +40° to −40°C. The crystallization patterns of milkfat are also very complex, due in part to the large variation in fatty acids and large numbers of different triglycerides present (21). Consequently, there is always a combination of liquid and crystalline fat at refrigeration and subzero temperatures. Alteration of this solid: liquid ratio at freezer barrel temperatures, through natural variation or fat fractionation, may affect the ice cream structure formed. The best source of milkfat in ice cream for high quality flavor is fresh sweet cream, from fresh sweet milk (1). Other sources of milkfat include sweet (unsalted) butter, frozen cream, or condensed milk blends. Whey creams have also been used, but may lead to flavor or texture problems.

Vegetable fats are used extensively as fat sources in ice cream in the United Kingdom and parts of Europe, but only to a very limited extent in North America. Three factors of great interest in selection of fat source are the way in which the fat crystallizes, the temperature-dependent melting profile of the fat, especially at refrigerator and freezer temperatures, and the flavor and purity of the oil (6). For optimal partial coalescence during freezing, it is important that the fat droplet contain an intermediate ratio of liquid:solid fat at the time of freezing. Crystallization of fats occurs in three steps: subcooling of the oil (below the equilibrium crystallization temperature) to induce nucleation, heterogeneous or homogeneous nucleation (or both), and crystal propagation. In bulk fat, nucleation is predominantly heterogeneous, with crystals themselves acting as nucleating agents for further crystallization, and subcooling is usually minimal. However, in an emulsion, each droplet must crystallize independently of the next. For heterogeneous nucleation to predominate, there must be a nucleating agent available in every droplet, which is often not the case. Thus in emulsions, homogeneous nucleation and extensive subcooling are expected (6). Blends of oils are often used in ice cream manufacture, selected to take into account physical characteristics, flavor, availability, and cost. Hydrogenation is often necessary to achieve the appropriate melting characteristics. Palm kernel oil, coconut oil, palm oil, sunflower oil, peanut oil, and fractions thereof with varying degrees of hydrogenation are all used to some extent. Tong and co-workers (22) substituted a portion of milkfat in ice cream with safflower oil, a highly unsaturated oil, in an attempt to lower the saturated fatty acid content of the final product. They reported that increasing concentration of safflower oil decreased overrun, but had little effect on the extent of fat destabilization at lower substitution levels.

There has been a great interest in the marketplace for the development of lower fat alternatives to traditional ice cream products. As a result, a large amount of product development time has been used in searching for a combination of ingredients that will replace the textural and flavor characteristics of fat in ice cream (17,18,23). These often involve the use of fat substitutes. Such products may be formulated with starch or other polysaccharides, proteins, or lipids, but their main requirement is to provide less calories to the product than traditional fat sources in the diet. A great deal of technical literature exists on the various properties of the products being marketed by a number of commercial firms. Schmidt and co-workers (24) studied the rheological, freezing, and melting properties of ice milks manufactured with protein-based or maltodextrin-based fat alternatives. They concluded that the carbohydrate-based alternatives resulted in greater affects on mix rheology, while the protein-based alternatives were more similar to ice cream, due in part to the functional contributions of proteins to food systems, especially in the area of emulsification and air incorporation. Ice cream products are very complex systems, both in structure and flavor. In creating products that are meant to deliver to the consumer the same attributes but with less fat or calories, it is imperative that the structural element of fat be considered to the same extent as flavor in order to deliver high quality products and develop market share for these products.

2. Milk Solids-not-Fat

The milk solids-not-fat (msnf) or serum solids improve the texture of ice cream, aid in giving body and chew resistance to the finished product, are capable of allowing a higher overrun without the characteristic snowy or flaky textures associated with high overruns, and may be a cheap source of total solids (25). The msnf contain the lactose, caseins, whey proteins, minerals (ash), vitamins, acids, enzymes, and gases of the milk or milk products from which they were derived. The content of msnf used in a mix can vary from 10 to 14% or more. Whole milk protein blends contain both caseins and whey proteins, and this category includes most of the traditional sources of milk msnf, fresh concentrated skimmed milk, or spray dried low-heat skim milk powder. However, most ice cream formulations now use another source or sources of msnf or milk protein to replace all or a portion of skim milk solids, for both functional and economical reasons (26).

When assessing replacements for skim milk solids, an important consideration is the levels of protein, lactose, and ash in the ingredients being assessed (27). Lactose is not very sweet and not very soluble, and therefore, during

freezing of ice cream, it is freeze-concentrated beyond maximum solubility (supersaturated) and thus potentially prone to crystallization. Lactose crystals are very undesirable in ice cream, causing the defect known as sandiness. Lactose, being a disaccharide, also contributes to freezing point depression in the mix, so its concentration must be closely controlled. In addition, the milk salts affect both the flavor and texture of ice cream. Also, when replacing skim milk solids, sufficient total solids must be added to limit the water content of the mix and meet legal minimum total solids requirements. For these reasons, it is often desirable to replace skim milk solids with a product(s) with similar concentrations of lactose and protein. Lactose can be reduced through ultrafiltration, or modified by limited hydrolysis to its constituent monosaccharides; either change will affect the concentration of the ingredient that can be used and the subsequent protein level achieved in the ice cream. Buttermilk solids have often been cited as a useful substitute for skim milk solids. Buttermilk contains a higher concentration of fat globule membrane phospholipids than skim milk. Thus, it can be used for its emulsifying properties to reduce the need for emulsifiers, or in formulations where it is undesirable to add emulsifiers (1).

It is possible to produce concentrated protein products from the casein portion of milk proteins, the most common for use as a food ingredient being sodium caseinate. The use of sodium caseinate in ice cream has been investigated, and a small percentage may be useful in contributing to functional properties, particularly aeration and emulsification (28,29). However, the functionality of sodium caseinate is different than that of micellar casein, the form in which it is found in milk ingredients, and this needs to be considered when proposing its use. It can contribute positively to aeration, but may lead to an emulsion that is too stable to undergo the required degree of partial coalescence. It is therefore most desirable in the serum phase, rather than at the fat interface.

There has been a great deal of attention to the use of whey products in ice cream. Whey contains fat, lactose, whey proteins, and water, but very little, if any, casein. While skim milk powder contains 54.5% lactose and 36% protein, whey powder contains 72–73% lactose and only about 10–12% protein. Thus, it can aggravate some of the problems associated with high lactose. However, an increasing number of whey products are available that have higher protein and lower lactose contents, mostly processed by membrane technology. Many of these can provide much higher quality than the traditional whey ingredients (26,29). Whey protein concentrates with similar protein and lactose contents to skim milk solids can be produced. Protein content can vary from low values of 20–25% to 75% or more. In addition, the level of lactose can be modified by hydrolysis, although the freezing point depression effect of the higher monosaccharide content must be considered. Ash content can be reduced by demineralization. Whey protein isolates, which contain no lactose, are also available for blending with other ingredients to form the msnf content of ice cream formulations.

Proteins contribute much to the development of structure in ice cream, including emulsification, whipping, and water holding capacity (8,30). The interfacial behavior of milk protein in emulsions is well documented, as is the competitive displacement of proteins by small molecule surfactants (31–35). In ice cream, the emulsion must be stable to withstand mechanical action in the mix state, but must undergo sufficient partial coalescence to establish desirable structural attributes when frozen. These include dryness at extrusion for fancy molding, slowness of melting, some degree of shape retention during melting, and smoothness during consumption. This implies the use of small molecule surfactants (emulsifiers) to reduce protein adsorption and produce a weak fat membrane that is sensitive to shear action (7,11,12,29,36–41). Bolliger and coworkers (42) showed that protein adsorbed to the fat droplets (mg m^{-2}) in ice cream mix correlated with major characteristic analyses describing the fat structure in ice cream (fat agglomerate size, fat agglomeration index, solvent extractable fat) (Figure 154.1). The loss of steric stability from the globule, which was contributed from micellar adsorption, accounts for its greater propensity for partial coalescence during shear. Partial coalescence is responsible for establishing a three-dimensional aggregation of fat globules that provide structural integrity (see Section II.B.4). This is especially important if such integrity is needed when the structural contribution from ice is weaker (i.e., before hardening or during melting). Variables that affect the destabilization of fat in ice cream have been well studied (43–46).

With respect to protein contribution to fat globule integrity, it is obvious from the studies to date that a weak surface layer is most desirable (8). Segall and Goff (47) examined the susceptibility of ice cream emulsions to partial coalescence during shear when the emulsion was prepared with varying concentrations and type of protein, while still retaining sufficient quiescent emulsion stability. The membranes of fat globules stabilized by whey protein isolate were more susceptible than those made from sodium caseinate or casein micelles, while those made from partially hydrolyzed whey proteins did not show sufficient quiescent emulsion stability. However, when casein was added to the whey protein-stabilized emulsion, after homogenization, further casein adsorption to the whey protein membrane was rapid. Nevertheless, an understanding of protein structures and protein:surfactant interactions at the fat interface may lead to better control over the extent of partial coalescence desirable in the finished product.

Milk proteins are well known for their foaming properties, and during the manufacture of ice cream, air is

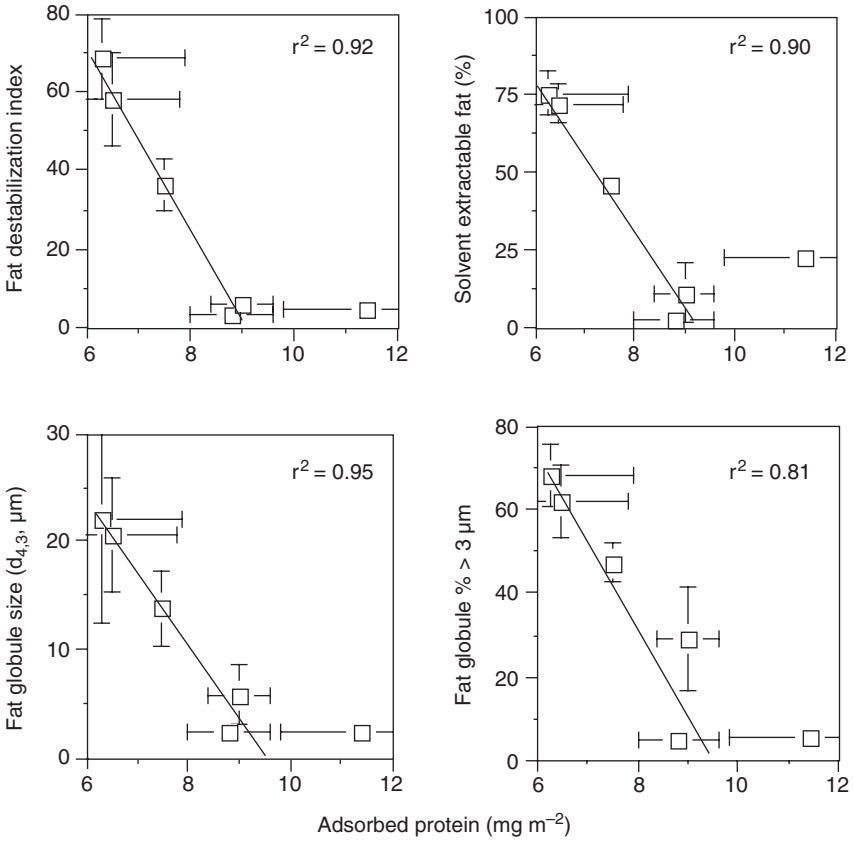

FIGURE 154.1 The effect of protein adsorbed to the fat globules in the mix on the fat destabilization index, solvent extractable fat, and fat agglomerate size in ice cream (42).

incorporated to about 50% phase volume. Thus, it should not be surprising that milk proteins contribute to stabilizing the air interface in ice cream. This air interface is very important for overall structure and structural stability (48). Loss of air can lead to a defect known as shrinkage (see Section III.B.3), the occurrence of which is fairly common and very significant for quality loss and unacceptability of the product (49). The process of whipping heavy cream includes an initial protein adsorption to the air interface, and a subsequent adsorption of fat globules and their associated membrane to the existing protein air bubble membrane (13). Globular fat adsorption to air interfaces is known to stabilize air bubbles from rapid collapse (50). Proteins at the fat interface have also been shown to play an important role during the aeration of emulsions (51). However, the actual contribution of protein to ice cream aeration and its interaction with both the added emulsifying agents (which are also surface active) and partially coalescing fat at the air interface has been less well studied. Incorporation of air into ice cream is rapid, within seconds, and at the same time, viscosity of the surrounding matrix is increasing exponentially due to freezing, such that air bubbles after formation become physically trapped into a semi-solid matrix, making their collapse quite difficult.

Similar to the role of milk protein in aeration, the role of this protein in the unfrozen aqueous phase is recognized but less well studied than the role at the fat interface. Milk proteins interact with water, and the subsequent hydration is responsible for a variety of functional properties, including rheological behavior. Thus, freeze-concentration of proteins in ice cream must lead to a sufficient concentration to have a large impact on the viscosity of the unfrozen phase and its subsequent effect on ice crystallization, ice crystal stability, and solute mobility (52). Jonkman and co-workers (53) studied the effect of ice cream manufacture on the structure of casein micelles and found that the micelles *per se* were not affected by the process. Although the stability of the micelle was expected to be affected by low temperature, this was offset by an increasing concentration of milk salts in solution during freeze-concentration, such that the micelle remained intact in a similar state to that found in mix.

Polysaccharides are also added to ice cream mix to enhance solution viscosity and to impact ice crystallization behavior. Commonly used polysaccharides can be incompatible in solution with milk proteins, leading to a microscopic or macroscopic phase separation (54), a phenomenon that has been studied in milk and ice cream-type systems (55–57). Goff and co-workers (58) examined the

interaction between milk proteins and polysaccharides in frozen systems using labeled polysaccharides and fluorescence microscopy, and demonstrated a clear phase separation between the two, leading to discernable networks created by freezing from both locust bean gum and milk proteins. It has also been shown in ice cream that when in solution with polysaccharides, the casein aggregates into distinct networks (58). Flores and Goff (59) demonstrated that milk proteins had a large impact on ice crystal size and stability. It thus appears that microscopic phase separation of the milk protein induced by polysaccharides, and "aggregation" of casein into a weak gel-like network, promoted also by freeze-concentration, may be at least partly responsible for ice crystal stability, and thus improvement of texture during consumption.

Lactose, or milk sugar, is a disaccharide of glucose and galactose that does not contribute much to sweetness of ice cream, since it is only 1/5 to 1/6 as sweet as sucrose (21). Lactose is relatively insoluble and crystallizes in two main forms, α monohydrate and β anhydrous, depending on conditions. The α monohydrate crystals, which take on a characteristic tomahawk shape, lead to the defect known as sandiness when they are allowed to grow sufficiently large (about 15 μm). Lactose content of ice cream mix is about 6% if no whey powder has been used in the formulation. Levels of lactose in ice cream mix in excess of this leads to reduced freezing point, causing a softening of the ice cream and the potential for development of iciness, a greater potential for lactose crystallization or sandiness, and salty flavors (60). The lactose solubility in water at room temperature is about 11% (21). During freezing, this concentration is exceeded as a result of freeze concentration (water removal in the form of ice). When 75% of the water is frozen in a mix consisting originally of 11% msnf (6% lactose), the lactose content in the unfrozen water corresponds to ~40%. Probably much of the lactose in ice cream exists in a supersaturated, amorphous (non-crystalline) state, however, due to extreme viscosity (61). Stabilizers help to hold lactose in a supersaturated state due to viscosity enhancement.

3. Sweeteners

Sweet ice cream is usually desired by the consumer. As a result, sweetening agents are added to ice cream mix at a rate of usually 12–17% by weight. Sweeteners improve the texture and palatability of ice cream, enhance flavors, and are usually the most economical source of total solids (1). Their ability to lower the freezing point of a solution imparts a measure of control over the temperature-hardness relationship (see Section II.B.1). In determining the proper blend of sweeteners for an ice cream mix, the total solids required from the sweeteners, the sweetness factor of each sugar, and the combined freezing point depression of all sugars in solution must be calculated to achieve the proper solids content, the appropriate sweetness level, and a satisfactory degree of hardness (5,6,62). The most common sweetening agent used is sucrose, alone or in combination with other sugars. Sucrose, like lactose, is most commonly present in ice cream in the supersaturated or glassy state, so that no sucrose crystals are present (6,61).

It has become common practice in the industry to substitute sweeteners derived from corn starch or other starch sources such as rice, for all or a portion of the sucrose (1,4). A typical sweetener blend for an ice cream mix usually includes 10–12% sucrose and 4–5% corn syrup solids (corn starch hydrolysate syrup, commonly referred to as "glucose solids") (1,4). The use of corn syrup solids in ice cream is generally perceived to provide enhanced smoothness by contributing to a firmer and more chewy texture, providing better meltdown characteristics, bringing out and accentuating fruit flavors, reducing heat shock potential which improves the shelf-life of the finished product, and providing an economical source of solids (62,63).

During the hydrolysis process, starch, a high molecular weight polymer of the monosaccharide glucose (dextrose), is continually and systematically cleaved by enzymes (α amylase, glucoamylase, and β amylase) to produce mixtures of medium and low molecular weight units (Figure 154.2). The medium molecular weight saccharides (dextrins) are effective stabilizers and provide maximum prevention against coarse ice crystal formation, which is reflected in improved meltdown and heat shock resistance. They also improve cohesive and adhesive textural properties. The smaller molecular weight sugars provide smoothness, sweetness, and flavor enhancement. With the appropriate use of enzyme technology, corn syrup manufacturers have the ability to control the ratios of high to low molecular weight components, and the ratios of maltose, the disaccharide, to glucose, the monosaccharide. Glucose monosaccharide offers sweetness synergism with sucrose, but, being half the molecular weight, has greater freezing point depression than either sucrose or maltose. The ratio of higher to lower molecular weight fractions can be estimated from the dextrose equivalent (DE) of the syrup. Figure 154.2 shows that as the DE decreases, the sweetness increases, but the freezing point decreases (more freezing point depression) and the contribution to viscosity and chewiness in the mouth also decreases. Thus, optimization of DE and concentration of corn sweeteners are required for the most beneficial effects. Ice cream manufacturers usually use a 28 to 42DE syrup, either liquid or dry (1,62). High maltose syrups modify the effect of dextrose on the freezing point (62,63). With further enzyme processing (glucose isomerase), glucose can be converted to fructose (Figure 154.2), as in the production of high fructose corn sweeteners. The resultant syrup is much sweeter than sucrose, although it has half the molecular weight, and thus contributes more to freezing point depression than sucrose. These modifications to properties would also

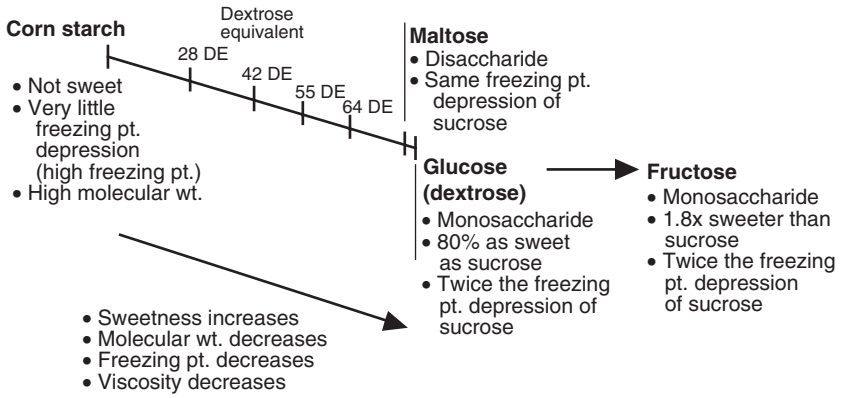

FIGURE 154.2 An illustration of the products that result from the hydrolysis of corn starch and their properties relevant to ice cream manufacture.

require optimization of all sugars for appropriate use of HFCS, although it has been shown that blends of high fructose syrup, high maltose syrup, and low DE syrup can be utilized to provide appropriate sweetness, freezing point depression and total solids in the absence of sucrose (62,63).

4. Stabilizers

Ice cream stabilizers are a group of ingredients (usually polysaccharides) commonly used in ice cream formulations. The primary purposes for using stabilizers in ice cream are to produce smoothness in body and texture, retard or reduce ice and lactose crystal growth during storage, especially during periods of temperature fluctuation, known as heat shock (64), and to provide uniformity to the product and resistance to melting (1,4). They also increase mix viscosity, stabilize the mix to prevent wheying-off (e.g., carrageenan), aid in suspension of flavoring particles, produce a stable foam with easy cut-off and stiffness at the barrel freezer for packaging, slow down moisture migration from the product to the package or the air, and help to prevent shrinkage of the product volume during storage (65). Stabilizers must also have a clean, neutral flavor, not bind to other ice cream flavors, contribute to acceptable meltdown of the ice cream, and provide desirable texture upon consumption (65). Limitations on their use include production of undesirable melting characteristics, excessive mix viscosity, and contribution to a heavy, soggy body. Although stabilizers increase mix viscosity, they have little or no impact on freezing point depression.

Gelatin, a protein of animal origin, was used almost exclusively in the ice cream industry as a stabilizer, but has gradually been replaced with polysaccharides of plant origin due to their increased effectiveness and reduced cost (1). Stabilizers currently in use include: a) carboxymethyl cellulose, derived from the bulky components or soluble fibre of plant material; b) locust bean gum (carob bean gum) which is derived from the beans of the tree *Ceratonia siliqua*, grown mostly in the Mediterranean; c) guar gum, from the guar bush, *Cyamoposis tetragonolba,* a member of the legume family grown in India and Pakistan for centuries, and now grown to a limited extent also in the USA; d) xanthan, a bacterial exopolysaccharide produced by the growth of *Xanthomonas campestris* in culture; e) sodium alginate, an extract of seaweed, kelp, or brown algae; or, f) carrageenan, an extract of *Chondus crispis (*Irish Moss), a red algae, originally harvested from the coast of Ireland, near the village of Carragheen. Each stabilizer has its own characteristics, and often two or more of these stabilizers are used in combination to lend synergistic properties to each other and improve their overall effectiveness. Guar, for example, is more soluble than locust bean gum at cold temperatures, thus it finds more application in HTST pasteurization systems. Carrageenan is a secondary colloid used to prevent wheying-off of mix, which is usually promoted by one of the other stabilizers (1,6); hence it is included in most blended stabilizer formulations.

The mechanisms by which ice cream stabilizers affect freezing properties or limit recrystallization (see Section III.B.1) have been extensively studied, but are as yet not fully understood. Ice recrystallization in ice cream has recently been reviewed (10,66). It appears from the literature available to date that stabilizers have little (67) or no (68,69) impact on the initial ice crystal size distribution in ice cream at the time of draw from the scraped surface heat exchanger. They also has little or no impact on initial ice growth during quiescent freezing and hardening (52,70,71), but do limit the rate of growth of ice crystals during recrystallization (59,67–69,72–78). They have no effect on the freezing properties of an ice cream mix, e.g., freezing point depression (79,80), amount of freezable water or enthalpy of melting (71,81,82), or heterogeneous nucleation (83), and thus may not have been expected to

affect initial ice crystallization processes. With respect to recrystallization, there has not been a demonstrable correlation between viscosity of the unfrozen mix and recrystallization rate (74,79,80,84). The protective effect of stabilizers also appears not to be related to a modification of the glass transition (74,82,84,85). However, it has been suggested that they modify the ice crystal serum interface, either through surface adsorption to the crystal itself (68,69,76,78); by modifying the rate at which water can diffuse to the surface of a growing crystal during temperature fluctuation, or the rate at which solutes and macromolecules can diffuse away from the surface of a growing ice crystal (67,85); or by some other modification of the ice serum interface (86). It must be remembered that freeze-concentration of the unfrozen phase results in a polysaccharide concentration several times higher than what was present in the original mix. Most polysaccharides are also incompatible in solution with milk proteins, which leads to further localized concentrations. Recent research by Goff and co-workers (58) has focused on the ability of at least some stabilizers to form a cryo-gel and entrap ice crystals within this gel. Phase separation of polysaccharides and proteins also appears to be related. Control of ice recrystallization may then relate to microstructural differences in solute concentration at the surface of the crystal.

5. Emulsifiers

Emulsifiers have been used in ice cream mix manufacture for many years (87,88). They are usually integrated with the stabilizers in proprietary blends, but their function and action is very different than that of the stabilizers. They are used for: improvement of the whipping quality of the mix; production of a drier ice cream to facilitate molding, fancy extrusion, and sandwich manufacture; smoother body and texture in the finished product; superior drawing qualities at the freezer to produce a product with good stand-up properties and melt resistance; and more exact control of the product during freezing and packaging operations (1,87–89). Their mechanism of action can be summarized as follows: They lower the fat/water interfacial tension in the mix, resulting in protein displacement from the fat globule surface, which in turn reduces the stability of the fat globule to partial coalescence that occurs during the whipping and freezing process, leading to the formation of a fat structure in the frozen product that contributes greatly to texture and meltdown properties (12). The extent of protein displacement from the membrane, and hence the extent of dryness achieved, is a function of the emulsifier concentration (6,90). Their role in structure formation will be described further in Section II.B.4.

Egg yolk was formerly commonly used as an ice cream emulsifier. Emulsifiers used in ice cream manufacture today are of two main types: the mono- and diglycerides, and the sorbitan esters. Mono- and diglycerides are derived from the partial hydrolysis of fats of animal or vegetable origin. The sorbitan esters are similar to monoglycerides, in that the sorbitan esters have a fatty acid molecule, such as stearate or oleate, attached to a sorbitol molecule; whereas the monoglycerides have a fatty acid molecule attached to a glycerol molecule. To make the sorbitan esters water soluble, polyoxyethylene groups are attached to the sorbitol molecule. Polysorbate 80, polyoxyethylene sorbitan monooleate, is the most common of these sorbitan esters. Polysorbate 80 is a very active drying agent in ice cream (12), and is used in many commercial stabilizer/emulsifier blends.

II. MANUFACTURING AND STRUCTURE OF FROZEN DESSERT PRODUCTS

A. Mix Manufacture

Ice cream processing operations can be divided into two distinct stages: mix manufacture and freezing operations (Figure 154.3). Ice cream mix manufacture consists of the following unit operations: combination and blending of ingredients, batch or continuous pasteurization, homogenization, and mix aging.

1. Blending

Ingredients are usually preblended prior to pasteurization, regardless of the type of pasteurization system used. Blending of ingredients is relatively simple, if all ingredients are in the liquid form, as automated metering pumps or tanks on load cells can be used for measurement, and tanks, usually conical-bottom and agitated, are used for mixing. When dry ingredients are used, powders are added through either a pumping system under high velocity, or through a liquifier, a large centrifugal pump with rotating knife blades that chop all ingredients as they are mixed with the liquid (3).

2. Mix Calculations

The general object in calculating ice cream mixes is to turn the formula, which is based on the desired components, into a recipe, which is based on the actual ingredients to be used to supply the components and the amount of mix desired. The formula is given as percentages of fat, msnf, sugar, corn syrup solids, stabilizers, and emulsifiers. The ingredients to supply these components are chosen on the basis of availability, quality, and cost. Table 154.8 illustrates the relationship between the major components, the main ingredients that supply the major components, and the minor components that are supplied with the major ones for each ingredient.

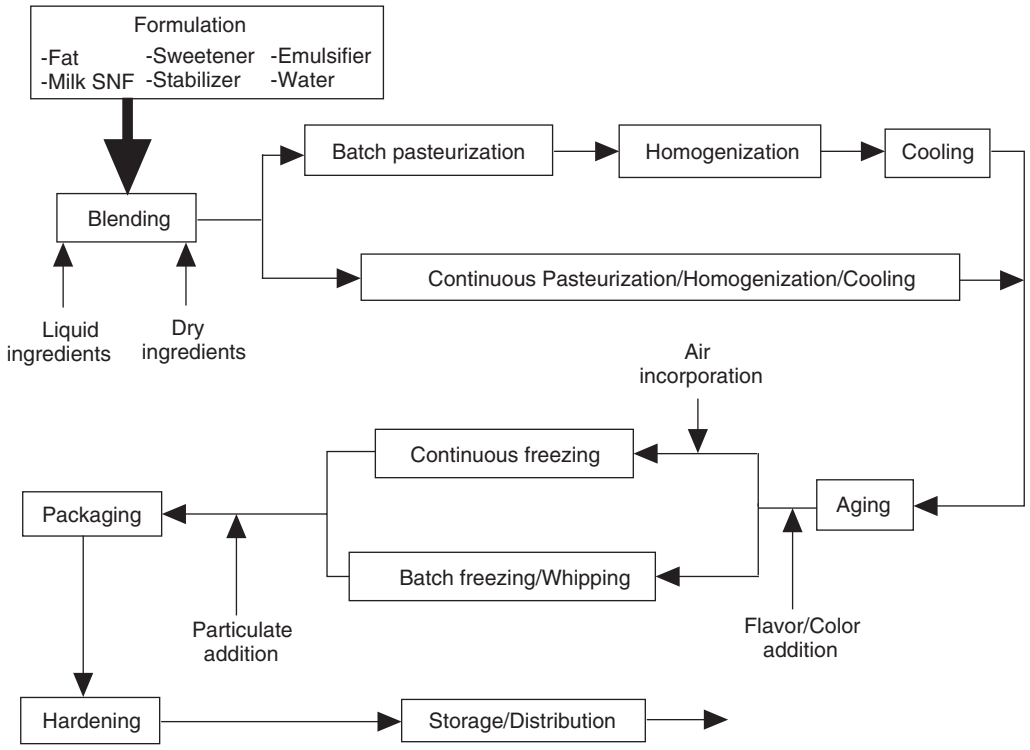

FIGURE 154.3 A schematic illustration of the processing steps in ice cream manufacture.

The first step in a mix calculation is to identify the composition of each ingredient. In some cases the percentage of solids contained in a product is taken as constant or provided by an ingredient supplier, while in others, the composition must be obtained by analysis (e.g., the fat content in milk or cream). If there is only one source of the component needed for the formula, for example, the stabilizer or the sugar, it is determined directly by multiplying the percentage needed by the amount needed, e.g., 100 kg of mix @ 10% sugar would require 10 kg sugar. If there are two or more sources, for example 10% fat coming from both cream and milk, then an algebraic method may be utilized. Computer programs developed for mix calculations generally solve simultaneous equations based on mass and component balances. For manual calculations, a method known as the "Serum Point" method has been derived (1,4). This method has solved the simultaneous equations in a general way so that only the equations need to be known and not resolved each time. In the Serum Point method, 9% msnf is assumed in the aqueous (serum), non-fat portion of all milk ingredients. Thus, the msnf content of milk or cream is calculated as (100 − percent fat) × 0.09. This section will illustrate mix calculation solutions using algebraic techniques and the Serum Point method.

EXAMPLE PROBLEM 1 - Mix using cream, skim milk, and skim powder (three sources of msnf, three sources of water), solution shown by both the Algebraic and Serum Point Methods.

Desired : 100 kg mix @ 13% fat, 11% msnf, 15% sucrose, 0.5% stabilizer, 0.15% emulsifier.

On hand: Cream @ 40% fat; skim milk; skim milk powder @ 97% msnf; sugar; stabilizer; emulsifier.

TABLE 154.8
Sources of the Major Components in Ice Cream Mix, as well as the Minor Components Supplied by these Ingredients

Component	Ingredients to Supply (but also supplies)
Milkfat	Cream (msnf, water)
	Butter (msnf, water)
Milk solids-not-fat (msnf)	Skim powder (water)
	Condensed skim (water)
	Condensed milk (water, fat)
	Sweetened condensed (water, sugar)
	Whey powder (water)
Water	Skim milk (msnf)
	Milk (fat, msnf)
	Water
Sweetener	Sucrose
	Corn syrup solids
	Liquid sugars (water)
Stabilizers/ emulsifiers	

Solution via an algebraic method:
Solution (Note: only one source of fat, sugar, stabilizer, and emulsifier, but two sources of msnf):

Cream

$$100 \text{ kg mix} \times \frac{13 \text{ kg fat}}{100 \text{ kg mix}} \times \frac{100 \text{ kg cream}}{40 \text{ kg fat}}$$

$$= 32.5 \text{ kg cream}$$

Sucrose

$$100 \text{ kg mix} \times \frac{15 \text{ kg sucrose}}{100 \text{ kg mix}} = 15 \text{ kg sucrose}$$

Stabilizer

$$100 \text{ kg mix} \times \frac{0.5 \text{ kg stabilizer}}{100 \text{ kg mix}} = 0.5 \text{ kg stabilizer}$$

Emulsifier

$$100 \text{ kg mix} \times \frac{0.15 \text{ kg emulsifier}}{100 \text{ kg mix}} = 0.15 \text{ kg emulsifier}$$

Skim milk and skim powder, Note: two sources of the msnf
Now, let x = skim powder, y = skim milk.

MASS BALANCE (All the components add up to 100 kg, so skim powder + skim milk = 100 − mass of other ingredients)

$$x + y = 100 - (32.5 + 15 + 0.5 + 0.15)$$

MSNF BALANCE (Equal to 11% of the mix and coming from the skim milk, the skim powder, and the cream, so the portion from the skim powder and skim milk = 11 kg − the contribution from the cream). The msnf portion of the skim milk and cream are taken as 9% of the non-fat portion, i.e., 9% in the case of the skim milk and (100−40) × 0.09 = 5.4% in the case of the cream.

$$0.97\,x + 0.09y = 0.11(100) - (0.054 \times 32.5)$$

Once the appropriate equations have been written, they need to be solved algebraically.

$$x + y = 51.85 \quad \text{so} \quad y = 51.85 - x \qquad \text{from the mass balance}$$
$$0.97\,x + 0.09\,y = 9.245 \qquad \text{from the msnf balance}$$
$$0.97\,x + 0.09\,(51.85 - x) = 9.245 \qquad \text{substituting}$$
$$0.97\,x - 0.09\,x + 4.67 = 9.245$$
$$0.88\,x = 4.58$$

$$x = 5.20 \text{ kg skim powder}$$
$$y = 46.65 \text{ kg skim milk}$$

The above shows the simultaneous solution of 2 equations with 2 unknowns. Likewise, if there were 3 unknowns, e.g., fat, msnf, and the total weight, then three equations could be written, one for each of fat, msnf, and weight. However, the above problem could also be solved with the Serum Point method, and the solution of the above example by that method, along with the derivation of the equations, follows. The Serum Point calculation assumes 9% msnf in skim milk and the skim portion of all dairy ingredients. It then solves the calculation beginning with the most concentrated source of msnf first. It is advisable to solve a problem with the Serum Point method on the basis of 100 kg, and then scale it up to the desired mix quantity by multiplying by the appropriate factor, e.g., solution for each component for 100 kg × 50 = solution for 5000 kg.

Solution of Problem 1 via the Serum Point method:

1. Amount of skim milk powder needed is found by the following formula:

$$\frac{\text{msnf needed} - (\text{serum of mix} \times 0.09)}{\%\ \text{msnf in powder} - 9} \times 100$$

$$= \text{kg skim powder} \qquad (154.1)$$

The derivation of Equation 154.1 is shown at the end of the problem. For now, just assume that this equation will work!

The serum of the mix is found by adding the desired percentages of fat, sucrose, stabilizer, and emulsifier together and subtracting from 100 [i.e., "serum" = msnf (or "serum solids") + water]. In the present problem then,

$$100 - (13 + 15 + 0.5 + 0.15) = 71.35 \text{ kg serum.}$$

Substituting in Equation 154.1 we have:

$$11 - \frac{(71.35 \times 0.09)}{97 - 9} \times 100 = \frac{4.58}{88} \times 100$$

$$= 5.20 \text{ kg skim powder}$$

2. The weight of cream (since there is only one source of fat) will be

$$13 \text{ kg} \times \frac{100 \text{ kg cream}}{40 \text{ kg fat}} = 32.5 \text{ kg cream}$$

3. The sucrose will be 15 kg/100 kg mix.
4. The stabilizer will be 0.5 kg/100 kg mix.
5. The emulsifier will be 0.15 kg/100 kg mix.
6. The weight of mix supplied so far is,

Cream	32.50 kg
Skim powder	5.20 kg
Sucrose	15.00 kg
Stabilizer	0.50 kg
Emulsifier	0.15 kg
	53.35 kg

The skim milk needed therefore is

$$100 - 53.35 = 46.65 \text{ kg.}$$

It is always important to check your solutions to ensure they give the desired result. Such a proof is shown below, where the quantities of each ingredient and the quantities

of each component in each ingredient are laid out in a table and summed. The total mass of each component divided by the total mass of mix should yield the desired percentage.

Proof:

Ingredients	Kilograms	Kgs. Fat	Kgs. msnf	Kgs. T.S.
Cream	32.50	13.0	1.75	14.75
Skim milk	46.65	—	4.20	4.20
Skim powder	5.20	—	5.05	5.05
Sucrose	15.00	—	—	15.00
Stabilizer	0.50	—	—	0.50
Emulsifier	0.15	—	—	0.15
Totals	100.0	13.0	11.0	39.65

Derivation of the Serum Point equations:
Problem 1 is resolved again using simultaneous equations in a general way to show where the serum point equations come from.

On hand: cream @ 40% fat
(supplies fat, water, and msnf, therefore can be thought of as a mixture of fat and skim milk)
skim milk @ 9% msnf
(supplies water and msnf)
skim milk powder @ 97% msnf
(supplies water and msnf)
sucrose
stabilizer
emulsifier

Solution

- Only one source of fat, sucrose, stabilizer, and emulsifier

$$\text{kg fat} = 100 \text{ kg mix} \times 13 \text{ kg fat}/100 \text{ kg mix} = 13 \text{ kg fat}$$

(The explanation for this assumption becomes clearer in a moment!)

$$\text{kg sucrose} = 100 \text{ kg mix} \times 15 \text{ kg sucrose}/100 \text{ kg mix} = 15 \text{ kg sucrose}$$

$$\text{kg stabilizer} = 100 \text{ kg mix} \times 0.5 \text{ kg stab.}/100 \text{ kg mix} = 0.5 \text{ kg stabilizer}$$

$$\text{kg emulsifier} = 100 \text{ kg mix} \times 0.15 \text{ kg emul.}/100 \text{ kg mix} = 0.15 \text{ kg emulsifier}$$

- Two sources of msnf

Let X = skim powder (kg)

Let Y = skim milk (kg) + skim milk in cream (kg)

MASS BALANCE

$$X + Y = \text{Total mix} - \text{components already added}$$

$$X + Y = 100 - (13 + 15 + 0.5 + 0.15)$$

(the "Serum of the Mix")

$$X + Y = 71.35$$

$$(\text{so } Y = 71.35 - X)$$

MSNF BALANCE

$$0.97X + 0.09Y = (0.11 \times 100)$$

"Serum solids fraction in powder" *"Serum solids fraction in skim"* *"Serum solids fraction in mix"*

$$0.97\,X + 0.09\,(71.35 - X) = 11$$

$$0.97\,X + (0.09 \times 71.35) - 0.09\,X = 11$$

$$0.97\,X - 0.09\,X = 11 - (0.09 \times 71.35)$$

$$X = \frac{11 - (0.09 \times 71.35)}{0.97 - 0.09}$$

Which is equal to:

kg skim powder

$$= \frac{\text{msnf needed} - (0.09 \times \text{serum of mix})}{\%\text{ msnf in powder} - 9} \times 100$$

(which is Equation 154.1!)

$$X = \frac{4.58}{0.88} = 5.20 \text{ kg powder}$$

$$\text{kg cream} = 13 \text{ kg fat} \times 100 \text{ kg cream}/40 \text{ kg fat} = 32.5 \text{ kg cream}$$

$$\text{kg skim} = 100 - 32.5 - 15 - 0.5 - 0.15 - 5.2 = 46.65 \text{ kg}$$

EXAMPLE PROBLEM 2 - Mix using cream, milk, and skim powder (three sources of msnf, three sources of water, and two source of fat); solved by both the Algebraic and Serum Point Methods.

Desired: 100 kg mix containing 14% fat, 9.5% msnf, 15% sucrose, 0.4% stabilizer, 1% frozen egg yolk.

On hand: Cream 30% fat, milk 3.5% fat, skim milk powder 97% solids, sucrose, stabilizer, and egg yolk (50% solids).

The solution to this problem will be shown by the simultaneous solution of 3 equations, since there are three sources of msnf, three sources of water, and two source of fat, and by the Serum Point method. Both produce the same results. Follow whichever method you prefer. Computer programs exist that solve simultaneous equations; writing

the equations, however, requires an understanding of the objectives of the problem.

Solution via the algebraic method:

$$\text{Sucrose: } 100 \text{ kg mix} \times \frac{15 \text{ kg sucrose}}{100 \text{ kg mix}} = 15 \text{ kg sucrose}$$

$$\text{Stabilizer: } 100 \text{ kg mix} \times \frac{0.4 \text{ kg stabilizer}}{100 \text{ kg mix}} = 0.4 \text{ kg stabilizer}$$

$$\text{Egg yolk: } 100 \text{ kg mix} \times \frac{1 \text{ kg egg yolk}}{100 \text{ kg mix}} = 1 \text{ kg egg yolk}$$

Now, let x = skim powder, y = milk, and z = cream.

MASS BALANCE All the components add up to 100 kg, so the sum of the three unknowns = 100 − the sum of the known mass of the other components.

$$x + y + z = 100 - (15 + 0.4 + 1)$$

MSNF BALANCE Equal to 9.5% of the mix and coming from the milk, the skim powder, and the cream; assume 9% in the skim portion of the milk and cream so that the msnf of the milk = 0.09 × (100 − 3.5) and of the cream = 0.09 × (100−30)

$$0.97x + 0.08685y + 0.063z = 0.095\ (100)$$

FAT BALANCE Equal to 18% of the mix and coming from the milk and cream

$$0.035y + 0.3z = 0.14\ (100)$$

These equations could now be solved to produce the final outcome:

$$x = 3.7 \text{ kg skim powder}$$

$$y = 37.7 \text{ kg milk}$$

$$z = 42.3 \text{ kg cream}$$

Solution via the Serum Point method:

1. Determine the amount of skim milk powder required by using Equation 154.1:

$$\frac{\text{msnf needed} - (\text{serum of mix} \times 0.09)}{\%\ \text{msnf in powder} - 9} \times 100 = \text{skim powder}$$

Serum of mix = 100 − (14 + 15 + 0.4 + 1.0) = 69.6.

Substituting we have,

$$\frac{9.5 - (69.6 \times 0.09)}{97-9} \times 100 = \frac{3.236 \times 100}{88} = 3.68 \text{ kg powder}$$

2. Amount of sucrose required is 15.0 kg.
3. Amount of stabilizer required is 0.4 kg.
4. Amount of egg required is 1.0 kg.
5. Determine amount of milk and cream needed.

