Brochothrix thermosphacta is a Gram-positive, catalase-negative bacterium which is capable of growing in chilled, packed products. In vacuum-packed, high-pH meat, *B. thermosphacta* is able to grow (36) and its metabolism (carbohydrate fermentation and lipolytic ability) gives rise to compounds like acetoin and diacetyl, both of which are off-odourous. Acetoin requires glucose as substrate whereas other carbohydrates may be metabolized to, e.g., diacetyl (37). *B. thermosphacta* is also typical of spoilage of cured, packed meat products where it grows to high numbers producing off-odours and then dies off as *Lactobacillus* species become dominant (38). Although *B. thermosphacta* can often be isolated from aerobic packed meat, pseudomonads will eventually dominate and spoil the product (39). In contrast, *B. thermosphacta* is often isolated from meats packed in CO_2-containing atmosphere (40) but does require a limited amount of oxygen to produce spoilage off-odours (41).

D. Sporeformers

Gram-negative, spore-forming organisms, *Clostridium* and *Bacillus*, have been identified as the specific spoilage organisms of several food commodities. Clostridia are typically involved in spoilage of packed (anaerobic) products due to their intolerance to oxygen, whereas *Bacillus* spp. tolerate oxygen and can grow also in non-packed products. Psychrotrophic clostridia have been involved in spoilage of chilled, vacuum-packed raw or cooked meats. Spoilage of vacuum-packed meat may sometimes present itself as a "blown pack" and *Clostridium* species have been identified as the causative agent (42, 43). Several clostridia produce both CO_2, hydrogen, or butyric acid, which can explain the blowing (43) but CO_2 and hydrogen are probably the main causes (44). It appears that several different psychrotrophic clostridia may cause spoilage, including *Cl. gasigenes, Cl. estertheticum* (45), and *Cl. frigidicarnis* (46). Similarly, outgrowth of *Cl. butyricum* can cause so-called late-blowing of cheese (especially hard cheeses) due to fermentation of lactate (47). Sugar-salted, barrel-stored herring may spoil due to growth of clostridial species (48).

Bacillus species spoil different food products which typically have been heat treated as part of processing; hence, spores survive and grow. "Rope" formation in bread is caused by growth of *Bacillus* (49) and "sweet curdling," e.g., clotting, of milk can be caused by *Bacillus* where exoproteases degrade the casein micelles of the milk (50). "Ropiness" is caused by the enzymatic degradation of the bread crumbs and the parallel production of exopolysaccharides by the bacilli (51, 52). *Bacillus stearothermophilus* is a thermophilic organism which may cause a so-called flat-sour spoilage of evaporated milk (53) or some canned products (54).

A unique kind of spoilage has been found in heat-treated fruit juices, where an acid-requiring, spore-forming organism, *Alicyclobacillus acidoterrestris*, has been identified as the cause of a disinfectant taint (2,6 dibromophenol and 2,6 dichlorophenol) (55, 56). The kinetics of spoilage are not completely understood as it appears that very low levels of spores are sufficient to cause spoilage (55).

E. Yeasts

Yeasts are involved in spoilage of a wide array of food products where they are detected due to visible colonial growth, the formation of gas, or production of off-odour (57). A range of pickled products (mayonnaises, ketchups, salad dressings) are preserved with low pH and, often, addition of preservatives. This eliminates most microorganisms but lactic acid bacteria and yeasts may grow. Yeast cells are typically much larger than bacterial cells and hence a lower cell number is required to cause spoilage. Several of the *Zygosaccharomyces* yeasts in particular, and some isolates of *Saccharomyces cerevisiae* are spoilage agents in foods high in sugar, low in pH, and/or containing food preservatives. Also, alcohol-containing products are prone to yeast spoilage. The most important are *Z. rouxii, Z. bailii*, and *Z. bisporus* (58). Foods with low a_w (e.g., high in sugar) are often spoiled by *Z. rouxii* or *Z. mellis* which has been identified in spoiled bakery products (59) and sugars and syrups.

Zygosaccharomyces bailii and, to some extent also *Z. bisporus*, have been involved in spoilage of mayonnaises, ketchups, and salad dressings. *Z. bailii* grows at low pH in acetic acid and salt (60) and may adapt to food preservatives such as sorbate and benzoate. *Z. bailii* is also associated with wine spoilage. At lower temperatures *Z. lentus* is also a spoilage agent in preserved products (61).

Saccharomyces cerevisiae are commonly isolated as wild yeasts in breweries and are potential spoilage organisms (62, 63). Fermented foods may spoil due to yeast metabolism of lactate and acetate or the production of CO_2 and ethanol. Several *Saccharomyces* species have been isolated from spoiled fermented products (64).

Various species of yeast (*Candida*, *Yarrowia*) have been detected at levels up to 10^5 cfu/g in chilled spoiling poultry; however, a role in spoilage has not been elucidated (65, 66).