Materials supplied so far are 3.68 kg powder, 15 kg sucrose, 0.4 kg stabilizer, and 1 kg egg yolk, a total of 20.08 kg. 100 − 20.08 = 79.92 kg milk and cream needed.

6. Determine the amount of cream by following formula:

$$\frac{\text{kg fat needed} - (\text{kg cream and milk needed} \times \frac{\%\ \text{fat in milk})}{100}}{\%\ \text{fat in cream} - \%\ \text{fat in milk}} \times 100 \quad (154.2)$$

Note: Equation 154.2 is derived from a generalized fat balance, in much the same way that Equation 154.1 was derived.

Substituting we have,

$$\frac{14 - \left(79.92 \times \frac{3.5}{100}\right)}{30 - 3.5} \times 100 = \frac{11.20}{26.5} \times 100 = 42.26 \text{ kg cream.}$$

7. Amount of milk needed = 79.92 − 42.26 = 37.66 kg of milk.

Proof:

Ingredients	Kilograms	Kgs. Fat	Kgs. msnf	Kgs. T.S.
Cream	42.26	12.68	2.66	15.34
Milk	37.66	1.32	3.27	4.59
Skim powder	3.68	—	3.57	3.57
Sucrose	15.00	—	—	15.00
Stabilizer	.40	—	—	.40
Egg yolk	1.00	—	—	.50
Totals	100.00	14.00	9.50	39.40

With Equations 154.1 and 154.2, most complex mix problems can be solved. There are additional complications for the use of condensed skim or whole milk, and for liquid sugars. See Ref. 1 for further details.

3. Pasteurization and Food Safety Issues

Pasteurization is the biological control point in the system, designed for the destruction of pathogenic bacteria. If raw milk or cream are used as ingredients, it could be

that these are contaminated with a human pathogen from the dairy farm. Therefore, it is essential that pasteurization be carefully designed and closely monitored. If raw dairy ingredients are not used, contamination from a human source could also occur, and thus the use of pasteurization conditions that eliminate pathogens is mandated by most legal jurisdictions. In addition, it serves a useful role in reducing the total bacterial load, and in solubilization of some of the components (proteins and stabilizers). Both batch and continuous (high temperature short time or HTST) systems are in common use (3). In a batch pasteurization system, blending of the proper ingredient amounts is done in large jacketed vats equipped with some means of heating, usually saturated steam or hot water. The product is then heated in the vat to at least 69°C (155°F) and held for 30 min to satisfy legal requirements for pasteurization, or equivalent times and temperatures as determined by the local legal jurisdiction. The heat treatment must be severe enough to ensure destruction of pathogens and to reduce the bacterial count to a maximum (e.g., 10,000 per gram), depending on the legal jurisdiction. Following pasteurization, the mix is homogenized using high pressures and then is passed across some type of heat exchanger (plate heat exchanger or double or triple tube heat exchanger) for the purpose of cooling the mix to refrigerated temperatures (4°C).

Continuous pasteurization is usually performed in an HTST heat exchanger following the blending of ingredients in a large, insulated feed tank. Some preheating, to 30 to 40°C, may be necessary for solubilization of the components. The HTST system is equipped with a heating section, a cooling section, and a regeneration section (Figure 154.4). Mix first enters the raw regeneration section, where cold or preheated mix is heated to as warm as possible on one side of a plate heat exchanger, while the pasteurized hot mix is cooled to as low as possible running countercurrent on the opposite sides of the plates. Following the raw regeneration section, the mix enters the heating section where a minimum temperature of 80°C is obtained. The mix is held at this temperature for 25 sec by flowing either through a series of holding tubes or through an additional set of plates in the HTST unit. Holding times much longer than the minimum can be accomplished with longer holding tubes. Holding times of 2 or 3 min may produce superior mixes that retain many of the advantages of batch pasteurization (4,6). After leaving the holding tube, the mix enters the homogenizer, depending upon the particular configuration, then flows back through the pasteurized side of the regeneration section and enters the cooling plates, where a chilled brine solution or chilled water bring the mix down to around 4°C.

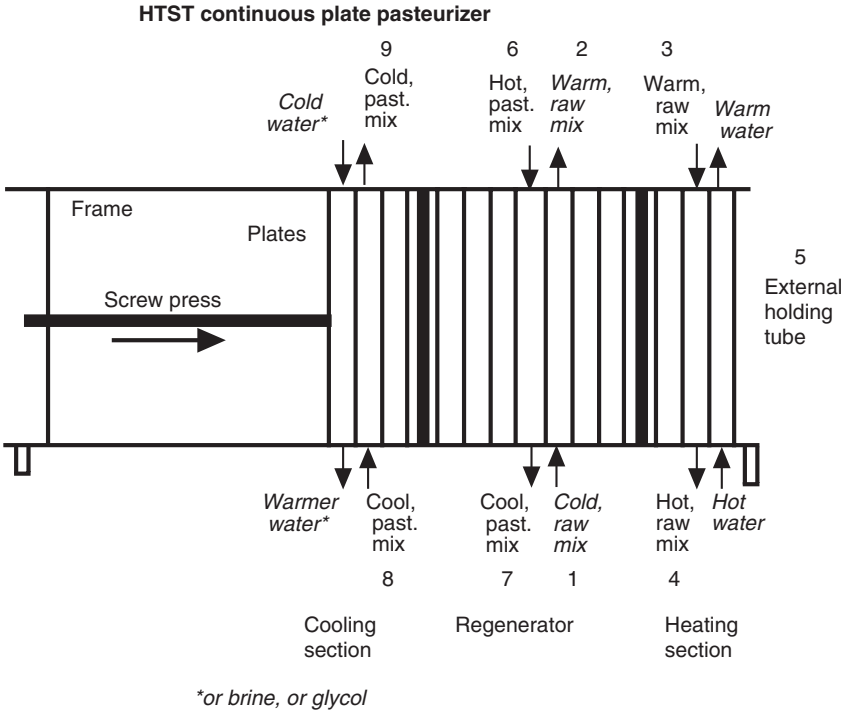

FIGURE 154.4 A schematic illustration of the side view of a plate heat exchanger used for HTST pasteurization of frozen dairy dessert mixes. Numbers indicate the sequence of flow of mix. Italics are used to differentiate the material on one side of a section from the material on the other.

4. Homogenization

Homogenization is responsible for the formation of the fat emulsion by forcing the hot mix through a small orifice under pressures of 15.5 to 18.9 MPa (2000–3000 psig), depending on the mix composition. The actual mechanism of fat disruption within the homogenizer is thought to result from turbulence, cavitation, and velocity gradients (energy density) within the valve body (91). The 4–8 fold increase in the surface area of the fat globules is responsible in part for the formation of the fat globule membrane, comprised of adsorbing materials attempting to lower the interfacial free energy of the fat globules (92,93). Koxholt and co-workers (94) have recently shown that sufficient fat structure in the mix for optimal ice cream meltdown was created by homogenization pressures on the first stage of 10 MPa, in mixes with up to 10% fat content, and that higher pressures were not required. With single stage homogenizers, fat globules tend to cluster as bare fat surfaces come together or adsorbed molecules are shared. Therefore, a second homogenizing valve is commonly placed immediately after the first, with applied back pressures of 3.4 MPa (500 psig) (3), allowing more time for surface adsorption to occur. However, Koxholt and co-workers (94) have recently shown that two-stage homogenization is not necessary for ice cream mixes up to 10% fat content in order to achieve optimal fat structuring and ice cream meltdown. The net effects of homogenization are in the production of a smoother, more uniform product with a greater apparent richness and palatability, and better whipping ability (1). Homogenization also decreases the danger of churning the fat in the freezer, and makes it possible to use products that could not otherwise be used, such as butter and frozen cream.

5. Aging

An aging time of four hours or greater is recommended following mix processing prior to freezing. This allows for hydration of milk proteins and stabilizers (some viscosity increase occurs during the aging period), crystallization of the fat globules, and a membrane rearrangement, to produce a smoother texture and better quality product (6,11). Non-aged mix is very wet at extrusion and exhibits variable whipping abilities and faster meltdown (1,6). The appropriate ratio of solid:liquid fat must be attained at this stage. This is a function of temperature and the triglyceride composition of the fat used; as a partially crystalline emulsion is needed for partial coalescence in the whipping and freezing step, as discussed in Section II.B.4. Emulsifiers generally displace milk proteins from the fat surface during the aging period (12,36,95), and this is also discussed in detail in Section II.B.4. The whipping qualities of the mix are usually improved with aging. Aging is performed in insulated or refrigerated storage tanks, silos, etc. Mix temperature should be maintained as low as possible (at or below 4°C) without freezing.

B. Dynamic Freezing

In a continuous, scraped surface freezer, numerous processes take place that ultimately influence the overall quality of the ice cream. One of the most important steps, of course, is freezing water into ice. At the same time as ice is being formed, there is also air incorporation, leading to development of air cells and the desired overrun. In addition, destabilization of the fat emulsion (partial coalescence, see Section II.B.4) takes place during freezing, which promotes incorporation and stabilization of the air cells. All of these processes take place simultaneously in the minute or less that ice cream spends in the dynamic freezing step. Following this initial phase of ice formation in a dynamic freezer, where about half of the water is turned into ice, there is a static freezing step, often called hardening (see Section II.D).

The mechanisms that lead to ice formation in an ice cream freezer are quite complex. Ultimately, the product exiting the freezer contains numerous, small ice crystals. As seen in Figure 154.5 (96), the ice crystals in ice cream at the exit of the freezer are somewhat block-shaped and vary in size from a few microns to over 100 μm. A typical size distribution for hardened ice cream is shown in Figure 154.6 (6). The large number of very small ice crystals, estimated to be 4×10^9 crystals per liter (97), gives ice cream its smooth, cool character. The ice crystals must remain below some threshold detection size, often given as about 50 μm mean size (1), for the ice cream to remain smooth. When crystals become larger than this, the ice cream may be considered coarse. Control of ice crystallization to produce the desired number and size of crystals is critical to producing high quality ice cream.

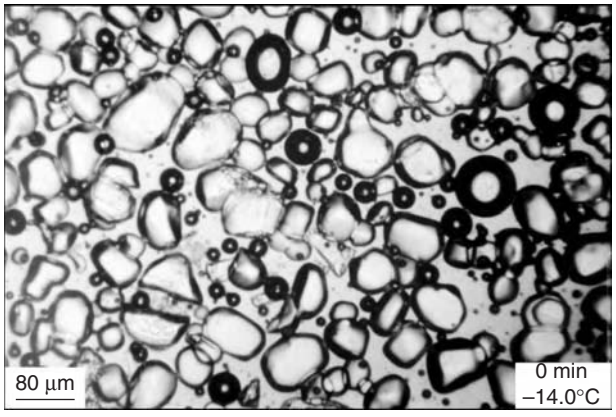

FIGURE 154.5 Ice crystals in ice cream, as observed using light microscopy (96).

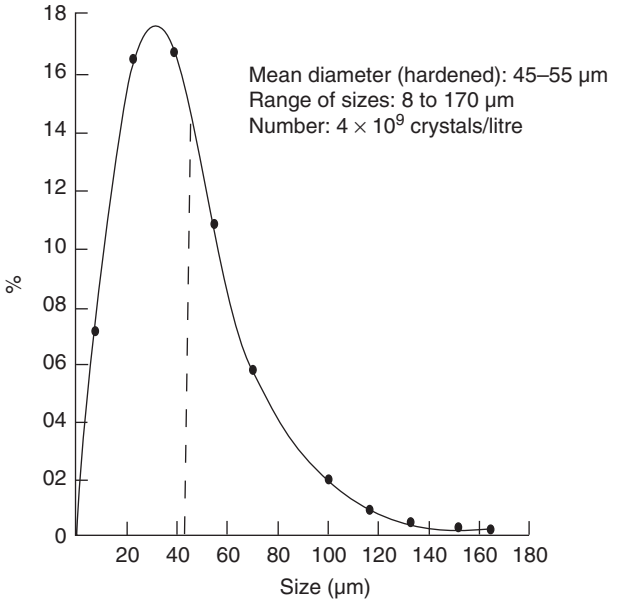

FIGURE 154.6 Typical ice crystal size distribution for hardened ice cream (6).

1. Principles of Ice Crystallization

When ice freezes or crystallizes from any solution, several steps must take place. First, the solution must be cooled below the freezing (melting) point of the solution. The temperature difference between the actual temperature and the freezing point temperature of the mix is the driving force for freezing. Once an appropriate driving force has been attained, formation of the solid ice phase from the liquid molecules must occur. This step is called nucleation, where tiny bits of crystalline ice have just started to form. Once these nuclei begin to form, they continue to grow until some phase equilibrium has been obtained. In freezing, ice continues to form until a thermal equilibrium between the freezing product and its environment has been reached. The total amount of ice that forms (at any storage temperature) depends on the system. For pure water, all of the water is converted to ice as long as the temperature is below 0°C. In ice cream, however, the other ingredients influence the freezing process and determine how much water turns to ice (the ice phase volume) at any temperature. Both the total amount of ice as well as the nature of the ice dispersion (size, shape, etc.) influence the physical properties of the final ice cream product.

After the product is frozen, the ice phase continues to undergo recrystallization. Recrystallization is a term used for a combination of several events, including melting, growth and ripening, that occur after the initial ice crystal phase has been developed. Recrystallization leads to changes in the distribution of ice crystals within the system based on the thermodynamic difference in melting point between large crystals and small ones. Typically, recrystallization occurs with no change in ice phase volume.

In continuous ice cream manufacture, mix is pumped into the freezer and flows along the length of the barrel. As the ice cream moves from the inlet to the outlet, ice is frozen, fat is destabilized and air is injected, as shown in Figure 154.7. The mix enters the freezer barrel at a temperature between 0 and 4°C and begins to freeze as it contacts the metal wall cooled by expanding refrigerant (ammonia or Freon). Ice forms at the barrel wall since this is where the driving force for freezing is the highest. However, the ice layer that forms is rapidly scraped off of the wall and dispersed into the center of the freezer barrel where the ice changes form depending on temperature conditions and mixing parameters. As the mix moves axially along the freezer barrel, the amount of ice formed increases as the bulk average temperature of the slurry decreases. At the draw (exit) of the freezer, approximately half of the initial water in the mix is frozen into ice and the product is a pumpable slurry of partially frozen ice cream. The change in temperature along the length of the freezer for a typical ice cream operation is shown in Figure 154.8 (98). The final temperature and the amount of ice formed depends on the rate of freezing within the barrel of the freezer. This is controlled by the flow of refrigerant (ammonia or Freon) on the outside of the barrel, the throughput rate of ice cream through the freezer and the type of mixing device used within the barrel of the freezer. In general, conditions in a scraped surface freezer

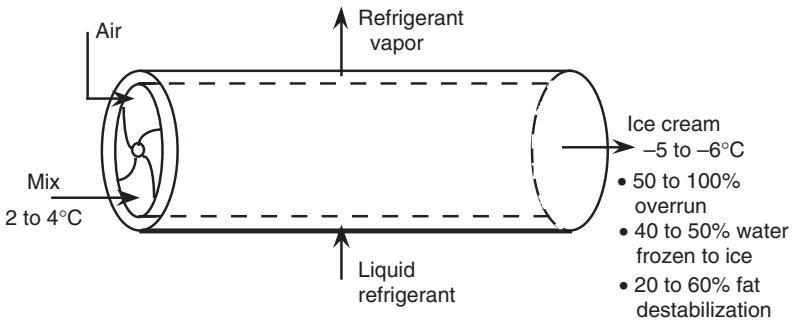

FIGURE 154.7 A schematic diagram to represent inputs and outputs during the continuous freezing of ice cream.

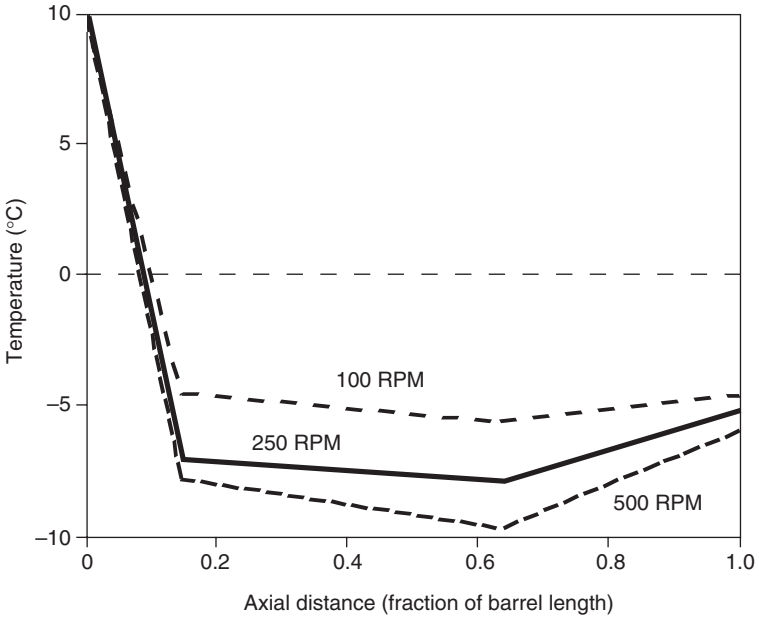

FIGURE 154.8 Axial profile of ice cream temperature as a function of dasher speed within the barrel of a scraped-surface ice cream freezer (98).

are controlled to give a compromise between the draw temperature (amount of ice frozen) and the stiffness of the ice cream exiting the freezer. The ice cream should be as frozen as possible (since here is where control of ice formation occurs), yet be sufficiently fluid to incorporate inclusions and/or fill the containers without leaving air gaps. This compromise depends to some extent on the type of product being produced and its final form.

a. Phase/state behavior

Freezing Point Depression. In order for ice to freeze, the temperature of the solution has to be lowered below its freezing point. The temperature at which a solution freezes, or the freezing point, is determined by the concentration and type of solutes present in the mix. The presence of dissolved salts and sugars causes the freezing point of water to be lowered. This freezing point depression occurs because the solute molecules interact with water and inhibit the ability of the water molecules to come together and form an ice crystal lattice (or freeze). The extent of freezing point depression is based on the number of solute molecules and their size. Small molecules have the greatest effect; the higher the concentration of these small molecules, the lower the freezing point. Thus, ice cream mixes made with a high concentration of milk salts and lactose, with high sugar content, or with high content of low-molecular weight sweeteners, have lower freezing points. For example, use of high fructose corn syrup as a sweetener gives a lower freezing point (compared to the use of sucrose) due to the addition of lower molecular weight sugars. Mixes made with high levels of msnf have a low freezing point due to the addition of milk salts and lactose.

The freezing point of the ice cream mix is an important quality control parameter since it governs the amount of ice that can form at a given temperature, which affects the quality and textural attributes of the ice cream. As seen in Figure 154.9 (99), melting rate increases and firmness decreases with increasing freezing point (as indicated by osmolality) (99,100). As the freezing point of the mix goes down (osmolality increases), ice cream contains less ice and more unfrozen water at any given temperature, which leads to ice cream that is less firm and melts at a faster rate.

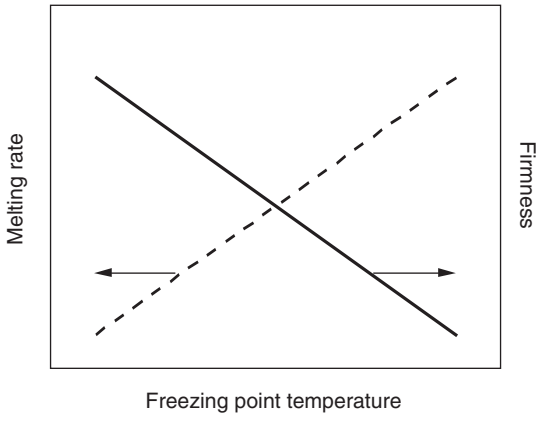

FIGURE 154.9 Effects of freezing point of ice cream mix on melting rate and firmness of final product (based on data from Ref. 99).

Freezing point depression also can be calculated based on principles of thermodynamics (96), assuming ideal solutions and dilute concentrations. At the point where the two phases (solid ice and liquid water) are in equilibrium, the chemical potentials of the two phases are equal and the following equation can be developed.

$$\frac{\Delta H}{R}\left[\frac{1}{T_0} - \frac{1}{T}\right] = \ln(X_w) \qquad (154.3)$$

Here, ΔH is the latent heat of fusion, R is the ideal gas constant, T_0 is the freezing point of pure water, T is the freezing point of solution with mole fraction of water of X_w. For aqueous foods, equation (154.3) may be modified to give:

$$(T_f - T_0) = K\frac{C}{MW} \qquad (154.4)$$

where, T_f is freezing point (°C) of a solution with concentration C (in g/100 g water), MW is the molecular weight of the dissolved solute, and K is a conversion factor (equal to 1.86 for water).

In simple systems, Equation 154.4 gives a good estimate of freezing point and can be used to show the relationship between freezing point and solute content. For example, the freezing point depression curves for several sugars are shown in Figure 154.10 (96). Note that fructose has a lower freezing point than sucrose at any equal concentration (wt %), because it has lower molecular weight and there are more molecules of fructose added (at equivalent mass of sugar). Conventional corn syrup solids (42DE), which contain numerous longer-chain saccharides, have a higher freezing point than sucrose. In more complex food formulations, the sum of each of the components that impact freezing point depression is needed. In ice cream mix, it is the combination of sweeteners and milk ingredients used in the formulation that leads to the specific freezing point depression curve for any mix. Sugars (from sweetener and msnf) and salts (from msnf) are the main components that impact freezing point depression of an ice cream mix.

Typically, freezing point depression of an ice cream mix is calculated from Equation 154.4 by taking the sucrose equivalents of all the important components that influence freezing point. Sucrose equivalency values for common sweeteners have been developed (101) for use in ice cream formulations. The contributions of both sweeteners and salts on freezing point are then summed (102) to obtain the initial freezing point of the mix. Equation 154.4 can also be used to calculate the amount of water frozen into ice for a given ice cream at any temperature by varying the concentration since freeze concentration of the unfrozen phase occurs during freezing. Based on the approximate freezing point depression curve and the assumption of slow freezing, the amount of water converted to ice at any temperature can be calculated by a mass balance. For a typical ice cream, a relationship between temperature and the amount of water frozen into ice is obtained, as shown in Figure 154.11 (103). Since Equation 154.4 technically only works for dilute, ideal solutions, it does not apply very accurately at higher concentrations found in the unfrozen phase of ice cream. Thus, correction factors have been developed based on experimental data for frozen sucrose solutions (104).

To calculate the freezing point of a given mix, the effects of sweeteners and salts must be summed. The effects of sweeteners are obtained by summing the

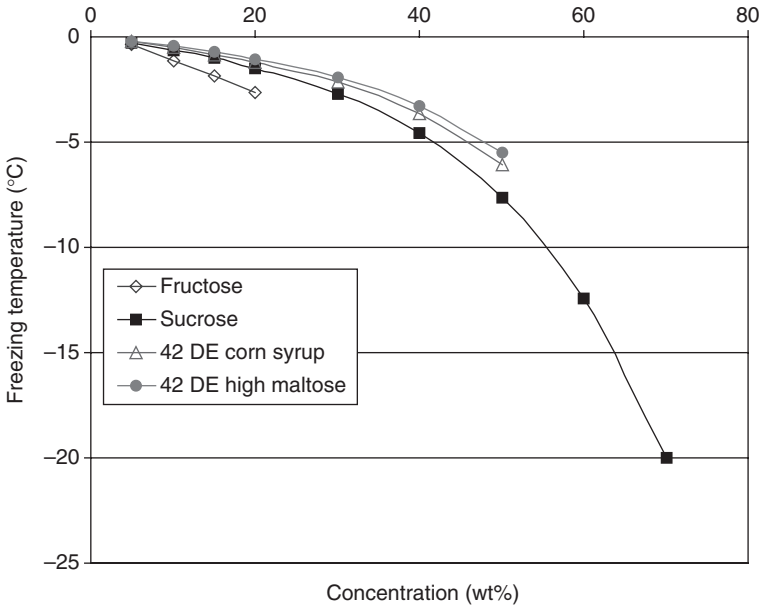

FIGURE 154.10 Freezing point depression curves (freezing temperature as a function of concentration) for several sugars (96).

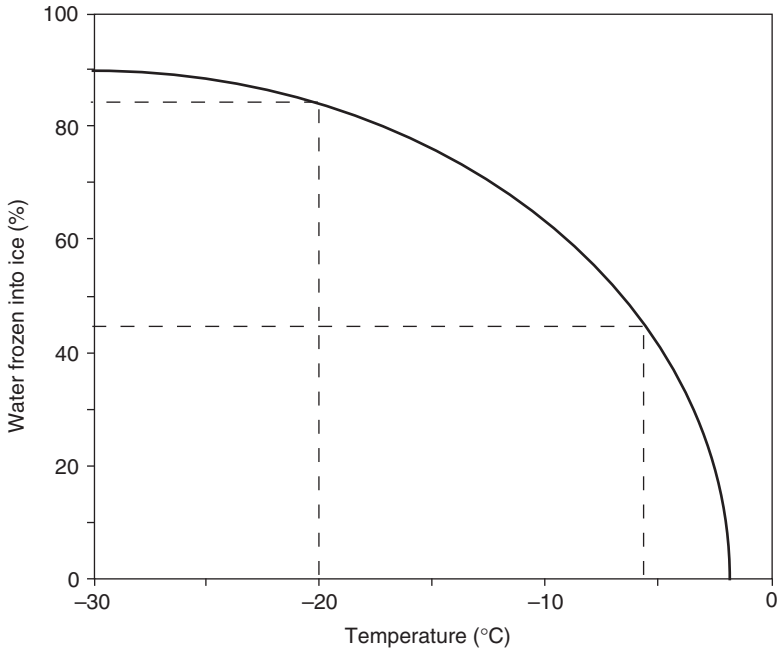

FIGURE 154.11 Examples of the approximate amount of water frozen into ice for ice cream of standard formulation at given temperatures, based on an equilibrium freezing curve for that formulation (based on Ref. 103).

contributions of sucrose, lactose (from msnf) and any corn syrups added. For an ice cream mix containing only sucrose, Equation 154.5 is used (1).

$$SE_{sw} = \frac{[(msnf \times 0.545) + S]100}{W} \qquad (154.5)$$

Here, SE_{sw} is the sucrose equivalence from sugars, S is sucrose content, W is water content (100 – total solids, %) and 0.545 is the percentage of lactose typically found in msnf. To obtain the freezing point depression associated with this level of sugars, FPD_{sw}, Table 154.9 is used (1). The contribution to freezing point depression from salts in msnf is found from Equation 154.6.

$$FPD_{sa} = \frac{msnf \times 2.37}{W} \qquad (154.6)$$

Here, FPD_{sa} is the sucrose equivalence for salts contained in msnf, and the constant 2.37 is based on the average molecular weight of the salts present in msnf. To obtain the freezing point depression of the ice cream mix, FPD_t, the two contributions are summed.

$$FPD_t = FPD_{sw} + FPD_{sa} \qquad (154.7)$$

EXAMPLE PROBLEM 3:

Calculate the initial freezing point of an ice cream mix containing 16% sucrose, 12% msnf, and 60% water (40% total solids). First, calculate the sucrose equivalents from Equation 154.5:

$$SE_{sw} = \frac{[12 \times (0.545) + 16]100}{60} = 37.57$$

TABLE 154.9
Freezing Point Depression in Sucrose Equivalents (1)

	Freezing Points	
Sucrose Equivalent (%)	(°C)	(°F)
0	0.00	32.00
5	−0.42	31.25
10	−0.83	30.50
15	−1.17	29.90
20	−1.50	29.30
25	−2.08	28.25
30	−2.67	27.20
35	−3.58	25.55
40	−4.39	24.10
45	−5.69	21.75
50	−7.00	19.40

Now, find the freezing point depression for this level of sucrose equivalent from Table 154.9. By interpolation,

$$FPD_{sw} = 2.31°C$$

For salts, from Equation 154.6:

$$FPD_{sa} = \frac{12 \times (2.37)}{60} = 0.47°C$$

Find the total freezing point depression for the mix from Equation 154.7:

$$FPD_t = FPD_{sw} + FPD_{sa} = 2.31 + 0.47 = 2.78°C$$

Thus, the initial freezing point temperature for this ice cream mix is −2.78°C.

Freezing Curve. In order for ice to form, the temperature of the system (T) must be below the freezing point (T_f) of the mix. The extent of subcooling ($\Delta T = T_f - T$) determines the rate of freezing, as discussed in the next section. Once freezing occurs, though, several things take place. The change in phase due to formation of ice causes a release of heat (latent heat of fusion), which increases the temperature in the vicinity of the phase change; this heat is removed by the refrigerant. At the same time, removal of water from the mix in the form of ice causes an increase in concentration of the remaining unfrozen phase, which has a lower freezing point due to the higher concentration. Thus, in the vicinity of the ice crystals, the temperature increases and the freezing point decreases. This leads to a freezing profile (Figure 154.12) dependent on the rate of freezing (96). For slow freezing, once nucleation starts, the temperature increases to approximately the melting point, due to fast release of latent heat, and then begins to decrease as further heat is removed and the concentration increases. Slow freezing results in a freezing profile that essentially follows the freezing point depression curve.

As freezing continues, the unfrozen phase becomes more and more concentrated and temperature continues to decrease. This leads to an increase in viscosity of the unfrozen phase until ultimately, the viscosity is sufficiently high that the freeze-concentrated unfrozen phase becomes glassy. That is, at some low temperature (the glass transition temperature, T_g), the unfrozen phase solidifies into a glassy state. Note that this is not a true solid (in the sense of a crystalline solid), but rather it is a high viscosity fluid that acts like a solid for as long as the temperature remains low. The point where the glassy state is formed during slow freezing is called the maximally freeze-concentrated temperature (T_g'), as seen in Figure 154.12. For various ice cream mixes, T_g' has been found to be around −30 to −35°C (85,105). For slow freezing, the amount of ice formed at any temperature is obtained as described in the previous section since the system follows the freezing point depression curve. If freezing is very rapid, the temperature and concentration of the solution falls somewhere below the freezing point depression curve, as shown in Figure 154.12. In this case, Figure 154.11 no longer applies and the amount of ice formed at any temperature is less than that shown in Figure 154.11 and is dependent on the rate of freezing.

b. Nucleation

The driving force for freezing is the temperature difference between the actual temperature of the system and the freezing (melting) point ($T - T_f$). At higher subcooling, freezing occurs more rapidly; that is, the rate of ice formation is a strong function of the thermal driving force (ΔT). The onset of nuclei formation is the point when the water molecules convert into molecules in an ice crystal lattice. When the temperature driving force is sufficiently high (temperature sufficiently below the freezing point), there is sufficient energy for the water molecules to overcome the energy barrier needed to form an ice crystal surface (the interface between crystal and liquid). Typically, ice formation begins on a surface that catalyzes the formation of ice crystals. This surface may

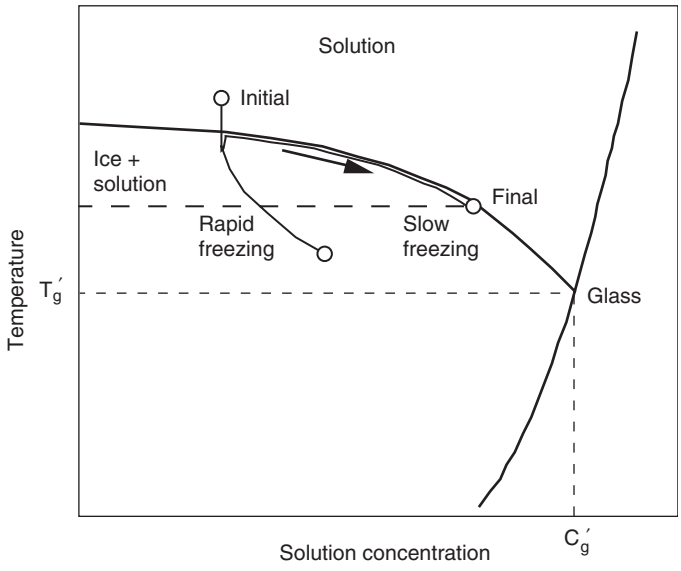

FIGURE 154.12 A phase diagram for solutions (e.g., ice cream mix) showing the path of freezing (temperature and solution concentration) for freezing at different rates. Figure shows schematic representation of freezing point depression and glass transition curves (adapted from Ref. 96). T_g' and C_g' represent point of maximally freeze-concentrated solution.

be that of the vessel that contains the solution or particles distributed throughout the solution that provide sufficient energy to order the water molecules in solution and promote nuclei formation. In commercial ice cream manufacture, it is likely that nucleation initially occurs by formation on the metal surface (inner barrel wall) exposed to the refrigerant, since that is where the driving force (ΔT) is highest. The rate of nucleation (number of nuclei formed per unit volume per unit time) for melt systems has been described by Equation 154.8 (96,106).

$$J = A\exp\left\{-\frac{BT_f^2}{(\Delta H_f)^2(T_f - T)^2} + \frac{\Delta G_v'}{kT}\right\} \quad (154.8)$$

Here, J is nucleation rate, A is a frequency factor (or preexponential term), B is a constant depending on the solutes present, T_f is freezing (melting) point, k is Boltzman's constant, ΔH_f is latent heat of fusion, T is system temperature and $\Delta G_v'$ is a diffusion-limited term that describes the mobility of water molecules.

Equation 154.8 clearly shows the dependence of nucleation rate on operating parameters, particularly the temperature driving force. When the system temperature, T, is close to the freezing point temperature, T_f, the temperature driving force (ΔT) and nucleation rate are low. In fact, at temperatures close to T_f, nucleation is so slow that the system may effectively remain unfrozen for long times, even though the temperature is below the freezing point of the solution. However, when ΔT is sufficiently high, or when system temperature falls sufficiently below T_f, Equation 154.8 predicts a sudden onset of nuclei formation. As the driving force (ΔT) increases, the rate of nuclei formation increases precipitously, giving rise to the spontaneous nature of freezing once it has initiated. When ΔT increases to too high a value, nucleation rate once again decreases due to the limited mobility of water molecules. As temperature goes down, the viscosity increases substantially, until eventually the system becomes glass-like. At this point, the $\Delta G_v'$ term overwhelms the ΔT term in Equation 154.8, and nucleation rate again goes to zero. Thus, there is a maximum in the nucleation rate curve as shown schematically in Figure 154.13 (9).

In a commercial scraped-surface freezer, the primary temperature driving force for nucleation occurs at the barrel wall. On the jacket side of this metal wall, liquid refrigerant (either ammonia or Freon) is vaporizing to provide the cooling effect. Vaporizing refrigerant removes heat from the ice cream mix nearest to the barrel wall and creates a high degree of subcooling in the mix at that region (9), as seen in Figure 154.14. Ice forms on the metal surface of the barrel wall where the temperature driving force is highest and catalytic nucleation sites exist (microscopic imperfections in the wall itself). Without agitation and scraping, this ice layer would continue to grow and increase in thickness until a thermal equilibrium

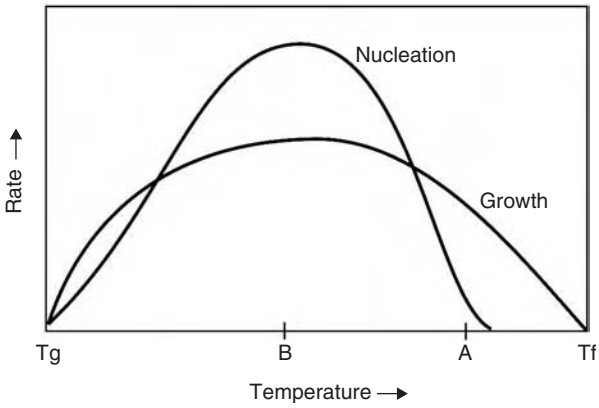

FIGURE 154.13 Rates of nucleation and growth of ice over the temperature range from glass transition temperature (T_g) to melting point (T_f). A and B represent temperatures where nucleation rate is low and high, respectively (9).

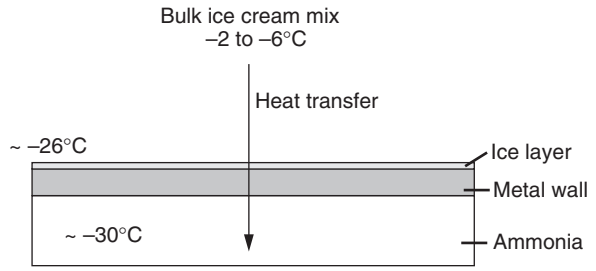

FIGURE 154.14 Approximate driving force (ΔT) for freezing of ice cream in a continuous freezer with vaporizing ammonia as refrigerant.

was attained between unfrozen mix and the coolant. In commercial freezers, the rotating scraper blades repeatedly clean off the metal surface of the barrel wall. Based on an agitator speed of 200 RPM and a six-bladed agitator, it can be calculated that the metal surface is scraped every 0.05 s. Thus, ice has very little chance to build up on the barrel wall. Recent studies (107,108) using videomicroscopy to observe ice formation on a cooled surface suggest that the scraper blade effectively cleans most of the ice off the metal wall at each scraping. Small pockets or shards of ice left on the wall serve as seeds for subsequent growth of the ice layer between scrapings. These studies suggest that the ice layer initially grows out along the surface to fill an ice layer on the metal wall rather than initially growing out into the solution. Most likely, the scraper blade removes the regrown ice layer before substantial growth into the solution (away from the wall) has occurred. The ice layer that is scraped off the metal wall is dispersed into the bulk mix circulating around the agitators.

The nature of the ice layer scraped off the metal wall in a commercial freezer has been the subject of much discussion in the past decades. Based on work by Schwartzberg and co-workers (109,110), it has been suggested that the ice layer in a scraped-surface freezer forms as dendritic (or needle-shaped) ice crystals extending into the solution (9). The scraper blade then removes these dendrites from the surface and disperses them into the center of the barrel, where subsequent recrystallization and ripening occur. Recent experiments suggest a different form of ice crystals at the barrel wall. Rather than dendrites extending into the solution, it appears that ice initially grows horizontally along the metal surface since this is the most favorable direction for heat transfer (107,108). The ice crystals in this layer are most likely needle-like although this has not been shown conclusively. Because growth is extremely rapid at the low temperatures of the metal wall, this ice layer is comprised of multiple ice crystals surrounded by concentrated mix. Before this layer has a chance to form more perfect crystals and exclude solvent molecules from the mix, it is scraped off by the blades and dispersed into the bulk of the freezer. In "slushie" machines that produce iced fruit drinks, the first evidence of ice formation when the refrigeration unit is turned on is thin "flakes" of ice removed from the refrigerated metal surface. Apparently, the scraper blade removes a layer of slush composed of ice and concentrated mix that temporarily maintains its integrity in the bulk, appearing as a thin layer or flake of ice approximately 0.5 to 1 cm in diameter. A submersed microscope in a batch scraped-surface freezer initially catches large (about 250 μm across) sheets of ice that take a hexagonal form (111). Similar forms have been seen growing horizontally along a cooled metal surface (108).

These polycrystalline ice flakes are distributed into the bulk of the freezer by the action of the scraper blades. What happens next depends to some extent on the nature of the bulk phase within the barrel of the freezer. For freezers with open dashers and internal mixers, the ice layer is mixed well with the warmer mix farther away from the refrigerated barrel wall. Here, the blades of the internal dasher can break the ice "flakes" into smaller shreds or pieces. In addition, melting, growth and ripening take place due to fluctuations in temperature that arise from the heat being removed by the barrel wall and the latent heat associated with melting and growth. A complex heat and mass transfer environment exists in which the ice crystals ultimately grow to product size and shape. Ice crystals exiting the scraped-surface freezer are typically disk-shaped with sizes ranging from a few microns to over 50 μm. In a closed dasher (one with high displacement of barrel volume), where the ice cream essentially flows in an annular space between the two cylinders (barrel and dasher), there is much less internal mixing and less opportunity for melting, growth and ripening. Nevertheless, enough of these processes take place that the ice crystals exit the freezer as disk-shaped crystals (as seen in Figure 154.5).

c. Growth, ripening, and equilibration

Within the barrel of the scraped-surface freezer, several complex processes related to freezing take place simultaneously. Furthermore, each process affects the nature of the other processes, primarily through influences on heat transfer. The thin layer of polycrystalline ice and slush that is scraped off the barrel wall is colder than the fluid at the center of the barrel. Thus, the first thing that happens is that the colder slush flake cools the surrounding environment as it, in turn, is warmed up. This warming, coupled with mechanical agitation, causes the flake to be broken down into smaller shreds, as has been observed by submersible microscope in a batch freezing apparatus (111). The polycrystalline ice crystals contained within the slush flakes are dispersed into the bulk solution where they melt, grow or ripen according to the conditions in their immediate environment. In regions where temperature is slightly higher than the slush from the wall, the ice crystals begin to melt. However, melting takes heat out of the solution as latent heat, which subsequently cools the surrounding environment. The direction of heat transfer determines which regions get the most cooling effect. In the regions where temperature is a little lower than the slush from the wall, ice crystals grow due to the temperature driving force. However, growth causes a release of latent heat, which warms the surrounding environment.

The rate of ice crystal growth is primarily influenced by two mechanisms. Ice crystal growth depends on the rate of counter-diffusion of solute molecules away from the growing interface and on the rate of heat transfer removal from the environment through either the solution or the ice crystal itself (112). The solute molecules present in the ice cream mix (i.e., sugars, salts, proteins, hydrocolloids, etc.) must diffuse away from the growing surface to allow incorporation of water molecules into the existing crystal lattice structure. The rate of diffusion of these solutes depends on the molecular size (larger molecules diffuse more slowly) and the concentration gradients existing during growth. Once water molecules are incorporated into the crystal lattice, there is a release of the latent heat of fusion, which must be removed by conduction and/or convection mechanisms. In an agitated environment, heat transfer generally occurs most rapidly by convective processes with fluid movement carrying away the heat from the growing crystal surface.

Further complicating these dynamics of melting and growth within the freezer barrel is the thermodynamic mechanism of ripening (112). Ripening is based on the slight difference in equilibrium (e.g., freezing temperature) between crystals of different size. It is well known that very small crystals (less than about 5 μm for ice) have

a slightly lower freezing point than large crystals (96). Thus, very small crystals may actually melt at the same time (in the same environment) that larger ice crystals continue to grow. In fact, it is this principle of ripening that leads to changes in ice crystals due to recrystallization in storage.

d. Controlling freezing

The principles of freezing discussed in the previous section are applied in commercial ice cream manufacture to make products with the desired number and size distribution of ice crystals for the highest quality. In the continuous commercial freezer described above, conditions are controlled to maximize production of numerous, small ice crystals. A low-temperature refrigerant (vaporizing ammonia or Freon) is used to lower the temperature of the mix quickly to about –25°C at the surface of the freezer barrel. This low temperature (high temperature driving force for nucleation) causes nucleation to occur rapidly, and results in formation of many small nuclei. Even though these nuclei ripen and grow as they make their way to the exit of the continuous freezer, they remain quite small (20 to 25 μm).

Compare the commercial situation above to that in a small batch home freezer. In both cases, ice forms on a cold metal surface in contact with a refrigerant, with a scraper blade periodically removing the ice layer formed at the wall. In the batch freezer, an ice-brine solution is made to lower the temperature of the ice cream mix. However, this brine reaches temperatures of perhaps only −10° to −12°C. This warmer temperature means that nucleation occurs at a significantly lower driving force than in the commercial freezer (liquid ammonia at about −30°C). According to Figure 154.13, the rate of nucleation is significantly lower in the batch freezer, due to the lower ΔT, than in the continuous freezer and thus, fewer ice crystals are formed. When the final ice cream products are hardened to the same temperature, the product from the batch freezer, which contains fewer crystals, ends up with significantly larger ice crystals (and potentially coarser ice cream) than the product from the continuous freezer, which has many more smaller crystals. This principle is described schematically in Figure 154.15 (113).

2. Operation of the Freezer Barrel

In larger ice cream manufacturing plants, ice cream mix is initially frozen into a semi-frozen slurry in continuous freezers. These units are scraped-surface freezers designed to carefully control ice formation, air incorporation and fat destabilization. Small-scale operations may utilize a batch freezer, where a single batch of ice cream is frozen at a time. In small soft-serve ice cream and custard stands, batch freezers are sometimes used that involve

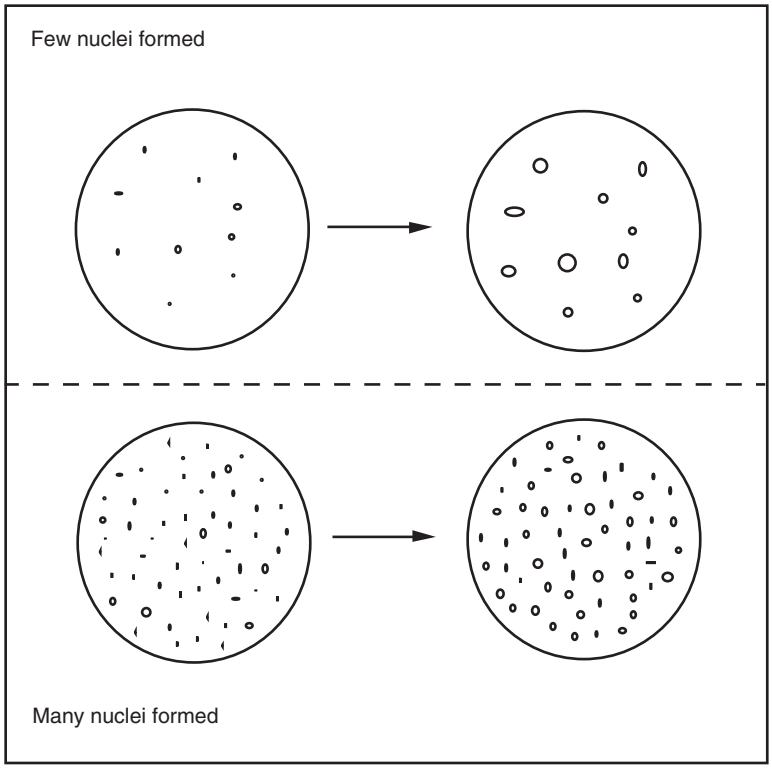

FIGURE 154.15 Schematic depiction of ice crystal size distributions obtained from batch (top) and continuous (bottom) ice cream freezers, based on nucleation rate (113).

discontinuous freezing, where ice cream is produced on an as-needed basis.

a. Continuous, scraped-surface freezer

A schematic of a commercial, continuous freezer is shown in Figure 154.16. Ice cream mix at a temperature of 0 to 4°C is pumped into the main barrel of the scraped-surface freezer under a pressure of 4–5 atmospheres (3) where it is frozen and aerated at the same time. The pressure inside the barrel is applied to reduce air phase volume and hence increase heat transfer. Refrigerant is introduced to the outside wall of the annular space between the two concentric cylinders, where vaporization of the refrigerant occurs to provide the refrigeration effect. Heat is removed from the ice cream as it freezes inside the barrel through the walls. Typically, either ammonia or Freon, kept at high pressure to maintain the liquid state, is pumped into the freezer where a lower pressure allows it to expand and vaporize to provide the refrigeration effect. Vaporized refrigerant is removed from the freezer and recompressed in a mechanical refrigeration system. Refrigerant pressure is controlled to maintain the desired temperature (about –30°C) and driving force for heat transfer removal. The rotating dasher, operating at 150 to 300 RPM within the freezer, holds scraper blades that contact the metal wall and scrape away the slush freezing on the inside of the barrel wall.

As the mix enters the freezer barrel, several things take place at the same time: water freezes in the mix, air is incorporated and the fat emulsion becomes partially coalesced. Control of these multiple factors is necessary to make ice cream with the desired physical and sensory characteristics. As discussed in the previous section, freezing of water occurs in the barrel and control of ice crystal formation is critical to product quality and shelf-life. Since the mix enters the freezer slightly above its freezing point, sensible heat must be removed to lower the temperature to the point where nucleation occurs. This occurs first at the barrel wall with vaporizing refrigerant separated from the ice cream mix by only a thin layer of metal. At the wall, the mix is quickly cooled below the freezing point and nucleation occurs. It has been estimated that the temperature just on the inside of the barrel wall is about −26°C, based on heat transfer resistances of the metal wall and perhaps a thin layer of ice present on the inside of the barrel wall (9). Since the initial freezing point of the mix is about −2°C, there is a significant driving force {(−2) − (−26) = 24°C} for nucleation at the wall and freezing occurs rapidly. Since the refrigerant temperature is maintained along the length of the freezer, the temperature at the barrel wall along the length of the freezer does not change significantly. That is, temperature just at the inside of the barrel wall is likely to be close to −26°C along the length of the entire freezer barrel.

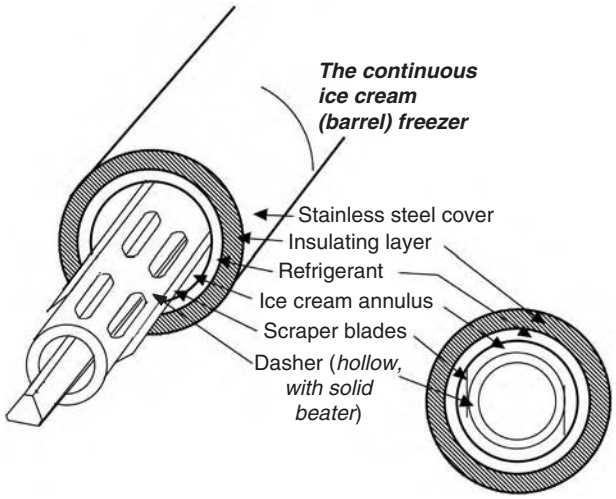

FIGURE 154.16 Schematic of the main components of the heat exchanger in a typical continuous ice cream freezer.

In the center of the barrel, however, the mix temperature is quite different from at the wall and a temperature gradient in the radial direction exists. Temperature in the center of the barrel may remain above the freezing point for some time as the mix works its way from the inlet to the outlet of the freezer. Eventually, as more and more ice scraped from the wall is mixed in with the warmer mix at the center of the barrel, the temperature in the center gradually decreases. It is at the center of the barrel where melting, growth and ripening occur, as discussed in the previous section. Thus, temperature at the center is essentially adiabatically controlled, based on the complex interactions (melting, growth, ripening, etc.) that take place.

It is thought that the decrease in temperature along the length of the barrel at the center of the freezer follows approximately the freezing point depression curve as more and more water is removed in the form of ice (9). Russell and co-workers (98) measured the temperature profile along the length of an experimental freezer and found that temperature decreased rapidly initially (near the inlet), decreased more slowly in the middle section and then increased slightly towards the outlet of the freezer, as seen in Figure 154.8 (98). At higher (500) dasher RPM, the temperature decreased to a greater extent than at lower (100) dasher RPM, which suggests that convective mixing from the colder environment near the wall is better with higher agitation rates. However, the mechanical energy input at the wall of the freezer with a higher agitation rate decreases the efficiency of nucleation and leads to ice cream with larger mean ice crystal size (98). There was slight increase in temperature of the ice cream just prior to the end of the barrel where the ammonia jacket ended and no longer provided a cooling effect. This indicates that the ice cream within the freezer barrel was slightly subcooled below the freezing point and the

release of latent heat at the end of the freezer caused the temperature to go up slightly. Once the ice cream was removed from the freezer, however, no temperature changes were observed when the ice cream was held adiabatically. This indicates that no additional crystallization took place once the ice cream was removed from the freezer and suggests that ice cream as it exits the freezer is at a point nearly on the freezing point depression curve for that temperature. Thus, estimates of the amount of water frozen into ice at any temperature that are based on freezing along the freezing point depression curve are essentially correct.

The importance of surface nucleation of ice at the barrel wall was shown by attempts to promote nucleation of ice through addition of ice-nucleating bacteria in a commercial continuous ice cream freezer (114). Ice-nucleating bacteria (*Pseudomonas syringae*) were added to an ice cream mix, and the mix was frozen under typical operating conditions in a pilot plant freezer. Ice crystal size of the ice cream exiting the freezer was identical for the control mix and the mix containing the ice nucleator. Since these nucleators promote nucleation in the bulk solution, this result suggests that the rate of ice nucleation at the wall of the freezer barrel was so high that the presence of ice nucleators had no effect on the total number of crystals formed in the freezer.

At the same time as freezing is taking place within the barrel, changes are also occurring to the lipid phase and air component. In commercial scraped-surface freezers, filtered compressed air is injected under pressure through a diffuser at the end of the barrel where the mix is input (3). The fine air bubbles formed in the diffuser are incorporated within the mix as the dasher rotates within the barrel. The air cells are broken down into smaller and smaller bubbles based on the shear forces within the freezer as the ice cream is formed (115). Dispersion of air into fine bubbles (about 20 μm in size after draw) requires that freezing occur at the same time to increase the shear forces within the freezer. Whipping air into ice cream mix without freezing results in lower amounts of overrun incorporated and larger air bubble sizes (115).

The fat emulsion also undergoes important changes in the barrel of the scraped-surface freezer (see Section II.B.4). Emulsifiers are added to the ice cream mix to decrease the stability of the emulsion droplets and allow partial destabilization during freezing. The shear forces within the freezer result in breakdown of the fine (< 3 μm) emulsion droplets and lead to partial coalescence of the fat globules. In this case, partial coalescence of the emulsion results in clusters of fat globules that are attracted to the air-serum interface. These partially-coalesced fat globules provide stabilization to prevent coalescence of the air cells so that many small air bubbles remain intact within the ice cream. It is this network of clusters of fat globules that provides meltdown resistance to the finished ice cream.

The refrigeration effect needed for ice cream freezing has been estimated by treating the distinct phases of the freezing process (116). The total energy required may be estimated as the sum of the energy required to cool the mix from the initial temperature to the freezing point, the energy associated with the latent heat needed to convert a certain amount of water into ice and the energy needed to cool the slush to the draw temperature (1). Although this approach gives only an approximation of the true refrigerant requirements for freezing ice cream, based on the simplifying assumptions, the values obtained give a starting point for calculating refrigeration load in an ice cream facility.

b. Batch freezer

Operation of a batch freezer proceeds in much the same manner as for a continuous freezer with several notable differences. That is, similar events take place in batch freezing as just described for continuous freezing, with the ice cream remaining in one place rather than moving along the length of the freezer barrel as in a continuous freezer. One notable difference in batch freezing is that there is typically a lower ratio of heat transfer surface to volume of ice cream. Thus, heat transfer is generally not as efficient in batch freezers compared to continuous freezers. Another typical difference between continuous and batch freezing is the nature of the refrigerant used. In commercial batch freezers, as found for soft-serve or custard-type freezers, vaporizing Freon may be used to provide the refrigeration effect. In this case, the temperature differential at the wall of the freezing cylinder may be as low as those found in continuous freezers. Hence, very small ice crystals are formed at the wall, scraped off by the mixing blades and then dispersed into the mix at the center of the cylinder. The temperature profiles at the wall and center of the freezing cylinder are very similar to those found in continuous freezers, except the temperature changes with time during freezing. When the temperature of the bulk of the ice cream reaches the desired draw temperature, or when the consistency of the ice cream within the barrel reaches some preset or desired value, the ice cream is drawn from the freezer. Typically, draw temperatures from batch freezers are similar to those in continuous freezers. However, due to the quantity of mix to freeze, the residence time required to achieve this draw temperature is much longer than in the continuous freezer, typically 15–30 minutes compared to approximately 1 to 2 min, and the resulting slower rates of freezing result in more recrystallization events in the barrel, larger crystal sizes, and slightly coarser texture when first frozen.

Another significant difference between batch and continuous freezing involves the nature of air incorporation. In batch freezers, the mix is allowed to whip at atmospheric pressure. Hence, whipping properties of the mix are very important and overrun is more variable, being controlled simply by the headspace remaining after the mix charge is put into the barrel. In the continuous freezer, air is injected through controlled valves, so whipping properties of the mix are perhaps less important and overrun control is

exact. Air distribution occurs under pressure in the continuous freezer, and it is the rapid expansion of the air bubbles at draw that establishes the air bubble interface.

Soft-serve ice cream freezers contain a swept-surface barrel freezer similar to the batch freezer, but they also contain a mix hopper that permits entry of a charge of mix each time a portion of the semi-frozen ice cream is removed. Thus, the complete barrel is only emptied on shut-down. The air handling systems of some large installation soft-serve ice cream freezers are a hybrid between batch and continuous freezers, in that the air inlet and barrel itself are pressurized to allow more exact control of overrun.

3. Overrun Calculations

Overrun is the industrial calculation of the air added to frozen dessert products, and it is calculated as the percentage increase in volume that occurred as a result of the air addition. The following examples will show calculations of overrun by volume and by weight, without and with the addition of particulates, and will also show calculations of target package weights. When packages are being filled on a processing line, package weights should be closely monitored. Deviations can be attributed to variations in the fill level of the package (packaging machine adjustment), variations in the ratio of ice cream to particulate addition (ingredient feeder or ripple pump adjustment), or variations in the overrun of the ice cream (freezer barrel adjustment).

Determining manufacturing overrun by volume, no particulates:
The equation for overrun determination of a production run, based on the definition of overrun as above, is as follows:

$$\% \text{ Overrun} = \frac{\text{Vol. of ice cream produced} - \text{Vol. of mix used}}{\text{Vol. of mix used}} \times 100\% \qquad (154.9)$$

Example. 500 L mix gives 980 L ice cream, using Equation 154.9:

$$\frac{980 - 500}{500} \times 100\% = 96\% \text{ Overrun}$$

Any flavors added, such as chocolate syrup in the next example, that become homogeneous with the mix can incorporate air and are thus accounted for in the following way.

Example. 80 L mix plus 10 L chocolate syrup gives 170 L chocolate ice cream, using Equation 154.9:

$$\frac{170 - (80 + 10)}{(80 + 10)} \times 100\% = 88.8\% \text{ Overrun}$$

Determining manufacturing overrun by volume, with particulates:
Example. 40 L mix plus 28 L pecans gives 110 L butter pecan ice cream, using Equation 154.9:
110 − 28 = 82 L actual ice cream surrounding the nuts.

$$\% \text{ Overrun} = \frac{\text{Vol. of ice cream} - \text{Vol. of mix used}}{\text{Vol. of mix used}}$$

$$= \frac{82 - 40}{40} \times 100\% = 105\%$$

The pecans do not incorporate air. This type of a determination might be useful if, for example, defects in a given mix were known to show up at >115% overrun. Otherwise, in a calculation of total output, a calculation similar to the one above, with no particulates, may be more useful.
Determining package overrun by weight, no particulates :

$$\% \text{ Overrun} = \frac{\text{Wt. of mix} - \text{Wt. of same vol. of ice cream}}{\text{Wt. of same vol. of ice cream}} \times 100\% \qquad (154.10)$$

Must know density of mix (wt. of 1 L), usually 1.09 − 1.1 kg /L (*see example below*).

Example. If 1 L of ice cream weighs 560 g net weight (exclusive of package), assuming a density of 1.09 kg/L, using Equation 154.10:

$$\% \text{ Overrun} = \frac{1090 - 560}{560} \times 100\%$$

$$= 94.6\% \text{ Overrun}$$

Determining package overrun by weight, if the ice cream has particulates in it, gives very little information because both the ratio of ice cream to particulates and the air content of the ice cream affect the final weight.

Determining mix density:
The density of mix can be calculated as follows:

$$(\text{Wt. per litre of water}) \Big/ \left[\frac{\% \text{ fat}}{100} \times 1.07527 + \left(\frac{\% \text{ total solids}}{100} - \frac{\% \text{ Fat}}{100} \right) \times 0.6329 + \frac{\% \text{ Water}}{100} \right] = \text{Wt./L mix} \qquad (154.11)$$

Example. Calculate the weight per litre of mix containing 12% fat, 11% msnf, 10% sugar, 5% corn syrup solids,

0.30% stabilizer, and 38.3% total solids, using Equation 154.11:

$$\frac{1.0 \text{ kg/L}}{0.12 \times 1.07527 + (0.383 - 0.12) \times 0.6329 + 0.617} = 1.0959 \text{ kg/L of mix}$$

Determining target package weights, no particulates:

Use the following formula:

$$\text{Weight of given vol. of ice cream} = \frac{\text{Wt. of same vol. of mix}}{\frac{(\text{Desired overrun} + 1)}{100}} \quad (154.12)$$

Example. Desired 90% overrun, mix density 1.09 kg/L, using Equation 154.12

$$\text{net wt. of 1 L} = \frac{1.09 \text{ kg}}{\frac{(90 + 1)}{100}} = 573.7 \text{ g}$$

Also, the density of ice cream can be calculated in a similar manner from Equation 154.12,

$$\text{Density of ice cream} = \frac{\text{density of mix}}{\frac{(\text{Overrun} + 1)}{100}}$$

Example: Density of mix 1100 g/L,

$$@100\% \text{ Overrun, density of ice cream} = \frac{1100 \text{ g/L}}{\frac{(100 + 1)}{100}} = 550 \text{ g/L}$$

Figuring target package weights, with particulates:
Example. Ice cream with candy inclusion; density of mix 1.1 kg/L; overrun in ice cream 100%; density of candy 0.748 kg/L*; candy added at 9% by weight, (i.e. 9 kg to 100 kg final product).

In 100 kg final product, we have:

$$9 \text{ kg of candy } \left(\text{or } \frac{9 \text{ kg}}{0.748 \text{ kg/L}} = 12.0 \text{ L}\right)$$

$$91 \text{ kg of ice cream } \left(\text{or } \frac{91 \text{ kg}}{1.1 \text{ kg/L}} = 165.4 \text{ L}\right)$$

$$\left(\frac{100}{100} + 1\right)$$

So, 100 kg gives a yield of 12 + 165.4 = 177.4 L

$$1 \text{ L weighs } \frac{100 \text{ kg}}{177.4 \text{ L}} = 564 \text{ grams}$$

In many cases, ice creams of different flavors are manufactured to provide the same weight per package for the consumer. As a result, overrun of the actual ice cream in the product varies from flavor to flavor, depending on the density and addition ratio of the particulate ingredients.

4. Fat Destabilization and Foam Stabilization

The texture of ice cream is perhaps one of its most important quality attributes. It is the sensory manifestation of structure; thus, establishment of optimal ice cream structure is critical to maximal textural quality. While the dynamic freezing process is generally associated with the formation of the ice phase, aeration and agitation during this process are also responsible for the formation of colloidal aspects of structure, viz., the formation of air bubbles and the partial coalescence of the fat into a major structural element (Figure 154.17). The colloidal structure of ice cream begins with the mix as a simple emulsion, with a discrete phase of partially crystalline fat globules surrounded by an interfacial layer comprised of proteins and surfactants (Figure 154.18) The continuous, serum phase consists of the unadsorbed casein micelles in suspension in a solution of sugars, unadsorbed whey proteins, salts, and high molecular weight polysaccharides. During the "freezing" stage of manufacture, the mix emulsion is foamed, creating a dispersed phase of air bubbles, and is frozen, forming another dispersed phase of ice crystals (Figure 154.19). Air bubbles and ice crystals are usually in the range of 20 to 50 μm and are surrounded by a temperature-dependent unfrozen phase (60). In addition, the partially-crystalline fat phase in the mix at refrigerated temperatures undergoes partial coalescence during the concomitant whipping and freezing process, resulting in a network of agglomerated fat, which partially surrounds the air bubbles and gives rise to a solid-like structure (Figure 154.18) (12,40,43,44,117).

The development of structure and texture in ice cream is sequential, basically following the manufacturing steps. To properly describe the role of fat in the structure, it is necessary to begin with the formation of the emulsion and the role of the ingredients present at the time of homogenization, with particular reference to the fat, proteins, and emulsifiers. After preheating or pasteurization, the mix is at a temperature sufficient to have melted all the fat present, and the fat passes through one or two homogenizing valves. Immediately following homogenization, the newly

* Note: density of particulate pieces containing void spaces must be determined by first crushing the material to eliminate void spaces, given that ice cream will fill in the voids after incorporation.

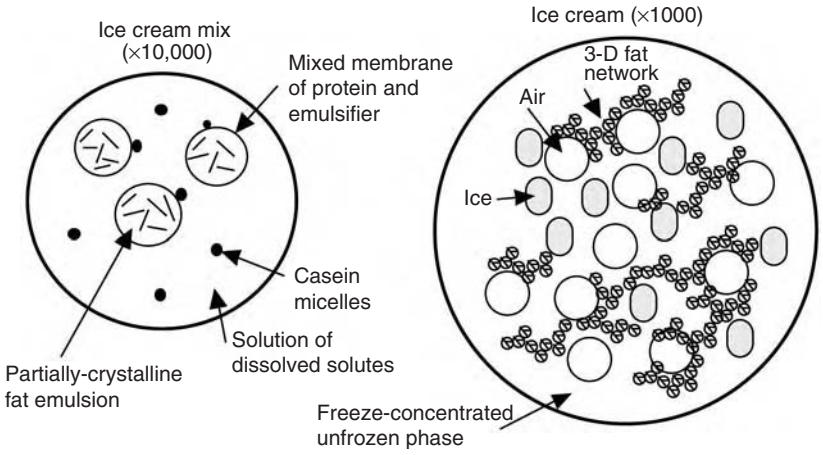

FIGURE 154.17 A schematic representation of the structure of ice cream mix and of ice cream.

formed fat globule is practically devoid of any membranous material and readily adsorbs amphiphilic molecules from solution (93). The immediate environment supplies the surfactant molecules, which include caseins, undenatured whey proteins, phospholipids, lipoprotein molecules, components of the original milkfat globule membrane, and any added chemical surfactants (6,93). These all compete for space at the fat surface. By controlling the adsorbing material present at the time of homogenization, it may be possible to predetermine the adsorbing substances and thus create a membrane with more favorable functional attributes, utilizing natural proteins rather than relying on the chemical surfactants (47). The membrane formed during homogenization continues to develop during the aging step and rearrangement occurs until the lowest possible energy state is reached (95). The transit time through a homogenization valve is in the order of 10^{-5} to 10^{-6} seconds (91). Protein adsorption or unfolding at the interface may take minutes or even hours to be complete (21). It is clear, therefore, that the immediate membrane formed upon homogenization is a function of the microenvironment at the time of its creation, and that the recombined membrane of the fat globule in the aged mix is not fully developed until well into the aging process (12).

Emulsifiers are not needed in an ice cream mix to stabilize the fat emulsion, due to an excess of protein and other amphiphilic molecules in solution (87,88). If a mix is homogenized without any emulsifier, both the whey proteins and the caseins will form this new fat globule membrane, with the caseins contributing much more to the bulk of the adsorbed protein. However, if added emulsifiers are present, they have the ability to lower the interfacial tension between the fat and the water phases lower than the proteins. Thus they become preferentially adsorbed to the surface of the fat (12,32,95). As the interfacial tension is lowered and proteins are eliminated from the surface of the fat, the surface excess (quantity of adsorbed material, mg/m^2) is reduced (42) and the actual membrane becomes weaker to subsequent destabilization. This is due to the fact that the protein molecules, and particularly the caseins, are considerably larger than the emulsifier molecules, such that a membrane made up entirely of emulsifier is very thin (Figure 154.18). This results lower surface excess, although the emulsion is thermodynamically favored due to the lowering of the interfacial tension and net free energy of the system.

Crystallization of fat also occurs during aging, creating a highly intricate structure of needle-like crystals within the globule (Figure 154.18). The high melting point triglycerides crystallize first, and continue to be surrounded by liquid oil of the lower melting point triglycerides. It has been reported that fat crystallization of emulsified milkfat at refrigerated temperature reaches equilibrium within 1.5 hours (6). A partially crystalline fat droplet is necessary for clumping to occur. van Boekel and Walstra (118) found emulsion stability of a paraffin oil in water emulsion to be reduced by six orders of magnitude when crystals were present in the dispersed phase. This has been attributed to the protrusion of crystals into the aqueous phase causing a surface distortion of the globule (118). The crystal protrusions can then pierce the film between two globules upon close approach. As the crystals are preferentially wetted by the lipid phase, clumping is thus inevitable. This phenomenon may account for partial clumping of globules under a shear force. The clusters thus formed actually hold the ice cream serum in their interstices resulting in the observed dryness. These fat globule chains may also envelope the air cells thus improving overrun (36), however, fat crystals are also known to impair overrun development in whipped cream (21).

The next stage of structure development occurs during the concomitant whipping and freezing step. Air is incorporated either through a lengthy whipping process (batch freezers), drawn into the mix by vacuum (older continuous freezers) or injected under pressure (modern continuous freezers) (1). This process causes the emulsion to undergo partial coalescence or fat destabilization, during which clumps and clusters of the fat globules form and build an

E-F, ice cream with no emulsifier and with added Polysorbate 80, respectively, as viewed by thin section transmission electron microscopy with freeze substitution and low temperature embedding; a=air bubble, f=fat globule, c=casein micelle, fc=fat cluster, bar= 1 μm. See Ref. 121 for methodology. G-H, melted ice cream with no emulsifier and with added Polysorbate 80, respectively, as viewed by thin section transmission electron microscopy; f=fat globule, c=casein micelle, fn=coalesced fat network, bar= 1 μm in G and 5 μm in H. See Ref. 36 for methodology.

internal fat structure or network into the frozen product (1,6) in a very analogous manner to the whipping of heavy cream (13). During the initial stages of whipping of cream, air bubbles have been shown to be stabilized primarily by beta casein and whey proteins with little involvement of fat (13). Adsorption of fat to air bubbles occurred when the fat globule membrane coalesced with the air water interface. Only rarely did fat spread at the air water interface. The final cream is stabilized by a cross-linking of fat globules surrounding each air cell to adjacent air cells, thus building an infrastructure in the foam (119). In skim milk foams, the initial air water interface is also formed by the serum proteins and soluble β-casein, with little involvement of micellar casein. Micelles become attached as a discontinuous layer, but are not deformed or spread (21). It can be postulated that air cell incorporation into ice cream mix follows a similar mechanism. Cross-linking of fat globules from one air cell to the next, thus forming an infrastructure, is less likely due to the reduction in dispersed phase volume from the heavy cream system to the ice cream mix system. However, it must also be borne in mind that the air bubbles, fat globules, and aqueous phase are being freeze-concentrated at the same time.

The fat globule clusters formed during the process of partial coalescence are responsible for surrounding and stabilizing the air cells and creating a semi-continuous network or matrix of fat throughout the product, resulting in the beneficial properties of dryness upon extrusion during the manufacturing stages (aids in packaging and novelty molding, for example), a smooth-eating texture in the frozen dessert, and resistance to meltdown or good stand-up properties (necessary for soft serve operations) (6,120). Fat destabilization is enhanced by the emulsifiers in common use (12,88). When the emulsion is subjected to the tremendous shear forces in the barrel freezer, the thin membrane created by the addition of surfactant is not sufficient to prevent the fat globules from colliding and coalescing, thus setting up the internal fat matrix (36). If an ice cream mix is subjected to excessive shearing action or contains too much emulsifier, the formation of objectionable butter particles can occur as the emulsion is churned beyond the optimum level. Polysorbate 80, having a small molecular weight and producing the lowest interfacial tension compared to mono- and diglycerides displaces more protein, resulting in a very thin membrane, and thus produces the maximum amount of fat destabilization (36).

The extent of fat destabilization can be quantified in several ways. It is sometimes presented as a % change in turbidity as measured by a spectrophotometer on diluted samples of mix and ice cream (12). It can also be determined based on a solvent extraction technique using a mild solvent, since coalesced fat becomes increasingly susceptible to extraction, whereas emulsified fat does not (95). As well, it can be presented as a change in size distribution of fat globules as measured by laser light scattering techniques (e.g., %>3 μm, since 0% of the mix emulsion was greater than 3μm) (42).

Gelin and co-workers (37) demonstrated through light scattering measurements of fat globule size distribution

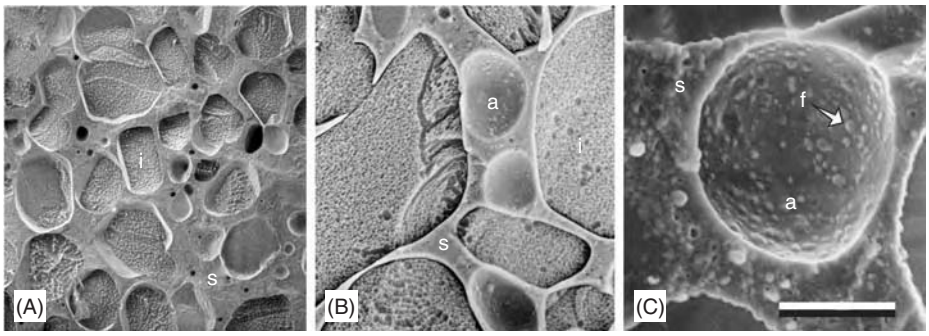

FIGURE 154.19 Low temperature scanning electron micrographs of the overall structure of ice cream. A) General overview of spatial distribution of ice crystals (i) within the unfrozen phase (s). Bar (in C) = 100 μm. B) Higher magnification showing air bubbles (a) and ice crystals (i) embedded into the unfrozen serum (s) as discrete phases. Bar (in C) = 40 μm. and aggregation that the freezing step is responsible for considerable fat aggregation. This aggregation is initially reversible through dissociation with SDS, but not after fat crystal sintering has occurred. They have also shown the changes occurring to the protein distribution between the aqueous and adsorbed states. It was obvious from their study that the homogenization step accounted for a large amount of adsorbed protein, and that casein was preferentially adsorbed over the whey proteins. The aging and freezing-hardening-thawing steps each accounted for subsequent protein desorption, again mostly of the caseins. The sequential process of partial coalescence during ice cream freezing has also been examined (12). The incorporation of air alone, or the shearing action alone, independent of freezing, are not sufficient to cause the same degree of fat destabilization as when ice crystallization occurs concomitantly. The freezing process causes an increase in concentration of the mix components, such as proteins and mineral salts, in the unfrozen water phase. It is believed that the ice crystals contribute to the shearing action on the fat globules, due to their physical shape, and that the concentration of components also leads to enhanced destabilization. However, to create the desired extent of fat destabilization, whipping and freezing must occur simultaneously (87).

Goff and co-workers (121) examined air interfaces in ice cream and fat:air interactions using transmission electron microscopy with freeze-substitution. The structures created by increasing levels of fat destabilization in ice cream (achieved through increased emulsifier concentration in the mix in both batch and continuous freezing) were observed as an increasing concentration of discrete fat globules at the air interface (Figure 154.18), and increasing coalescence and clustering of fat globules, both at the air interface and within the serum phase (Figure 154.18). Air interfaces at the highest levels of fat destabilization were not completely covered by fat globules. It has been suggested that the air interface in ice cream may be covered by a thin layer of non-globular liquid fat (6). However, there was no evidence of a surface layer of free fat in the work of Goff and co-workers (121). Further, air interfaces in a fat-free ice cream formulation showed a very similar, continuous membrane as those from a formulation containing fat. This further suggests that the air bubble membrane itself is comprised of protein, with discrete and partially-coalesced fat globules subsequently adsorbed.

C. Flavors and Flavor Addition

Ice cream and frozen dessert manufacturers offer a wide variety of flavors and particulate ingredients to consumers, which are often the basis upon which consumers make selection choices. Some of the major flavors and flavor categories, based on consumption in North America, are shown in Table 154.10. Ingredients are added to ice cream in three ways during the manufacturing process: in the mix tank prior to freezing (for liquid flavors, colors, fruit purees, flavored syrup bases, or anything else that will become homogeneous within the ice cream); through a variegating pump (for ribbons, swirls, ripples, revels, etc.); or through an ingredient feeder (for

TABLE 154.10
Ice Cream Consumption by Flavor, 2002 Annual, Canada and the U.S.

Flavor	Percentage of Production Volume
Vanilla	28.4
Nut Flavors	10.4
Chocolate	8.0
Fruit flavors	7.6
Neapolitan	7.4
Bakery Flavors	5.8

Data from the International Dairy Foods Association.

particulates — fruits, nuts, candy pieces, marshmallows, cookies and bakery pieces, etc.). In the case of the latter two, this equipment is added in series after the continuous freezer, when the ice cream is already semi-frozen. Often, these may be placed in sequence for complex flavors involving multiple components, e.g., a variegating pump and an ingredient feeder or two ingredient feeders. Ingredients added into the semi-frozen ice cream should be as cold as possible, either refrigerated or stored at subzero temperatures, so as not to cause any melting and recrystallization of the ice crystals at this point in the process.

Vanilla. Vanilla is the most popular flavor for ice cream in North America. Vanilla ice cream is used to make milkshakes, sundaes, floats and other types of desserts at the retail level, and is often an a accompaniment to other desserts, such as cakes or pies. Vanilla is also used in many other flavors as a flavor enhancer, e.g., chocolate flavor is improved by the presence of a small amount of vanilla.

Vanilla comes from a plant belonging to the orchid family called *Vanilla planifolia*, grown typically in Mexico, the islands off the east coast of Africa (particularly Madagascar), Tahiti, South America (Guadeloupe, Dominica, Martinique), and Indonesia (Java). Bourbon beans from Madagascar are often considered the finest and account for over 75% of world production. From each blossom of the vine that is successfully fertilized comes a pod that reaches 15–25 cm in length, picked at 6–9 months. It requires temperatures of 24–29°C day and night throughout the season, as well as frequent rains with a dry season near the end for development of flavor. Pods are immersed in hot water to stop biological activity of the seed (which also serves to increase enzyme activity), then fermented for 3–6 months by repeated wrapping in straw to "sweat" and then uncovering to sun dry. 5–6 kg green pods produce 1 kg cured pods. Beans are then aged 1–2 years. Enzymatic reactions during aging produce many compounds, of which vanillin is the principal flavor compound. However, there is no free vanillin in the beans when they are harvested. It develops gradually during the curing period from glucosides, which break down during the fermentation and "sweating" of the beans. Extraction takes place as the beans are chopped (not ground) and placed in a stainless steel percolator. Cold alcohol (no heat involved) and water are pumped over and through the beans until all flavoring matter is extracted. Vacuum distillation takes place for a large part of the solvent. The desired concentration is specified as twofold, fourfold, etc. Each multiple must be derived from an original 10g beans/100 mL of alcoholic extract.

Vanillin can be and is produced synthetically to a large extent. Vanillin is contained in many types of woods and thus is a by-product of the pulp industry. Compound flavors are produced from combinations of vanilla extract and vanillin. Vanillin may be added at one ounce to the fold for compound flavors. The number of folds plus number oz. of vanillin equals the total strength, e.g., 2 fold + 2 oz. = 4 fold vanilla-vanillin. However, more than 1 oz to the fold is deemed imitation. Usage level in the mix is a function of purity and concentration. Typically a single fold natural vanilla is recommended at 3–6 mL/L mix, a two fold vanilla-vanillin at 2–3 mL/L mix. Some vanillin may improve flavor over pure vanilla extract, so often natural and artificial compound flavors are more desirable than pure natural flavors; however, too much vanillin results in harsh flavors.

Chocolate and Cocoa. The cacao bean is the fruit of the tree *Theobroma cacao* ("Cacao, food of the gods"), which grows in tropical regions such as Mexico, Central America, South America, West Indies, and the African West Coast. The beans are embedded in pods on the tree, 20–30 beans per pod. When ripe, the pods are cut from the trees, and after drying, the beans are removed from the pods and allowed to ferment for 10 days (microbiological and enzymatic fermentation). Beans then are washed, dried, sorted, graded and shipped for processing. Figure 154.20 shows a flow diagram for the processing of chocolate and manufacture of cocoa. At the processing plant, beans are roasted, the seed coat is removed and the interior of the bean, called the nib, is ground. Friction melts the fat and the nibs flow from the grinding as a liquid, known as chocolate liquor. The composition of chocolate liquor is about 55% fat, 17% carbohydrate, 11% protein, 6% tannins and many other compounds. After the cocoa butter is pressed from the chocolate liquor, the remaining press cake is now the material for cocoa manufacture. The amount of fat remaining determines the cocoa grade: medium fat cocoa, 20–24% fat; low fat 10–12% fat. There are many types of chocolate that differ in the amounts of chocolate liquor, cocoa butter, sugar, milk, other ingredients, and vanilla. Imitation chocolate is made by replacing some or all of the cocoa fat with other vegetable fats. For ice cream, this provides improved coating properties and enhanced resistance to melting. White chocolate is made with cocoa butter, milk msnf, sugar, but no cocoa or chocolate liquor.

There are two types of cocoa available, namely, American (domestic) and Dutch (alkalized). The latter is treated with an alkali (sodium hydroxide, etc.) to increase solubility, darken the color, and modify the flavor. The Dutch type is usually preferred in ice cream because it gives a darker, less red color but the choice depends upon consumer preference, desired color (Blackshire cocoa may also be used to darken color), strength of flavor, and fat content of the ice cream (19). For chocolate ice cream manufacture, cocoa is more concentrated for flavoring than chocolate liquor (55% fat) because cocoa butter has relatively low flavor. Hence, low fat cocoa powders are usually utilized at 2–3% (w/w) in the mix. Cocoa is usually added with other dry ingredients at the blending

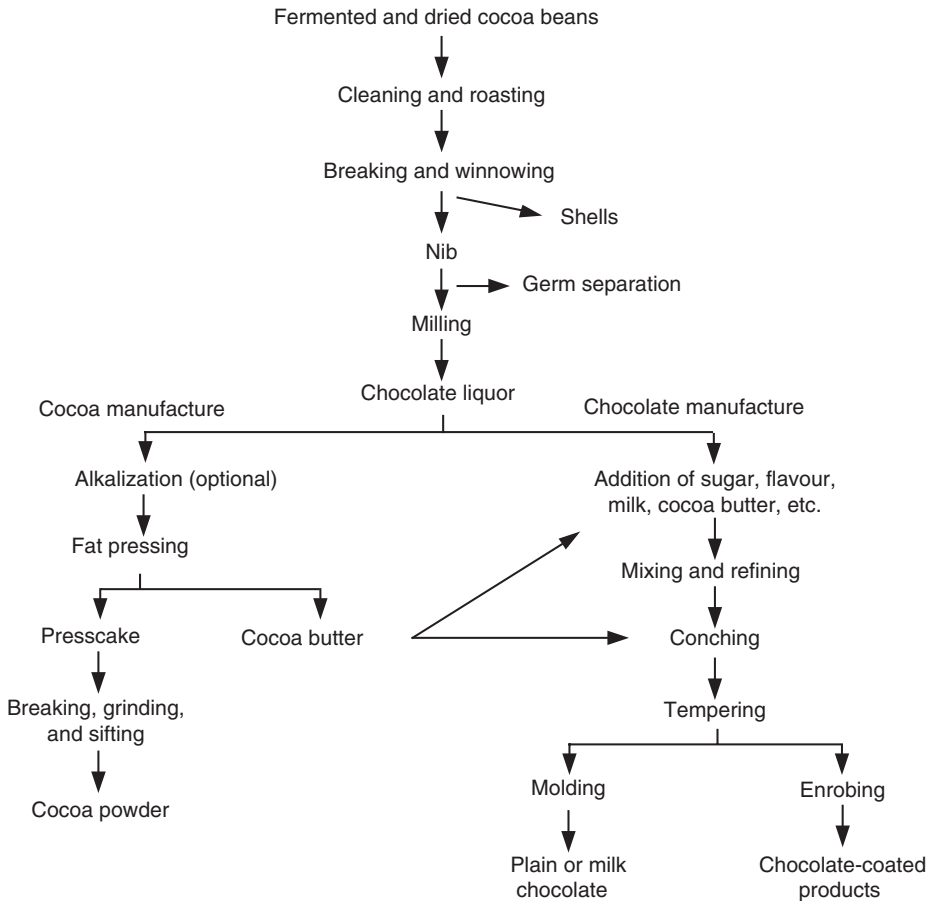

FIGURE 154.20 The processing of cocoa into ingredients typically used in chocolate ice cream.

stage, and pasteurized and homogenized with the rest of the mix. Blends of cocoa (2–3%) and chocolate liquor (2%) or chocolate liquor alone (5%) can also be used to produce a chocolate ice cream with enhanced smoothness and with the typical full-fat flavor of chocolate products. Chocolate mixes have a tendency to become excessively viscous, so stabilizer and corn syrup solids content and homogenizing pressure need to be slightly lowered to account for the enhanced viscosity. Sucrose content is generally increased by 2–4% (w/w) in the mix to offset the slight bitterness from the cocoa.

One frequent defect with chocolate ice cream, particularly soft-serve, is chocolate specking. Cocoa becomes entrapped in partially coalesced fat, which then darkens. Alleviation of excessive fat destabilization usually alleviates this problem.