F. Filamentous Fungi

Filamentous fungi (moulds) may grow in many different types of food products and it is estimated that 5–10% of foods are lost *post-harvest* due to growth of filamentous fungi (2). They may affect sensory quality of the products in several ways: through visible filamentous growth, through production of exo-enzymes which degrade the product, or through production of small off-odourous compounds, such as geosmin (5). They may be involved in spoilage of a very broad range of food commodities but are commonly involved in spoilage of low water activity products (grains, nuts, dried fish, cheeses, fermented meats, bread and bakery products) and in spoilage of fruits and vegetables. Although the production of mycotoxins by filamentous fungi is a food safety issue, companies encountering food spoilage often wish to determine whether mycotoxin production may also have occurred. This often requires specialist advice (5, 67).

Foods spoiled by filamentous fungi are divided into two categories: living products such as fresh fruits and vegetables, cereals and nuts before harvest, and stored, processed, or preserved products (i.e., dried cereals, nuts, meat and fish, bread, bakery products, cheese, juice and beverages) (2).

Living plant foods rely on natural defense mechanisms to prevent microbial growth. Fruits have skins which require penetration, while cereals and nuts may produce phytoalexins or other natural antifungal material. Fresh animal foods are more liable to spoilage by bacteria than fungi. Stored processed and dried products must rely

on classical food preservation techniques such as drying of cereals, nuts, meat, and fish, or heat processing and/or the use of preservatives for juices and beverages. The genera *Aspergillus, Penicillium, Fusarium, Alternaria, Botrytis, Rhizopus*, and *Eurotium* are common causes of food spoilage. Although many species within each genera may have a spoilage potential, only 2–12 species seem to be important in spoilage (5) and for many types of living food, only 1–2 species are of major importance. For instance, some fungi (e.g., *Rhizopus*) have specific enzymes allowing skin penetration whereas others (e.g., *Pencillium*) have mechanisms for overcoming the specific antifungal defenses (2). Although many fungi may potentially spoil citrus fruits, the primary spoilage fungi are *Pen. italicum* and *Pen. digitatum* (2, 5).

An overview of the spoilage mycobiota of different foods is presented in Table 51.2.

G. Others

Several of the groups/species of spoilage organisms described above are involved in spoilage of several foods or products. However, in some products it appears that one single species appears and is involved in spoilage of only one specific product. This may of course just be a matter of understanding the ecology and metabolism of a particular organism to predict if it will have spoilage activity in other products. One such example is the spoilage of flavoured bottled water by species of the aerobic Gram-negative bacteria, *Gluconobacter*, which produces sour off-odours (68, 69). This organism is closely related to the acetic acid bacteria and proliferates at very low pH values (e.g., pH 3.5) (69), hence being adapted to these particular products.

IV. SPOILAGE PATTERNS OF FOODS

A summary of examples of typical spoilage substrates and metabolites is presented in Table 51.3.

A. Vegetables

Vegetables have a high water content (80–90%) and their texture is built by pectins or other carbohydrate polymers such as starch. They typically contain low amounts of protein and simple carbohydrates and many are rich in pigments. pH is around 6 (5.5–7). In some countries, vegetables are distributed at chill temperatures. Increasingly, vegetables are sold processed into ready-to-eat salads (70). Spoilage of vegetables is primarily caused by microorganisms capable of degrading the polymers of the product. The main spoiling organisms are *Pseudomonas* spp., Enterobacteriaceae (mostly *Erwinia*), and filamentous fungi. The bacterial spoilage is evident when high numbers ($>10^8$ cfu/g) are reached. Typically, these organisms are pectinolytic and hence cause softening of the tissue, known as soft-rot. Also, during degradation off-flavours and off-odours are formed. In some bacteria, spoilage is enhanced by proteolytic capability (22), probably because proteolysis causes an increase in pH and some pectate lyases have a higher activity at high pH (8–9) (71).

The expression of hydrolytic enzymes (proteases, pectinases, cellulases) in the plant-pathogenic *Erwinia carotovora* subsp. *carotovora* is regulated in a quorum

TABLE 51.2
Associated Spoilage Mycobiota of Different Foods (Modified from References 2, 5)

TABLE 51.3
Examples of Typical Spoilage Substrates and Metabolites Found in Microbiologically Spoiled Foods (160)

Sensory Impression	Spoilage Product	Spoilage Substrate	Food Product	Specific Spoilage Organism	Reference
Slime	EPS (dextran)	Sucrose	Kimchi	*Leuconostoc*	31
			Turkey breast	*Leuconostoc*	35
		Sugars	Wine	*Pediococcus damnosus*	29
		Sugars	Bread	*Bacillus*	49
Slime	Hydrolysed polymer	Pectin	Vegetables	*Erwinia, Pseudomonas*	70
Fishy off-odour	Trimethylamine (TMA)	Trimethylamine oxide (TMAO)	Fish	*Shewanella putrefaciens*	161
				P. phosphoresum	19
				Aeromonas spp.	96
Ammonia, putrid	NH_3	Amino acids	Proteinaceous foods	Many microorganisms	
	Biogenic amines	Amino acids	Meat	*Enterobacteriaceae* and LAB	7
			Fish[1]	*Enterobacteriaceae*, LAB	10
			Fish[1]	*P. phosphoreum*	10
Sulhidy off-odour	H_2S	Cysteine	Fish, meat	*S. putrefaciens*	98, 162
				Enterobacteriaceae	4
				Lb. saké, Lb. curvatus	
Greening	H_2S	Cysteine	Meat	*Lb. plantarum*	33
Sulphydryl off-odours	$(CH_3)_2S_2$	Methionine	Fish, meat	*Pseudomonas* spp.	163
				Enterobacteriaceae	164
Acid off-odour	Acetic acid L,D-lactic acid	Glucose, ribose, other CHO	Meat	LAB	165
"Sweet curdling"	Proteinaceus fat particles	Phospholipid	Milk	*Bacillus cereus*	166
Fruity off-odour	Esters		Fish	*Ps. fragi*	167
			Milk	*Ps. fragi*	84
				Ps. putida and *Y. intermedia*	85
Cheesey off-odour	Acetoin, diacetyl, 3-methylbutanoyl	Glucose	Meat	*B. thermosphacta*	4
				Enterobacteriaceae	
				Homofermentative LAB	
Medicine off-odour	2-methoxy-phenol, sediment	Sugars	Juice	*Alicyclobacillus acidoterrestris*	55
Musty odour	Trichloroanisol	2,4,6 Trichlorophenol	Wine	*Penicillium brevicompactum*	5
				Aspergillus flavus	