Fruit Ice Cream. Fruit flavors are quite popular in ice cream. Fruit for ice cream can be utilized as fresh fruit, raw frozen fruit, "open kettle" processed fruit, or aseptically processed fruit cooked in swept-surface heat exchangers. Fruit additions should use sufficient fruit (15–25% w/w) of choice quality for best fruit ice cream. The more highly flavored the fruit, the less required in ice cream. Fruit should be kept in large pieces in the ice cream where possible, and that is usually a function of the incorporation method. Ingredient feeders are used with continuous freezers to add the fruit pieces or sugared fruit preparations, while a portion or all of the fruit juice, as appropriate when straining of fruit is employed, is added directly to the mix. In the batch freezer, fruit juice is added with the mix at the start of the batch, and the fruit pieces are added when the mix has been partially frozen or at draw.

Some small-scale ice cream processors may find it desirable, for a variety of reasons, to use fresh fruit. Such use involves all of the preparation steps of washing, sorting, peeling, destoning, etc. If fresh fruit is being added to ice cream, it should be prepared with sugar in such a way as to allow the sugar to penetrate the fruit. Otherwise, it will freeze to form solid lumps in the ice cream. Sugar draws out juice by osmotic dehydration. If fruits are to be pureed, this will not be necessary, although sugar does help to bring out flavor. With strawberries it is advisable to slice in half and treat with sugar at the rate of at least 20–30% sugar, allowing the berries to stand in a cool temperature until sufficient sugar has been absorbed. Sugared fruit can

either be strained to separate juice from pulp, or can be cold-stabilized with the use of pectin or starch prior to adding to the ice cream. In this way, the juice and pulp can be added at the same time through the ingredient feeder.

Frozen fruit for ice cream is usually frozen with the addition of a suitable content of sugar, usually 25–30%. Frozen packs must be thawed before use. Forced thawing with heat will cause rupture of the fruit with resulting poor appearance. Where discrete fruit pieces are not desired in the ice cream, forced thawing may be used. Thawing usually results in juice separation, unless the product has been cold-stabilized with starch or pectin, and if so, this juice should be strained and added to the mix before freezing. Polysorbate 80 (see Section I.B.5) is sometimes added to the mix prior to the freezing of fruit ice cream, particularly if the fruit is "wet." This aids in producing a dry ice cream to help incorporate the fruit addition. Depending on the strength of flavor of the fruit preparation and the concentration utilized, it may be necessary to augment fruit flavors with the addition of natural or artificial flavors. Also, sometimes the addition of citric acid to the mix is desirable.

Fruit can be processed by cooking in a syrup with added sugar to a total sugar content (°Brix) of 50–60%, and is often stabilized with pectin or starch. This processed fruit moves the problems of procurement, variability, and quality from the ice cream manufacturer to the fruit manufacturer/supplier. The fruit manufacturer can source fruit from around the world and blend it from a variety of sources to achieve year-round supply and consistency. Fruit preparation ensures removal of debris, stones, pits, skins, etc., and cooking ensures microbial safety. By cooking in sugar, the fruit will not freeze as a solid in the ice cream, which provides a more pleasant texture. For the ice cream manufacturer, this product is available in a ready-to-use form, with no need for thawing, straining, etc., so it involves no product loss. Fruit processed by open kettle methods, however, often provides a cooked flavor that detracts from the natural fruit flavor desired by the ice cream manufacturer and consumer. The processing of such fruit aseptically in scraped surface heat exchangers provides the opportunity to offer an improved flavor and color, a more consistent product, no preservatives, and a longer shelf-life.

Variagates. Variagates are injected through a positive pump connected to a small-diameter nozzle or nozzles within the stream of ice cream from the continuous freezer. They are available as a prepared base, e.g., chocolate, butterscotch, marshmallow, strawberry, cheese cake concentrate, etc., and are usually incorporated at 10% (w/w) of ice cream. Almost any flavor can be variegated into ice cream in a variety of contrasting ice cream flavors and colors. A good variegating syrup should not settle out or run into pools in the ice cream. It must not become icy during storage.

Nuts in Ice Cream. Nut-flavored ice creams are also very popular, although concern for consumers with nut allergies has meant strict segregation of nuts from non-nut products and declaration of possible cross-contamination with nuts, and has limited the use of nut flavors in recent years. Nuts should be used in generous amounts, usually around 10% (w/w), and kept in large pieces. Commonly used are walnuts, pecans, filberts, almonds, and pistachios. Brazil nuts and cashews have been tried without much success. Pecans are usually roasted with butter and incorporated into a butter pecan ice cream. Pistachios may be treated in somewhat the same manner as pecans, or may be used in the characteristic pistachio ice cream, which is usually colored green and is flavored with bitter almond. Raw walnuts may be preferred to roasted for flavor, but some form of heat (oven) treatment should be given to walnuts to eliminate surface microbial contamination. Walnuts are often used with a maple flavoring. Almonds are commonly dry roasted to a point just before burning, and are added to the mix flavored with vanilla or almond flavoring. Filberts are roasted dry to a light brown color. The skins are removed (blanched), and the nuts reduced in size by chopping. They are added to a mix mildly flavored with vanilla.

Due to potential contamination with extraneous (e.g., shells) and foreign matter, nuts require extensive cleaning and screening. Nuts must be processed in a clean sanitary premise following good manufacturing practices. Nuts should be either oil roasted or heat treated to reduce any bacteria. Microbiological testing for Standard plate count, coliforms, *E. coli*, yeasts, molds, and *Salmonella sp.* is carried out randomly but routinely, and testing for aflatoxin (mold toxin from *Aspergillus flavus*) is performed on peanuts. Nutmeats should be stored either at subzero temperatures in a freezer, or at least at 2–4°C to maintain freshness and reduce problems with lipid oxidation in the nuts.

Color in Ice Cream. Ice cream should have a delicate, attractive color that is closely associated with the type of flavoring material that has been added. In some instances, ice cream mix may be slightly colored to give it the shade of the natural product, e.g., 15% (w/w) fruit produces only a slight effect on color and may need to be augmented. Some fruit solid packs may already be colored by the fruit manufacturer, for convenience to the ice cream manufacturer. Most colors are of synthetic origin and can be purchased in liquid or dry form. Color solutions can easily become contaminated, and therefore must be fresh.

D. Packaging and Static Freezing

Once the ice cream exits the freezer as a partially-frozen slush, particulate flavors can be added, and then it is pumped into a package, sealed, and hardened. When the semi-solid ice cream exits the continuous freezer, it should have the correct stiffness, or ability to flow, for its

intended use. For ice cream intended for direct packaging, about half of the water is frozen to ice when the ice cream exits the freezer, and it should still be sufficiently fluid to flow and completely fill a package without leaving void spaces. If the draw temperature of the freezer is too low, or the mix is otherwise frozen too much, the ice cream exiting the freezer will be too stiff for proper packaging. In some cases, as for frozen novelties, this high degree of stiffness may be desired so that the ice cream maintains its shape prior to hardening.

Packages of ice cream are sent to a hardening room or tunnel for further freezing. The aim of hardening is to remove heat so that the ice cream cools quickly to temperatures below –18°C. The time required for hardening primarily depends on the size of the package entering the hardening facility, and the nature of the refrigeration process within the hardening facility. Very small containers, as in 0.5L or smaller cups, may take as little as 30 minutes to harden properly; whereas larger bulk-sized containers may take 24 hours. If cartons of ice cream are collected on a pallet prior to hardening, the time for the center-most container to reach hardening temperatures may be substantially longer than 24 hours. Most commercial facilities allow between 12 and 24 hours in the hardening facility to ensure proper freezing.

As the ice cream cools, additional ice freezes in accordance with the freezing point depression curve. It is important to note that, typically, no new ice crystals (nuclei) are formed during hardening, since the thermal driving forces are generally too small to promote nuclei formation. Thus, the increase in ice content (ice phase volume) comes about through a general increase in the size of all existing ice crystals. Clearly, the number of ice crystals formed in the initial freezing step will have a big impact on the ice crystal size of the final hardened ice cream. Typically, ice crystals increase in size about 10 to 15 μm during hardening. That is, the mean ice crystal size after drawing from the continuous freezer may be about 25 to 30 μm, but the mean size after hardening is more likely to be between 40 and 45 μm.

The speed of cooling has a significant impact on the ice crystal size, and this may vary through the container. The ice cream near the outside of the package cools the fastest. The ice cream near the center is insulated by the rest of the ice cream and cools much more slowly. For example, Donhowe (122) followed the temperature decrease at different locations in a half-liter cylindrical container of ice cream during hardening, as shown in Figure 154.21 (10). The surface cooled most rapidly, with the center taking nearly 10 minutes to even start cooling. During that 10 minute delay, the ice crystals at the center of the package were undergoing recrystallization at a rapid rate due to the high temperature. The result is that the ice crystals in the ice cream at the center of the container had substantially larger mean size than the ice crystals in the product near the surface, as seen in Figure 154.22 (10). This effect becomes even more dramatic when larger-sized containers are hardened. For example, the ice cream at the center of a pallet of containers may remain at elevated temperatures for substantially longer than the 10 minutes in this example, and the mean size can get considerably larger. Proper hardening is critical to maintaining the highest quality of the ice cream.

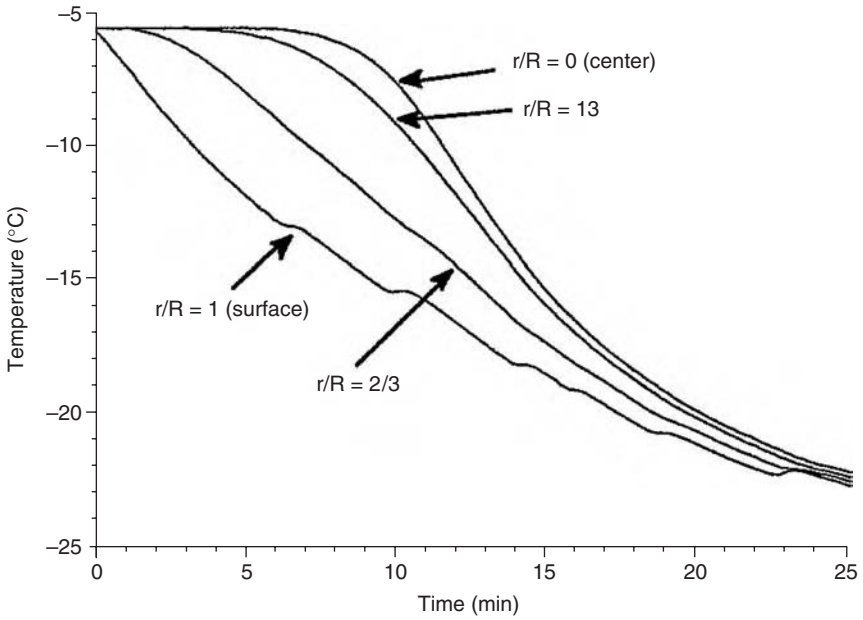

FIGURE 154.21 Temperature profiles as a function of time at different distances from the center (relative radial dimension, r/R) during hardening of a half-liter cylindrical container of ice cream at –30°C (10).

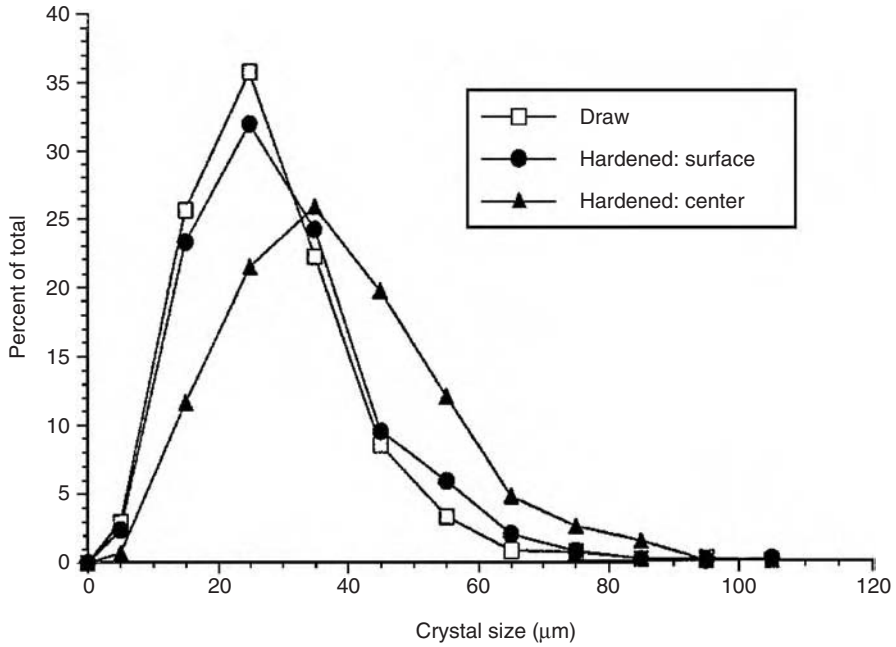

FIGURE 154.22 Ice crystal size distributions for ice cream at different points within a half-liter container after hardening to –30°C. Points correspond to container positions in Fig. 154.21 (10).

The speed of cooling in the hardening facility also depends on the type of refrigeration system chosen. There are numerous options for hardening ice cream. The choice of hardening facility depends on many factors, including the size of the operation, the types of ice cream products being frozen, as well as other economic factors. In some cases, as in small operations, the packages of ice cream may simply be transported to an air blast freezer for hardening. In this case, cold air blowing across the packages removes heat from the ice cream as it freezes further. Typically, air at –30°C, cooled by a mechanical refrigeration system, blows past the packages. Good air flow across each individual package is necessary to obtain the fastest rate of cooling.

In larger operations, packages of ice cream are placed on a conveyor (e.g., spiral configuration) and transported through a hardening tunnel to provide rapid convective cooling. The tunnel is maintained at −35° to −40°C and with very high air velocity. The residence time of a package on the conveyor may be between 40 and 160 minutes, which is sufficient to lower the temperature to about –18° to −25°C (1). Again, cold air (−30 to –40°C) blowing across the individual packages provides a rapid rate of cooling in the hardening tunnel. Product exiting the tunnel is then transported to a storage freezer for further distribution.

Another type of hardening system is the plate freezer, which works well for products in containers with flat sides. In the plate freezer, the containers come in contact with a metal surface (the plates) on both sides (top and bottom). The plates are cooled internally with circulating refrigerant so conductive heat transfer is excellent between plates and ice cream. Hardening in a plate freezer can be accomplished in as little as 2 hours (1).

The choice of packaging material is based on many considerations. From a heat transfer standpoint, the package should have a sufficiently high heat transfer rate that the ice cream cools rapidly in the hardening facility, so that ice crystals are maintained as small as possible. However, during storage and distribution of the ice cream, a good insulating package is desired to minimize thermal fluctuations (and minimize recrystallization during storage). Thus, a compromise on the type of packaging material used is necessary, and often the choice comes down to marketing considerations and the price of the packaging material, with heat transfer and product concerns essentially ignored.

E. Novelty/Impulse Product Manufacture

Ice cream products designed for single servings are widely available, and are often purchased to be handheld items, eaten immediately after purchase. Many of these items are designed specifically for the children's market, so a vast array of shapes exist, and new introductions and variations occur frequently. As a result, this category of products is often referred to either as novelty or impulse products, and account for a larger share of the ice cream and frozen dessert market in many countries of Europe and Asia than do packaged items designed for home consumption. Examples include stick or stickless bars, cups, and cones. They can be made of many types

of frozen desserts, including ice cream with its various fat contents, frozen yogurt, sherbet, puddings, tofu, sorbet, gelatin, and fruit ices. To these are frequently added chocolate, baked items such as wafers and cakes, and numerous kinds of fruit. Recent advances in novelty manufacture equipment have greatly increased the number of products available. This equipment is usually high-speed for mass production, but at high capital cost, so production of such items is a specialty market. Strict portion control is a common attribute of modern equipment. Marketing of these items is a large factor in their success.

Novelties can be formed in any of several ways. Most novelty freezing equipment uses ice cream direct from a continuous freezer, at various draw temperatures, in order to get the appropriate consistency for the next step. Different configurations of novelty items include direct filling into a preformed single-service cup or edible cone, layering ice cream between biscuits, as in ice cream sandwiches, filling into molds and then quiescently freezing the molds, or extruding ice cream through various shapes or dyes (1).

In the molding method (Figure 154.23), unfrozen mix, such as juice or fruit ice formulations, or ice cream from the continuous freezer, usually at higher than normal draw temperature so it is not too stiff, is transferred to molds that are immersed in or sprayed with chilled brine or glycol. After the product has been partially frozen, sticks are inserted and freezing is completed in the molds. The molds then progress to a section where they are lifted from the secondary refrigerant and briefly exposed to heat (warm brine or water) to loosen the bar. An extractor there picks up the novelty by the stick and passes it to the next station. This station can be an enrober, decorator, or packaging apparatus. Individual packaged items are typically placed in bags or boxes, which may be packed in cartons. Because they typically are very hard when packaged, it is unnecessary to transfer them through a hardening tunnel before sending them to cold storage. Some flexibility with external shapes is possible, however with the use of metal molds, the mold shape must allow for the product to be extracted. Some machines are equipped with flexible molds that peel off the surface of the frozen product during extraction, allowing for more surface features. It is also possible to produce "splits," products with multiple layers from exterior to inner core, on molding machines by filling the mold with the first layer (e.g., fruit ice), allowing for partial freezing of this layer, then sucking the remaining unfrozen material from the inner core and refilling with another material (e.g., ice cream). In belt-type molding equipment, as in Figure 154.23, the molds are then cleaned prior to refilling. Mold freezing equipment is also available in a rotary table-type configuration.

The extrusion method (Figure 154.24) involves extraction of ice cream from a continuous freezer at

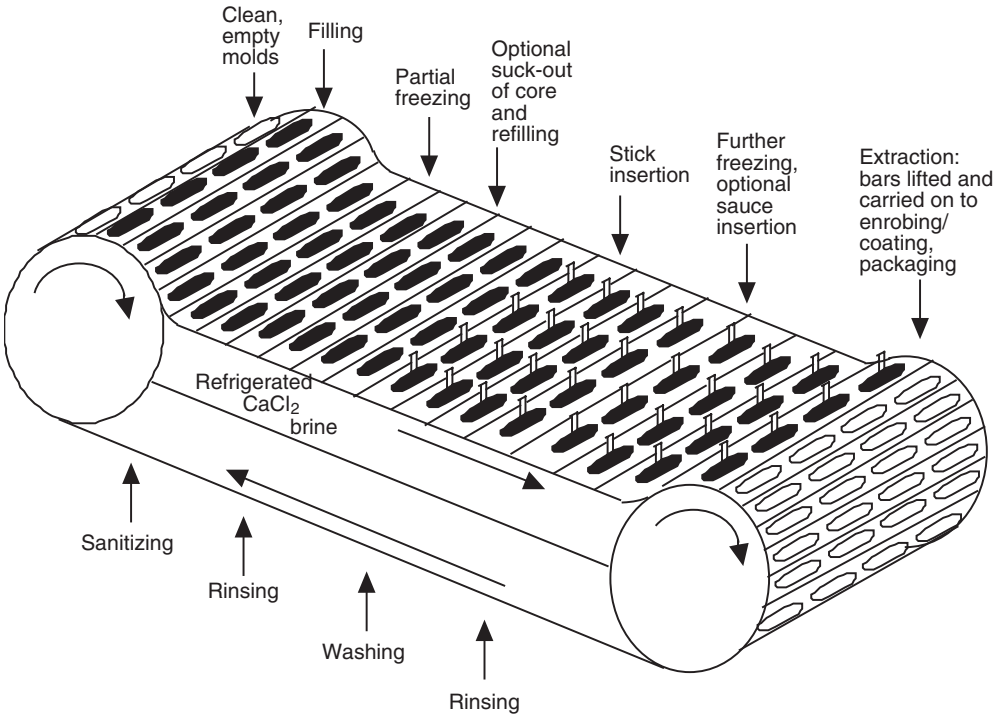

FIGURE 154.23 A schematic illustration of molded novelty freezing equipment used in the production of molded ice cream novelties.

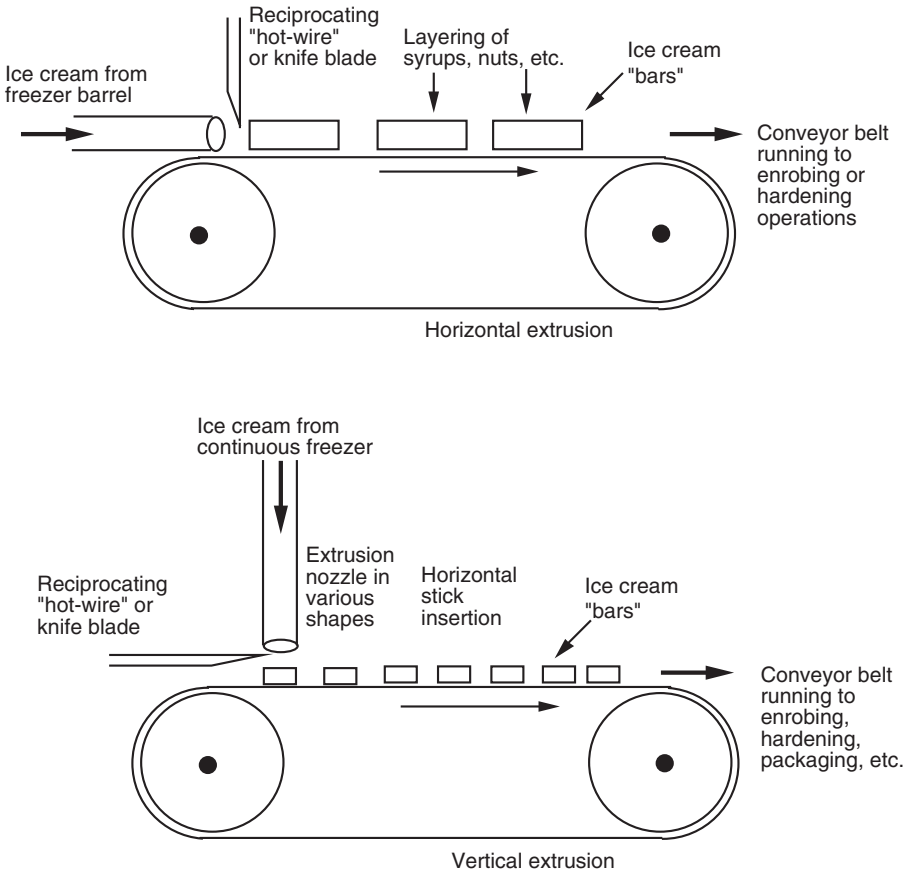

FIGURE 154.24 A schematic illustration of horizontal and vertical extrusion and continuous belt-type freezing equipment used in the production of extruded ice cream novelties.

lower-than-average draw temperatures, about −6° to −8°C. The ice cream is then pumped through an extruder nozzle and sliced into portions by an electrically heated wire cutter. The extruder may take a horizontal or vertical form (Figure 154.24). The external contour of the slice may be almost any desired shape, as is dictated by the shape of the extruder nozzle. By placing different extrusion nozzles inside each other, intricate designs can be formed. Complex extrusions in which multiple flavors or colors are extruded require the use of multiple continuous freezers. Cold-forming or pressing of the extruded item is also possible, allowing complex shapes, designs, patterns, words, etc., to be embossed into the frozen item. If a stick item is desired, the stick is inserted in the extruded ice cream. The pieces are formed on or dropped onto carrier plates and pass through a freezing chamber at −40°C, with rapid air circulation for fast freezing. Each piece is removed from the carrier plate as it emerges from the freezing chamber. Alternatively, a liquid nitrogen dip can be utilized for rapid setting of surface layers. Portions to be coated with chocolate or other coating are then transferred to an enrober, then through a chill tunnel to set the coating.

F. Storage and Distribution

Once ice cream has been frozen and hardened, it then goes through a storage and distribution system designed to get the product to the point of commercial use. This may be a retailer's freezer cabinet, and ultimately, in the case of take-home packaging, the consumer's freezer; or it may be another retail outlet like a scooping shop. Whatever the case, the steps and sequence of storage and distribution are critical to maintaining the highest possible quality of the ice cream.

Once the ice cream comes out of the hardening facility, it is typically stored in a low-temperature (−25 to −30°C) freezer within the plant itself until it is shipped to its next destination. It is difficult to generalize the series of distribution points for ice cream, since this depends on many factors, including the size of the ice cream manufacturer, the radius of distribution, and the facilities available. Some companies have their own distribution resources, including refrigerated trucks, whereas other companies must rely on contractors for distribution. In some cases, the ice cream goes first to a central warehouse; whereas in other cases the product may go directly

to retail outlets. Everington (123) shows a typical time-temperature history for distribution of ice cream.

Keeney (124) reported on a survey of ice cream manufacturers and presented some typical time scales for storage at several points in the distribution chain. The time ice cream spent in the factory before shipping varied from 1 to 4+ weeks, with 2 weeks being most common (36%). The next stage in distribution was a warehouse or distribution center, where most companies (64%) reported that the ice cream spent over 4 weeks before being shipped to the point of purchase. The majority of ice cream (68% of respondents) was purchased within 2 weeks at the retail outlet and used within 2 weeks of the consumers getting the product to their homes. However, in both the retail and consumer stages, some respondents (21%) reported that the ice cream was kept for greater than 4 weeks. Since temperatures are typically more variable in retail outlets and the consumer's freezer than in the factory or warehouse freezers, ice cream that spends a long time at warmer temperatures is more prone to becoming coarse, as the ice crystals continue to get larger by recrystallization.

Ben-Yoseph and Hartel (125) report some typical conditions and storage times at various stages in ice cream distribution, as shown in Table 154.11. These numbers were obtained from anecdotal reports from various sources, and are only meant to indicate the range of conditions that might be found (122). Ben-Yoseph and Hartel (125) used data on recrystallization of ice cream, coupled with rates of heat transfer into a half-gallon container of ice cream, to predict the increase in size of ice crystals at various locations within the container (center to surface) as it progressed through the distribution system presented in Table 154.11. Not surprisingly, the retailer's outlet and the consumer's freezer were two of the most significant sources of quality loss. However, any point of transport from one center to another is cause for concern, as temperature spikes (heat shock) due to lack of control can cause significant product damage in a short time.

TABLE 154.11
Approximate Distribution Sequence for Ice Cream (125)

Storage Site	Storage Time	Mean Air Temperature	Fluctuation[a] Amplitude
Manufacturing plant	2 weeks	−22.0°C	2.0°C
Distribution vehicle from plant	6 hours	−19.0°C	2.8°C
Central warehouse	4 weeks	−24.0°C	6.0°C
Distribution vehicle from warehouse	3 hours	−19.0°C	2.8°C
Supermarket storage	1 week	−15.6°C	2.8°C
Consumer vehicle from supermarket	0.5 hour	21.0°C	0°C
Home freezer	1 week	−12.0°C	2.8°C

[a] Approximate amplitude of temperature fluctuations.

III. PRODUCT QUALITY AND SHELF-LIFE

A. Flavor Defects

There can be numerous flavor and textural defects associated with ice cream. Excellent reviews on ice cream defects can be found in Refs. 1 and 126. Flavor defects are classified according to origin, and include those associated with the flavoring system (lacks fine flavor, lacks flavor, too high flavor, unnatural), the sweetening system (lacks sweetness, too sweet, syrup flavor), the dairy ingredients (acidic, salty, lacks freshness, old ingredient, oxidized/metallic, rancid, whey), processing (cooked), and others (absorbed from storage, stabilizer, neutralizer, foreign).

The dairy ingredients give rise to many of the common flavor defects in frozen dairy dessert products. Acid flavors may develop due to microbial growth in the dairy ingredients used in the manufacture of mix or in mix before freezing. However, off-flavor development due to microbial growth is dependent on the type of organisms present. Acidity is developed by lactic-acid organisms, but the organisms that grow at refrigerated temperatures are mostly psychrotrophs, and off-flavors associated with their growth are usually fruity and/or bitter in nature, due to peptides derived from proteolysis. Salty flavors may arise from formulations that are too high in msnf, especially if whey powder is used. Whey powder tends to be higher in natural milk salts than does skim milk powder. However, it should also be recognized that salt is often an ingredient in mix formulations, for flavor enhancement, and too much salt may have been used. Another source of high salt flavor may be salted butter, used in error rather than sweet butter.

Defects in ice cream flavor associated with the fat phase are usually related to either lipolysis of free fatty acids from triglycerides by the action of lipases (known in the dairy industry as rancidity), or autoxidation of the fat resulting in oxidized flavors (oxidative rancidity as distinct from lipolytic rancidity). These defects tend to be present in the raw ingredients used in ice cream manufacture, rather than promoted by the manufacturing process itself. However, similar precautions to the processing of milk must be taken to ensure that these flavor defects are not present.

Oxidation of milk and other fats proceeds by the well-known autoxidation reaction in three stages: initiation, propagation, and termination. In milk, the initiation reactions involve phospholipids present in the fat globule membrane. Free radicals formed from phospholipids are then able to initiate oxidation of triglycerides, especially in the presence of copper and proteins (21). During propagation, antioxidant compounds, such as tocopherols and ascorbic acid, are depleted, while peroxide derivatives of fatty acids accumulate. Peroxides, which have little flavor, undergo further reactions to form a variety of carbonyls, some of which are potent flavor compounds, especially

some ketones and aldehydes. Most methods available to monitor lipid oxidation are unsuitable as an early index of oxidized flavor development in milk: measurement of peroxides is not useful because peroxides are unstable intermediates; tests based on colorimetric reaction of thiobarbituric acid with malonaldehyde show some correlation to sensory values, but are rather insensitive; and direct measurement of oxygen uptake is only suitable for controlled experimental conditions.

Milk may oxidize as a result of either factors extrinsic or intrinsic to the milk (21,127). Important extrinsic factors include contamination with metals, temperature of storage, oxygen tension, heat treatment, agitation, light, and acidity. Both copper and iron may catalyze lipid oxidation, but probably only copper is significant in milk. Added copper is much more potent than natural copper, because a significant portion of added copper goes directly to the fat globule (21). Significant intrinsic factors affecting milk fat oxidation include metallo-proteins, such as milk peroxidase and xanthine oxidase, endogenous ascorbic acid which acts as a co-catalyst with copper to promote oxidation, endogenous copper content, and endogenous antioxidants, mainly tocopherols. Fresh forage is well known to control spontaneous oxidation, as indicated by obvious seasonal effects on the incidence of oxidized flavor. This effect is probably due to increased levels of endogenous antioxidants.

Hydrolysis of fatty acid esters by the action of lipases results in the common flavor defect known as lipolytic or hydrolytic rancidity, and is distinct from oxidative rancidity (127,128). Lipolysis in dairy fats can be extremely detrimental, due to the number of highly volatile, short chain fatty acids present, especially butyric acid. Lipases are unique among enzymes, in that they are active at the lipid-serum interface. In milk, lipases are ineffective unless the fat globule membrane is damaged or weakened in some way. Lipolysis may be caused by the lipoprotein lipase (LPL) that is endogenous to milk, or by bacterial lipases. The properties of the fat globule membrane are most important to lipolysis. Mastitis, which alters milk composition, also increases sensitivity of the fat globule to lipolysis. Other factors that destabilize the fat globule membrane, especially agitation and/or foaming, also promote lipolysis. Lipolysis is accelerated by the replacement of the native membrane with surface active material (mainly casein micelles and whey proteins) from the plasma (128). This effect is at least partly due to redistribution of LPL from the plasma to the fat globule membrane, and accounts for greatly increased lipolysis after homogenization. In the milk from some animals, lipolysis may proceed without subsequent thermal or mechanical activation. This effect, frequently referred to as spontaneous lipolysis, is unlikely to occur in herd or pooled milks, because it is prevented by the mixing of affected milk with three to five times its volume of normal milk. The major conditions that influence spontaneous lipolysis are late lactation, insufficient fresh forage, and low yielding cows.

Cooked flavors in dairy products, including ice cream mix, are caused by using milk products that have been heated to too high a temperature, or by using excessively high temperatures in mix pasteurization. The flavor is typified by scalded milk, and is caused by sulfhydral groups from denaturation of disulfide bonds in whey proteins. If it is mild, it can dissipate with time as the sulfhydral groups oxidize, so it is most often noticeable directly after heat processing. A mild cooked flavor is not objectionable, but intense heating can cause the defect to linger and become increasingly objectionable.

Ice cream can sometimes absorb off-flavors from its storage environment. Volatile compounds like smoke, ammonia, paint or diesel fumes have been known to be detectable in ice cream after inadvertent exposure to these odors. It is thus important to recognize that storage environments must be kept free of strongly volatile materials.

B. Texture Defects

Considerable effort goes into processing ice cream so that the final product has the desired consumer appeal. From a structural standpoint, this involves controlling ice crystallization, air incorporation, and fat destabilization. During storage, however, significant changes can occur to the structural elements that lead to loss of quality. Textural defects common to ice cream include recrystallization of ice crystals, lactose crystallization (sandiness), and shrinkage.

1. Recrystallization

In ice cream, numerous small crystals are desired for the smooth texture that they impart. Thermodynamically, however, this state is inherently unstable due to the very high surface area of ice crystals. In principle, this system would be in a lower energy state if the ice phase took the form of a single, very large crystal to minimize the surface area (or more correctly, the surface energy). Thus, there is a thermodynamic driving force for the small crystals in ice cream to disappear, leaving fewer and larger ice crystals. Recrystallization is seen as an increase in mean size and widening of the range of sizes (Figure 154.25), and is accompanied by a decrease in the number of crystals (96).

The driving force for this rearrangement is based on the Kelvin equation, which states that the equilibrium temperature of a crystal surface is dependent on its radius of curvature. Thus, smaller ice crystals have a slightly lower equilibrium temperature than larger crystals. In a mixture of ice crystals as found in ice cream, the small crystals are less stable than the larger ice crystals. During storage, the smaller ice crystals melt away at the same time that the larger ice crystals grow larger, as shown

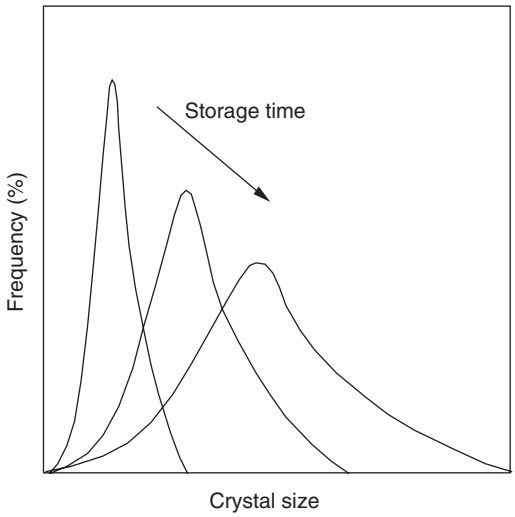

FIGURE 154.25 Typical changes in crystal size distribution during storage (96). The arrow represents a decrease in frequency of crystals found within a size range with increasing mean size.

schematically in Figure 154.26(A). This increase in size of larger ice crystals at the expense of smaller crystals is often called Ostwald ripening, or simply ripening.

However, calculations of the difference in equilibrium temperature between small and large ice crystals in ice cream show that this difference is only significant for very small crystals (10,122). The difference in driving force, expressed as a difference in equilibrium temperature, between crystals of only 1 μm in radius is less than 0.05°C. For a crystal of 10 μm radius, the temperature difference is less than 0.005°C. Thus, the driving force for Ostwald ripening of ice crystals in ice cream is very small. In fact, Donhowe and Hartel (72) did not observe true Ostwald ripening in extensive studies of mechanisms of ice recrystallization during storage of ice cream under accelerated recrystallization conditions on a microscope slide. It was found that other mechanisms were more important in ice cream. Nevertheless, it is this slight difference in equilibrium temperature between large and small crystals that, over long periods of time, can lead to significant changes in the state of ice crystals in ice cream (and other frozen foods).

The main static (constant temperature) mechanisms for recrystallization of ice crystals during storage of ice cream include accretion and isomass rounding (10). When storage temperature is constant, these two mechanisms are responsible for recrystallization of ice crystals in ice cream (72). Isomass rounding is very similar to Ostwald ripening, but is based on regions of a single crystal with different radii of curvature. A spherical ice crystal would not undergo isomass rounding, since the radius of curvature is uniform at all points of the sphere. In other words, a sphere has the minimum surface area to volume ratio. Ice crystals in ice cream are not spherical in nature (see Figure 154.5), so have a higher surface area to volume ratio. Ice crystals in ice cream are somewhat irregularly shaped, based on the mechanisms of ice formation in the freezer barrel. Thus, there is a driving force for the sharper edges (protruberances) to melt away, and for the flatter sides to grow out until the ice crystal approaches a more spherical state (Figure 154.26(B)). This process has been observed for ice crystals in ice cream held at relatively warm temperatures (−5°C) (72). In this case, the ice crystal dispersion in ice cream progressed from the initial irregular-shaped crystals

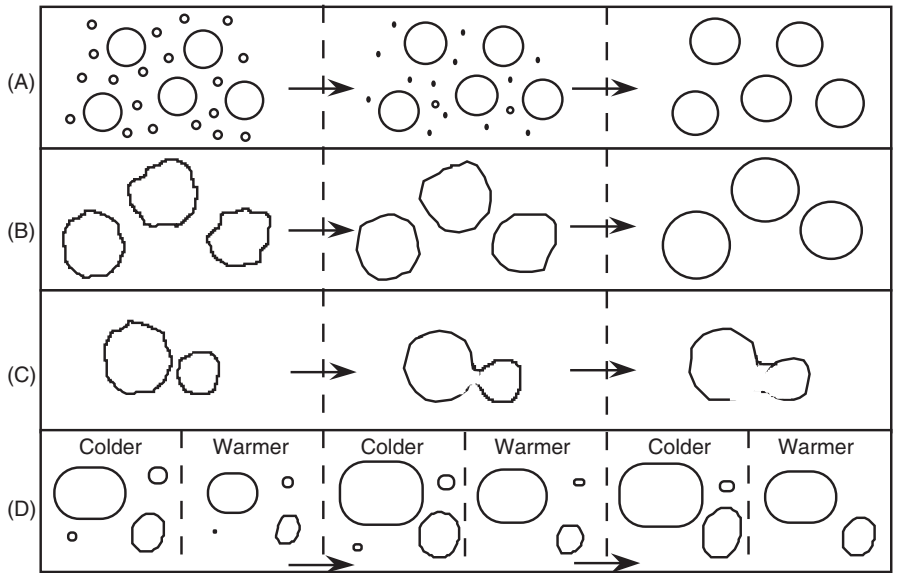

FIGURE 154.26 Mechanisms of recrystallization: (A) Ostwald ripening, (B) isomass rounding, (C) accretion, (D) melt-refreeze.

to essentially spherical crystals over time. Because the driving force for this transition is very small (the differences in size characteristics are very small), the process is relatively slow compared to other recrystallization mechanisms.

Another important mechanism of recrystallization under constant temperature conditions is accretion. It has been estimated, based on the physical number and sizes of ice crystals and air cells, that ice crystals in freshly hardened ice cream are separated, on average, by a serum film that is less than 10 μm thick (6). This close proximity leads to an instability in the region between the two crystals that leads to bridge formation, and eventually to accretion (Figure 154.26(C)). Accretion has been found to be the main mechanism of recrystallization during the initial stages when ice crystals are closely packed together. Once the crystals have become larger and more separated, the importance of accretion diminishes (72,75).

Although it is informative to understand these static mechanisms for recrystallization, ice cream is rarely (if ever) stored under conditions where temperature is constant. As documented in Section II.F, temperatures are continuously changing during storage and distribution of ice cream. Even when stored under "constant" temperatures, most refrigeration systems evoke some temperature fluctuation as compressors cycle on and off. Thus, the process of melting and refreezing is continually occurring, and this process can have a dramatic impact on the ice crystals. In fact, the melt-refreeze mechanism of recrystallization is probably the most important process leading to the change in ice crystals in ice cream during frozen storage (59,72). As temperature fluctuates in ice cream, the amount of ice (phase volume) changes accordingly. If the temperature fluctuations are relatively slow, the ice phase volume changes according to the equilibrium freezing point depression curve. This can be seen schematically in Figure 154.27 (96). When temperature increases, the amount of ice present decreases according to the freezing point depression curve. All ice crystals melt away to some extent, but the smallest crystals melt away a little faster (due to the lower equilibrium temperature) and may eventually disappear (melt away completely). Once a crystal has disappeared, it no longer returns and no new crystals nucleate (driving force is too low). The mass initially contained in that ice crystal must now be redistributed on the remaining crystals when the temperature is lowered and the ice phase volume increases. This process is seen schematically in Figure 154.26(D). The melt-refreeze mechanism is the primary mechanism for recrystallization in ice cream under conditions where temperature is changing (59,72).

The rate of recrystallization in ice cream during storage and distribution is dependent on numerous factors, including the initial state of ice crystals in the ice cream, storage temperature and fluctuations, and formulation factors (10). Extended shelf-life requires that the ice crystals are maintained as small as possible for as long as possible.

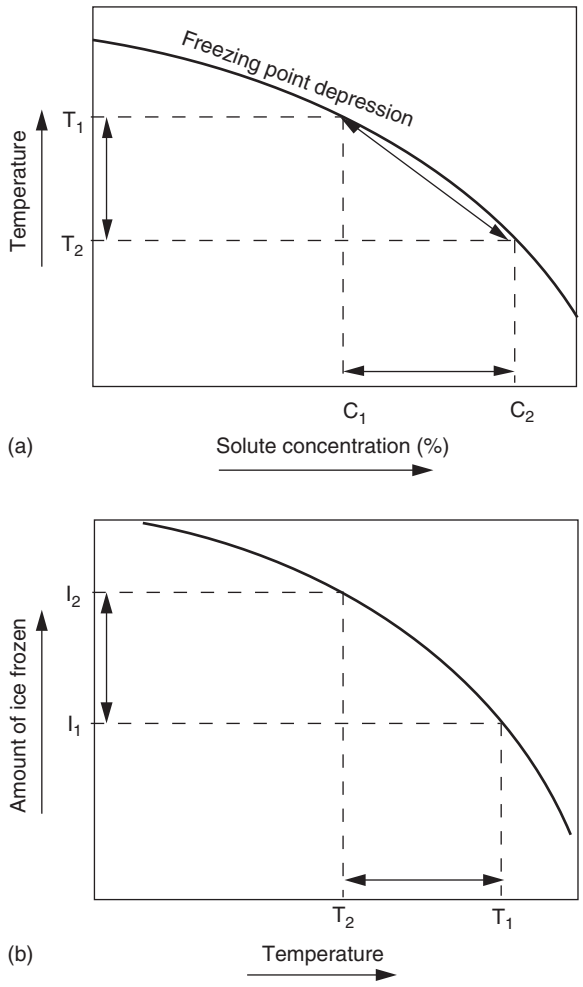

FIGURE 154.27 Effects of fluctuations in temperature (from T_1 to T_2) on a) change in the concentration of the unfrozen phase (C_1 to C_2), and b) change in amount of ice frozen (I_1 to I_2) (96).