[1] Biogenic amines may not be the cause of spoilage but can serve as a spoilage index (10).

sensing dependant way. The bacterium produces small hormone-like signal molecules (acylated homoserine lactones, AHLs) that allow the bacterial population to sense its own density (72). Expression of hydrolytic enzymes is up-regulated at high densities. Interestingly, the production of pectin-degrading enzymes in an onion spoiling *Burkholderia* (73) and the production of protease and cellulase in a bean sprout spoiling *Serratia* (22) are regulated also by AHLs. Hence, AHL-negative mutants have a lower spoilage activity.

In vegetables high in simple carbohydrates, such as sugar beets which contain high concentrations of sucrose, levan (slime) formation may cause both spoilage and technical problems during further processing (74).

The spoilage of potatoes is caused by different organisms including *Pseudomonas*, *Streptomyces*, and a range of filamentous fungi (75). Spoilage may present itself as soft-rot, dry-rot, wilt, and blight. It may be initiated pre-harvest but the causative organisms can also attack during storage.

B. Fresh Proteinaceous Foods (Milk, Meat, Fish)

Liquid milk consists of water, protein (casein), carbohydrate (lactose), salts, and lipids in varying proportions. Water activity is high, the pH is between 6 and 7 and preservation parameters include pasteurisation and chill storage. Pasteurised liquid milk products undergo different types of spoilage. Typically, spoilage results from action of *Bacillus*, *Pseudomonas*, or Enterobacteriaceae (76, 77) and is evident when high numbers ($> 10^7$ cfu/ml) are reached (13). Sometimes, degradative enzymes which survive pasteurisation cause spoilage during storage with no bacterial growth (78). Spoilage by *Pseudomonas* and Enterobacteriaceae is the result of post-pasteurisation contamination (79, 80) whereas spores of *Bacillus* may survive pasteurisation and grow during storage. Several types of psychrotrophic *Bacillus* have been involved in spoilage of chill-stored, liquid milk (81, 82). At normal chill storage temperatures, *Pseudomonas* spp. will typically become the dominant

spoilage organism (83). Spoilage is characterized by bitter, sour, or fruity off-flavours (76) and/or by clotting ("sweet curdling"). The bitter off-flavours can be caused by proteolytic action of pseudomonads (78) and protelytic degradation of the casein-micelles leads to clotting of milk. Rancid off-flavours may be caused by lipoytic activity of, for instance, *Pseudomonas* spp. (13), whereas fruity off-flavours arise from esters producted by *Pseudomonas* spp. or Enterobacteriaceae (84, 85).

Water is the main constituent of red meat and poultry. It contains protein, lipid, and several non-protein nitrogen-containing compounds such as amino acids and creatine. Carbohydrates are present as glycogen, glucose, and lactate. In non-stressed animals, pH will decrease significantly (to approx. 5.5) in red meat *post mortem* due to glycogen metabolism. Glycogen depots are depleted in stressed animals *pre mortem* and pH after slaughter reaches 6.0–6.5. These differences can have a profound impact on the spoilage microbiology of vacuum-packed meats since the hydrogen sulphide-producing bacteria *Shewanella putrefaciens* may grow in packed, high-pH meat and cause rapid spoilage (4). The *Shewanella* spoilage is characterised by sulphidy off-odours and H_2S may cause greening of the meat due to conversion of myoglobin to sulfmyoglobin (33, 34). *S. putrefaciens* will not grow at pH 5.0–5.5 and hence packed, normal pH meat has a much longer shelf life. Greening of cured meat is caused by lactic acid bacteria (86) where H_2O_2 converts myoglobin to a green iron (III) complex (87).

"Meat" covers muscle tissue from a range of different animals: beef, veal, lamb, poultry (fatty, lean). Whole meat is typically more stable than ground meat. In aerobic atmosphere, whole meat has a shelf life of approximately 1 week at 5°C whereas ground meat will spoil in 1–2 days depending on the initial bacterial count. The bacterial counts of ground meats are, in general, higher than on non-comminuted meats. Typically, gound meat contains trimmings and has a much greater surface-to-volume ratio allowing a more rapid spoilage (88). Packaging extends shelf life and the atmosphere of packaging will have a marked influence on the extension. Vacuum-packing can extend storage life of beef (held at 0°C) from 2–4 weeks to more than 15 (41). Packing in 100% CO_2 may extend shelf life at 4–5°C to 8–12 weeks (4). Many packaging atmospheres do contain oxygen as this allows retainment of the red oxygenated myoglobin colour.

The microflora on fresh meat is a mixture of many different species originating from hides, environment, and the gastro-intestinal tract. During aerobic storage, psychrotrophic pseudomonads become dominant (4). After 1–2 weeks, counts of 10^8–10^9 are reached and spoilage is detectable as slime and off-odours. Vacuum-packing or CO_2-packing (in O_2-impermeable films) eliminate pseudomonads and the microflora becomes dominated by lactic acid bacteria belonging to *Lactobacillus, Leuconostoc*, and *Carnobacterium* (35, 89). Enterobacteriaceae and *Brochothrix thermosphacta* are often present in quite high proportions reaching 10^3–10^7 cfu/g (4, 9). Depending on the level of oxygen addition to the modified atmosphere packaging, shelf life (at 5°C) may be increased to 3–12 weeks.

Metabolism of glucose and amino acids supports bacterial growth. Off-odours in aerobically packed meat are not detected as long as glucose is metabolised; however, off-odours and spoilage of aerobically packed meat become evident when glucose is depleted and amino acids are metabolised (90). During glucose metabolism, the sweet, fruity off-odours of incipient spoilage are caused by ethyl esters produced by *Ps. fragi*. Degradation of amino acids is the cause of production of sulphur-containing compounds giving the putrid off-flavours in the advanced stages of spoilage.

Packed meats are typically characterised by sour off-odours being produced by the dominant lactic acid bacteria. The so-called cheesey off-odour often detected in vacuum-packed meat products is caused by acetoin and di-acetyl which are produced by *Br. thermosphacta* in packed (high pH) meats (4, 9).

Fresh fish is rich in water, protein and, for some species, lipids. Fish muscle also contains free amino acids, nucleotides and, in some species, trimethylamine oxide (TMAO) (11). TMAO, which is an odourless compound, is typically accumulated in marine fish species, especially the gadoid species, but may also be detected in fish from fresh waters (91). Some bacteria can use the oxygen in TMAO in anaerobic respiration and this reduction results in the formation of trimethylamine (TMA) which has the characteristic "fishy" flavour. As opposed to meat from mammalian animals, fish do not accumulate glycogen and pH therefore does not decrease *post mortem*. As in high-pH meat, this allows psychrotolerant *Shewanella* to grow during storage. Fish are cold-blooded animals and the microorganisms on newly caught fish from temperate waters are adapted to low temperatures. This combination of several factors explains why fish is a very perishable product and should be stored at low temperatures, preferably in melting ice (0°C). The shelf life of iced fish varies from 2 weeks (cod-like fish) to 4 weeks (fish from tropical waters). Some fatty fish species such as herring and mackerel have short shelf lives if left unpacked due to lipid oxidation and development of rancid off-flavours.

During storage of fish in ice, psychrotrophic pseudomonads, shewanellae, and *Neisseria* species become dominant (92–95). *Pseudomonas* spp. spoil freshwater fish when counts reach 10^8–10^9 cfu/g (96). Spoilage is typically characterised by sweet, sulphydryl, rotten off-odours. In contrast, the sensory impression of spoilage of marine fish is characterised as putrid, rotten, fishy due to formation of TMA and H_2S by psychrotrophic *Shewanella* species (97, 98). The off-odourous compounds are typically formed by

bacterial metabolism of low-molecular-weight compounds (99). Spoilage proceeds very rapidly (12–48 hours) if fish is left at ambient temperature and mesophilic *Vibrio* and *Aeromonas* species are causing the spoilage. Packing of fish from marine waters causes selection of the CO_2-resistant, psychrotolerant *Photobacterium phosphoreum* which is the dominat spoilage organism of CO_2 packed fish (19, 100). Fish from fresh waters and fish from tropical waters probably do not harbour this organism and organisms such as lactic acid bacteria become dominant in these products.

C. Cured or Processed Proteinaceous Foods

A wide range of "cured" milk products are produced world-wide. This covers yogurts, soft unripened cheeses, and an enormous range of hard or ripened soft cheeses. Some of these products are acidified by fermenting microorganisms (mostly lactic acid bacteria); in others the curdling is caused by addition of protelytic enzymes (rennet) which degrade the casein-micelles and allow a curd to be formed. Pasteurization, acidification, and, often, chilling, are effective preservation hurdles; however, spoilage of the acidified products can be caused by yeasts and filamentous fungi. In particular flavoured yogurts, where sugar/fruit is added, are good substrates for yeast spoilage organisms (101, 102) and spoiling filamentous fungi (103).

The most important spoilage organisms of hard, semi-hard, and soft cheeses are the filamentous fungi; especially *Pencicillium* species (5, 104, 105). In some cheeses, the development of fungi is part of the processing; however, growth of other filamentous fungi is a sign of spoilage. Fresh, unripened cheeses such as cottage cheese, may also spoil because of bacterial growth and especially *Pseudomonas* spp. and psychrotrophic Enterobacteriaceae produce visible colonies on the surface and cause development of off-odours (106). Bacterial gas formation may be the cause of spoilage of cheeses. So-called "early blowing" can be caused by a range of bacteria producing CO_2 from lactose (107). "Late blowing" is specifically caused by growth and production of butyric acid by clostridia during storage and ripening of hard cheeses (47).