Of the parameters that influence recrystallization, storage conditions and formulation factors are two of the most important.

The rate of recrystallization is a strong function of temperature, with the rate decreasing significantly as storage temperature decreases (59,72). Each of the mechanisms of recrystallization described above progresses more slowly as the temperature is decreased. The result is that the rate of recrystallization decreases as storage temperature decreases. In fact, if ice cream is stored below its glass transition temperature, molecular mobility will be sufficiently low, and the recrystallization rate effectively goes to zero. The glass transition temperature of ice cream is about –32°C (85,105). However, the rate of recrystallization typically is quite low if storage temperature is maintained below about –20°C (72). The extent of temperature fluctuations also influences the rate of recrystallization through the effect on the melt-refreeze mechanism. Based on Figure 154.26, the effect of temperature fluctuations depends on the storage

temperature since the change in ice phase volume with a given change in temperature decreases as temperature decreases (72). Thus, storage at –20.0 ± 2.0°C has much less effect on recrystallization than storage at –8.0 ± 1.0°C. A heat shock index can be used to quantify this effect (129).

Since the temperature changes during the various stages of storage and distribution, the rate of recrystallization changes during storage according to the local temperature and fluctuations. Furthermore, different points within a single package experience different thermal conditions and undergo recrystallization at different rates. Donhowe and Hartel (73) showed that ice crystals at the center of a half-gallon container of ice cream remained the smallest, whereas ice crystals near the package surface experienced the greatest rate of recrystallization. The thermal insulating capacity of ice cream, in effect, protects the interior of ice cream from external temperature fluctuations. Ben-Yoseph and Hartel (125) used typical temperatures and times in different stages of distribution of ice cream, and the rates of heat transfer into a package, to predict the ice crystal size at any point in a container of ice cream based on the recrystallization kinetics of Donhowe and Hartel (72). The effects of storage temperatures on ice crystal size at different points in the distribution system were clearly demonstrated.

Of the formulation factors that influence recrystallization, stabilizer and sweetener types are the two most important. In fact, stabilizers are added to ice cream primarily to control recrystallization during storage. However, it is still not clear exactly how stabilizers affect recrystallization (see Section I.B.4). Several potential mechanisms have been hypothesized for the effect of stabilizers on recrystallization (10). These include (1) an increase in viscosity of the unfrozen phase, (2) specific inhibition of ice crystal growth rates, (3) physical obstruction due to formation of a weak gel structure (58,71), (4) a change in thermal properties of ice cream due to addition of stabilizer (82), and (5) a decreased perception of iciness due to addition of stabilizers (81). It is possible that each of these potential mechanisms plays a role in the effect of stabilizers on recrystallization. However, further work is needed to verify exactly how stabilizers act to inhibit ice recrystallization during storage of ice cream.

The type of sweetener used in the mix formulation has also been found to influence the rate of recrystallization during storage of ice cream (74,84). The effect of sweetener type, however, is primarily related to the amount of water frozen into ice at any temperature. Hagiwara and Hartel (74) correlated recrystallization rate during storage of ice cream with the calculated amount of water frozen into ice for ice creams made with different sweeteners. Recrystallization rate decreased proportionally as the amount of water frozen into ice increased. Since the amount of water frozen at any temperature is directly related to freezing point, recrystallization rate also was seen to decrease as the freezing point temperature increased. Since recrystallization is a diffusion-limited process (based on migration of water molecules), more ice at a given temperature (and less water) leads to slower recrystallization, due to the lower mobility of the water molecules. The lower mobility correlates with an increase in glass transition temperature of the ice cream (74).

2. Lactose Crystallization

The problem of "sandiness" in some ice creams during storage has been related to crystallization of lactose from the milk solids in the formulation (1,130). It is not only that lactose crystals appear in ice cream during storage, but that these lactose crystals must grow to sufficient size that they can be detected by the palate and distinguished from ice crystals (131). Based on various sources, it has been estimated that the critical size for lactose crystals in ice cream is about 15 μm. Above this size, their presence can be detected as a sandy or grainy characteristic that is different from the coarse texture associated with large ice crystals. When present in ice cream, lactose crystals dissolve at a much slower rate than ice crystals melt. Thus, the lactose crystals remain in the mouth even after the ice cream has melted; hence, the sandy mouthfeel.

Lactose in ice cream crystallizes when the concentration in the serum phase (unfrozen concentrate) exceeds the solubility concentration of lactose. Since the solubility of lactose is very low (and decreases as temperature goes down), lactose is supersaturated and prone to crystallize at almost any level in ice cream stored at common freezer temperatures. In fact, thermodynamically, lactose should crystallize in just about all ice cream, since it is in the supersaturated state at storage temperatures. The fact that lactose does not crystallize in all ice cream during storage may be attributed to the slow kinetics of lactose nuclei formation at these conditions. The viscosity of the unfrozen phase is sufficiently high that lactose nucleation is inhibited for extended periods of time (and may not occur within the shelf-life of an ice cream product).

Thus, two competitive forces are at work that govern crystallization of lactose in ice cream. The first is the increase in concentration driving force as temperature is decreased, which tends to promote lactose crystallization at lower temperatures. Working against this, however, is the decrease in molecular mobility as the temperature is decreased. Thus, there is a storage temperature where lactose crystallization is at a maximum. For a wide range of commercial ice creams, this temperature occurs at about −10 to −12°C (130,132,133). Storage in this temperature range leads to the most rapid lactose crystallization in ice cream. Storage at both higher and lower temperatures requires longer times for onset of lactose nuclei formation (132).

Of the formulation factors responsible for lactose crystallization, the initial milk solids level in the mix is probably the most important. An upper limit of 15.6 to 18.5% msnf has been suggested to prevent lactose crystallization, with the higher limit for products that move

quickly through the distribution chain (1). The presence of sucrose and stabilizers may have an inhibitory effect on lactose crystallization, perhaps through their effect on viscosity of the unfrozen phase during storage. However, addition of powdered or particulate ingredients (e.g., nuts) after initial freezing tends to promote lactose crystallization through two potential mechanisms. Any particulate material added may act as nucleation sites for lactose and promote graining, and it is widely recognized that agitation of a supersaturated sugar solution enhances the likelihood of nucleation (134).

3. Shrinkage

In some situations, ice cream that has been improperly handled exhibits shrinkage, where the ice cream pulls away from the walls of the container. Many parameters have been implicated in the mechanism of shrinkage, including formulation factors like improper use of proteins, emulsifiers and stabilizers, and external factors like atmospheric pressure (49). Shrinkage results from a loss of discrete air bubbles as they coalesce and begin to form continuous channels, eventually leading to collapse of the product itself into the channels (48). Shrinkage tends to occur most often after the ice cream experiences a decrease in pressure, as when ice cream is shipped across mountains or transported by plane, which first causes a volume expansion followed by collapse. The extent of air channeling, and hence a measure of ice cream susceptibility to collapse and shrinkage, can be measured by determining the response in volume of the ice cream to pressure changes, given that the volume of discrete bubbles will correlate directly to pressure changes, while the volume of air channels will not (135).

According to the ideal gas law, the size (volume) of an air bubble is related to the external temperature and pressure, assuming the volume is free to change. As temperature is decreased, at constant pressure, the volume of an air bubble will decrease. As pressure is increased, at constant temperature, the air bubble should also contract. For example, when ice cream exits the draw of a continuous freezer, pressure is reduced (pressure within the freezer is higher than atmospheric pressure), and all of the air bubbles should expand slightly. At this point, though, the viscosity of the ice cream is sufficiently low that this expansion can easily be accommodated by the surrounding matrix, and the air bubbles approach an equilibrium at atmospheric pressure. Cartons of ice cream are filled to their final weight and volume at this point, and any changes in volume during later storage and distribution may lead to negative changes in the ice cream appearance. After hardening, when the surrounding matrix has stiffened considerably, subsequent changes in pressure (or temperature) can lead to changes in the forces between the air cells and the surrounding matrix. Expansion or shrinkage, depending on the conditions, may be the result.

Goff et al. (136) reported on the effects of vacuum storage on expansion and shrinkage of ice cream. Containers of ice cream at –16°C were exposed to reduced pressure (8 in Hg) for 3 hours and then stored for 6 days at –16°C. Volume changes were measured 3 hours after release of vacuum, and again at the end of 6 days of storage. Expansion of the ice cream was observed after the vacuum storage, in accordance with the ideal gas law. However, after 6 days of storage those same ice creams exhibited shrinkage. In all cases, ice creams made with higher overrun had the greatest expansion and subsequent contraction. At –16°C, the unfrozen matrix must still be sufficiently pliable that a change in atmospheric pressure can cause a change in volume of the ice cream. Interestingly, although the period of vacuum exposure caused expansion, the ultimate result when pressure was brought back to atmospheric was shrinkage of the ice cream volume. This suggests that the unfrozen matrix expanded with the increased air bubble size initially, and then relaxed to a smaller volume than originally found. Goff et al. (135) related this to the nature of the interface between the air bubble and the unfrozen serum. They suggested that components like proteins, stabilizers, and emulsifiers play an important role in determining the viscoelasticity of this interface and subsequent changes in ice cream volume during pressure or vacuum storage.

IV. CONCLUSIONS

Ice cream is one of the most complex food products, since it contains multiple phases (ice crystal dispersion, foam, emulsion, viscous unfrozen matrix, and potentially, a weak gel system and a glass). Formation of the different phases is controlled during freezing, but the process of forming one phase generally influences the formation of the other phases. Thus, manufacturing of ice cream requires careful control of both ingredient formulation and processing conditions. Since ice cream and related products are some of the few food products consumed in the semi-frozen state, the freezing process is most important to ultimate smooth texture. As ice cream readily undergoes ice recrystallization, especially during periods of temperature fluctuation, precise control of frozen storage and distribution conditions is also critical for the preservation of optimal textural quality. For all these reasons, ice cream type products present processing, storage, and distribution characteristics that are unique amongst the frozen foods.

155 Edible Fats and Oils Processing and Applications

Richard D. O'Brien
Fats and Oils Consultant

CONTENTS

I. INTRODUCTION

Fats and oils have been recovered for thousands of years from oil bearing seeds, nuts, beans, fruits, and animal tissues. These raw materials serve a vital function in the United States and world economics for both food and nonfood applications. Edible fats and oils are the raw materials for oils, shortenings, margarines, and other specialty or tailored products that are functional ingredients in food products prepared by food processors, restaurants, and in the home. The major nonfood product uses for fats and oils are soaps, detergents, paints, varnish, animal feeds, resins, plastics, lubricants, fatty acids, and other inedible products. Interestingly, many of the raw materials for industrial purposes are by-products of fats and oils processing for food products; however, some oils are produced exclusively for technical uses due to their special compositions. Castor, linseed, tall, and tung oils are all of vegetable origin and are produced for industrial uses only. The USDA Economic Research Service statistics indicate that, of the 27.472 billion pounds of edible fats and oils used in the year 2000, 76.6% was for food products and 23.4% was for nonfood products [16].

Fats and oils occur naturally in a wide range of sources and each source provides a separate and distinctive material. There are hundreds of oil bearing seeds and fruits, all animals produce fat, and marine sources provide oils; however, only a few are of economic importance. All edible fats and oils are water insoluble substances which consist predominantly of glyceryl esters of fatty acids, or triglycerides, with some nonglyceridic materials in small or trace quantities. The terms "fats" and "oils" are used interchangeably and the choice of terms is usually based on the physical state of the material at ambient temperature and tradition. Generally, fats appear solid at ambient temperatures and oils appear liquid. In the final analysis, it is the chemical composition that defines the characteristics of the individual fat or oil, which in turn determines the suitability of this ingredient for various processes and applications.

II. FATS AND OILS CHARACTERIZATION

Both the chemical and physical properties of fats and oils are largely determined by the fatty acids that they contain and their position within the triacylglycerol molecule. Chemically, all fats and oils are esters of glycerin and fatty acids. Nevertheless, the physical properties of natural fats and oils vary widely. This is because (i) the proportion of the fatty acids vary over wide ranges, and (ii) the triacylglycerol structures vary for each individual oil and fat. Fats and oils are commonly referred to as triglycerides because the glycerin molecule has three hydroxyl groups where a fatty acid can be attached. All triglycerides have the same glycerin unit, so it is the fatty acids which contribute the different properties. The fatty acid components are distinguished in three ways: (i) chain length, (ii) the number and position of the double bonds, and (iii) the position of the fatty acids within the glyceride molecule. Variations in these characteristics are responsible for the chemical and physical differences experienced with edible fats and oils.

The structure of a fatty acid is commonly denoted by a systematic name after the nomenclature of its parent hydrocarbon, by its common name, or by a convenient shorthand designation showing the number of carbon atoms and the number of double bonds. The fatty acids carbon chain lengths vary between 4 and 24 carbon atoms with up to three double bonds. The most prevalent saturated fatty acids are lauric (C-12:0), myristic (C-14:0), palmitic (C-16:0), stearic (C-18:0), arachidic (C-20:0), behenic (C-22:0), and lignoceric (C-24:0). The most important monounsaturated fatty acids are oleic (C-18:1) and erucic (C-22:1). The essential polyunsaturated fatty acids are linoleic (C-18:2) and linolenic (C-18:3).

The triglyceride structure of an edible fat or oil is affected by the fatty acids present and the point of attachment of each fatty acid to the glycerin. Triglycerides with three identical fatty acids are called monoacid triglycerides. Triglycerides containing more than one type of fatty acid are called mixed triglycerides. A mixed triglyceride containing three different fatty acids has three regioisomeric forms and six stereo-isomeric forms, depending on which fatty acid is in the middle, sn-2, or beta position of the glycerol portion of the molecule and which fatty acids are in the alpha or outer positions (sn-1 and sn-3). The distribution of the fatty acids is considered to be nonrandom when the saturated fatty acids are positioned predominately in the sn-1 and/or sn-3 positions and the unsaturated fatty acids are positioned predominately in the sn-2 position [17].

The fatty acid compositions of natural fats and oils vary significantly depending not only on the plant or animal species but also within the same species. Among the factors that affect the vegetable oil fatty acid compositions are climate conditions, soil type, growing season, plant maturity, plant health, microbiological, seed location within the flower, and the genetic variation of the plant. Animal fats and oils composition vary according to the animal species, diet, health, fat location on the carcass and maturity [12].

A. Edible Fats and Oils, Nonglyceride Components

The primary constituents of extracted fats and oils are triglycerides but they also contain varying amounts of nonglyceride materials. Some of the nonglyceride components are undesirable, and can be considered a food safety hazard, while others are very beneficial. Therefore, the objective in all of fats and oils processing is to remove the

objectionable materials with the least possible damage to the desirable constituents. In most cases, free fatty acids, phospholipids, moisture, color pigments, oxidation products, waxes, trace metals, proteins, pesticides, meal, dirt, and other gross impurities are the materials that need to be removed. Most vegetable oils contain tocopherols, which are natural antioxidants that protect the oils from oxidation and should be retained. For some products, neither the color pigments nor waxes are detrimental and need not be removed. The major product quality concerns are with free fatty acids, phospholipids, oxidation products, proteins, and trace metals; all materials that affect the odor, flavor, and flavor stability of edible fats and oils products. In the U.S., fats and oils color is usually a major concern from a cosmetic sense to include pigments adsorption as a major impurities concern especially for products marketed directly to consumers. The major food safety concerns are with residual pesticides, mold, bacteria, and impurities developed during processing or with mishandling.

III. SOURCES OF FATS AND OILS

Humans have survived as hunters and gatherers for a majority of their known existence on earth. It was only during the last 10,000 years that they learned to domesticate plants and animals. During this period, the evolution of cultivated plants has been shaped to the needs of modern man. Today's agricultural crops are mankind's creation. Humans cannot survive without them, nor can the crops that have been developed survive without human care. The combined largest source of vegetable oils are the seeds of annual plants grown in relatively temperate climates. Most of these annual plants are cultivated not only as a source of oil, but are also utilized as protein-rich foods.

A second source of vegetable oil are oil-bearing trees. Olive, coconut, and palm oils are extracted from the fruit pulp rather than the seed of the fruit. Palm also has seeds, which provide palm kernel oil. All of the oil-bearing tree fruits require a relatively warm climate; i.e., tropical for coconut and palm and a warm climate for olive trees. Most of the oil-bearing tree fruits and kernels provide the highest oil yields. Oilseeds are annual plants which must be replanted each year, whereas the fruit oils are harvested from trees with long life spans. Olive trees are the most hardy and can live several hundred years. Coconut trees start to bear fruit after 5 to 6 years; their life expectancy is as long as 60 years. Palm trees start to bear fruit after 4 to 5 years and continue for another 20 years.

Edible meat fats are supplied almost entirely by three kinds of domesticated animals, i.e., lard from pigs, tallow from cattle and sheep, and milk fat or butter from cows. These animals are raised in the greatest quantities, where they thrive the best, in temperate climates. Animal husbandry has evolved to the stage that these domestic animals not only require a temperate climate but also intensive agriculture to provide a plentiful supply of foodstuffs to produce the desired quality and quantity.

IV. GENETICALLY MODIFIED VEGETABLE OILS

Plant breeding to modify the genetics of crops has been practiced for centuries. Historically, plant breeders have used crossing and selection techniques to enhance yields, oil contents, climate adaptation, and to effect changes in oil quality, composition, and resistance to pests or pesticides. Introduction of high-oleic safflower in 1964 and low erucic acid rapeseed oil, which became known as canola oil in 1978, are examples of successful fatty acid composition modifications using this technology. Mutagenesis, another plant breeding technique, where the seed is treated with a chemical or gamma-radiation to alter its physiological functions, was utilized by the Russians to develop high-oleic sunflower oil. These traditional tools used by plant breeders have been combined with biotechnology to broaden their capabilities.

The traditional breeding methods cause thousands of genes to be transferred at each cross, whereas molecular genetic engineering can now transfer or alter a single gene. Genetic engineering can also transfer a gene from one species to another, which is impossible with the traditional methods. The genetic modification of oilseeds by conventional breeding techniques, combined with molecular genetic transformations, provide a much broader array of possibilities to improve food products. One of the first modified oil compositions produced commercially with this process was high-laurate canola oil. High-laurate canola was engineered by inserting a single gene from the California bay laurel tree that provided a substantial quantity of lauric fatty acid (C-12:0) in the oil [5]. This genetic engineering feat proved that a gene from one plant could be transferred to another to produce an oil with specific fatty acid groups in selective positions for either performance or nutritional effects. Agronomically, high-laurate canola was a total success but it failed in the marketplace. Two reasons were suggested for its failure. First, potential customers for genetically modified products were reluctant to commit because of consumer opposition to genetically modified crops. Second, the specialty oil was marketed at a premium price, which was twice that of most other oils [1].

Genetic varieties have been developed to modify the oilseed's fatty acid profile to create new value-added oils. Regardless of the oilseed variety, most of these efforts have followed the same directions: (i) low-saturates for dietary needs; (ii) low-linoleic for flavor stability; (iii) high-oleic for health and oxidative stability; and (iv) high-saturates to replace hydrogenation. Currently, most of these modified varieties have captured very little market share or have never been commercialized. The major

reason these improved oils have not found acceptance is the high cost. Some of the key factors which drive up the costs for these modified oils are [9]:

- Lack of competitive field yields—most modified oilseeds provide only about 85 to 95% of the yield potential of the regular oilseed variety. Farmers require a high premium to grow these lower yielding varieties.
- Identity preservation systems—separate handling systems are required at every stage from seed handling, planting, growing, harvesting, transportation, storage, extraction, and final processing.
- Low trait stability—environmental effects have caused inconsistent oil compositions in modified oilseed products.

Currently, the commercially available genetically modified oilseed crops are primarily varieties with improved agronomic traits, such as herbicide tolerance and pest resistance. In the U.S. these bioengineered herbicide-tolerant or pest resistant soybeans, cotton, canola, corn, and sunflowers have the same oil and protein compositions as their traditional counterparts, and do not require post-harvest segregated handling. Global acreage devoted to growing these genetically modified (GM) crops continues to rise. The United States produces 68% of the GM crops worldwide; Argentina, 22.5%; Canada, 6.1%; and China, 2.9%. Estimates, by the USDA National Agricultural Statistics Service, indicate that 74% of the soybean crop, 32% of the corn acreage, and 71% of the cotton planted in the United States in 2002 were GM hybrids [2].

V. PROCESSING FLOW SEQUENCE

The fats and oils, extracted from the oilseeds, nuts, beans, fruits and animal tissues, vary from pleasant smelling products that contain few impurities to very offensive smelling, highly impure materials. Fortunately, researchers have developed technologies for processing the fats and oils products to make them more suitable for foods and other applications. Developments in lipid processing technology have produced ingredients that have been instrumental in the development of many of the current food products available that provide the functional and nutritional requirements of discerning and better informed consumers. Processes have been developed to make them flavorless and odorless and lighter in color, modify the melting behavior, rearrange the molecular structure, remove potential disease causing impurities, capture possible harmful materials, and provide other changes to make them more desirable for the intended application.

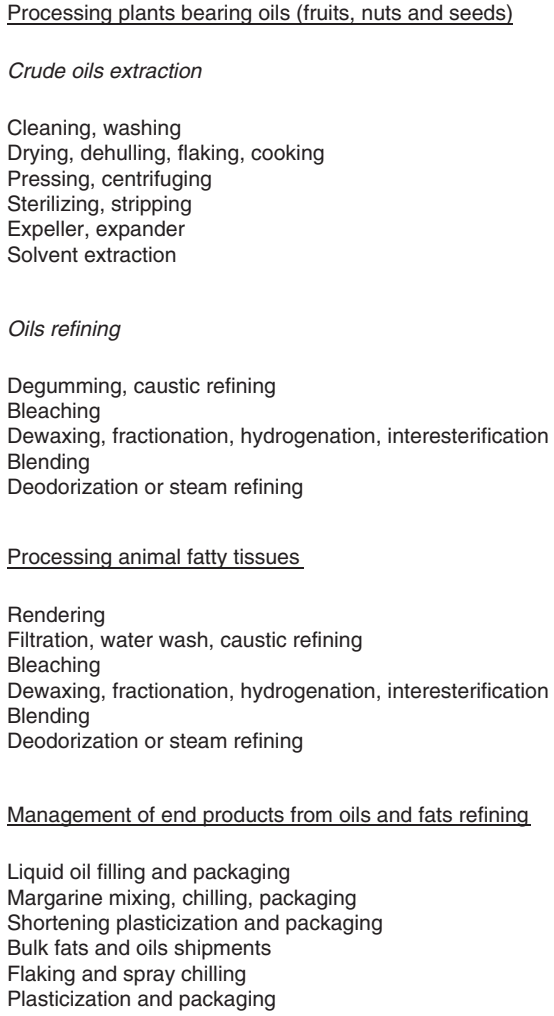

FIGURE 155.1 General steps in processing oils and fats from plant and animal products.

Edible fats and oils processing involves a series of processes in which both physical and chemical changes are made to the raw material. Figure 155.1 illustrates most of the potential processing flow sequencing to produce the various fats and oils products. Processing of fats and oils is initiated by an extraction or rendering process to remove the fat or oil from the seed, bean, nut, fruit, or fatty tissues. Vegetable oil's processing after extraction almost always includes neutralization or refining, bleaching, and deodorization with the major differences being the choice of equipment and techniques utilized. Rendered animal fats are normally clarified to remove impurities, bleached and deodorized, again with differences in equipment and techniques providing the major differences. Clairification, neutralization, bleaching and deodorization are all purification processes which affect the flavor, flavor stability and appearance of the fat or oil product while removing harmful impurities. A review of the major fats and oils processes follows.

A. Extraction

Cleaning is the first step in the processing of vegetable oils. Typically, oilseeds contain stems, pods, leaves, broken grain, dirt, sand, small stones, and other extraneous seeds. These foreign materials reduce the oil content, adversely effect oil quality and increase the wear and damage potential to the extraction equipment. Shaker screens are used to separate the particles on the basis of size, whereas aspiration separates on the basis of density and buoyancy in a stream of air. Tramp iron, extraneous metal acquired during harvesting, storage or transportation is removed to prevent damage to the equipment by the placement of magnets in chutes just ahead of vulnerable processing equipment.

Extraction of oil from materials of plant origin is usually done by pressing with the use of a continuous screw press or by extraction with volatile solvents. Prior to 1940, mechanical pressing was the primary method used. Mechanical pressing had limits because the oil recovery is poorer than with solvent extraction and the high temperatures generated damaged both the oil and the meal. The solvent method allows a more complete oil extraction at lower temperatures. Solvent extraction plants can be either batch or continuous. The continuous extraction plants can be percolation, immersion or direct extraction plants. Generally, the oilseeds may be divided by oil content; above and below 20% oil content. In most cases, oilseeds with a low oil content are subjected to both continuous and batch solvent extraction. High oil content seeds are normally extracted in two stages; first pressing and then solvent extraction; however, many single step continuous direct solvent extraction systems are in current use.

To be used legally in the United States, oilseed extraction solvents and food processing substances must have been subjected to an approval by the U.S. Food and Drug Administration (FDA) or the U.S. Department of Agriculture (USDA), be generally recognized as safe (GRAS) for this use, or be used in accordance with food additives regulations promulgated by the U.S. FDA. Commercial hexane has been in major use since the 1940s as an oilseed extraction solvent on the determination that it is GRAS, and it may also be subject to a prior sanction. Like many other food-processing substances, there is no U.S. FDA regulation specifically listing n-hexane as GRAS or having prior sanction. However, it has been cleared as a solvent in a number of other food products, one of them a cocoa butter substitute with a 5 ppm maximum limit. Because edible fats and oils are subjected to deodorization and other purification processes as a part of the manufacturing process before being used as a food product, they should not contain any of the extraction solvent, if proper practices are followed [19].

B. Rendering

The fatty tissue from meat animals which is not a part of the carcass or that trimmed from the carcass in preparation for sale is the raw material from which lard and tallow are obtained. Separation of fat from the fatty tissues of animals is called rendering. The rendering process consists of two basic steps. First, the meat by-product is heated to evaporate the moisture, melt the fat present and condition the animal fibrous tissue. Two alternative cooking temperatures are used: fat temperatures below 120°F and fat temperatures above 180°F. A more complete separation of the fat and protein is accomplished with the higher temperature processing but a better quality protein is obtained with the lower temperature processing. Normally, the value of the protein dictates that the lower temperature poorer separation technique be used which probably leaves trace quantities of protein in the rendered lard or tallow. After cooking, the fat is separated from the solid proteinaceous material. In batch rendering the cooked material is allowed to separate and the fat to drain followed by filtration to complete the separation. Continuous rendering, introduced to replace the batch systems, normally consists of a continuous cooker which requires less cooking time and is more energy efficient with better quality control [11].

C. Refining Systems

Processors have the option of approaching edible oil purification in two ways; either chemical or physical refining. The two systems utilize very similar processes with the major difference being the method used for free fatty acid removal. Chemical refining, the conventional method used for removal of the nonglyceride impurities from edible fats and oils, consists of optional degumming, caustic neutralization, bleaching and deodorization. The alkali refining process produces good quality oil and is flexible with the ability to treat different oils and different qualities of individual oils. However, caustic refining has three major drawbacks: (1) the soap produced promotes a tendency for emulsion formation which will occlude neutral oil to increase oil losses; (2) oil losses are particularly high when processing oils with free fatty acids over 3.0%; and, (3) disposal of the soapstock produced has become more difficult.

The second process, which has become known as physical refining, consists of removing the fatty acids from the oil by steam distillation under vacuum after the phosphatides have been removed by a degumming process followed by a pretreatment process before bleaching. The major advantages for physical refining are the elimination of soapstock, lower capital costs and fewer processes to operate and maintain. The objective of the initial processing step in either refining method is the

removal of phosphatides, color bodies, and trace metals. Removal of these non-triglyceride impurities is crucial to ensure good product quality. Herein lies the major drawback for the physical refining system; i.e., complete phosphatide removal with degumming and bleaching is very difficult. Some of the other problems with physical refining systems can be: (1) additional bleaching earth is usually required; (2) pesticides are co-distilled with the fatty acids during steam refining; (3) phosphoric acid treatment may darken the gums produced and incomplete removal can produce off-flavors in the oil after deodorization; (4) steam distillation or deodorizer units must be designed to handle higher concentrations of free fatty acids; (5) cottonseed oil cannot be physically refined because the gossypol pigment must be removed with alkali refining; and, (6) it may be necessary to steam refine before hydrogenation or other processing to adjust melting characteristics followed by a second deodorization step. Physical refining is favored for processing high free acidity oils with low phosphatide contents; it has been demonstrated to produce good quality product from coconut, palm kernel, palm, lard, tallow, and some of the seed oils [20].

D. Degumming

Degumming is the treatment of crude vegetable oils with water, salt solutions. or dilute acids such as phosphoric, citric, or maleic to remove phosphatides, waxes, and other impurities. Degumming converts the phosphatides to hydrated gums, which are insoluble in oil for separation as a sludge by settling, filtering, or centrifugal action. Phosphatide removal is the first process for the physical refining system, and can also be used in chemical refining. However, with chemical refining the processor has the option of removing the phosphatides for their by-product value as lecithin or treating them as impurities to be removed along with free fatty acids during caustic neutralization.

E. Caustic Neutralization

The conventional caustic neutralization process is the most widely used and most well known purification system. The addition of an alkali solution to a crude oil brings about a number of chemical and physical reactions: (1) the alkali combines with the free fatty acid present to form soaps; (2) the phosphatides absorb alkali and are coagulated through hydration; (3) pigments are degraded, absorbed by the gums, or made water soluble by the alkali; and, (4) the insoluble matter is entrained with the other coagulable material. Efficient separation of the soapstock from the neutralized oil is a significant factor in caustic neutralization which is usually accomplished with centrifugal separators. The conventional caustic soda neutralization systems have the flexibility to efficiently refine all of the crude oils presently utilized for food products [8].

Caustic neutralization is ordinarily accomplished by treating the fat or oil with diluted sodium hydroxide. This treatment forms soapstock with the free fatty acids, phosphatides, trace metals, pigments, and other nonglyceride impurities that can be separated by settling or centrifugal force from the neutralized oil. The neutral oil is usually water washed and again separated by settling or centrifuged to remove trace impurities and residual soaps from the neutralization and separation processes. After water washing, the oil is either dried with a vacuum dryer or immediately bleached to remove the trace quantities of remaining water.

F. Bleaching

Edible fats and oils bleaching is popularly and correctly regarded as the partial or complete removal of color; however, bleaching is also an integral process in both the chemical and physical refining systems. Bleaching is relied upon to clean up the traces of soap and phosphatides remaining after caustic neutralization and water washing for the chemical refining system. For physical refining, the technical feasibility depends upon bleaching as a pretreatment to remove phosphatides, trace metals, waxes, and the color pigments. Another, very important function of bleaching in both refining systems, is the removal of peroxides and secondary oxidation products.

The usual method of bleaching is by adsorption of the pigments and other nonglyceride impurities on bleaching earth. In a typical process, the bleaching materials are added to the oil in an agitated vessel, either at atmospheric pressure or under a vacuum. The oil is heated to bleaching temperature and held to allow contact time with the bleaching earth. After the adsorbent has captured the color pigments, soap, phosphatides, trace metals, and polar materials, it becomes an impurity which must be removed from the oil with a filtration system. Control point impurities analyses are used to monitor the removal of the potential food safety hazard.

G. Animal Fat Purification Systems

Traditionally, the method used to purify meat fats has been a form of physical refining. The two main impurities in meat fats are proteins carried over from the rendering process and free fatty acids. The pretreatment phase for meat fats is the removal of the proteinaceous materials. Typically, this is easily accomplished by adding small amounts of diatomaceous earth and/or bleaching earth followed by filtration. An alternative clairification or pretreatment method is to water wash the fat to remove the proteins. This method also requires bleaching or at least drying to remove the moisture remaining in the oil after water washing. A third method for meat fat clarification is caustic refining. Chemical refining is usually reserved for poor quality animal fats or for specialty products used undeodorized to preserve the characteristic meat fat

flavor. The caustic refining system consists of caustic neutralization, water washing and vacuum drying.

H. Hydrogenation

The hydrogenation process is an important tool for the edible fats and oils processor. With hydrogenation, liquid oils can be converted into plastic or hard fats more suitable for a particular food product. There are two reasons to hydrogenate a fat or oil; (1) to change the physical form for product functionality improvement, and (2) to improve oxidative stability. Hydrogenation involves the chemical addition of hydrogen to the double bonds in the unsaturated fatty acids. The reaction is carried out by mixing heated oil and hydrogen gas in the presence of a catalyst. After the hydrogenation end point has been achieved, the hardened oil is cooled and filtered to remove the nickel catalyst.

Most hydrogenations are performed in batch reactors due to the variation in raw materials and the desired end products. Normally, batch hydrogenation is performed in an agitated tank reactor with heating and cooling capabilities designed to withstand pressures of 7 to 10 bar. First, the catalyst is suspended in the oil. Then, hydrogen gas, dispersed as bubbles, must be dissolved in the oil to reach the surface of the catalyst. The three reaction variables, pressure, temperature, and rate of agitation, are controlled to reduce batch-to-batch variation for preparation of the desired hydrogenated product or basestock. The typical analytical evaluations for endpoint control which measure consistency are refractive index, iodine value, and various melting points. A food safety control point would be the incomplete removal of the nickel catalyst after the reaction is completed; however, this is not a critical control point because the post bleaching process immediately following hydrogenation is designed to remove the remaining trace catalyst impurities.

I. Post Bleaching

A separate bleaching operation, immediately following the hydrogenation process, has three purposes: (1) insurance that all traces of the prooxidant hydrogenation catalyst that have escaped the filtration system after hydrogenation have been removed; (2) to remove undesirable colors generally of a greenish hue, accentuated during hydrogenation by heat bleaching of the red and yellow pigments; and, (3) removal of peroxide and secondary oxidation products. Post bleach systems are usually batch systems for the same reasons as for hydrogenation systems; production of a wide variety of hydrogenated basestocks.

J. Fractionation

Edible fats and oils are fractionated to provide new materials more useful than the natural product. Fractionation may be practiced to remove an undesirable component, which is the case with dewaxing and winterization, or to provide two or more functional products from the same original fat or oil, as is the case with cocoa butter equivalents or substitutes and high stability oils.

The three fractionation process types practiced commercially to produce the value-added products are: (1) dry fractionation; (2) solvent fractionation; and, (3) aqueous detergent fractionation. Dry fractionation, which includes winterization, dewaxing, hydraulic pressing, and crystal fractionation processes, is probably the most widely practiced. Solvent or aqueous detergent fractionation processes provide better separation of specific fractions for the more sophisticated fats and oils products. All of these fractionation processes practice the three successive stages of fractionation: (1) cooling the oil to supersaturation to form the nuclei for crystallization; (2) progressive growth of the crystalline and liquid phases; and, (3) separation of the crystalline and liquid fractions. A food safety control point identified for the solvent fractionation system would naturally be removal of the solvent used. Complete solvent removal is assured with steam distillation in the deodorization process which is downstream.

K. Interesterification

The interesterification process can alter the original order of distribution of the fatty acids in triglyceride-producing products with melting and crystallization characteristics different from the original oil or fat. Unlike hydrogenation, interesterification neither affects the degree of saturation nor causes isomerization of the fatty acid double bond. It does not change the fatty acid composition of the starting material but rearranges the fatty acids on the glycerol molecule. The process of interesterification can be considered as the removal of fatty acids from the glyceride molecules, shuffling them, and then replacement on the glyceride molecules at random. This change in the distribution of the fatty acids affects the structural properties and melting behavior of the fats and oils. Commercially, the interesterification process has been utilized for the production of confectionery fats, margarine oils, cooking oils, frying fats, shortenings, and other special application fats and oils products.

Two types of chemical interesterification process are practiced: random or directed. Random rearrangement of fats and oils can be accomplished using either a batch or continuous process. Both random interesterification processes perform the three important rearrangement steps: (1) pretreatment of the oil; (2) reaction with the catalyst; and, (3) deactivation of the catalyst. In the directed rearrangement process, one or more of the triglyceride products of the interesterification reaction is selectively removed from the ongoing reaction. Continuous processes are normally used for directed rearrangements for better

control. Trisaturated glycerides are crystallized and separated from the reaction which upsets the reaction equilibrium so that more trisaturated glycerides are produced.

L. Blending

Different stocks are blended to produce the specified composition, consistency, and stability requirements for the various fats and oils products, such as shortenings, frying fats, margarine oils, specialty products, and even some salad or cooking oils. The basestocks may be composed of hydrogenated fats and oils, interesterified products, refined and bleached vegetable oils, purified animal fats, and/or fractions from winterization, dewaxing, or another form of fractionation. The products are blended to meet both the composition and analytical consistency controls identified by the product developers and quality assurance. The consistency controls frequently include analytical testing for solids fat index, iodine value, various melting points, fatty acid composition, and other evaluations designed to insure compliance with customer requirements. The blending process requires scale tanks and meters to proportion the basestocks accurately for each different product. The blend tanks should be equipped with agitators and heating to assure a uniform blend for consistency control [8].

M. Deodorization

With conventional edible oil processing, deodorization is the last in a series of process steps used to improve the taste, odor, stability, and food safety of the fats and oils by the removal of undesirable substances. In this process, the fats and oils products are steam-distilled under vacuum. The object is to remove the volatile impurities from the oil. The foremost concern from a quality aspect is the volatile impurities which have objectionable flavors and odors; however, deodorization is also very important from a food safety aspect. Steam distillation removes any trace pesticide and "heavy" metals contents obtained during the growing process. Deodorization is primarily a high-temperature, high-vacuum, steam distillation process to remove volatile, odoriferous materials present in edible fats and oils. It is the last major processing step through which the flavor and odor and many stability qualities of a fat or oil product can be changed. From this point forward, efforts must be directed toward retaining the quality that has been built into the fat and oil product with all of the preceding processes [8].

The odoriferous substances in fats and oils are generally considered to be free fatty acids, peroxides, aldehydes, ketones, alcohols, and other organic compounds. Experience has shown that the removal of flavor, odor, and other undesirables correlates well with the reduction of free fatty acids. Therefore, all commercial deodorization consists of steam stripping the oil for free fatty removal. Currently, batch, semicontinuous, and continuous systems of various designs are utilized by edible fats and oils processors to produce deodorized oil. All of the systems utilize steam stripping with four interrelated operating variables: (1) vacuum, (2) temperature, (3) stripping steam rate, and (4) holding time.

N. Liquid Oil Filling and Packaging

Most salad and cooking oils are packaged shortly after deodorization in containers for home, restaurant, or large food processor use. The processing necessary for most oils are oxidative stability preservation measures, such as nitrogen protection, temperature control, light avoidance, and the addition of any additives required by the individual products. The oil is filtered for a final time in-line to the bottle filler. The effectiveness of this final filtration is monitored with laboratory filterable impurities testing of packaged product samples obtained utilizing a statistical sampling plan. Food safety concerns for retail liquid oils were lessened with the packaging change from glass to plastic containers. Glass breakage and contamination of other containers were major concerns when glass bottles were used. Exposure of the oil to the atmosphere is limited to a micro-second for most filling lines with a tamper-evident seal applied to the container before the cap is applied.

O. Shortening Plasticization and Packaging

Plasticized shortening products can be defined as fats with a consistency that can be readily spread, mixed, or worked. Considerably more is involved in the plasticization of shortening and margarine than merely lowering the temperature to cause solidification. Slow cooling of these products produces a grainy, pasty, non-uniform mushy product that lacks the appearance, texture, and functional characteristics associated with plasticized products. Development of these characteristics are a function of controlled crystallization or plasticization. The final consistency of a shortening is the culmination of all the factors influencing crystallization and plasticization: chilling, working, tempering, pressure, and gas incorporation.

The plasticization process involves the rapid chilling and homogenization of a shortening mixture. Most shortenings are quick-chilled in closed thin-film scraped-wall heat exchangers with extrusion valves to deliver a smooth homogeneous product to the package at 17 to 27 atm pressure. Nitrogen is injected at 13 ± 1% into most shortenings to increase the product's workability and provide a white, creamy appearance. After packaging, many processors temper shortenings at temperatures slightly above the packaging temperature to allow the crystal structure of the hard fraction to reach equilibrium and form a stable matrix. After tempering, shortenings are usually stored and shipped at controlled temperatures of

70 to 80°F (21.1 to 26.7°C) to avoid crystal change and loss of the plastic properties [7].

P. Margarine Mixing, Chilling, and Packaging

Margarine was developed as and continues to be a butter substitute. It is a flavored food product containing 80% fat, made by blending selected fats and oils with other ingredients, such as milk, salt, color and fortified with vitamin A, to produce a table, cooking, or baking fat product that serves the purpose of dairy butter, but is different in composition and can be varied for different applications. Now, spreads have been developed as margarine substitutes. The major difference between spreads and margarine is that spreads are not required to contain a minimum of 80% fat.

Processing for margarines and spreads begins with the preparation of an emulsion of the ingredients. Emulsions are prepared by adding the oil soluble ingredients to a heated margarine oil formulation in an agitated emulsion tank. Concurrently, a pasteurized aqueous phase is prepared by mixing all of the water soluble ingredients together in another vat. The water phase is then added to the oil phase to make the emulsion. The emulsion is rapidly chilled with scraped-wall heat exchangers similar to those used for shortening products. The plasticized products are then formed into prints, or filled into the various containers for consumer, restaurant, or food processor use. Most margarine and spread products are stored at refrigerator temperatures immediately after packaging, with the exception of some specialized baking products [8].

Q. Flaking and Spray Chilling

Fat flakes describe the higher melting fat and oil products solidified in a thin flake form for ease of handling, quick remelting, or for a specific function in a food product. Chill rolls and processed oil formulations have been adapted to produce several different flaked products that can provide distinctive performance characteristics in specialty formulated foods. The flaked products, produced almost exclusively for restaurant and food processor consumers, are hardfats or stearines, shortening chips, icing stabilizers, confectioners fats, hard emulsifiers, and other customer-specific products.

The flake products are solidified on a chill roll, which has been described as an endless moving chilling surface held at a temperature below the crystallization point of the applied fat or oil product to form a congealed film on the outer surface. Specifically, chill rolls are usually 4 foot diameter hollow metal cylinders, in various lengths, with a machined and ground smooth surface, internally refrigerated, that revolve slowly on longitudinal and horizontal axes, with several options for feeding the melted oil onto the surface. After application, a thin film of liquid fat is carried over the roll, and as the revolution of the roll continues, the fat is partially solidified. With all chill roll designs, the solidified fat is scraped from the roll by a doctor blade positioned ahead of the feeding mechanism. Flakes are packaged in kraft bags, corrugated cartons with vinyl liners, or other suitable containers for storage and shipment [7].