Meat is processed/cured to produce an enormous range of products including bacon, sausages, cooked and sliced product. Raw cured products (ham, fermented sausages) are preserved to an extent where bacteria do not grow well and hence spoilage is typically caused by yeasts or filamentous fungi. Bacterial spoilage by Enterobacteraiceae or clostridia may occur during processing before the salt concentration is high enough (108, 109). Cooked, perishable products include frankfurters and luncheon meat products. *Pseudomonas* are the main spoilage agent of such product-stored aerobically, whereas vacuum or modified atmosphere packaging selects for the same types of organisms as described under fresh meats. The spoilage organisms typically include lactic acid bacteria, *Br. thermosphacta* and Enterobacteriaceae (9, 90, 110). Spoilage may be detectable as slime formation (111) as sour off-odours (26), or as the cheesey off-odours produced by *Br. thermosphacta*.

As meat products, fish are preserved using salting, acidifying, and heat treatments. Lightly preserved products, e.g., cold-smoked fish, typically spoil due to growth and metabolism of lactic acid bacteria and Gram-negative bacteria, either Enterobacteriaceae or *P. phosphoreum* (112–114). *Br. thermosphacta* also may be detected in levels between 10^3 and 10^7 cfu/g (115) and in pure culture it does produce rotten off-odours (116). Growth and spoilage by Gram-negative bacteria are inhibited in semi-preserved products which are salted, lightly acidified, and kept at chill temperatures. Spoilage is caused by growth of lactic acid bacteria or yeasts and may involve souring or gas formation (28). Packed and heated products which are distributed at chill temperatures may spoil due to growth of Gram-positive, spore-forming organisms (117). Heavily salted fish products may spoil due to growth of strictly halophilic bacteria which cause discolouration (red colour) due to their own pigmentation (118) and rotten off-odours due to protelytic degradation. In heavily salted fish which is re-hydrated, bacterial growth resumes and *Psychrobacter* spp. producing musty odours have been identified as spoilage organisms (119). Shelf life of dried fish species may be limitied by fungal growth (2).

D. Fruits

Fruits contain high amounts of easily digestible sugars and the water content of fruits is high. However, bacteria do not grow well because the pH is low (in the range of 2–5) and most bacteria are inhibited under these conditions, so spoilage is caused by filamentous fungi (120). Spoilage manifests itself in many ways as spots, scabs, soft rot, or dry rot. Cucumber, capsicum, and tomatoes are fruits with a pH closer to neutral and spoilage is also often caused by growth of Gram-negative, pectin-degrading bacteria, (*Pseudomonas* spp. or *Erwinia* spp.) (21, 120).

E. Dressings, Ketchup, and High Fat Products

Foods dealt with in this section are typically highly preserved using mayonnaise-based dressings and/or low levels of water activity and/or high levels of preservatives. Typical examples are coleslaw, ketchup, and various dressings. Most Gram-negative bacteria and many Gram-positive bacteria are effectively inhibited by the preserving parameters, and typical spoilage organisms are lactic acid bacteria and yeasts (121, 122). Their spoilage is detected as sour off-odours or swelling of the product (123). Off-odour or slime formation may also characterise the spoilage (124). Many of these types of product contain acetic acid and

only organisms resistant to this acid are involved in spoilage. Several types of *Lactobacillus* have been isolated from spoiled products (124, 125).

Products such as margarine and butter which are low in water activity and high in fat/lipid content are typically stable products but may spoil due to growth of yeasts or filamentous fungi. Thus, *Penicillium* species have commonly been isolated from spoiled margarine (104). Filamentous fungi (e.g., *Chrysosporium* species) have been the cause of chocolate spoilage (126).

F. Beverages

Fruit juices and most soft drinks are high in sugar and typically have a low pH. Hence, yeasts, fungi, and acid-tolerant bacteria can grow in the products and some will ultimately cause spoilage. *Saccharomyces* and *Zygosaccharomyces* strains are common spoilage organisms (127). Also, some lactic acid bacteria have been identified as spoilers of soft drinks (128) and the acid-tolerant, spore-forming *Alicyclobacillus acidoterrestris* has been detected as the cause of medicinal off-odour in pasteurised fruit juices (55).

Wines are typically preserved by the dominance of the fermenting organism and the subsequent production of alcohol. Lactic acid bacteria and yeasts are the major causes of spoilage (57, 63) although strictly anaerobic Gram-negative bacteria have also been the cause of off-odour (129, 130). Beer spoilage organisms may be wild yeasts present in the brewery (63) and can be transferred to the product where they grow and spoil the product (57). Alcohol and hop components are inhibitory to most bacteria. However, several beer-spoiling microorganisms have the ability to grow in hop which will inhibit most microorganisms (129, 131). Sluggish or stuck wine fermentations have sometimes been linked to growth of lactic acid bacteria which may inhibit growth of the desired fermenting organisms (132). Growth of spoilage microorganisms may cause a range of off-odours or may be visible as slime formation (30).

G. Bakery Goods

Filamentous fungi are the most prominent spoilage organisms of bakery products (2, 5, 133). The combination of their ability to grow at low water activities and the easy spreading of spores in the dry baking environment gives them a selective advantage. Another typical spoilage problem is the so-called ropiness caused by *Bacillus* species, especially *B. subtilis* (49, 134).

V. CHEMICAL ANALYSIS OF SPOILAGE

As defined at the beginning of this chapter, "spoilage" is any change in sensory properties that renders a product unacceptable for the consumer. Sensory methods can be developed to a very high degree of standardization using trained panels (135, 136). Using multivariate statistics, sensory analysis may be combined with chemical analysis to determine which compounds are causing specific odours and flavours. Specific electronic chemical gas sensors (so-called "electronic noses") may be used to profile the odours (137) and so-called "electronic tongues" to detect flavours (138).

Gas chromatographic separation followed by mass spectrometry is often used for profiling odours of spoiled foods. Examples include GC-MS studies of bacterial spoilage of prawns (12), cold-smoked salmon (116, 139), and chilled chicken (140). GC-MS analysis also has been used to determine mycological quality of barley grains (141).

Recently attempts have been made to combine non-destructive chemical methods with statistical analyses of complex patterns derived to correlate with spoilage and/or shelf life. An example of such studies include use of sophisticated techniques to determine well-known indicators of spoilage, such as the use of ion mobility spectrometry to determine biogenic amines (142). Sometimes such compounds are indeed only indicative (143) and may not necessarily be the ones responsible for the off-odours and off-flavours. The volatile compounds developing during spoilage of packed, chilled meat were analysed using a so-called electronic nose sensitive to several volatiles (144). Subsequently, multivariate analyses were used to correlate the magnitude of the "nose signals" with sensory impressions. Whilst this allowed an expression correlated to the quantitative degree of spoilage, no information on individual spoilage components was obtained. A somewhat similar approach was described by Ellis et al. (145) that used Fourier transformed infrared spectroscopy data to evaluate spoilage of meat. Different spectra were found in fresh and spoiling meat and peaks indicative of spoilage were identified.

VI. PRESERVATION STRATEGIES

Food preservation in ancient times relied on experience with treatments that ensured lack of spoilage. Examples are heavily dried or salted products and a range of fermented products. Development of more modern food preservation allowed the use of processes eliminating microorganisms, for example pasteurisation or autoclaving, or processes preventing growth completely, for example by freezing. The trend towards so-called milder preservation techniques typically combines a variety of parameters that allow growth to be controlled but not completely abolished. Examples include packaging, chill-storage, mild salting, etc.

Currently a range of new preservation procedures is under investigation. This includes physical treatments such as high hydrostatic pressure which is a promising non-thermal treatment allowing inactivation similar to

heat treatments (146). The high hydrostatic pressure affects the bacterial membrane (147). Other inactivation processes include high-voltage electrical discharges and high-magnetic-field pulses (148).

The use of live bacterial cultures (149) or the antimicrobial peptides (bacteriocins) produced by lactic acid bacteria (150) has been intensively studied, in particular with the purpose of inhibiting pathogenic bacteria. Also, natural antimicrobial enzyme systems (151) or naturally occurring antimicrobials (152–154) are being tested as food preservatives.

Several biopreservation techniques have been assessed for their inhibition of spoilage microorganisms. For instance, Pepe et al. (52) demonstrated that lactic acid bacteria could inhibit rope-producing *Bacillus* in bread. The delay/control of ropiness was seen both when lactic acid bacteria were added to bread inoculated with *Bacillus* and, more importantly, when lactic acid bacteria were used as a starter during dough preparation. Also, a bacteriocin-producing lactic acid bacterium (*Leconostoc* spp.) allowed control of spoilage of vacuum-packed beef by a sulfide-producing lactic acid bacteria (155).

VII. MODELLING GROWTH OF SPOILAGE MICROORGANISMS AND PREDICTION OF SHELF LIFE

Modern "predictive microbiology" was in some ways born with mathematical descriptions of spoilage as a function of, for instance, temperature (156) but has increasingly focused on determining, modelling, and predicting the growth or survival of food-borne pathogenic organisms as a function of changing environmental factors.

Modelling of growth of spoilage bacteria as a function of environmental and preservative parameters allows (i) determination of the range of products in which the particular organism may be imporant (e.g., will have the ability to grow) and (ii) prediction of remaining shelf life of a particular product in which the number of spoilage organisms can be determined in the fresh product. Results as obtained in (i) may reduce the number of challenge trials required to determine shelf life of new products with altered preservation profiles.

For instance, the growth of the soft-drink spoilage organism *Gluconobacter oxydans* under different pH, acidity, sugar, and benzoate concentrations was determined and modelled (157) allowing the effect of change in each parameter on growth to be quantified. Membre and Kubaczka (158) not only modelled the growth of a vegetable juice spoilage bacterium but also described how the actual spoilage process (kinetics of pectin compound degradation) evolved. Parts of the "seafood spoilage predictor" may exemplify (ii) from above. This software includes models for growth of specific spoilage organisms and allows relative rates of spoilage to be predicted based on temperature profiles (159).