Spray chilled or powdered fats are specialized products developed for ease of incorporation, handling, melting efficiency, uniform delivery with addition systems, encapsulation, and other special purpose uses. The spray chilling process consists of atomizing a molten fat in a crystallization zone or tower, maintained under temperature conditions where a very fine mist of the melted fat is contacted with cooled air or gas to cause crystallization without marked supercooling [8].

R. Bulk Fats and Oils Shipments

Food processors that use fats and oils in large quantities often have the facilities to handle this liquid ingredient in bulk. All of the products packaged for shipment and use can be provided to the customers in tank cars or tank trucks, except margarine and spread mixes, which contain milk and salt. The customers for these bulk products must have fats and oils bulk handling systems to receive, store, and handle the liquid products.

VI. U.S. EDIBLE FATS AND OILS CONSUMPTION

Climate and availability certainly influenced the eating habits of our ancestors. Inhabitants of central and northern Europe obtained their edible fats from animals, while people in southern Europe, Asia, and Africa acquired their edible oils from vegetable sources. The food products developed in these different regions used the available fats and oils products. Consequently, the cuisine of the central and northern Europe countries developed around the use of solid fats like butter, lard, and tallow for breads, pastries, and many other baked products. Similarly, the diets of inhabitants from the warmer climates were developed around liquid oils for food products like sauces, dressings, etc. These trends appear to continue to be the preference of their descendants.

Immigrants to the United States brought their food preferences with them and introduced them to others from different regions of the world. Fats and oils technology has further increased the varied and rich American diet by improvement of existing products and development of new food products. The resultant North American eating habits have made the U.S. a consumer of almost every available fat and oil. The American consumer is offered these fats and oils as a liquid oil, margarine, shortening, or as an ingredient in a prepared food product. The fourteen

major U.S. fats and oils sources are listed in Table 155.1, which reviews the annual usage of both animal and vegetable oils over the past 50 years [14–16].

Fats and oils consumption has been categorized into visible and invisible sources. Visible fats and oils are those isolated from animal tissues, oilseeds, or oil fruits and used for food preparation as shortening, margarine, or salad oil. Invisible fats and oils are consumed as part of meats, poultry, eggs, dairy products, fish, fruits, or vegetables, and account for approximately 60 percent of fat consumption. The pounds per person values reported in Table 155.1 are those from visible sources only. Visible fats and oils usage has more than tripled in the United States over the past 50 years, not only due to population increases, but also from increased consumption. Average per person consumption has increased by almost 50% during this period. The fats and oils usage data in Table 155.1 reflect some distinct trends: (a) a move away from animal fats to vegetable oils; (b) replacement of previously established fats and oils with different source oils; (c) introduction of new vegetable oils; (d) a rise and fall of some individual source oils; (e) source oil changes reflecting the results of medical studies; (f) introduction of new oil seed varieties; and more.

VII. EDIBLE FATS AND OILS UTILIZATION

Fats and oils are the raw materials for margarine, shortening, liquid oil, and other specialty or tailored products that become essential ingredients in food products prepared in the home, restaurants, and by food processors. Butter, lard, and tallow are fats that are used as raw materials for margarines or shortenings, as well as for direct use with little or no processing. The direct usage of animal fats has decreased considerably since 1950, as shown in Figure 155.2 [14,15]. Butter usage decreased 58% from 1950 to 2000. Lard and tallow direct use also had a substantial decrease (82.5%) through 1990, but rebounded for only a 53% overall decrease from 1960 to 2000. Margarine, developed as a butter substitute, has also experienced a decrease (40%) in popularity since 1980. Shortening usage more than doubled between 1950 and 1990, but slowed to only a 3.6% increase for the decade ending 2000. The usage rate for liquid oils almost tripled since 1950 to absorb all of the other fats and oils product losses and then some. Overall, the per capita fats and oils visible consumption rate

Fats and oils products, per capita consumption data

	1,950	1,960	1,970	1,980	1,990	2,000
Butter	8.6	8	5.3	3.6	3.5	3.6

Other	0	2	2.4	1.5	1.2	1.6

FIGURE 155.2 Fats and oils products per capita consumption during 1950–2000.

increased 63% for the last half of the twenty-first century, with a move toward liquid oils. The increased popularity of liquid oils is more than likely due to:

1. Diet modifications to reduce saturated fats, trans isomers, and cholesterol
2. Awareness of the high polyunsaturated or essential fatty acid content of liquid oils
3. More convenient handling of the liquid oils than that of solid fats
4. Improved product formulations and processes to accommodate liquid oils
5. Reduced dependence on the crystalline properties of solid fats for functionality through the use of emulsifiers

A. Shortening Products

Originally, shortening was the term used to describe the function performed by naturally occurring solid fats like lard and butter in baked products. These fats contributed a "short" or tenderizing quality to baked products by preventing the cohesion of the flour gluten during mixing and baking. Shortening later became the product identification used by all vegetable oils processors in the United States to abandon the lard substitute concept; hence, shortening was an American invention. As the shortening product category developed, the limited application also expanded to include all baked products. Today, in the U.S., shortening has become virtually synonymous with fat to include many other types of edible fats designed for applications other than baking. In most cases, products identified as shortening will be 100% fat; however, there are exceptions such as puff pastry and roll-in shortenings which may contain moisture. Generally, a fat product containing at least 80% fat and the required vitamin A content, is margarine. Products that do not meet this criteria have been identified as shortening since shortening does not have a U.S. Standard of Identity. Currently, a description for shortening would be: processed fats and oils products that affect the stability, flavor, storage quality, eating characteristics and the eye appeal of prepared foods by providing emulsification, lubricity, structure, aeration, a moisture barrier, a flavor medium, or heat transfer [8].

Most shortenings are identified and formulated according to usage. The packaged shortening forms that have emerged to satisfy the requirements of the consumers and the food industry are plasticized, pumpable liquid, flakes, powders, chips, and beads. Almost all of these shortening products can also be shipped to large customers in liquid bulk quantities. A brief description of each of the shortening forms follows [7]:

- Plasticized Shortenings - General purpose plasticized shortenings are still identified as all-purpose, unemulsified, emulsified, animal-vegetable blends, all vegetable, or the like; while the trend is to formulate foodservice and food processor shortenings to perform a specific function for the intended food product. These shortenings are also identified by their intended usage, i.e., a baking application such as cakes, icings, puff paste roll-in, and others; frying applications, specific dairy analog products, household use, and so on.
- Liquid Shortenings - The pumpable liquid shortening designation covers all fluid suspensions that consist of a hard fat, usually beta tending, and/or a high melting emulsifier dispersed in a liquid oil. This shortening type was developed to pour or pump at room temperature for volumetric measurement or metering for either packaged or bulk-handled products.
- Flakes - Hardfat, hardbutter, hard emulsifier, and stabilizer flakes are high melting fats- and oils-based products solidified into thin flake form for ease in handling and quick melting, and are used to perform many different functions in food products.
- Chips - Shortening chips are made thicker and larger than flakes for incorporation into baked products to provide a flaky product similar to danish pastry without the labor intensive roll-in process.
- Powders - The higher melting fats and oils products can be spray chilled to produce powders. Most of the products flaked can also be powdered for ease in handling or encapsulation of a food product for protection and/or delayed release in a finished food product.
- Beads - Shortening beads have irregular granular shapes that can be metered at more uniform rates with vibratory or screw feeders and resist stratification or separation in mixtures with other granular materials.

B. Margarine and Spread Products

Margarine is a prepared food product developed because of a butter shortage in France. Its evolution to a highly accepted table spread and ingredient for cooking, baking, and prepared foods is a prime example of fats and oils technology. Margarine has evolved from an imitation of dairy butter to a nutritive food which provides a concentrated source of energy, a uniform supplement of vitamin A, a source of essential fatty acids, satiety, a universally accepted flavor, and a compliment to other foods. United States FDA and USDA regulations define margarine as a plastic or liquid emulsion food product containing not less than 80% fat and 15,000 international units per pound of vitamin A, and may contain optional ingredients with

specific functions. The usual optional ingredients are water, milk or milk products, emulsifiers, flavoring materials, salt and other preservatives, and colorants.

Low fat spreads, originally introduced in the 1960s as diet margarines, are available with a multitude of fat levels between 20 and 70%. Low calorie and low fat marketing created a consumer interest in spreads after the diet margarines had been rejected by consumers for poor melting and eating characteristics. Functionally, the spread products are intended to be used as a tablespread or for cooking and most packages have a statement that the spread is not intended for baking or frying.

1. Consumer Margarines and Spreads

Margarine prints generally in quarter pound and one pound solids were the basic margarine products available until soft margarines were introduced in 1962. The soft margarines, with higher unsaturated fatty acid levels, were packaged in plastic tubs in both regular and whipped versions. The whipped margarines were easier to spread and provided less calories per serving due to the 30% nitrogen content. The nutritional appeal of the soft margarines was carried even further with the introduction of spreads, which began to capture market share in the 1970s; the spreads market share increased from less than 5% in 1976 to more than 74% in 1995.

The major uses for consumer margarines and spreads continue to be as a tablespread, cooking ingredient, seasoning agent. The consumer-directed functional aspects of the margarine and spread products are spreadibility, oiliness, and melting properties. Spreadibility continues to be one of the most highly regarded attributes of consumer margarine products, second only to flavor. Oil-off is the most serious for print products, as the inner wrappers become oil soaked and oil may even leak from the outer package. The melting properties of the margarine oil ingredient, the emulsion tightness, and the processing, tempering, and storage conditions which help determine crystal development and stability have a direct affect upon the mouth feel and release of the flavoring materials, as well as the consistency.

Scratch baking in the home decreased considerably with the introduction of good quality prepared mixes and frozen ready-to-eat products. Nevertheless, for any home baking, the U.S. consumer will usually choose shortening or a print margarine. Measurement of soft margarine requires a different scale than stick products because of the creaming gas content: 5% in regular and 30 to 35% in whipped soft margarines. Also, spreads have exceptionally poor baking functionality due to the high moisture/low fat content.

2. Industrial Margarines and Spreads

Foodservice and food processor margarine and spreads are usually considered industrial products. The most popular foodservice margarine is the consumer stick margarine formulation packaged in 1-pound solids, which is used for cooking and seasoning. Individual serving or portion control spread products are also popular foodservice dining room products. Additionally, a bakers' margarine formulated with an all-purpose shortening base is used by many foodservice kitchens for their baking requirements.

Food processor margarine and spread products are formulated for more specific uses than either the foodservice or consumer products. The stick margarine formulations are packaged in 50 pound cube cases for use in prepared foods. Margarines are also formulated and plasticized with Danish pastry roll-in capabilities, like the shortening products discussed in section V.A, to take advantage of the flavor, color and moisture incorporated into the emulsion. Spread type products were used by food processors before the consumer had accepted them, but for different applications. One of the applications is for self-basting of meat and poultry products during baking. Another is a biscuit topping with special dairy flavor notes and buttermilk curd. Others employ different flavors, spices, or other special ingredients for specific applications, products, or processes.

C. Liquid Oils

A liquid oil is usually identified by its physical state at ambient temperature, irregardless of whether the source material is animal, vegetable, or marine. Some source oils appear to disagree with this designation until the mean temperature at the place of origin is considered. For example, oil products from palm and coconut trees are a solid at ambient temperatures in cool climates, but a liquid at the prevailing temperatures in the tropical climates where these plants grow. Therefore, the definition of a liquid oil would be: any oil that is a clear liquid without heating.

Liquid oils are further classified by their functionality traits; cooking, salad, and high stability. The definition for each of these classifications is:

- Cooking Oil - An edible oil that is liquid and clear at room temperature, or 75°F (23.9°C), that may be used for cooking. Cooking oils are typically used for pan frying, deep fat frying, sauces, gravies, marninates, and other non-refrigerated food preparations where a clear liquid oil has application. Cooking oils usually congeal or solidify at refrigerator temperatures.
- Salad Oil - An edible oil that is suitable for the production of a mayonnaise or salad dressing emulsion and which is stable at low temperatures. This requirement has been refined to require that, in order to qualify as a salad oil, an oil sample must remain clear without clouding for at least 5½ hours while submerged in an ice bath.

- High Stability Oil - An edible oil that possesses an exceptional oxidative or flavor stability, and is a clear liquid at room temperature. The measure of oxidative stability used for high stability oils is the Active Oxygen Method (AOM) or AOCS Method Cd 12-57. High stability oils will withstand the AOM abuse for periods in excess of 75 hours, and some longer than 300 hours, as opposed to the 8 to 20 AOM hours for cooking and salad oils.

1. Consumer Liquid Oils

Cooking and salad oils available for home use are bottled and marketed through grocery stores and other retail outlets. The source oils available to the retail consumer are canola, corn, cottonseed, olive, peanut, safflower, soybean, sunflower, blends of these source oils, and some other specialty oils. Most of the oils are only refined, bleached, and deodorized, with the exception of those that require dewaxing or winterization to remain clear liquids on the grocery store shelves, like canola, corn, cottonseed, and sunflower.

A steady growth in the consumption of cooking and salad oils is evident from the USDA Economic Research Service statistics in the Oil Crops Situation and Outlook Yearbook. In fact, salad and cooking oils were the sole fats and oils growth area for the year 1997. The trend away from solid fats to liquid oils indicates that the U.S. consumer is reacting to the cautions of the medical profession regarding the relationship of fats and oils to coronary disease. As a result, consumers have replaced solid shortenings and margarines with liquid oils.

2. Industrial Cooking Oil Applications

Cooking oils are utilized wherever liquidity is permissible or important and the application does not require a clear liquid oil at cool temperatures. Cooking oils may be used for pan frying, deep fat frying, gravies, and other applications. Cottonseed oil has a unique flavor property that makes it a desirable frying oil for snack foods. Corn oil is regarded as exceptional in flavor and quality, with a healthy image for incorporation into processed foods, and also for snack foods frying. Peanut oil maintains a respectable cooking oil market for snack frying and foodservice frying operations, especially for fish and chips. Some of the other applications for cooking oils are packing canned meats and fish products, pan-release products, bread, buns, and sweet doughs.

3. Industrial Salad Oil Applications

Salad oils are required in most dressing products, sauces, and other food products prepared or stored at cool temperatures. Salad oils were developed for use in mayonnaise, and are a necessity for the preparation of other salad dressings, sauces, and other food products that are emulsions prepared at cool temperatures or must withstand clouding or congealing at refrigerator temperatures after preparation. Most of these products require high quantities of oil in the formulation, 30 to 80%, to provide the eating characteristics and consistency desired.

4. High Stability Oils

The primary prerequisites of a high stability oil is liquidity at ambient temperatures and resistance to oxidation. Most oils which are liquid at room temperature contain high levels of unsaturated fatty acids. They are most susceptible to oxidation, which limits application to products where an extended shelf-life is not a requirement. Technology has identified two techniques to enhance the stability of liquid oils: (1) hydrogenation and fractionation to separate the hard fraction from the liquid oil fraction, which retains a high stability, and (2) the use of plant bleeding techniques to produce liquid oils with very high monounsaturated fatty acid levels. The applications established for the high stability oils are [8]:

- Deep Fat Frying - The high stability oils have substantially increased frying stability by limiting the opportunities for oxidation due to the absence of polyunsaturates. Frying stability for the high stability oils is near the performance for heavy duty frying shortenings, with the convenience and fried food appearance of a liquid oil.
- Protective Barrier - Surface application to food products with the high stability oils provides protection from moisture and oxygen invasion, prevents clumping, and imparts a glossy appearance. Specific applications include raisins and other fruits, breakfast cereals, nut meats, snacks, croutons, bread crumbs, spices, and seasonings.
- Carrier - Colors, spices, flavors, and other additives may be blended in the high stability oils to preserve the flavor, color, and activity without development of off-oil flavors for long periods.
- Pan-release Agents - As a major ingredient in the preparation of oxidative stable spray or brushing lubricants for baking pans, confectionery products, and other materials.
- Food Grade Lubricants - The high stability oils are food grade alternatives to the mineral oil products for lubrication of equipment that contacts food products.
- Compatibility - Unlike solid fats, the high stability oils are compatible with all types of fats and oils since crystal type is not a concern.

156 Fat Hydrogenation in Food Processing

Jan Sajbidor
Faculty of Chemical and Food Technology, Slovak University of Technology

CONTENTS

Increasing the degree of saturation of fatty oils via hydrogenation is the most important process of the fatty oil industry, particularly in the production of edible fat products. This reaction makes possible the synthesis of food products such as shortening and margarine. Vegetable oils are too soft for margarines because of their liquid nature, while on the other hand saturated fats are too hard. Depending on the end use, most shortening fat systems require an intermediate hardness. Industries use this process to turn cheap oils into simulated butter products. Hydrogenation is an excellent process for consistency change and prolongs shelf stability. However**,** there are medical side effects due to the *trans* isomers produced that can cause many health problems if too much is consumed.

Hydrogenation of edible oils and fats are chemical processes in which hydrogen is added to double bonds of unsaturated fatty acids in lipid. Lipid is usually in the form of triacylglycerol, but other structures containing ethylenic linkages can be also hydrogenated [7]. The general aim of hydrogenation processes is to adjust their melting properties and improve their stability [32]. Besides fat and hydrogen, this process requires a catalyst — usually nickel deposited on a silicate support. Though already a classical process, widely applied since the early 20th century, it is not yet possible to a predict the molecular composition of the hydrogenated oil as a function of feed stock composition, catalyst type and concentration, reaction pressure, temperature and time. This is partly due to the complexity of the process, with a large number of hydrogenation reactions occurring in parallel, and partly due to the simultaneous occurrence of isomerization and double bond conjugation reactions. The complexity of the reaction is further illustrated by noting that the partial hydrogenation of soybean oil results in the production of a minimum of different linoleic, linolenic and oleic esters, the *cis* and *trans* forms of which could produce more than 4000 different triacylglycerols.

Understanding hydrogenation is important because it is a major reaction, which leads to many everyday products. Besides margarine and shortenings, hydrogenated oils end up in such things as ice cream, candy, chocolate, potato chips and baked goods.

I. HISTORICAL BACKGROUND

Although reactions involving catalytic hydrogenation of organic substances were known prior to 1897, the property of finely divided nickel to catalyze the fixation of hydrogen on hydrocarbon double bonds was discovered by the French chemist, Sabatier. Thus, unsaturated hydrocarbons in the vapor state could be easily converted into saturated ones when passing hydrogen gas over a catalytic metal. Soon after this report a liquid-phase hydrogenation of fatty oils was patented in 1903 in England by German chemist Normann [23] and this title was passed to the British firm Joseph Crossfield and Sons. In 1909, Procter and Gamble Company acquired the American rights to the Crossfield patents. Soon after that Procter and Gamble introduced its hydrogenated shortening, "Crisco," on the market.

The first hydrogenated products were a blend of totally hydrogenated cottonseed oil and refined liquid cottonseed oil. This created a product that had the consistency of lard but which was less likely to liquefy at warmer temperatures. The technique of partial hydrogenation was developed in the 1930s and it complemented the development of

a high-yield solvent extraction method to render fats from vegetables and seeds.

The advent of hydrogenation led to possibilities for a new branch of science — oleochemistry. In the mid-1930s, a stainless steel stirred autoclave for hydrogenating tallow fatty acids was constructed. One of the earliest, and still exceedingly important oleochemical products, was fabric softener, whose principal ingredients were fatty amines, manufactured by hydrogenating fatty nitriles derived from fatty acids. Esterification of fatty acids, followed by hydrogenolysis, produces fatty alcohols, another of the major products in the manufacture of oleochemicals.

II. BASIC PRINCIPLES OF EDIBLE OIL HYDROGENATION

The basic chemical equation for hydrogenation of an unsaturated carbon-carbon double bond is shown below. While it appears very simple, in reality it is extremely complicated.

$$-CH = CH- + H_2 \rightarrow -CH_2 - CH_2-$$

It includes the following steps:

1. Transfer and/or diffusion of individual reactants (unsaturated fatty acids and hydrogen);
2. Hydrogen adsorption on the surface of a catalyst;
3. Addition of hydrogen on double bonds accompanied with their *cis*/*trans* and positional isomerization;
4. Desorption of reactants from catalyst surface and *trans*fer to the bulk of liquid oil.

During a hydrogenation reaction three different modifications can occur:

1. A double bond can be changed to a single bond, e.g., changing a 2-polyunsaturated fatty acid into a monounsaturated fatty acid, or a monounsaturated fatty acid into a saturated fatty acid.
2. The location of the double bond can be moved up or down the fatty acid chain, and/or the configuration of the double bond can be changed to either *cis* or *trans*.
3. Highly polyunsaturated fatty acids are the most susceptible to the process of hydrogenation, as they contain more double bonds than other fatty acids.

Depending on the conditions applied during the process, hydrogenation can be classified as either a selective or non-selective process. Reaction selectivity is defined as the conversion of a diene to a monoene, compared with the conversion of a monoene to a saturate. The simple reaction model for triene hydrogenation was published by Bailey in 1949, and later mathematically defined by Albright [1]. This model considered each reaction to be first order and irreversible.

It could be used for measuring the relative reaction rate constants (K) for each hydrogenation step during the batch hydrogenation of oils containing triene fatty acids.

$$\text{Linolenic} \xrightarrow{K_1} \text{Linoleic} \xrightarrow{K_2} \text{Oleic} \xrightarrow{K_3} \text{Stearic}$$

$$Ll = Ll_0 e^{-K_1 t}$$

$$L = Ll_0 \left(\frac{K_1}{K_2 - K_1}\right)\left(e^{-K_1 t} - e^{-K_2 t}\right) + L_0 e^{-K_2 t}$$

$$Ol = Ll_0 \left(\frac{K_1}{K_2 - K_1}\right)\left(\frac{K_2}{K_3 - K_1}\right)\left(e^{-K_1 t} - e^{-K_3 t}\right) - Ll_0 \left(\frac{K_1}{K_2 - K_1}\right)\left(\frac{K_2}{K_3 - K_2}\right)\left(e^{-K_1 t} - e^{-K_3 t}\right) + L_0 \left(\frac{K_2}{K_3 - K_2}\right)\left(e^{-K_2 t} - e^{-K_3 t}\right) + Ol_0 e^{-K_3 t}$$

Where:
Ll_0 = concentration of linolenic acid in time t = 0
L_0 = concentration of linoleic acid in time t = 0
Ol_0 = concentration of oleic acid in time t = 0
K_{1-3} = relative reaction rate constants (K) for each hydrogenation step
t = time

In a theoretical sense, an oil hardened with perfect preferential selectivity would, first of all, have its linolenic acids reduced to linoleic acids before any linoleic was reduced to oleic acid; then all linoleic acids would be reduced to oleic, before any oleic acids were saturated to stearic acid. Unfortunately, this does not happen in the actual practice. For practical application, if the relative reaction rate constant calculated for linoleic to oleic divided by the reaction rate constant for oleic to stearic is 31 or above, the hydrogenation is termed selective, if below 7.5, it is non-selective.

Hydrogenation can be partial or complete. This reaction does not proceed at room temperature, and requires a catalyst to overcome activation energy. These catalysts can be heterogeneous, such as nickel, platinum, or palladium, or homogeneous, such as the Wilkinson's catalyst. These reactions give off heat, which can determine the degree of saturation and predict stability as well. Transition metal complexes make good catalysts, since they bring the reactants together and break the hydrogen bond. These reactions are stereoselective, in that the hydrogens are added in such a way as to predict the outcome.

Hydrogenation can take place only when the liquid unsaturated oil, the solid catalyst and the gaseous hydrogen have been brought together in a heated stirred reactor. Interaction between chemisorbed hydrogen on the catalyst surface and the double bond of fatty acyl is the first step of heterogeneous hydrogenation. Another hydrogen atom may add to the adjacent position and the saturated molecule is desorbed; or if there is no hydrogen atom available, hydrogen may be removed from a chain carbon atom by the catalyst. Addition of one hydrogen atom results in the opportunity of free rotation to reorient the geometry of the molecule from *cis* to the thermodynamically more stable *trans* configuration. Whether *cis* or *trans* is formed depends on the geometric positioning of the carbon chains attached to the double bonded carbons. The double bond in the original position may also be converted to *trans*. The double bonds in the new position may also be shifted. As hydrogenation proceeds, the isomerized double bonds tend to be shifted farther and farther along the chain, and the *trans* isomer content increased until the monoenes are saturated.

Hydrogenation of the polyunsaturated fatty acid chain is similar to that for the saturated fatty acid chain. During partial saturation of polyenes**,** besides hydrogenation of one double bond, the positional migration or *trans* formation of the other bonds can occur. Methylene-interrupted dienes on the catalyst surface can be conjugated or hydrogenated to saturated equivalent. If the mixture to be hydrogenated contains monoenes, dienes, and polyenes, there will be competition among the different unsaturated systems for the catalyst surface. By simple arithmetic probability, an ethylenic linkage from one of the more unsaturated esters will be preferentially adsorbed from the oil to the catalyst surface, isomerized and/or hydrogenated, and then desorbed to diffuse to the main body of the oil.

Factors that affect the hydrogenation and consequently the resultant products, are the temperature of the oil mixture, hydrogen gas pressure, catalyst activity, catalyst concentration, agitation of the mixture, and time duration of the process [7]. The degree of selectivity in hydrogenation also affects the crystal stability of the resulting fat. Commonly, the selective reaction conditions cause more isomerization to *trans* isomers and less stearic acid development to effect high solids at the lower temperatures [24]. Since the *trans* form of an unsaturated fatty acid has a higher melting point in comparison to the *cis* form, the occurrence of the *trans* form in the product helps to create desirable solid levels. Although it has a beneficial effect on the quality of the product, it also increases the risk of coronary heart diseases [27].

A study carried out by Yap [36] showed that selectively hydrogenated canola oil formed a mixture of beta-prime and beta crystals, whereas non-selective hydrogenation resulted in the beta form of crystals. Incorporation of *trans* fatty acids through selective hydrogenation favors beta-prime crystallization. Therefore, it becomes difficult to obtain desirable acceptability in terms of melting profile, low *trans*-acids, and favorable polymorphic behavior (and indirectly rheological behaviour) by sticking to only one technique of hydrogenation. Thus, hydrogenation conditions are manipulated to choose the most desirable set of processing parameters.

III. EFFECTS OF PROCESS CONDITIONS

In the hydrogenation process, the composition and properties of the final product depend on various operating factors. Temperature has a significant influence on the rate of hydrogenation, selectivity and *trans*-isomer production. It has been reported that selectivity is directly proportional to the temperature applied during hydrogenation [7]. This fact is the consequence of different activation energies for various hydrogenation reactions. Reduction of double bonds in the unsaturated fatty acid chain is an exothermal process. σ bonds formed between the carbon and hydrogen atoms are, together, stronger than the hydrogen-hydrogen σ bond and π bonds being broken. The heat of hydrogenation can be measured and is simply the amount of heat evolved when one mole of the unsaturated compound becomes hydrogenated. Increasing temperature accelerate**s** the rate of saturation and influence on hydrogen solubility of oil. The common temperature interval for partial catalytic hydrogenation of edible oils is between 160–210°C. High temperature of the oil during hydrogenation favors greater selectivity and thus results in more *trans* fatty acid generation.

Heat of hydrogenation is an important measure of stability. The *trans* isomer gives off the least amount of heat, while the hydrogenation of the terminal double bond gives off the most. The *cis* isomer is in the middle of the two. All three consume one mole of hydrogen and yield the same product. The *trans* isomer is usually more stable than the *cis* isomer because the substituents are farther apart in the *trans* isomer than in the *cis*, and it is sterically more favorable.

Among important factors influencing the hydrogenation process is the type of catalyst. Currently, the most widely-used commercial catalyst for edible oil hydrogenation is active nickel supported on an inert substance [6], [35]. High catalyst concentration favors selectivity with large amounts of *trans* isomer formation. There is, however, some concern about the toxicity of traces of nickel remaining in the oil [31]. Other catalysts including copper on silica [15], nickel–silver [17] or copper chromite [29] have been investigated. Noble metal catalysts are not generally used because of their high cost. However, their high activity in small quantity and the possibility of reuse with fixed bed reactors may offset the cost disadvantage. Palladium on carbon has been used for some commercial hydrogenation because of its high linolenic and linoleic activity at low temperature [22]. Platinum on carbon had been found to be highly active but with low selectivity

producing the saturated fat [5]. A more recent report [16] found that a modified platinum on carbon catalyst by incorporating a small amount of ammonia in the hydrogen has high selectivity with low *trans*-isomerization.

Rubin et al. [30] reported on the first mixed system containing both homogeneous and heterogeneous catalysts for edible oil hydrogenation. Using Ni and methyl benzoate chromium tricarbonyl [$MeBeCr(CO)_3$], they showed it was possible to retain the advantages of both catalysts while using them in combination. $MeBeCr(CO)_3$ is highly stereoselective toward *cis*-monoenes. However, because it hydrogenates via a cisoid mechanism in which methylene interrupted double bonds must be conjugated prior to hydrogenation, the reaction rate is limited by the slow conjugation reaction. When $MeBeCr(CO)_3$ was paired with Ni, minimal *cis–trans* isomerization was maintained while higher hydrogenation rates, more characteristic of Ni, were observed.

Polymer stabilized noble metal nanoclusters for selective hydrogenation of small molecule substrates such as unsaturated aldehydes and hydrocarbons have been studied [34]. These catalysts were also reported to possess high enantiomeric selectivity [38]. Polymer stabilized platinum has been found to have ~5 times higher activity than Pt/C with increased selectivity for partial hydrogenation of allyl alcohol at 25°C and atmospheric pressure. In general, metal nanoclusters have properties and activity that are quite different from the corresponding conventionally prepared supported and unsupported metal catalysts. Their potential as catalysts for selective hydrogenation for the oil and fat in the oleochemical industries is only scarcely being explored.

Hydrogen solubility in oil is directly proportional to its pressure. Mattil [19] reported that high hydrogen gas pressure during hydrogenation increased the rate of hydrogenation and caused a decrease in the selectivity of the reaction. Such conditions favor less TFA (*trans* fatty acids) formation. Change of hydrogen pressure from 103 to 310 kPa for example can reduce hardening time by at least 60%. All edible oils contain trace amounts of poisons deactivating reaction sites of catalyst. The minimum amount of catalyst necessary for their neutralization is called the threshold concentration. Once this threshold level has been reached, additional catalyst increases reactivity in a mathematically predictable manner. Under conditions of high temperature and pressure, a more than doubling of catalyst concentration (from 0.005% nickel to 0.0125%) increased the reaction rate above 50%. This is a very important factor in keeping solid catalyst in oil bulk and facilitating solubilization of hydrogen in the oil. Increases in the degree of agitation favors non-selectivity hydrogenation and suppresses the formation of high melting *trans*-isomers [3]. Beal and Lancaster [4] studied the effect of agitation and batch size on the rate of hydrogenation, and on the stability of the fat. They observed that the rate of hydrogenation increased with an increase in the degree of agitation of an oil or mixture of oils. Furthermore, the stability of the fats increased with an increase in the hydrogenation batch size. Achieving the optimum degree of mixing is not difficult in the laboratory; but it can be difficult in the plant.

Researchers conducting optimization tests of the hydrogenation process, have investigated reactor configurations [12], alternative energy sources such as microwave, magnetic, ultrasonic, etc., in addition to heat [11] or alternative sources of hydrogen, such as metal hydrides or soluble hydrogen donors [22]. In 1992, Yusem and Pintauro [37] developed an edible oil hydrogenation electrolytic process using atomic hydrogen produced at the cathode. Since hydrogen was generated *in situ* directly over the catalytic surface, it eliminated the need for enhancement of hydrogen transfer rates. As a result, high temperatures and pressures were not required.

IV. HYDROGENATED FAT IN HUMAN NUTRITION

The medical viewpoint of hydrogenation is strongly discussed, especially for the role of *trans* fatty acids (TFA). In 1993, a report published in Lancet by Willett et al. [35] an extensive study of more than 85,000 nurses concluded that women who ate four or more teaspoons of margarine a day had more heart attacks than women who rarely ate margarine. The main goal of this controversial study was the correlation of dietary vegetable oil-based *trans* fatty acids intake with coronary heart disease. The results started biochemical, toxicological and epidemiological research aiming to elucidate the real nutritional and health impact of *trans* fatty acids. On the other hand, it is known that cows' milk or dairy products contain *trans* isomers of fatty acids because of intestinal bacterial activity [18]. Depending on the diet, milk fat has 2–9% total TFA isomers vaccenic acid [28]. There are many other side effects of *trans* fatty acids including allergic reaction, arteriosclerosis, increased risk of cancer, decrease in insulin response, lowered quality of breast milk and slight immune dysfunction. Because of the effects of TFAs on the metabolism of gamma-linolenic and arachidonic acid [13], ingestion of *trans* isomers can affect the metabolism of prostaglandins and other eicosanoids and may alter platelet aggregation and vascular function as well [2]. TFAs also show competitive interactions with essential fatty acid metabolism (EFA) by inhibiting its incorporation into membrane phospholipids and reducing the conversion of EFAs to eicosanoids. In 1991 Koletzko [14] supposed that isomeric *trans* fatty acids could actually reduce tumor growth and metastasis. Up to the present time, there is little evidence that TFAs are related to the risk of cancer at any of the major cancer sites [10]. On the contrary, association between some forms of cancer in humans and the intake of hydrogenated vegetable fats has also been reported [8]. The general conclusion is that increasing the intake of TFAs (at expense of *cis* fat) does not produce an adverse outcome with respect to cancer risk.

It has been demonstrated that TFA ingestion increases low-density lipoprotein (LDL) cholesterol to a degree similar to that of saturated fats [20]. The increase in LDL concentration has been attributed in part to the down-regulation of the LDL receptor. In contrast to other forms of fats, *trans* isomers decrease high-density lipoprotein (HDL) cholesterol [9]. This can be responsible for a markedly increased risk for coronary heart disease, a relationship that is different and must not be confused with serum low-density or high-density lipoprotein (LDL or HDL) cholesterol levels [21]. *Trans* fatty acids can make platelets stickier, which increases the chance of a clot in a blood vessel. This is the cause of strokes, heart attacks and circulatory occlusions in other organs like the lungs.

Our body, fortunately, has natural ways to protect itself from massive TFA intake. There are certain enzymes which recognize the conformational difference and reject the *trans* fatty acids. Enzymes can refuse to use these molecules for processes for which they are not suited. Our brain is also protected from the *trans* fatty acids and, as well, an unborn child will have no exposure to the side effects imposed by them, as the placenta is impermeable to *trans* fatty acids [25]. Our body will also break them down as quickly as possible for energy use to ensure that the *cis* fatty acids are reserved for more important, vital roles.

Strong hydrogenation of soybean oil allows for the formation of variable small amounts of conjugated linoleic acids (CLA). They have been claimed to affect immunomodulation and body composition alteration, and to prevent or cure atherosclerosis and stomach, colon, skin, and prostate cancer. CLA has also been linked directly to increased insulin sensitivity, normalized glucose tolerance, improved hyperinsulinemia and lowered levels of circulating free fatty acids. Recent findings suggest that not only does CLA affect many different pathways, but that individual isomers of CLA act differently. Several studies have demonstrated that the *cis*-9, *trans*-11 isomer is responsible for the anticarcinogenic effects of CLA [26], [33]. Obviously, we have to wait for human clinical studies to confirm all these claims.

157 Manufacture of Asian (Oriental) Noodles

Shin Lu
Department of Food Science, National Chung Hsing University

Wai-Kit Nip
Department of Molecular Biosciences and Bioengineering, Univeristy of Hawaii-Manoa

CONTENTS

I. INTRODUCTION

The term "Asian (oriental) noodles" is used very broadly to describe mostly noodle-like products produced mainly in Eastern, Southeastern or Pacific Asian countries using common wheat flour, rice (or rice flour) or other starch materials as the main structural ingredient. Even though the terms "noodles" and "pasta" are often used interchangeably, they are technically different. The common wheat-based "Asian or oriental noodles" differ from the Western style pasta that uses durum wheat flour as the main structural ingredient. The term "noodles" also differs from the US definition of noodles that contains egg solids as part of the Standard of Identity, and readers for this chapter should be aware of these differences. At this time, there is no Standard of Identity for Asian (oriental) noodles in the USA.

Asian noodles vary considerably in size, appearance (color and shape), ingredients, chemical properties, and methods of manufacturing. These variables are introduced briefly in this chapter. There are a few excellent reviews on Asian (oriental) noodles available and readers should consult these references for further information (1–8). Factors affecting the production of these Asian (oriental) noodles are also studied to some extent, and some references are provided at the end of this chapter for further information (9–37). It will not be surprising that considerable amounts of literature in Japanese, Korean, and Chinese are also available, but not easily accessible at the time of this writing.

It is generally believed that noodles originated in China several thousand years ago, and the present day form of noodle was developed at least two thousand years ago. In the Chinese language, the term "mien (mian)" is used to describe noodle-type products (with a few exceptions in shape) made from common wheat flour (main structural ingredient). In fact, the Chinese character for noodles has "mia (wheat)" on its side as part of its character structure. Similar products made from rice, mung bean, and other ingredients are all grouped under the term "fen" (rice noodles), for example, "mi fen" (rice noodle), "tung fen" (mung bean threads), and "ho fen" (oily rice stripes). The Chinese character for "fen" is written with "mi (rice)" on its side as part of its character structure, indicating it originated from rice or starch material.

It is also believed that "mien" and "fen" spread from China to its neighboring countries. This is supported by the terms with similar sounds used in these

countries: "men" (Japan); "mie" (Indonesia); "mee" (Thailand, Singapore, and Malaysia), "Pho" (Vietnam).

II. SIZE CLASSIFICATION, TYPES OF WHEAT-BASED ORIENTAL NOODLES AND SOME CHEMICAL PROPERTIES

Table 157.1 shows the classification of "Asian noodles" in two ethnic groups with examples: Chinese and Japanese. The two classifications are similar.

Table 157.2 shows the appearance of various types of wheat-based oriental noodles with typical examples, components, and quality of cooked products. It should be noted that these are only examples, and they may fall into different categories when some ingredients are substituted or omitted. For example, Chinese cat's ear noodles can be made with or without buckwheat. When they are made with buckwheat, they fall into the brownish buckwheat category, and when they are made with just common wheat flour, they fall into the white-salted category.

Table 157.3 compares the basic chemical properties of some common wheat-based Asian noodles. The major properties include protein content in the wheat flour, amount of water used in making the dough, amount of salt used in the formulation, and presence or absence of alkaline agents (sodium and/or potassium carbonate). All these factors affect the eating quality of the final product. It is obvious, with the addition of alkaline agent(s), the pH of the final product will be shifted to the alkaline range.

The addition of alkaline salts to the formulation not only alters the pH and color, but also improves the water absorption properties of the final product. In addition, addition of alkaline agents improves the texture of the cooked product, making it more chewy with less of a tendency to soften and paste after cooking. The flavor of the cooked product is also typical of an alkaline odor. The majority of consumers in Hong Kong, for example, prefer this type of Asian (oriental) noodles to the common white-salted noodles. However, the reverse is true for most of the consumers in central and northern China.

Oil is used to coat a few freshly-made oriental noodle-type products (see below). For instant noodles, the range of oil content in the final product depends on whether the noodles are oil-fried after steaming.

TABLE 157.1
Classification of Wheat-Based Noodles from Two Ethnic Groups

Ethnic Group	Class	Examples
Japanese	Very thin noodles	Somen
	Thin noodles	Hiya-mugi
	Standard	Udon
	Flat noodles	Kishi-men, Hira-men
Chinese	Very thin noodles	Longxu mian (China), Yinsi (silver threads) mien (Hong Kong)
	Thin noodles	Xi mien (China, Hong Kong, Taiwan)
	Flat noodles	Yangchun mien (China) Kuan (broad) mien (China, Taiwan)
	Wide flat noodles	Dai mien (China) Cu mien (China, Hong Kong, Taiwan)
	Thick noodles	Cu mien [Shanghai (China)], similar to Udon

III. GENERAL PROCEDURES IN THE MANUFACTURE OF WHEAT-BASED ASIAN (ORIENTAL) NOODLES

In general, wheat-based Asian (oriental) noodles are made by sheeting and rolling procedures in small factories

TABLE 157.2
Comparison of Major Types of Dry Wheat-Based Noodles

Types	Typical Examples	Components	Quality of Cooked Product
White-salted	Japanese udon Regular plain noodles	Common wheat flour, salt, water, egg (optional)	Soft, elastic texture and smooth surface
Yellow-alkaline	Cantonese-type noodles Taiwanese-type noodles	Common wheat flour, water, alkaline salts (sodium and/or potassium carbonate), salt (optional), egg (optional), yellow coloring (optional)	Firm, chewy, springy texture, and bright yellow appearance
Brownish buckwheat	Japanese soba, Chinese cat's ear noodle	Buckwheat flour, water, limewash or alkaline salts (optional), salt (optional), yam flour (optional)	Firm, chewy, tender texture
Instant	Japanese ramen, Cantonese E-mien (deep-fried noodle)	Common wheat flour, water, salt, alkaline salts (optional), oil/fat (optional),	Elastic, chewy
Savory	Cantonese shrimp egg noodle, Imitation	Common wheat flour, salt, water, alkaline salts (optional), savory ingredients	Firm, chewy, springy texture, color dependent on savory ingredient used

TABLE 157.3
Chemical Properties of Various Types of Dry Wheat-Based Noodles Ingredients

Types	Protein in Flour	Water Added	Salt Added	Alkaline Agent(s)	pH	Oil Added
White-salted	8 to 10%	30 to 35%	2 to 3%	No	6.5 to 7	None
Yellow-alkaline	10 to 12%	30 to 35%	Variable	Yes	9 to 11	None
Brownish buckwheat (60–70 parts common buckwheat to 30–40 parts wheat flour)	12 to 14 %	45 to 48%	Variable	Yes/No	6–5 to 7	None
Instant	8 to 12%	30 to 36%	Variable	Yes/No	6.5 to 7	15 to 21.5% (fried-type)
Savory	10 to 12%	30 to 35%	Variable	Yes/No	9 to 11% (alkaline type) 6.5 to 7% (regular type)	1.5 to 1.8% (dried type)

that is different from the extrusion procedure used commonly in the production of pasta (see chapter on dried pasta in this handbook). Figures 157.1–157.7 show the activities in the production of the dough, sheeting, rolling, and cutting of the dough sheets into noodle stripes. It should be noted that dough development is achieved to some degree in these sheeting and rolling processes (Figure 157.4).