VIII. CONCLUDING REMARKS AND PERSPECTIVES

Our understanding of microbial food spoilage is, for a range of products, very detailed. The organisms, their spoilage metabolites, and the conditions under which spoilage is important are known for several product types. This is particularly true for products where one specific organism is important, for instance the spoilage of packed marine fish (from temperate waters) by *P. phosphoreum*. In contrast, our understanding of more complex spoilage processes where several organisms are involved is less developed. Although we have identified the spoilage microbiota and may have some indication of which organisms contribute to the spoilage, we need to further our understanding of these products. In particular, products where "mild" combinations of preservation parameters are used allow the growth of several organisms. These products are often delicatessen products and understanding their spoilage would allow science-based quality indices to be developed and would allow prediction and labelling with appropriate shelf lives.

The evolution of such understanding will be facilitated and must run in parallel with development of methods for specific enumeration of spoilage microorganisms. Very sensitive methods are needed, especially for shelf life predictions based on numbers of specific spoilage organisms. Finally, the understanding of food spoilage and the spoilage process should enable design of more targeted food preservation methods where only the unwanted organisms or their unwanted metabolism is inhibited.

ACKNOWLEDGMENTS

Comments and suggestions from Jesper B. Bruhn on the complete chapter and from Dr. John Pitt on sections dealing with filamentous fungi have been most helpful.

CONTENTS

I. INTRODUCTION

Meat and poultry products are highly perishable foods since they support growth of microorganisms associated with spoilage. In addition, by their very nature and origin they may be implicated in the spread of microbial foodborne diseases. During the past twenty years, the increasing consumer demand for a wider variety of convenient

products of high quality and safety along with the producers' desire for economies of scale in production have led to dramatic changes in the processing, storage, distribution and packaging of meat and poultry products. As a consequence, the important areas of meat and poultry microbiology have also changed. Since the vast subject of meat and poultry microbiology has been discussed extensively in various books, book chapters and review papers (1–5), this chapter focuses on recent research interests and matters of current practice used within the meat and poultry production and distribution chain. The topics include sources, type and extent of microbial contamination including spoilage and pathogenic organisms, microbial changes during storage, methods for controlling microorganisms in meat and meat products, and management of processes for the microbiological safety of these foods.

II. MICROBIAL CONTAMINATION OF MEAT FROM LAND ANIMALS

A. General

In general, the muscle tissues of healthy animals and birds, before slaughter, can be considered sterile. Exceptions to this generalization are the lymph nodes and some organs that may carry limited microbial contamination. In contrast, surfaces of the animal exposed to the environment such as hide, pelt, feathers, fleece, the mouth and the gastrointestinal tract may be heavily contaminated (6–8). These parts of the animal are the major sources of meat and poultry carcass contamination. The extent of contamination transfer from the above sources to the carcass is greatly dependent on the conditions under which animals are reared, slaughtered and processed (4,6–8). Hygienic practices, sanitation procedures, product handling and processing procedures, and conditions of storage and distribution are the most important factors that determine the microbiological quality of the final meat and poultry products. Consequently, variations in facilities, raising methods and practices of slaughtering and processing operations may lead to significant differences in the type and extent of meat contamination (4). Sources of contamination during processing, and the factors affecting the type and extent of contamination are discussed in the following sections.

B. Sources of Microbial Contamination

1. Red Meat

a. Live animal

It is generally agreed that the majority of microorganisms on red meat carcasses originate from the live animals, which also serve as sources of environmental and water contamination. These sources introduce contamination in animal products or other foods through cross-contamination and through contamination of equipment and utensils. Contamination from surfaces exposed to the environment is transferred to the underlying sterile carcass tissue during animal slaughter and dressing. The hide of the animal is the most significant contamination source (7,9). During the raising of cattle, pigs and sheep, large numbers of spoilage and pathogenic microorganisms, mainly originating from soil, pastures and feces, can be found on the hides of the animals. For example, the total microflora of cattle hides may reach 10^{12} cfu/100 cm^2 (10), while an incidence of greater than 10% of *Escherichia coli* O157:H7 has been reported for cattle hides in the U.S. (11). The part of the hide with the highest incidence rate of pathogens is the brisket, followed by the flank and the rump (12). In a similar study, however, the part of the hide with the highest incidence of shiga-toxigenic *E. coli* O157 was found to be the back, followed by the neck, flank, ventrum and hock, in decreasing order (13).

A number of factors associated with the type, prevalence and extent of animal hide contamination have been identified in recent years including climate, season of the year, geographic location, and raising, transportation and holding methods (14). Animals raised in feedlots may carry more bacteria of fecal origin while soil microorganisms are usually more common on animals raised in pastures (4,15). During transport from farm to slaughter, animals may be exposed to further fecal, and therefore, pathogen contamination in the transport vehicles. In addition, animal-to-animal transfer of contamination can occur during transport, either directly via body contact or indirectly via contact with contaminated surfaces. Transportation of cattle from the feedyard to a commercial packing facility was found to result in a 14-fold increase in *Salmonella* prevalence on hides, and a 2-fold increase in fecal *Salmonella* levels (16).