FIGURE 157.5 Double rolling of dough sheets to form the gluten structure.

FIGURE 157.6 Connecting the upper rolls of dough sheets to the bottom roller.

IV. MANUFACTURE OF DRY ASIAN (ORIENTAL) WHEAT- AND RICE- BASED NOODLES

Dry Asian (oriental) noodles are common products with the advantages of stability and being easy to transport. However, they take a longer time to cook than the fresh product. Examples of selected wheat-based and rice-based Asian (oriental) noodles are described below with comments.

A. Wheat-based Noodles

The majority of Asian (oriental) noodles are sold in the dry form in plastic/cellophane wrappings or in cardboard boxes with cellophane wrapping. Chinese people are the major consumers of Asian (oriental) noodles, especially the regular white-salted and rice noodles.

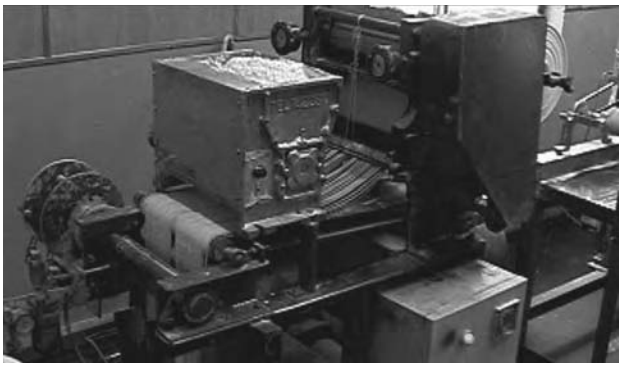

FIGURE 157.7 Cutting of dough sheets into raw noodle stripes.

Table 157.4 is a generalized scheme for production of dry noodles in China. It should be noted that savory-type noodles are also available in many varieties. The generalized scheme for production of dry noodles is a procedure that involves mixing, resting, sheeting, rolling, cutting, and drying. Similar products, such as Japanese somen, udon, and buckwheat sobo are produced in a similar manner, except that in some cases, extrusion procedures are used instead of sheeting and rolling.

Table 157.5 describes a procedure used in Taiwan to produce dry "La Mien" (stretched noodles). Making traditional "La Mien" (hand-swung noodles) manually is a very skillful technique (see below), accomplished by swinging the dough into very thin noodles. The "La Mien" thus produced is usually consumed right away by cooking in boiling water, followed by addition of seasonings, soup and other ingredients. However, due to the popular demand of such products, a dry form has been developed by varying the manufacturing process from hand-swinging to manually stretching, and the La Mien thus produced is dried for easy transportation and long term storage. It also can be produced in much larger quantity than the traditional hand-swinging process. Figures 157.8 to 157.15 show the unique operations in the production of dry Taiwanese La Mien (hand-stretched noodles) in a small factory.

Table 157.6 is a generalized production scheme for dry Taiwanese Yi-mien, an alkaline-type noodle with the addition of alkaline agent(s). This production scheme is also similar to that for Cantonese alkaline noodles except for the ingredients used (egg is used fairly commonly for Cantonese alkaline noodles) and the addition of a shaping process (also a common procedure in Cantonese alkaline noodles). Shaping is not common in other forms of oriental noodles except instant noodles. Figure 157.16 shows the sun drying procedure in the production of Taiwanese Yi-mien in a small factory.

Deep-frying the freshly-made noodles not only removes the moisture, but also cooks and alters the structure of the final product. The frying process makes the structure very porous, allowing it to more easily absorb

TABLE 157.4
Generalized Scheme for Production of Dry Wheat-Based Noodles in China

Weigh out the basic ingredients:
- wheat flour (100 parts)
- water (25–32 parts, dependent on gluten content of wheat flour, at 30°C)
- salt (2–3 parts)
- alkaline agent (optional, 0.1 to 0.2% of flour weight)

Weigh out additional ingredients (optional):
- Egg – 10% of flour weight (fresh egg); 8% of flour weight (frozen shelled egg), or 12.5% of flour weight (egg powder)
- Milk – 14 to 25% (fresh milk), or 2 to 3% (milk powder)
- Dried meat floss – 5% by flour weight plus 3% salt
- Tomato sauce – 5%
- Soymilk – made from 15 kg soybean for each 50 kg of flour
- Fish stock – made from 2.5 kg of fish plus 1 kg salt for 50 kg of flour
- Mung bean milk – made from 15 kg mung bean for each 50 kg of flour
- Chili powder – 1.5% by weight of flour plus 3% salt
- Monosodium glutamate (MSG) – 0.5 to 1.0%
- Egg white
- Egg yolk
- Butter
- Beef powder
- Prawn meat
- L-lysine hydrochloride
- Chicken broth
- Spinach juice
- Calcium powder

Mix up the flour, water, and other ingredients fully for 10–15 minutes to allow for hydration of the protein, starch, and other biological components to a uniform-colored, crumbly mixture without any pockets of dry flour. Linear velocity of dough mixer is adjusted to 2–3 m/sec.

Rest the dough for 10–15 minutes by mixing at low speed of 0.6 m/sec (10 rpm) at room temperature.

Sheet and roll the dough 6 to 7 times to reduce the dough to desirable sheet thickness (0.6, 0.8, 1.0, or 1.5 mm).

Cut the dough sheets to desirable width (0.8 to 1.0, 1.5, 2.0, 3.0, or 6.0 mm).

Dry the noodle stripes at a temperature below 50°C for about 2 hours, or at 38°C for about 7.5 hours (at controlled relative humidity between 70 to 80 %), or at 45°C for 3.5 hours (at 80% relative humidity) to 13.5 to 14% moisture content.

Machine-cut the dried noodles.

Weigh the noodles at 250 or 500 g each.

Pack the weighed noodles into appropriate plastic bags, followed by sealing of the bags.

Adapted from Refs. 3, 4, 5.

boiling water. The fried product puffs up and expands considerably during the frying process. This makes the final product very easy to rehydrate in the cooking process, generally in a matter of seconds after putting it into boiling water. Cantonese E-mien (E-fu-mien) has been a delicacy among the Cantonese community for decades. It is now available in regular laminated packs or

TABLE 157.5
Generalized Scheme for Production of Dry Taiwanese La Mien (Stretched Noodles)

Weigh out appropriate amount of medium strong wheat flour (9–10% protein)

Weigh out appropriate amount of salt (6%)

Mixing of the wheat flour and salt with appropriate amount of water (32–36%)

Sheet the dough and cut the sheets into threads

Coil dough threads onto two sticks (like spinning cotton into yarn) 20 cm apart, followed by stretching to 40 cm and then 60 cm, respectively

At 60 cm in distance, age the noodle stripes are aged (matured) for 2.5 hours

Stretch the noodle stripes again to 120 cm in distance

Sun dry or mechanically dry the noodle stripes to about 30% moisture

Fold the noodle stripes 4 times

Further reduce moisture content to about 13%

Packaging of final product in plastic or laminated packages

FIGURE 157.8 Dough stripes in a bowl.

FIGURE 157.10 Coiling the dough stripes on two sticks 20 cm apart.

FIGURE 157.11 Extending the noodle stripes to 40 cm apart.

FIGURE 157.12 Extending the noodle stripes to 60 cm apart.

FIGURE 157.13 Extending the noodle stripes to 120 cm apart for sun drying.

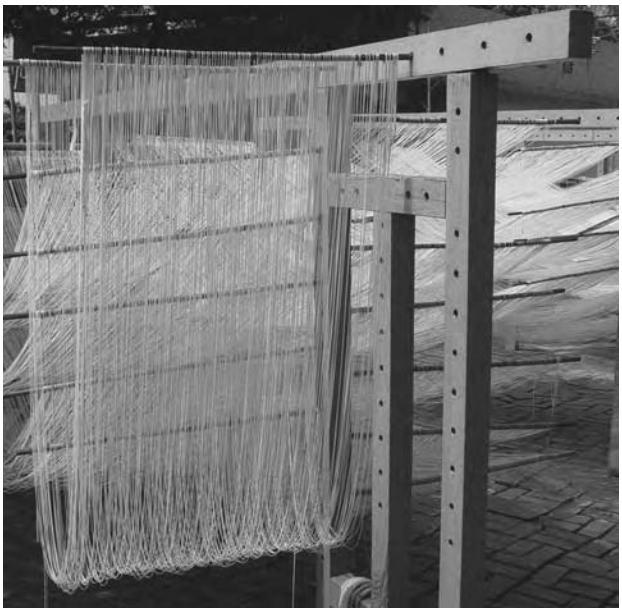

FIGURE 157.14 Partially sun-dried noodle stripes folded back to 60 cm apart.

as a vacuum-packed product in supermarkets in the US. It is also available as a freshly-made product directly from the factory. Table 157.7 shows a generalized production scheme for Cantonese E-mien (E-fu-mien).

Nissin Foods Company in Japan first invented Instant Chicken Ramen (noodles) in 1958, and packaged in laminated/cellophane pouches. This product that can be rehydrated in a bowl with boiling water in 3 minutes. It is produced by first steaming the noodle portions, followed by

FIGURE 157.15 Partially sun-dried noodle stripes folded back to 30 and 15 cm (final), respectively.

TABLE 157.6
Generalized Scheme for Production of Dry Taiwanese Yi-Mien

Weigh out appropriate amount of strong wheat flour (>11% protein)
Mix the four with 0.4 to 0.6% alkaline agent (sodium and/or potassium carbonate) and water to form a weak dough
Cover the dough and leave the dough for maturation for about 30 minutes
Sheet and roll the dough to desirable thickness (about 2–3 mm)
Fold the dough into plates of dough sheets
Cut the multi-layered dough sheets to make the noodle stripes
Noodle stripes are then shaped and sun-dried or mechanically dried to about 13% for long term storage (*see* also scheme for Taiwanese La Mien production)

FIGURE 157.16 Sun drying of Yi-mien on bamboo trays to reduce the moisture for long term storage.

brief frying in tropical oil. The seasoning was packed in a small packet. The fried noodle and the seasoning then were packed in a laminated/cellophane pouch. This form of package was later improved by using Styrofoam cups. However, both types of packaging are available today. Because of the concern in consuming tropical oils, a modified production process of drying the steamed noodles instead of frying was introduced. A separate packet of oil is included in the package for optional use by the consumer. Various flavors are available now. Table 157.8 is an example of a generalized production scheme for instant noodles in Taiwan, adapted from the Japanese procedure.

TABLE 157.7
Generalized Scheme for Production of Cantonese E-Mien (Deep-Fried Noodles)

Weighing of ingredients [wheat flour (medium strength), salt, water, egg (optional, potassium carbonate (optional)]
Mixing of dry ingredients for a short time
Adding water to adjust moisture content to about 36%
Mixing of dough for 10–15 minutes
Sheeting the dough through sheet rollers to reach 1–2 mm in thickness
Cutting of sheeted dough to strips of 1 mm in width to form long strings of noodles
Weighing of noodles to standard portions
Frying of noodle portions in a continuous oil fryer
Cooling of oil-fried noodles
Packaging of fried noodles into cellophane bags, cardboard boxes, or Styrofoam trays then wrapping with cellophane

TABLE 157.8
Example of Generalized Process for Dry Instant Noodle Manufacturing in Taiwan

Weighing of ingredients [wheat flour (medium strength), salt, water]
Mixing of dry ingredients for a short time
Adding of water to adjust moisture content to about 36%
Mixing of dough for 10–15 minutes
Sheeting the dough through sheet rollers to reach 2 mm in thickness
Cutting of sheeted dough to strips of 1 mm in width to form long strings of noodles
Weighing of noodles to 100 g portions
Steaming of portioned noodles for 2–3 minutes in temperature-controlled steamer (95°C)
Frying of steamed noodle blocks at 150°C for 1.5 minutes in a continuous oil fryer (fried-typed instant noodles) (net weight 80 g)
or
Drying of steamed noodle blocks in controlled temperature chamber to 80 g net weight
Cooling of oil-fried or dried instant noodle
Packaging of fried or dried noodles in plastic/cellophane bags, or Styrofoam cups
Adding packages of seasonings (dry, wet, and/or oils) into container
Sealing of container

The Instant Ramen developed by Nissin Foods Company was well accepted by the Japanese. It expanded its operation into other countries in the late 1960s and early 1970s. It is one of the most popular snack or regular meal items in many countries. Currently, instant rice noodles ("mi fen") are also available.

In comparing the production schemes for Cantonese E-mien and instant noodles, the instant noodle process can be considered as an improvement of the Cantonese E-mien process, as the noodle volume of instant noodle remains essentially the same, as compared to the expanded volume in Cantonese E-mien (3–4 times). This has the advantage of much smaller product volume. Also, seasoning are included in the product package. In addition, dried and not fried instant noodles are available. This satisfies the health-concerned consumers. However, Cantonese E-mien has the advantage of much reduced cooking time and unique texture. It probably will remain as a unique cuisine-type product, as compared to the instant noodles which are part of the mainstream food chain.

B. Rice-based Dry Asian (Oriental) Noodles

Rice noodles ("mi fen" or rice sticks) are a deviation of Asian (oriental) wheat-based noodles in that rice is the basic structural component. In addition, traditional procedures for the production of rice noodles involve the wet-milling of rice to remove the soluble constituents in the rice kernel, and the gelatinization of the rice starch. This process is tedious, and involves the problem of liquid waste disposal, even though it is not high in biological oxygen demand. A modified procedure is to use rice flour directly instead of the wet-milled rice flour, thus avoiding the liquid waste disposal problem. It should be noted that dry milled rice flour is not the same as the wet-milled rice flour, and the quality of the final product is not expected to be the same. It is generally believed that wet-milled rice flour has a smoother texture after gelatinization. Table 157.9 describes the general steps involved in the production of dry rice noodles. Consumers should be aware that in recent years, some manufacturers have begun to use corn starch or other starches partially or completely instead of rice flour to make similar products, and still call them "rice sticks." They have similar properties, but are not as good as the original rice noodles (rice stick).

TABLE 157.9
Generalized Scheme for Production of Dry Rice Noodles in Taiwan

Process A
Clean polished high-amylose rice to remove foreign matters
Soak rice kernels in water for 3 hours
Grind the soaked rice into a slurry with a suitable amount of water, avoiding the production of excessive damaged starch granules
Pour the rice slurry into a cloth bag and press the filled bag with a mechanical press to remove water
Mix the de-watered rice solids in a heated mixer for 50 minutes and partially cook the rice solids to a soft mass (addition of corn starch and/or wheat is optional)
Mix the soft rice mass a second time to further soften
Transfer the soft rice mass to a presser to form thick sheets, followed by extruding the sheets into rice noodles, cooling and loosening the extruded rice noodles immediately to avoid sticking together.
Steam-cook the extruded rice noodles for about 50 minutes
Cut the cooked rice noodles with a knife when still warm
Shape the cut rice noodles into bundles or blocks
Load the shaped rice noodles onto trays in carts
Mechanically dry the shaped rice noodles for 8 hours
Cool thoroughly before packaging into specific containers for retail or storage
Process B
Instead of soaking, grinding, and de-watering the rice, rice flour is used directly in mixing and partial cooking
The rest of the steps are essentially the same as Process A

V. MANUFACTURE OF FRESH ASIAN (ORIENTAL) WHEAT- AND RICE-BASED NOODLES

Considerable amounts of fresh Asian (oriental) noodles are produced for the retail market, restaurant trade, and at a household level. The makings of some of these products are described below.

Won Ton Mien is one of the alkaline wheat-based noodles produced for the fresh retail markets common in Taiwan. Similar products are also produced elsewhere. The production steps are similar to production of dry white-salted noodles, with basic mixing, sheeting, rolling, and cutting steps. It should be noted that a differently-shaped product called "pian er mien" (sheeted mien) is produced by similar procedures with or without alkaline salts; instead of cutting the dough sheets into thin stripes, the sheets are cut into about 1 inch squares. Also, the fresh Won Ton Mien can be dried into dry Won Ton Mien, like the other wheat-based "mien." Table 157.10 describes the basic steps in the production of Taiwanese Won Ton Mien. Figures 157.17 and 157.18 show the typical operation procedures in its production.

Fresh oily wheat-based "mien" are unique, in that oil is added to the cooked "mien" or "fen" to provide a special mouthfeel and *al dente*. They are common in southern China and southeastern Asian countries. The oily, alkaline wheat-based "mien" are sometimes called Hokkien-type noodles. The procedures for preparing the raw "mien" are essentially the same as other alkaline wheat-based "mien." They are then boiled once or twice, or steamed until they are completely cooked before coating with oil and food coloring. Table 157.11 describes the procedures of manufacturing Taiwanese oily wheat-based noodles in a small

TABLE 157.10
Generalized Scheme for Production of Fresh Taiwanese Won Ton Mien

Weigh out appropriate amount of strong wheat flour (>11% protein)
Mix the four with 0.35% alkaline agent (sodium and/or potassium carbonate) and water to form a weak dough
Cover the dough and leave for maturation for about 30 minutes
Sheet and roll the dough to desirable thickness (about 1 mm)
Fold the dough into plates of dough sheets
Cut the multi-layered dough sheets to make the noodle stripes or noodle squares
Noodle stripes and noodle squares are then sold fresh

FIGURE 157.17 Sheeting of dough to 1.0 mm thick sheet.

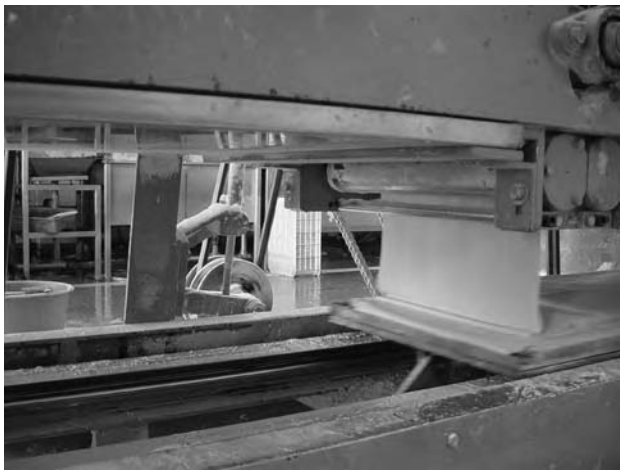

FIGURE 157.18 Dough sheets folded back and forth before cutting.

factory. Figures 157.19 to 157.22 show the unique steps in the manufacture of such product.

Another oily product is the Cantonese oily rice-based "ho fen" (rice stripes). It is produced first by preparing a rice

TABLE 157.11
Generalized Production Scheme for Fresh Oily Noodle Production

Weigh out appropriate amount of medium strong wheat flour (9–10% protein)
Weigh out appropriate amount of sodium carbonate (about 0.35 to 0.5%)
Mix wheat flour and sodium carbonate with water (about 32–36%) to make a weak dough
Leave the dough for maturation for about 30 minutes
Sheet and roll the dough to desirable thickness (about 2 mm)
Cut the dough sheets into noodle stripes (about 2–3 mm wide)
Steam the noodle strips for about 1.5 minutes until the noodle stripes are completely cooked
Cool the cooked noodles to room temperature
Mix the cooked noodles with small amounts of yellow coloring and liquid oil
Package the oily noodles in suitable containers for marketing

FIGURE 157.19 Cutting of dough sheets into noodle shape.

FIGURE 157.20 Cut noodles on conveyor belt.

FIGURE 157.21 Cooling of cooked noodles for a short time in a water bath.

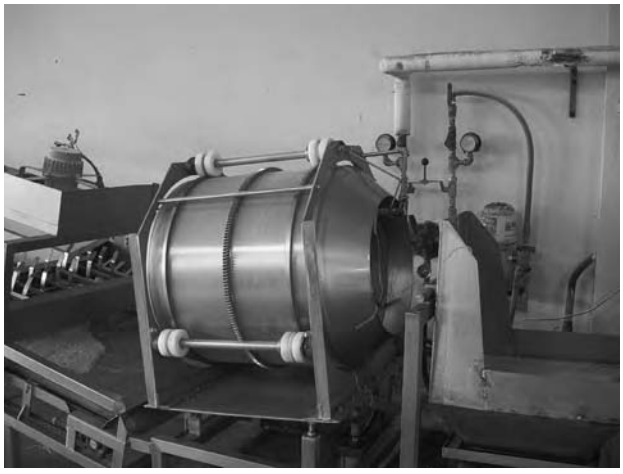

FIGURE 157.22 Mixing of cooked noodles with liquid oil in a rotating drum.

slurry from rice flour, followed by steaming a thin layer of the slurry on an oil-coated stainless tray or bamboo sheet. The gelatinized "fen" is then folded into layered slabs, followed by cutting of the slabs into stripes. These noodles are much thicker and broader than the Chinese "hand-cut mien" (see later) or Japanese "udon." Oily rice-based "ho fen" is very soft and smooth in texture. The granular size of rice flour used has a definite effect on the quality of the final product, as the difference in granular size can be detected easily. The original "ho fen" was made with wet-milled rice flour with a very fine texture. However, it is much more costly to make, and has the liquid waste disposal problem similar to dry rice noodles (rice sticks). Table 157.12 describes the basic steps in the making of Cantonese "ho fen."

Original Chinese hand-swung La Mien (La Mian) was made by skillful masters or chefs. They are considered a delicacy, as they take skill to make. The hand-swung La Mien is considered a fresh "mien," as it is cooked right after making. The addition of alkaline agent(s) is optional. Table 157.13 describes the procedures used in the making of hand-swung La Mien. It should be noted that the process can be modified to make the production less labor intensive, as described earlier.

TABLE 157.12
Generalized Production Scheme for Fresh Cantonese Oily "ho fen" (Thick Rice Stripes)

Prepare a rice slurry with rice flour and water.
Put a small amount of oil on stainless or bamboo trays to coat the trays evenly.
Pour rice slurry on the trays to form a thin layer (about 1–2 mm thick).
Place the trays on racks in the steamer.
Steam the trays of thin layers of rice slurry to gelatinize the starch.
Remove the trays from the steamer and cool.
Roll up the gelatinized rice sheet from each tray with a spatula (about 10 cm in depth).
Cut the layered rice sheets into 1 cm wide stripes ("ho fen").
Wrap the rice "ho fen" in paper.

TABLE 157.13
Generalized Scheme for Production of Hand-Swung La Mien in China

Weigh out medium strong wheat flour (about 10% protein, 1 kg), salt (20 g), water (550 g), and sodium carbonate (10 g)
Put wheat flour in a bowl
Dissolve salt in 500 ml (500 g) water with temperature at about 25°C (summer) to about 35°C (winter)
Add salted water gradually to the flour
Mix wheat flour and salted water to a crumbly consistency and knead the dough until uniform
Cover the dough with a clean cloth and rest for 30 minutes at 20–30°C
Dissolve sodium carbonate in 50 ml (50 g) water
Add the sodium carbonate solution to the rested dough and knead the dough until the sodium carbonate solution is uniformly distributed into the dough
Roll the dough into a long rope
Hold each end of the dough rope with each hand and swing the dough rope up and down
The elongated dough rope is folded and twisted
Repeat the swinging, folding and twisting 6 to 7 times to create a uniform dough piece
Place the dough piece on a table and dust the dough rope evenly with wheat flour
Hold the two ends of the dough rope with one hand and insert the four fingers of the other hand into the loop
Stretch by gently shaking the rope until the rope is 10–16 cm long
Repeat the dusting and stretching until 6 stretches with 64 strands of La Mien is achieved (for very thin La Mien, up to 12 stretches are used)
The La Mien then can be put into boiling water for a few minutes before consumption by mixing with other ingredients

Adapted from Refs. 1, 4, 5.

Noodles of various shapes other than the traditional stripes are made commonly by the Chinese people, especially those in the rural areas in the northern provinces. Table 157.14 describes three common Chinese hand-cut "mien." The addition of whole egg, egg white, or egg yolk is optional, depending on consumer preference in different locations. The hand-sheeted and cut noodle is the most common. "Cat's ear mien" and "knife-cut mien" are less common, and are considered specialty products. It should be noted this "knife-cut mien" has a thicker center, providing a special *al dente* texture.

VI. MANUFACTURE OF PRE-COOKED ASIAN (ORIENTAL) NOODLES

In recent years, precookd, ready-to-eat udon in sterilized pouches has been available. The cooked udon is sealed with water in pouch-type containers with lactic acid or sodium benzoate used as preservatives, and sterilized for long term storage.

Frozen precooked "saimen" (alkaline noodles) have also been available for some time. The "saimen" is precooked in water or steamed, cooked, cooled, packaged and sealed in plastic bags before freezing. The shelf-life of this product is good.

TABLE 157.14
Generalized Scheme of Hand-Cut Wheat-Based Noodles

Hand Sheeted and Cut Noodles
Weigh out special wheat flour (1000 g), cold water 400 g, and potato starch (50 g)
Mix the flour with cold water to make a dough
Knead the dough to a smooth and even condition
Flatten the dough with a rolling pin on a smooth surface into a rectangular shape by rolling in different directions to extend the dough evenly
Dust the dough sheet with potato starch
Repeat the rolling and dusting several times to stretch the dough to about 3 mm thick
The dough sheet is then folded accordian-like before cutting to 1.5 mm wide
The noodles are shaken to remove the potato starch
The noodles are then cooked in boiling water until done before consumption by mixing with other ingredients
Cat's Ear Noodle (Mao-er-dao)
Procedure similar to above for making dough
Cover the dough with a damp cloth and let stand for 20 minutes
Sheet and roll the dough to 1 cm thick
Cut the sheets into 5 cm parallelograms or squares
Pinch the small slanted squares into the shape of a cat's ear before cooking in boiling water
Knife-Cut Noodles (Dao Xian Mian, Paring Noodles with a Knife)
Weigh out appropriate amount of wheat flour (e.g., 600 g)
Mix the flour with appropriate amounts of salt (5 ml) and water (10 ml)
Knead the wheat flour, salt and water into a stiff dough cylinder
Hold the dough cylinder in one hand and pare long noodle stripes out of the dough with a knife. (Note: The stripes are not of even thickness, thicker in the center and thinner on the sides.)
Cook the noodle stripes in boiling water

Adapted from Refs. 3, 4, 5.

VII. MANUFACTURE OF SELECTED NON-WHEAT- OR RICE-BASED ASIAN (ORIENTAL) NOODLES

For decades, there have been products on the market that are made from materials other than wheat or rice, but are included in the Asian (oriental) noodle category. Table 157.15 lists some of these examples with their ethic origin and main ingredients. These products are sometimes called "starch noodles" as they are made from starch of various origins.

One of the most fascinating Asian (oriental) noodles made from materials other than wheat or rice are mung bean threads, sometimes called cellophane or transparent noodles by Westerners. This product has the unique property of being transparent like clear cellophane after it is cooked. The best mung bean threads can stay in their original shape and remain intact for about 2 days after being cooked and kept in the soup. This is because of their unique starch gelling properties, which also provide very good *al dente* properties. Table 157.16 describes the procedures used to make traditional mung bean threads.

True (pure) mung bean threads are made from mung bean only. However, the products today on the market may contain mung bean and other starch materials like broad beans and other starches. The bottlenecks of making true mung bean threads include the intensive labor required and liquid waste disposal. The liquid waste is fairly rich in nutrients as it contains all the vitamins, minerals and proteins in the mung bean. In the past, this waste was used as animal feed. Attempts have also been made to recover the protein from this liquid waste. Because of these problems, it is understandable that materials other than mung beans, and improvements in technology are being considered.

Korean sweet potato vermicelli ("dang myun") is a product similar to mung bean threads with transparency after it is cooked. However, the vermicelli is colorless, but kind of light brownish green. It also has very good *al dente* properties. Japanese "harusame" is also a similar starch noodle product as it is made also made from starches from potato, sweet potato, rice or mung bean.

Another unusual Asian (oriental) noodle is the translucent Japanese "Shirataki" noodle made from devil's tongue yam (elephant yam or konjac/konjak yam). This product is marked as a form different from others. It stays in liquid in a sealed container, is pasteurized and has to be kept refrigerated. This product is considered a low-calorie

TABLE 157.15
Oriental Noodles Made from Materials other than Wheat Flour and Rice Flour

Name	Ethnicity	Main Ingredient(s)
Bean threads	Chinese	Mung bean starch
cellophane noodles		
transparent noodles		
Chinese vermicelli		
fen si, fen sai, fun sai		
soo hoon, suhoon		
green bean thread noodles		
tung boon		
su un	Indonesian	
panit sotanghon	Tagalog (Philippines)	
won sen	Thai	
bun tau	Vietnamese	
tanghoon	Malaysian	
Harusame	Japanese	Potato, sweet potato, rice, or mung bean starch
Sweet potato vermicelli	Korean	Sweet potato
dang myun (tang myun)		
Korean buckwheat noodles	Korean	Buckwheat, potato starch
naeng myun		
Shirataki	Japanese	Devil's tongue yams
sirataki		
ito konnyaku		
yam noodles		
devil's tongue noodles		
Soba	Japanese	Buckwheat, common wheat
Buckwheat noodles		
Tapioca sticks	Vietnamese	Tapioca starch
tapioca starch noodles		
hu tieu bot loc		
Tientsin fen pi (sheets)	Chinese	Mung bean

TABLE 157.16
Generalized Scheme for Traditional Production of Dry Mung Bean Threads ("fun see," Cellophane, or Translucent Noodles)

Clean mung beans to remove foreign matter
Soak mung beans in water for 4 to 5 hours in summer and 10 hours in winter
Finely grind the soaked mung beans with added water using a stone grinder
Dilute the bean slurry with three times the amount of water and let sit for about 8–9 days to ferment (dissolving the nitrogenous and other undesirable matter)
  Remove the liquid when it gets foamy, leaving the sediment at the bottom
  Add clean water back to the sediment and mix
  Repeat the process for 7–8 days until the mung bean starch is pure
Filter out the mung bean starch in cloth bag by gravity
Divide the mung bean starch into two portions
Add small amount of cold water to the first half of mung bean starch to make a slurry
Add boiling water to make a thin paste
Mix in the second half of mung bean starch with stirring to form a sticky and elastic paste
Transfer the sticky and elastic paste to a perforated funnel
Press the paste in the funnel so that the paste is extruded out through the small openings
Drop the extruded mung bean threads into boiling water immediately and gelatinize the starch into transparent threads
Scoop out the transparent mung bean threads and spread them on bamboo trays, keeping the threads in an orderly arrangement
Sun dry the mung bean threads to dryness
Package the dried mung bean threads into suitable containers for retail or storage

food as it utilizes the gums (hydrocolloids) in the devil's tongue yam as the main structural material. Fresh elephant yam contains glucomannan (a soluble dietary fiber) and starch at a ratio of about 2:1, and has excellent water holding capacity. It is popular in Japan and Taiwan, and also available in the oriental markets in the US. Elephant yam is the original material used to make Konjac/kojac gum, a GRAS food ingredient.

VIII. FACTORS AFFECTING PRODUCT QUALITY OF ASIAN (ORIENTAL) NOODLES

In the manufacture of Asian (oriental) noodles, one or more of the following common procedures are applied, depending on the kinds of product to be produced:

- Selection of raw materials
- Mixing of ingredients to form a dough, slurry or paste
- Resting of dough
- Sheeting and rolling
- Extruding
- Shaping
- Pressing of slurry or paste through perforated funnel
- Steaming
- Boiling of cut noodle stripes
- Frying of noodles
- Cooling
- Drying of final product

In addition to the above-mentioned variables in a manufacturing process, the producer has to consider production cost, environmental issues, consumer preference, and market competition, as well as proprietary formulations and practices. This makes it very complicated to compare quality of similar types of product. Scientific measurements are helpful, and these have been applied. However, a food technologist or scientist is more interested in the composition of ingredients, kinds of oil used and amount absorbed, application of food additives to prolong shelf-life, rheology of dough, consistency of slurry, work needed to knead the dough, and other factors. Table 157.17 is a summary of the major factors that could affect the quality of Asian (oriental) noodles based on the literature published (9–37). The list of references at the end of this chapter does not answer all the questions a food technologist or scientist wants to ask, but it will provide some indications of what is known and what needs to be studied in the future.

Asian (oriental) noodles, with beginnings in a primitive, cottage-type industry, is now a big industry, especially for instant noodles. These noodles have captured the attention of consumers worldwide. With the improvement in technology, it is expected that this industry will grow further and gain further acceptence by more consumers in various regions.

TABLE 157.17
Factors Affecting Product Quality of Oriental Noodles

Group I. Ingredients	
	Wheat flour used (especially protein content)
	Buckwheat flour used
	Rice flour used (especially amylose to amylopectin ratio)
	Mung bean used
	Water quality
	Amount of salt used
	Kinds of frying oil used
	Amount of coating oil used
	Amount and kinds of alkaline salts used
	Kinds and amount of additional ingredients used (starchy materials, savory ingredients)
Group II. Dough Quality	
	Rheology of dough
	Viscosity of slurry
Group III. Processing Conditions	
	Mixing of ingredients
	Kneading of dough
	Drying temperature, duration and condition
	Dough resting condition and duration
	Cutting actions for dough or noodle stripes
	Stretching actions on dough
	Relative humidity in drying chamber and environment
	Steaming temperature and duration
	Frying temperature and duration
	Sheeting and rolling actions
	Starch extraction conditions
	Extruding condition
	Cooking conditions

CONTENTS

I. INTRODUCTION

Before the 1800s, pasta was made by hand. The first mechanical devices for pasta manufacturing were invented in the 1800s (1). Around 1850, the first hand-operated pasta press was built. By the early 1900s, mixers, kneaders, hydraulic piston-type extrusion presses, and drying cabinets were available for batch manufacturing of pasta. In 1933, the first continuous single-screw pasta press was invented. Before 1974, pasta was dried using low temperature drying profiles that mimicked open-air drying conditions typical of the region around Naples, Italy. It required 18 to 20 hours to dry pasta when using a low temperature drying profile. High temperature drying (60 to 80°C) of pasta was introduced in 1974 and ultra-high temperature (80 to 100°C) drying was introduced in the late 1980s. Drying at high or ultrahigh temperatures has reduced drying time of long goods (e.g., spaghetti) to about 10 and 6 hours, respectively. Today, pasta manufacturing is totally automated with pasta presses capable of producing spaghetti at 3,500 kg/h and macaroni at 8,000 kg/h.

II. INGREDIENTS

A. Semolina

1. Durum Milling

Semolina is the primary product of durum milling. A durum mill consists of a break-roll system, a sifter system, and a purifier system. Each break-roll consists of a pair of corrugated rolls that rotate at different speeds. The speed differential between the two rolls, typically 2.5:1, provides a shearing action that removes the bran and germ from the endosperm (2,3). Granulation of semolina is dependent on the number of corrugations per unit length. The sifter system sizes the granulated material through a series of sieves and returns large particles to a break-roll for further reduction. The fine material is collected as flour. The intermediate material goes to the purifier system, which uses air and sieves to further size and clean the semolina. Aspiration separates bran particles and other impurities from the semolina. Bran has a greater surface area to unit weight than semolina. Sieves associated with the purifier system size the semolina into specific particle size ranges (millstreams).

The final granulation depends on the durum mill and the millstreams collected. The coarse granulation of semolina results in better flow properties than does the very fine particle size of flour ($\leq$212 μm). Federal Code of Regulation (4) defines semolina as the food prepared by grinding and bolting cleaned durum wheat to such fineness that, when tested by a prescribed method, it passes through a No. 20 sieve (840 μm), but not more than 3% passes through a No. 100 sieve (149 μm). It is freed from bran coat, or bran coat and germ, to such an extent that the percent of ash therein, calculated to a moisture-free basis, is not more than 0.92%, and its moisture content is not more than 15%.

Semolina used for pasta processing is much smaller than the 840 μm maximum size and typically ranges in particle size from 450 to 150 μm. The particle size distribution of semolina from five commercial mills shown in Table 158.1 indicates that 60 to 70% of the semolina granules are between 425 and 250 μm. The short mixing times used by new pasta presses require a fine granulation because small granules hydrate quicker than large granules. However, the hard grinding required for fine granulation can result in starch damage, which can increase cooking losses and decrease cooked firmness (5). Uniform granulation is important for even hydration. Hydration of semolina having a wide range of particle sizes will tend to result in the small particles absorbing too much water and the large particles absorbing too little. Both over-hydration and under-hydration will adversely affect dough development and will result in poor pasta quality.

2. Semolina Quality

Semolina quality is determined by speck count, color, grit content, ash content, moisture content, protein content and quality, and microbial load. Defects in semolina are directly transferred to the pasta product (6,7).

a. Physical quality

Speck count is a quality control measure for semolina commonly determined at the mill. Specks in semolina are generally brown or black. Bran is a common source of brown specks. Black specks originate from bran of diseased kernels, weed seeds, dirt, and insect parts. Black specks are more noticeable than brown specks in semolina and in pasta. Speck counts of five commercial semolinas ranged from 17 to 30 specks/10 in^2 (Table 158.1). Speck counts greater than 40 specks/10 in^2 are considered undesirable (8). High speck counts indicate a possible problem with grain cleanliness and grain quality and/or with the mill.

Speck count is typically determined by a visual count of specks in a given area. The visual count of specks in semolina is generally determined under a constant light source for a fixed area of semolina that has been packed flat. Visual speck counts can vary greatly depending on the individual (9). Some mills have begun using digital image analysis to determine speck count (9,10).

Ash content reflects the purity of the semolina. Semolina with high ash content generally will have a high speck count. Bran, weed seeds, and soil are high in ash.

TABLE 158.1
Quality and Particle Size Distribution (%) of Semolina from Different Mills[1,2]

Commercial Sample	Mesh size, μm[1] 600	425	250	180	149	<149	Protein (%)	Ash (%)	Specks no/10 in^2
A	0.2	12.6	61.9	17.0	4.0	2.0	12.7	0.78	24
B	0.3	18.0	53.7	17.8	3.8	3.0	11.9	0.74	21
C	0.0	13.5	69.8	13.0	1.6	2.5	13.8	0.79	17
D	0.0	12.2	69.8	13.8	1.6	2.6	12.7	0.74	23
E	0.8	29.3	50.6	14.5	1.3	2.8	13.7	0.77	30

[1] Corresponding mesh size and sieve number: 600 μm mesh = No. 30 sieve; 425 μm mesh = No. 40 sieve; 250 μm mesh = No. 60 sieve; 180 μm mesh = No. 80 sieve; 149 μm mesh = No. 100 sieve.

[2] Protein and Ash based on 14% moisture.

For this reason, ash is commonly used in semolina specifications to ensure low contamination. In general, ash contents up to 0.80% are acceptable (11).

Grit is metal, stone, or glass particles found in semolina. Grit can clog screens, block the die orifice, and/or damage the Teflon coating of the die. Damage to the die will result in defects in pasta such as grooves or tears. Grit that contaminates pasta poses a health threat as it can damage consumers' teeth.

b. Compositional quality

Semolina contains up to 80% starch and 2 to 3% nonstarch polysaccharides (12,13). Durum starch is composed of 70 to 75% amylopectin and 25 to 30% amylose (14,15). The impact of variations in amylopectin-amylose ratio on pasta extrusion is probably minimal, since dough temperature during extrusion ranges from 45 to 50°C, which is below gelatinization temperatures for durum starch. Starch is important in determining cooking quality of pasta (16), as variations in starch properties impact water uptake, gel consistency, and gluten matrix integrity during cooking.

Starch damage in the semolina is a result of milling and of α-amylase catalyzed breakdown of starch during preharvest sprouting. Starch damage after milling is generally $\leq$5% (2,17). Some starch damage can occur during extrusion (18,19). Damaged starch is associated with increased water absorption and increased cooking losses.

Nonstarch polysaccharides are primarily composed of arabinoxylan. Nonstarch polysaccharides have high water binding capacity. For example, nonstarch polysaccharides isolated from hard red spring wheat absorbed 6.3 to 6.7 times their weight of water (20).

Semolina contains 1 to 2% lipid (21). Semolina lipids affect cooking loss and are important for color. Fatty acids can complex with amylose, which reduces water solubility of amylose and lowers cooking loss. Carotenoid pigments, particularly xanthophylls and lutein, are found in semolina and give pasta its characteristic yellow color (22,23). Semolina color can be evaluated by quantifying pigment concentration or by using a reflectance colorimeter. Johnston et al. (24) reported that reflectance values corresponded well with spectrophotometer values for pigment content. The apparent color of semolina varies with particle size. The yellow appearance decreases with a decrease in particle size, even though the yellow pigment content remains the same. The decrease in yellow color is due to greater light scattering with small than with large particles.

Pasta quality is greatly affected by semolina protein content and quality. Semolina typically contains 12 to 16% protein (25,26). For good pasta quality, protein content of at least 12% on a 14% mb is preferred. The target minimum used by the durum wheat breeding program at North Dakota State University for advancing durum lines is 12.5% protein on a 14% mb.

Semolina protein is composed of about 20% metabolic proteins (enzymes) and about 80% storage proteins. Storage proteins are composed of two classes of proteins, gliadins and glutenins, which, when hydrated and mixed, form gluten. Gluten gives dough its unique viscoelastic structure.

Gliadin proteins are monomeric and range in size from 30,000 to 80,000 kDa (27). Gliadin proteins provide cohesion to the gluten matrix and are responsible for extensibility and viscosity of gluten (28,29,30).

Glutenins are polymeric proteins consisting of subunits ranging in size from 12,000 to more than 130,000 kDa and can form polymeric protein complexes with molecular weights ranging from a few hundred thousand to several million (31). Unlike gliadins, subunits of glutenin proteins are capable of aggregation due to the formation of intermolecular disulfide bonds between subunits (32). Glutenins are responsible for the strength and elastic properties of gluten (33).

c. Gluten/dough quality

Gluten quality is assessed by the wet gluten/gluten index (approved Method 38-12) and sodium dodecylsulfate (SDS) microsedimentation tests (34,35). The wet gluten/gluten index test involves washing semolina with a 2% salt solution. During washing, the semolina is kneaded to develop the gluten and to help remove the starch. After washing, the remaining wet gluten is centrifuged in a special centrifuge tube that contains a perforated plate. Gluten index is the ratio of the weight of gluten remaining on the top of the perforated plate divided by the weight of the wet gluten. The stronger the gluten, the less likely the gluten will be forced through the perforations during centrifugation. Gluten index has been used to identify weak, strong, and very strong gluten lines (36). In general, gluten index values $<$5 indicate weak gluten and gluten index values $\geq$85 indicate very strong gluten. Durum grown in North Dakota and Montana typically has gluten index values of 45 to 55.

The SDS microsedimentation test involves hydrating ground durum wheat in a SDS/lactic acid solution. Proteins of high molecular weight and those having strong interactions with starch are insoluble in the SDS/lactic acid solution and form a sediment. The height of the sediment is measured. A high SDS microsedimentation value is associated with good protein quality. A SDS microsedimentation value $<$30 indicates weak gluten while a value $\geq$35 indicates strong gluten.

Dough properties of semolina generally are assessed by mixograph in North America and by farinograph or alveograph in other parts of the world. Mixograph records the torque transmitted through the dough, which is recorded by a pen on chart paper (37). Mixograms from semolina of four cultivars grown in the Northern Plains are presented in Figure 158.1. Mixogram peak represents maximum dough

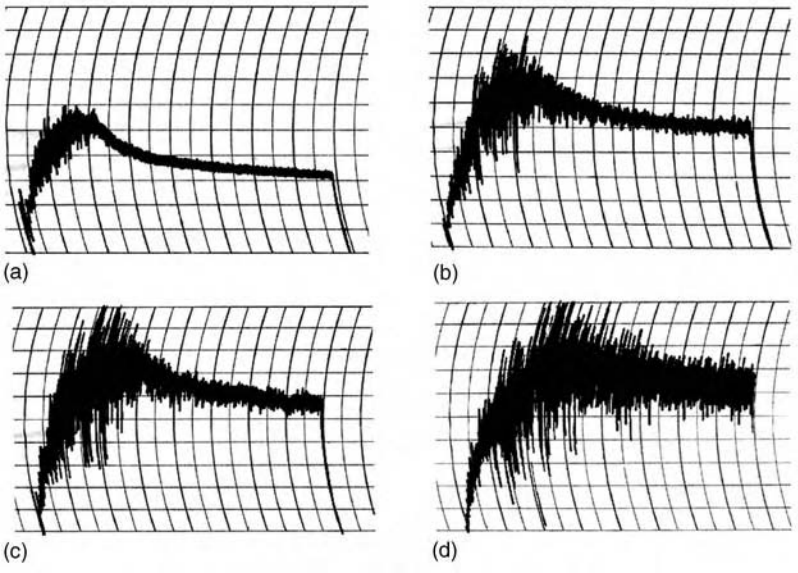

FIGURE 158.1 Mixograms for semolina from durum wheat cultivars: Rugby (a), Munich (b), Lebsock (c), and Belzer (d). Durum wheat cultivars were grown in North Dakota.

development. Time to peak gives an indication of time required to fully develop the dough. The drop in the curve after the peak gives an indication of dough stability. Both peak height and width of the curve at peak reflect dough strength. Rugby (Figure 158.1a) is known to be a weak gluten cultivar. Even though Rugby has excellent protein content, it has weak dough properties (low peak height and narrow band width) compared to Belzer (Figure 158.1d). Most cultivars grown in North Dakota, Montana, and Canada are considered to have strong gluten, and produce mixograms similar to Munich and Lebsock (Figure 158.1b,c).

B. Other Ingredients

Other ingredients sometimes are added to semolina to improve its nutritional quality or to make specialty pastas. In the United States, pasta is enriched with vitamins (thiamin at 8.8 to 11 mg/kg, riboflavin at 3.75 to 4.85 mg/kg, niacin or niacinamide at 59.4 to 74.8 mg/kg, and folic acid at 1.98 to 2.64 mg/kg) and minerals (iron at 28.5 to 36.3 mg/kg and calcium (optional) at 1100 to 1375 mg/kg). Wheat bran, oat flour, and barley flour are examples of materials added to pasta to increase dietary fiber content (38,39,40). Flours of edible legumes, buckwheat, amaranth, and lupin have been added to improve the content and nutritional quality of protein in pasta (41,42,43). Vital wheat gluten, disodium phosphate, surfactants, and lipids have been added to improve cooking or textural quality of pasta, particularly pasta that is refrigerated, frozen, or canned (44,45). A variety of non-wheat and non-cereal products have been added to pasta to improve its nutritional quality (46). Code of Federal Regulations (21 CFR Part 139) provides a list of ingredients that can be added to pasta products (4).

C. Water Quality

Water used in pasta processing should be pure, without chemical (including heavy metals) or bacterial contamination, have no off-flavors, and be slightly acidic, pH 6.6 to 6.9 (44). Water can have a maximum mineral content of 400 to 500 mg/L. Presence of iron salts should be avoided. Mineral impurities should not exceed 180 to 200 mg/L calcium and magnesium carbonates, 70 to 90 mg/L sulfates, 25 to 30 mg/L silicates, 5 to 10 mg/L chlorides, and 10 to 40 mg/L of organic matter (44,47,48).

III. PASTA PROCESSING

Modern pasta presses are capable of producing 3,500 kg/h of long goods (spaghetti, vermicelli, and linguine) and up to 8,000 kg/h of short goods (macaroni, rigatoni, and ziti). Pasta processing can be divided into four stages: mixing, kneading, shaping, and drying.

A. Mixing

1. Hydration

The goal of the mixing stage is to uniformly blend and properly hydrate ingredients. Semolina is typically hydrated to 30 to 32% moisture content. The hydration level often has to be adjusted higher or lower to obtain proper consistency of dough containing nontraditional

ingredients during extrusion (42,49). When nontraditional ingredients are present, the amount of water added will depend on the overall moisture content and the water binding properties of the various ingredients. For example, nonstarch polysaccharides have a high water binding capacity, which can affect water distribution in dough systems during pasta processing and drying. Due to high levels of nonstarch polysaccharides in bran, whole wheat and bran-semolina mixtures can require greater hydration to achieve proper dough development during extrusion than does semolina. Thus, it might take more water and time to properly hydrate whole wheat, compared to semolina, during the hydration/mixing stage of pasta processing (49,50,51).

Rate of hydration is promoted by warm water, warm semolina, and small semolina particle size. Semolina temperature is generally only a concern in winter, as semolina stored in unheated bins can be very cold. Cold temperature will slow the rate of hydration. Semolina containing fine granulation will hydrate quicker than semolina with coarse granulation, because of the increased surface area and increased starch damage associated with small granulation.

Uniform granulation is important for proper hydration. When semolina contains both large and small particles, the small particles tend to over-hydrate and large particles tend to under-hydrate. Over-hydration results in a soft, sticky dough. Pasta extruded from over-hydrated semolina requires more energy to dry and can stretch and stick together on the drying rods. Under-hydration results in a stiff dough which requires more energy for extrusion, generates more heat during processing, and can result in breakage problems for long goods hung on drying rods, as well as cutting problems for short goods.

Complete hydration of the semolina particles is very important for proper dough development. Protein must be hydrated before gluten can form. As the storage proteins (gliadin and glutenin) hydrate, they change their conformation and begin to unfold and interact by forming intra-molecular and inter-molecular bonds. Without adequate hydration, regions in the dough and pasta will exist where no gluten is formed, which results in discontinuity of the gluten matrix. These regions of discontinuity are areas of structural weakness and will appear as white starchy areas in extruded pasta.

2. Mixing Equipment

The mixer is divided into two sections: premixer and main mixer. The flow of dry ingredients into the premixer is regulated by volume or weight using a volumetric or gravimetric feeder, respectively. Warm water (35 to 40°C) is sprayed onto the semolina in the premixer. It is important that the water not be sprayed onto the metal parts of the premixer, as semolina will accumulate on wet metal. Ingredient buildup in the mixer represents a potential source of microbial activity. High speed premixers are commonly used to rapidly and evenly coat the semolina particles with water before entering the main mixer.

The principal function of the main mixer is to provide time for thorough hydration. Most mixers contain two counter-rotating parallel shafts with paddles set so that they move the hydrated material forward (Figure 158.2). The retention time in the mixing chamber depends on the speed of the paddles and the length of the mixing chamber. The time must be sufficient to allow for proper absorption of water by the semolina or semolina-ingredients. Conventional mixers have a retention time of 10 to 20 min. New systems are being developed that reduce the retention time to 2 to 3 min or less (52). Pasta lines using short retention time mixers require fine granulation of semolina to achieve rapid hydration.

Most dry pasta manufacturers apply a vacuum (−63 to −80 kPa) either at the mixer or just before the extrusion barrel (53). Vacuum promotes hydration by eliminating surface tension associated with air and reduces pigment oxidation by lipoxygenase enzymes (23). Vacuum also prevents air from being trapped inside the developing dough. Air trapped inside extruded pasta will appear as a series of very fine bubbles resulting in a hazy appearance. If dried at high or ultra-high temperatures, these bubbles will act as focal points for stress and ultimately result in checking of the finished pasta.

Fresh or frozen pasta manufacturers generally do not use a vacuum system in the process. Their product is opaque. The air bubbles in the product do not seem to have any significant impact on the end product appearance or cooking quality. The added equipment to produce a vacuum, combined with the maintenance required, do not seem to justify the cost.

B. Extruding

Hydrated semolina passes through several zones in the extruder: conveying, compacting, kneading, relaxing, and

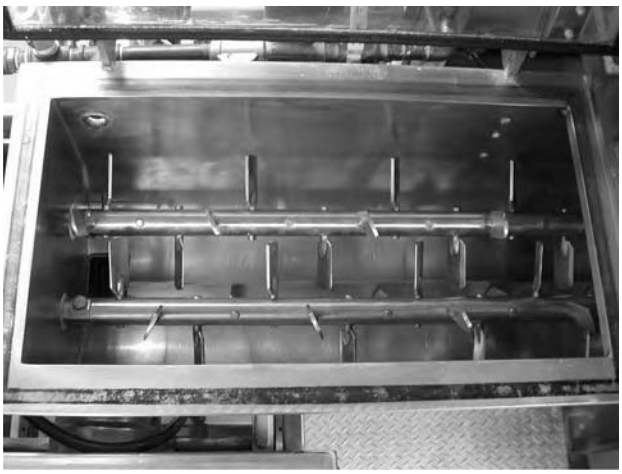

FIGURE 158.2 Mixing chamber. (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

extruding. Conveying, compacting, and kneading are associated with different regions of the extrusion screw. At the end of the screw, an extension tube often is used to allow the dough to relax before being extruded through the die.

1. Screw Design

The extrusion screw is made of stainless steel or chrome-plated steel. Traditionally, extrusion screws used in pasta processing were deep flighted with constant root diameter and uniform pitch the entire length of screw (Figure 158.3). Deep flights provided high screw conveying capacity and allowed high back pressure flow in the screw. Harper (53) reported a flight angle of 12 degrees for pasta extrusion. A sharper flight angle would increase mixing and decrease the conveying efficiency. Extrusion screws are designed with length-to-diameter ratios between 6:1 and 9:1 (53). The long length-to-diameter ratio results in low mechanical energy/unit throughput. Screws used to extrude pasta typically have diameters ranging between 12 to 20 cm.

Extrusion screws have become more sophisticated. Some newer pasta presses have screws with variable pitch and variable root diameter. These screws often begin with a large dough cavity and gradually get smaller in pitch and larger in root diameter toward the end of the screw (52). As pitch decreases, the number of flights on the screw increases, which increases the screw surface-to-volume ratio and increases the conversion of mechanical energy to heat through friction. Similarly, increasing root diameter decreases flight depth, which increases the amount of energy and pressure applied to the dough. Thus, the new screws increase the amount of work applied to the dough, which has allowed a reduction in screw speeds from 20 to 40 rpm with traditional presses, to typically 18 rpm, and still maintain output (52).

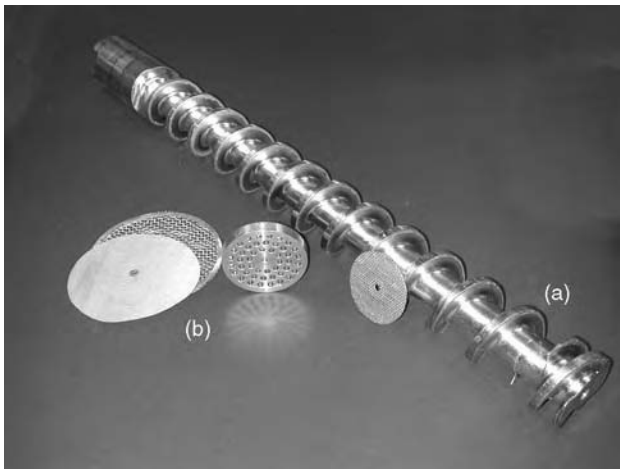

FIGURE 158.3 Extrusion screw (a) and kneading plate (b). (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

2. Screw Function

The beginning of the screw is involved with conveyance. This part of the screw is not fully encased by the extruder barrel, but is exposed to allow the hydrated semolina from the mixer to be deposited onto the screw. The screw is choke-fed. The hydrated semolina is conveyed forward into the barrel as the screw turns.

Compaction occurs once the hydrated semolina is conveyed inside the barrel. Pressure rapidly increases from 0 to 2 MPa after about two turns of the screw (54). Hydrated semolina exposed to 2 MPa begins to transition from a granular material into a fully compacted dough. Temperature changes during compaction are due to heat dissipation by friction against the barrel, which is then transmitted to the hydrated semolina. Le Roux et al. (54) reported that temperature rise was localized near the barrel wall and that the average temperature increase was about 5°C for a channel length of 10 cm under typical experimental conditions.

After compaction, the remaining length of the screw is involved in kneading and conveyance of the dough toward the die. Pressure continues to slowly increase as the dough progresses toward the end of the screw. Deep flights provide high conveying capacity and high back pressure (up to 12.7 MPa) in the screw (48). At the end of the screw, pressure declines slightly as the dough moves into the extension tube, where it is allowed to relax before being extruded through the die. For a commercial press, the pressure at the die is generally 10 MPa.

3. Dough Flow

Dough is conveyed in the channel of the screw. Dough moves toward the leading edge of the flight next to the cylinder wall and flows away from the flight near the root of the screw, which causes the dough to spiral down the channel. Forward flow and back pressure act together to knead the dough. During kneading, the gluten molecules are stretched and aligned according to rotational movement of the screw (55).

The flow of dough is not uniform in the channel. Dough near the root of the screw moves much more slowly than the material near the cylinder wall (55,56). The material against the metal wall is worked and heated more than the material at the center of the screw channel. Le Roux et al. (54) did not observe any recirculating regions within the channel, but noted that a large zone existed at the channel bottom where the product moved very slowly, less than 10 mm/s when the barrel velocity was 50 mm/s.

The uneven flow rate results in irregular dough development in the extrusion screw. At the end of the screw, the protein matrix is irregular, but is interconnected with some alignment of starch granules along the direction of flow (55). To reduce the heterogeneity of the dough, some

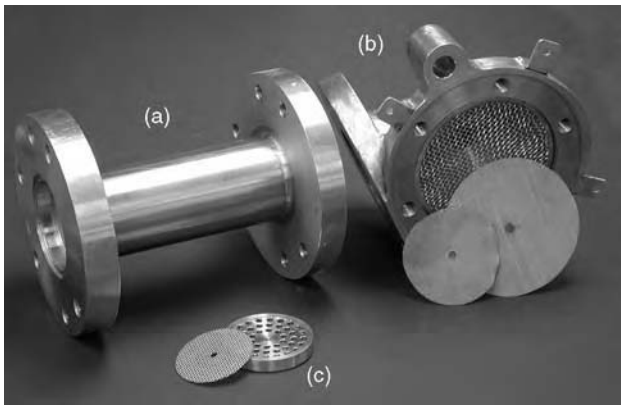

FIGURE 158.4 Extension tube (a), extrusion head (b), and kneading plate (c). (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

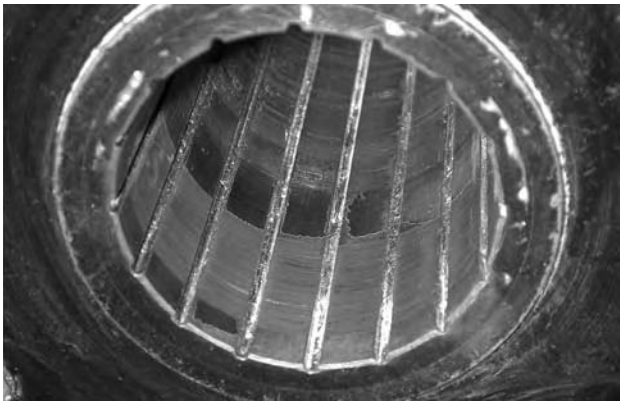

FIGURE 158.5 Longitudinal grooves machined along the inner surface of the extrusion barrel. (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

screw designs include a cut-flight or a kneading plate at the end of the screw (Figure 158.3). Kneading plates are stainless steel with small holes. Kneading plates split the dough into streams that recombine on the other side of the plate. An extension tube is sometimes placed after the kneading plate when extruding long goods (Figure 158.4). The dough flowing through the kneading plate enters the extension tube, which allows the dough a brief rest before entering the extrusion head where the dough flow is diverted downward 90° and forced through a die. At the beginning of the extension tube, after going through the kneading plates, the protein matrix is quite continuous and starch granules are clearly aligned. By the end of the extension tube, the dough is translucent and cohesive and is considered fully developed (55).

Friction between the dough and the extrusion barrel and between the dough and the screw is necessary for compression of the dough and for conveyance of the dough through the extrusion barrel. Without friction, the screw would turn and the dough would remain stationary relative to the screw. To have proper conveyance of the dough, the friction associated with the barrel must be greater than the friction associated with the screw. Longitudinal grooves are machined along the inner surface of the extrusion barrel (Figure 158.5) to enhance the friction between the dough and the barrel. To reduce friction between the dough and the screw, the screw surface is made of polished stainless or chrome-plated steel. Experimental values of the coefficient of friction corresponding to the screw smooth surface have been estimated to be between 0.2 and 0.4. Le Roux et al. (54) reported that a screw with a deep flight and a uniform pitch and root diameter needed a barrel coefficient of friction greater than 0.5.

4. Frictional Heating

Heat is generated by friction between the dough and metal surfaces of the barrel and the screw. The target dough temperature during extrusion is 45 to 50°C (48,57). Protein begins to denature at dough temperatures >50°C. Denatured storage proteins (gliadins and glutenins) are unable to form gluten. High dough temperature during extrusion will cause a soft sticky product when cooked. Excess heat generated by friction during extrusion is removed by use of a water jacket which surrounds the extrusion barrel. A high volume of warm water is used to maintain both the barrel and dough temperature near 45°C. Circulating cold water in the water jacket would result in overcooling the dough at the barrel surface, which would adversely affect dough viscosity.

Frictional heating of dough can be calculated by knowing the moisture content of hydrated semolina and the specific mechanical energy (SME, kJ/kg) for pasta extrusion. Heat capacity of wheat dough can be estimated using the equation presented by Baird and Reed (58),

$$c_p\ (\text{kJ/kg°C}) = 1.44 + 2.74X_w$$

where c_p is heat capacity and X_w is moisture content.

If the moisture content of hydrated semolina is 31%, then the heat capacity of the hydrated dough would be 2.29 kJ/kg°C. If the SME is assumed to be 70 kJ/kg (59,60), then the heat generated during extrusion would be 70 kJ/kg divided by the heat capacity of the hydrated dough (2.29 kJ/kg°C) to give a temperature rise of 31°C. If the hydrated semolina entered the extrusion screw at 35°C, it would exit the extruder at 66°C. With a target dough temperature of 45°C, two thirds of the heat would need to be removed by a circulating water jacket. These results are similar to those reported by Harper (53) and Hoskins (56).

5. Dough Viscosity

Dough systems have non-Newtonian flow properties. Dough is a viscoelastic system. Viscoelastic properties of

dough are dependent on gluten strength of the semolina used, temperature, hydration, and amount of work applied to the dough. Dough viscosity decreases with increased temperature and hydration. Dough viscoelastic properties are decreased when overworked. This can be seen in the mixograms in Figure 158.1, where dough strength declines with time after reaching peak height.

Apparent viscosity of a dough system can be described by:

$$\mu_a = m v^{n-1}$$

where μ_a = apparent viscosity, m = consistency, v = shear rate, and n = flow index.

Using a dough made from semolina, Le Roux et al. (54) demonstrated that the power law remained valid over a wide range of shear rates, typically 0.1 to 1000 s^{-1}, which encompasses the range expected in pasta extrusion. A typical shear rate for a commercial pasta press has been estimated to be 5 s^{-1} (59). Power law (or flow) index, n, increased with hydration, but remained within 0.4 to 0.5 (54). Food extrudates exhibit flow indices between 0.25 and 0.5 (61). Within normal extrusion temperatures, 45 to 55°C, consistency, m, varies with hydration and temperature according to exponential laws.

6. Die Assembly

The die is attached to the end of the extrusion head (Figure 158.6). A die is composed of a support and multiple inserts (Figure 158.7). Die support is made from bronze or stainless steel. The support must be capable of withstanding a tremendous amount of pressure over time without yielding. Stainless steel can tolerate higher pressures, but tends to retain more heat than bronze (62). Most industrial die supports are made from stainless steel. Inserts are miniature dies that are housed inside holes that have been bored into the supports (Figure 158.7). Inserts are generally made from bronze, due to their low heat retention. The advantage of using inserts is that worn inserts can be replaced easily without having to return the entire die to the manufacturer.

The number of inserts in the die will determine production output and must be balanced with the pasta press. Too many inserts can weaken the die, which could cause the die to bend under pressure, could reduce the density of the product, and could cause strands to overlap during extrusion. Too few inserts can cause excessive back pressure that can damage the die and/or the extruder and can reduce production output.

Die supports are typically 100 mm thick, and their inserts are typically 20 mm thick (63). Thus, dough flows into the hole in the die support, then into and through the orifice in the insert. Pasta comes in hundreds of shapes, which are determined by the flow of dough through the die orifice during extrusion. For example, inserts for spaghetti contain a round orifice, whereas inserts for shells have a horizontal orifice that is slightly larger at the center. The dough will flow faster at the center than at the ends of the orifice in the shell die, which causes curvature (62,63).

The orifice in the insert is often coated with a fluorocarbon polymer such as Teflon. A Teflon-coated orifice will have a low coefficient of friction, which will reduce back pressure needed for extrusion and increase the rate of extrusion (53,56). Dies with Teflon inserts are used when a smooth translucent surface is desired. Surface texture affects cooking and culinary properties of the product. Pasta with a rough surface has a greater exposed surface area, which tends to absorb water quicker and retain more sauce when compared to pasta with a smooth surface.

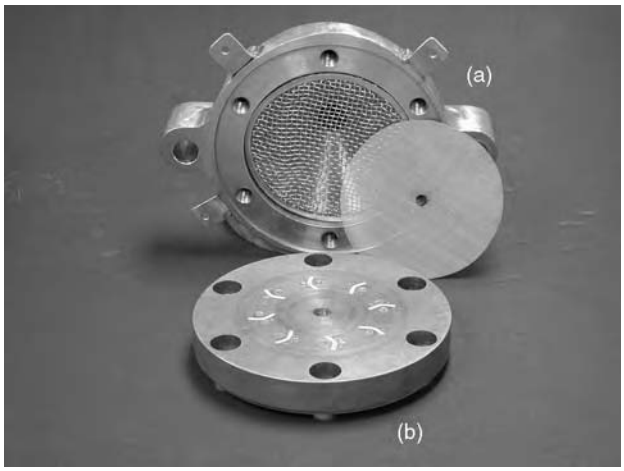

FIGURE 158.6 Extrusion head (a) and die (b). (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

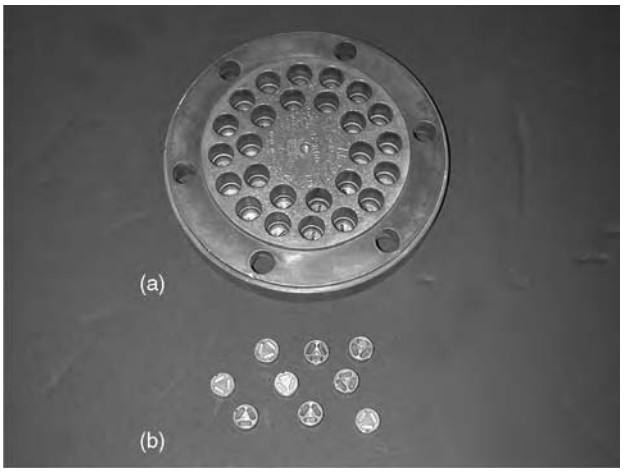

FIGURE 158.7 Die support (a) and inserts (b). (Photograph courtesy of Northern Crops Institute, Fargo, ND.)

The shape of the die support depends on the product produced. Short goods generally have a round die support, while long goods generally have a rectangular support. Extruded long goods are collected by a spreader, which spreads long goods on sticks and cuts the long goods from the die. Since product discharge is not uniform across the die, the strands are cut to a uniform length and the trim is reintroduced into the mixer via the trim return system. Pasta hanging on the sticks is conveyed to the dryer. Dried pasta is cut to length and the trim is reground and reintroduced into the semolina at amounts up to 15% (64,65). Extruded short goods are cut by a special rotary cutter with one or more blades. The cut pasta falls onto trays or a conveyer where it moves into the dryer. Short good length is determined by extrusion rate and speed of the rotary cutter. An uneven rate of discharge across the die will result in variable lengths of the short goods.

7. Extruder Output

In-depth mathematical descriptions and discussion of extrusion can be found in several references (53,66,67).

Extruder output is described by the following equation:

Extruder output = drag flow − pressure flow − leakage flow.

Drag flow is the forward movement of the dough due to the relative motion between the screw and the barrel (68). Drag flow increases with increased screw speed and flight depth to screw diameter ratio. Pressure flow is the backward flow of dough in the screw channel due to a pressure gradient. Leakage flow is the backward flow between the flights and the extruder barrel due to a pressure gradient. Pressure flow is proportional to the pressure gradient across the screw length (69). An increase in flight depth to screw diameter ratio increases drag flow more than pressure flow. Flight depth to screw diameter ratio for a commercial pasta press is typically 0.25 to 0.33 (59). Both drag flow and pressure flow increase with increased pitch angle (70). Leakage flow is related to pressure flow. Leakage flow occurs within the clearance between screw flights and the barrel and within the longitudinal grooves in the barrel wall. A typical clearance between the screw and barrel is 0.5 mm (66). The clearance will increase over time due to wear. An increase in clearance will be manifested by a decrease in output and an increase in energy transferred to the product, with associated increase in dough temperature.

Hoskins (56) estimated that the ratio between pressure and drag flow in a pasta press screw is about 0.6. If pressure flow and leakage flow are combined, then drag flow and pressure flow can be estimated if press output is known.

For example, assume that a pasta press extrudes 3,500 kg/hr of long goods.
Then: Drag Flow − Pressure Flow = 3,500 kg/hr and Pressure Flow/Drag Flow = 0.6.
Drag Flow × 0.6 = Pressure Flow
Drag Flow − Drag Flow × 0.6 = 3,500 kg/hr
Drag Flow (1 − 0.6) = 3,500 kg/hr
Drag Flow = 8,750 kg/hr
Pressure Flow = 5,250 kg/hr

The amount of energy transferred to the product during extrusion is designated as SME (kJ/kg). SME transferred to the pasta is calculated as the mechanical energy (kJ/s) to extrude pasta divided by the amount of pasta processed (kg/s). Mechanical energy required to operate the empty press is subtracted from the mechanical energy required to operate the press under load. Dough temperature and hydration level greatly affect SME required for extrusion. Abecassis et al. (60) reported that an increase in dough temperature or hydration decreased dough viscosity and subsequently decreased SME. A SME of 70 kJ/kg is typical for pasta extrusion, under normal operating conditions (54,59,60).

C. Pasta Drying

Like many other foods, pasta is dried to give a longer storage time. Shelf-life of pasta products is commonly listed as two years. Vitamins degrade over time. When the vitamin claim on the nutritional label is no longer valid, then the processors must declare the pasta expired. Therefore, fortification level and the levels claimed on the label determine the shelf-life.

Typically, industry will dry pasta to 12% moisture, although the Federal Code of Regulations (4) allows the moisture content to be as high as 13%. Pasta is a difficult product to dry. Pasta's low moisture, coupled with dimensional changes during drying, can result in checking (stress cracks in the product). Checking occurs when the stresses in the product exceed the strength of the pasta. As drying temperatures increase, the properties of the pasta change, due primarily to inactivation of enzymes and protein denaturation. A list of changes can be found in *Pasta Technology Today* (47) and in *Pasta and Noodle Technology* (71).

The pasta drying process is generally divided into three main stages: predrying, final drying, and cooling/stabilizing stages.

1. Drying Stages

a. Predrying

The predrying stage begins when the product exits the die. Typically, ambient air (possibly heated) flows at the face of the die, which provides some surface drying of the

product. This is referred to as the initial predrying. Initial predrying serves several purposes. The primary purpose is to dry the surface of the product sufficiently to prevent pieces from sticking together. Initial predrying increases the rigidity of the pasta surface, which minimizes collapsing or deforming of hollow products (such as elbows, shells, and ziti) when they drop onto a solid surface or have the weight of other pieces resting on them. The amount of moisture removed during the initial predrying step is small (<1%), but is a necessary step for maximum pasta quality.

After initial predrying at the die, the product is conveyed to the predrying section of the dryer. In the case of long goods, the product is collected onto rods, which are mechanically conveyed directly into the dryer. In the case of short goods, the product can either be dropped directly into the dryer (if the extruder is positioned above the dryer) or conveyed to the dryer, usually by a mesh belt conveyor or other conveying system able to keep airflow on the pasta.

The moisture content of the pasta entering the predryer section of the dryer is ~29 to 31%. The predrying stage is ~10% of the total drying time and removes about one-third of the total water in the pasta. The high drying rate is possible because the pasta is still in a plastic state, which prevents a buildup of stress in the pasta. Depending on the temperature of the dryer, the pasta will remain plastic as moisture content is decreased to 18% (for ultrahigh temperature, ≥80°C, drying) or 21% (for low temperature, <60°C, drying). Water is one plasticizing agent, which allows the product to deform without creating residual stresses. Temperature is another factor that helps plasticize the product. The moisture content at which the pasta transitions from plastic to elastic state decreases as temperature increases.

The predrying stage (and the final drying stage) will generally have a "resting" stage (sweating stage) scheduled in the drying profile or built into the dryer design. During the "resting" stage, the driving force for the drying (temperature and humidity of the air) is low enough that the product is not losing water to the surrounding air. The moisture inside the product redistributes during this time. The core, which has higher moisture content than the surface of the product, will lose water to the surface of the pasta product. Redistribution of the moisture helps even out the dimensional change and minimizes stress due to moisture loss in the product. If enough moisture reaches the surface, the surface becomes plastic and stresses are relieved.

b. Final dryer

The product will have ~18 to 21% moisture content upon entering the final dryer and will exit the dryer at ~12%. The rate of moisture removal in the final dryer is critical, because the product is in an elastic state. If drying is too fast, the stresses near the surface of the product will exceed the strength of the pasta and checking will occur. While stress accumulated during the final drying can result in checking, the root cause of stress in the product may be due to events that occur earlier in pasta processing. For example, product thickness will increase as the insert wears during extrusion. A thick product is more difficult to dry; and if no changes are made in the drying profile, checking will occur.

c. Cooling/stabilization stage

The product is brought to near ambient temperature and exposed to ~50% relative humidity during the cooling/stabilization stage. The product is equilibrated with the ambient environment to minimize the possibility of checking due to environmental stresses. Moisture is more evenly distributed as the product moves through the cooling stage. Some of the water near the core of the product will migrate toward the surface, which will relieve some of the stresses that accumulated during the drying process.

One difficulty in humid environments is that the surface of dried pasta will begin to absorb moisture from the atmosphere. Stress occurs as the absorbed moisture causes the surface of the product to expand. This stress, coupled with the residual stresses in the product from drying, may result in checking of the product. Even with little or no residual stress, checking will occur in pasta if the relative humidity is ≥75% (72). To prevent checking in humid environments, dried pasta may need to be packaged within 3 hours of exiting the dryer.

Advances in drying technology have resulted in three drying intensity categories that describe processing temperature and relative humidity ranges: conventional drying, high temperature drying, and ultrahigh temperature drying. Conventional drying (low temperature drying) imitates the conditions that occur in the Mediterranean region of Italy, the origin of pasta. The drying of pasta originally took place in the open air or in a ventilated room. High temperature drying is a drying cycle where the maximum temperature applied is between 60 and 80°C. Whereas, ultrahigh temperature (very high temperature or tres haute temperature) is a drying cycle where the temperature applied reaches ≥80°C.

As drying temperature increases, the relative humidity of the drying cycle increases and drying time decreases. Spaghetti (a thick product) may take about 24 hours to dry with low temperature drying, 12 hours with high temperature drying, and 5 hours or less with ultrahigh temperature drying. The exact drying cycle used is dependant on the product being dried and the equipment manufacturer, so exact drying profiles are not provided here. The drying profiles used by the Durum Wheat Quality and Pasta Processing Laboratory in the Department of Cereal and Food Sciences at North Dakota State University can be found in Yue et al. (14).

2. Moisture Migration during Pasta Drying

Factors that have a strong influence on drying rate include pasta thickness (doubling the thickness of the pasta will reduce the drying rate 75%) and air temperature, while factors that have a small influence on drying rate include relative humidity and airspeed (73).

Pasta is a dense, continuous product with very few capillaries. Like similar products (soap, gels, pastes), pasta drying is unsteady-state and can be modeled using Fick's second law:

$$\frac{\partial X}{\partial t} = D\frac{\partial^2 X}{\partial x^2} \quad \text{(for a slab) or}$$

$$\frac{\partial X}{\partial t} = D\left|\frac{\partial^2 X}{\partial r^2} + \frac{1}{r}\frac{\partial X}{\partial r}\right| \quad \text{(for a cylinder)}$$

where X = moisture content, t = time, x = ½ the thickness of the product, and r = radius of the product.

Fick's second law describes drying in materials where liquid water is diffusing toward the surface of the material. Research indicates that Fick's second law is not a perfect model for the pasta drying process, because the moisture gradient in the pasta is steeper than the Fickian model predicts (74,75). However, Fick's second law may be a reasonable starting point.

A wide range exists for diffusivity values (at least two orders of magnitude between the highest and lowest reported values), but the majority of results include diffusivity values in the range of 25×10^{-12} m^2/s to 50×10^{-12} m^2/s (73,74,76). Diffusivity is unaffected by total pressure in the drying environment, indicating that moisture migrates in pasta as liquid or adsorbed water and not as water vapor (76).

3. Maillard Reactions during Pasta Drying

Maillard reactions result in the development of a red or orange color, which is significantly different from the golden color expected in pasta. Maillard reactions can also result in the development of off-flavors in pasta. The Maillard reaction requires a reducing sugar and a free amino group. The reducing sugars for the Maillard reaction are provided by damaged starch. The damaged starch can be the result of growing conditions, milling, mixing with water, or extrusion (77,78,79). The free amino group is generally from a lysine residue in protein.

Maillard reactions can occur during high temperature and ultrahigh temperature drying. Water activity of 0.75 to 0.80 (80) and/or a moisture content of ~15% (77) are optimum moisture conditions for the Maillard reaction to occur in pasta. Pasta in equilibrium with a high relative humidity environment (97% rh, water activity = 0.97) is unlikely to develop an off-color during drying (79). The development of off-colors also may be limited by not applying high temperature in the dryer until the pasta reaches a water activity of 0.7 (81).

The Maillard reaction is and will continue to be a concern in pasta production. The industry has accepted high temperature and ultrahigh temperature drying as optimal drying cycles, producing the highest quality pasta. This higher quality comes with the risk of its own defect: "browning" during drying. Most pasta produced under high temperature and ultrahigh temperature drying cycles will not have the browning defect, but there are factors that can increase the likelihood of Maillard reactions occurring. Factors directly caused by the semolina or the drying cycle have been researched to some degree (77,79,80). However, there are factors not easily anticipated in a research environment, such as "holding" of product in the dryer due to other equipment problems, effect of equipment wear on the amount of starch damage in the product, and poorly calibrated sensors. While the Maillard reaction may not be a concern for most pasta processors today, it would be unusual not to see some reddish-colored pasta on the shelf in a local supermarket.

4. Checking in Pasta

There are two types of checking in pasta: predryer checking and final dryer checking. Predryer checking, as the name implies, occurs in the predryer section. This defect will appear as spots in the finished product. The spots will generally be round and be near the surface of the product. These spots may appear similar to spots due to insufficient vacuum during extrusion. Final dryer checking is easily identifiable. In the spaghetti, final dryer checking will appear as an oval on the surface of the spaghetti, and can be described as a "crescent," "canoe," or "half-moon" (Figure 158.8). In other products, final dryer checking

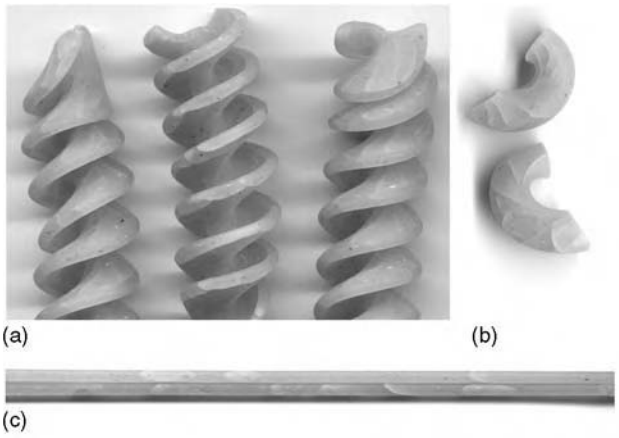

FIGURE 158.8 Final dryer checking in rotelle (a), elbow macaroni (b) and spaghetti (c). Note partial and full oval shaped checking in spaghetti and checking on the outside and on the face of vanes of rotelle.

will be visible as cracks in the pasta. The stresses causing final dryer checking are created during final drying, but the actual checking of the product may not occur for up to 10 days after drying.

Both predryer and final dryer checking are caused by removing moisture too quickly from the pasta. Predryer checking can be corrected by increasing the relative humidity and or the residence time in the drying chamber. These changes may ensure that the moisture content going into the final dryer is appropriate for that dryer. Because each dryer is different, knowing the operating conditions and properties of the product when the production line is running correctly cannot be over-emphasized. While general values of moisture content at various stages in the drying can be found for "typical" dryers, knowing the exact conditions in the dryer that you are trying to troubleshoot is extremely valuable. Final dryer checking can be corrected by increasing the relative humidity in the final dryer section. Increased relative humidity in the final dryer section may slow drying enough to require increased drying time. Final dryer checking can be due to improper predryer conditions. Final drier checking may also be due to pasta leaving the predryer at too high of a moisture content.

Frequently, only minor changes in the dryer will correct a checking problem. For example, a pasta manufacturer was producing a penne product that was checking badly. The plant producing this product eliminated the checking by increasing the relative humidity in the final dryer section by 3%. The root cause of this plant's problem appeared to have been worn die inserts. The thickness of the product had increased enough to cause these drying problems.

5. Pasta Defects/Troubleshooting

Defects in pasta production do occur, and being able to locate the source of the problem is important in solving the defect problem. Having accurate data on the optimal drying parameters as measured and controlled in the process being investigated cannot be over-emphasized. Having a "base-line" for comparison will help to solve many problems quickly. Table 158.2 lists some of the more common defects found in dried pasta along with the likely cause(s).

IV. GOOD QUALITY PASTA

The goal of pasta production is to make a dried pasta that is translucent (although some portions of the market prefer pasta extruded through a bronze die, which will result

TABLE 158.2
Troubleshooting Pasta Defects

Defect	Possible Cause	Possible Solution
Specks in the pasta	Raw ingredients	Check for grit and black or brown specks. Ensure it meets the plant's specifications.
White spots and streaks on the pasta (see Figure 158.9)	Wide semolina particle size distribution	Narrow the size distribution of semolina
	Very dry semolina	Use semolina with a higher moisture content
	Insufficient hydration time	Increase residence time in the mixing chamber
Circular bubbles in the pasta	Loss of vacuum on the extruder	Make sure vacuum system is clean and operating properly
	Predryer stress	Ensure relative humidity the product is exposed to from the die and through the predryer is correct
Deformed pasta	Varying dough moisture at die	Ensure semolina and water flow rates are consistent
	Poor die pressure distribution	Check for possible obstructions to flow at the die
Cracks (checking) in pasta	Drying too fast in the final dryer section "canoe" or "crescent" shape in spaghetti (see Figure 158.8c). Cracks in other products (see Figures 158.8a,b)	Check conditions in the final dryer, possibly increase relative humidity to slow the drying process
		Ensure product does not drop far or onto too solid a surface when conveyed
	Mechanical damage (sections of pasta chipped out of the ends of tube products (see Figure 158.10)	Post-dryer checking can occur if ambient relative humidity is too low (<10%) or too high (>75%) and the product is exposed to the conditions for 3 hours or more
	Post-dryer checking	
	Rough mechanical handling	Pasta may be dropped from too great a height, fracturing the product. In tubular products, this will result in squares or triangles being knocked out of the ends, instead of cracks on the entire length of product
"Red" or "orange" color in the pasta	Maillard reaction occurring in the pasta	Check RH and temperature in the final dryer section
		Check semolina for excessive sugars or ash (indicating a high semolina extraction)

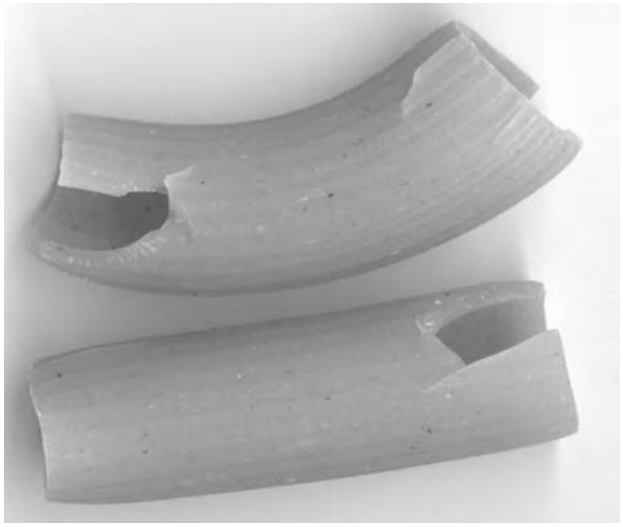

FIGURE 158.9 Rigatoni showing mechanical damage. Cracks in the pasta are only at the ends of the pasta and broken areas are roughly rectangular.

FIGURE 158.10 Hydration problem. Rotelle viewed from the end. Note hydration streaks about 1/3 the distance from the center of the product.

in a rough surface) and free of visual defects such as checking, hydration spots, and specks. This pasta should cook to a non-sticky, firm product with little cooking loss, and resist overcooking.