Although it may be assumed that the cleanliness of the animals prior to slaughter is a crucial factor that determines the microbiological quality and safety of carcasses after processing, studies have shown this not to be the case (17,18). For example, no association was found between tag (mud, bedding and feces) on the hides of beef cattle and bacterial counts of carcasses (17). Furthermore, preharvest management practices (wool length, use of bedding and wet versus dry pens) appeared to have no effect on the microbiological quality of lamb carcasses (18). However, evaluation of microbial contamination of the stock presented for slaughter may be beneficial for adjustment of the speed of processing lines or the separate processing of highly contaminated animals (19,20).

b. Slaughter and dressing

During the slaughtering process bacteria can enter the tissues through the bloodstream from contamination of the sticking knife. However, bacteria introduced into the bloodstream do not survive for long in the tissues due to the defense mechanisms of the animal that continue for at

least 1 h after death (6). Thus, if high levels of contamination from slaughter instruments are avoided by reasonable hygienic precautions, carcass contamination from this source should not be a problem.

Most of the bacterial contamination of the carcass is acquired during the dressing process. Knife incisions for the removal of cattle and sheep hides introduces microorganisms from the hide onto the underlying tissue. Further bacterial transfer may occur from contact of the hide with exposed carcass tissue or from aerosols, dust, wool and hair from the hide or fleece (7). Unlike cattle and sheep, the skin of pigs is usually not removed during the dressing procedure, although certain facilities process skinned pork carcasses. After slaughter, pigs are scalded to loosen the attachment of the hair to the skin before dehairing (7). Although the scalding operation reduces the number of microorganisms on the skin, recontamination may occur during dehairing due to the high level of contamination of dehairing equipment (21). The numbers of such contaminants can be reduced by the singeing process used to burn hair remaining on the carcass. However, as the singeing of the surface is usually uneven, significant numbers of bacteria, including both spoilage and pathogenic types, can persist on some areas of the carcass or be introduced or spread during carcass polishing operations (8,22,23).

Other significant sources of contamination during the dressing process are the mouth and the viscera of the animals. The mouth harbors large numbers of bacteria including pathogens such as pathogenic *E. coli* and *Salmonella* (13,24). If other areas of the carcass are handled by workers after handling the throat and the tongue, then carcasses may be heavily contaminated with bacteria from the mouth. During evisceration, contamination can occur if the intestinal tract is pierced or if fecal material is released from the rectum during removal of abdominal contents. Careful handling of the head and viscera as well as the use of plastic bags to enclose the head and the end of the cut bung of animals reduces contamination from these sources.

In addition to the hide, head and viscera, bacteria may be introduced onto the carcass during the dressing process from the processing environment such as floors, walls, contact surfaces, knives and workers' hands. Thus, hygienic conditions and sanitation procedures are important factors affecting the microbiological quality of the dressed carcasses.

c. Chilling

Before fabrication, carcasses need to be chilled to adequately low deep muscle temperatures in order to avoid microbial proliferation during and following fabrication (15). Most carcass cooling processes are operated so as to reduce deep muscle temperatures to 7°C or lower within a 12–24 h period (25). However, due to their size, commercial chilling of beef carcass sides requires 18–36 h for temperatures of <7°C to be reached. Traditionally, carcasses were chilled by exposure to a flow of cold air only, which, due to the evaporation of water, resulted in drying of the carcass surface (26). Experimental studies have shown that depending on the temperature, humidity and air velocity, this type of chilling may result in increases, decreases or no changes in total numbers of aerobic bacteria of carcasses (6). Drying of the carcass surface, however, results in loss of carcass weight, which in turn leads to economic losses (27). Hot carcass weight losses of at least 2% during the first 24 h of air chilling have been reported for beef (28,29), pork (30) and lamb (31). In order to circumvent this, most packing plants in North America use intermittent spraying of carcasses with chilled water, especially during the initial stages of chilling, which facilitates carcass temperature decreases without loss of surface moisture. Spray chilling results in carcass weights that are slightly less than those of carcasses entering the chilling process (8). The practice of spray chilling is uncommon outside North America, partly due to concerns that the prevention of drying of the carcass surface would allow growth of pathogenic bacteria (26). Experimental studies, however, have shown that as for traditional air chilling of carcasses, microbial levels on carcasses can increase, decrease or remain unchanged by adjusting air temperatures and speeds, as well as the frequency, intensity and duration of spraying (32–34). The incorporation of chlorine (35,36), acetic and lactic acids (37,38) in the spray chilling process have been evaluated as a means of sanitizing beef carcasses during the chilling process.

d. Fabrication

The chilling process is followed by cutting (fabrication) of the carcass into primal and sub-primal cuts, and trimmings. The meat receives extensive handling during these operations and high levels of cross-contamination may occur by contact of freshly cut meat surfaces with work surfaces, hands and equipment. Factors affecting the extent of contamination during fabrication include temperature of the boning room, the time duration that meat is held there, and the cleanliness of fabrication equipment. Equipment such as cutting tables, conveyor belts, saws and knives can carry high numbers of spoilage and pathogenic bacteria (21,39). In order to minimize cross-contamination and spreading of contamination during fabrication, adequate cleaning of the plant and equipment as well as sanitation practices to prevent microbial contamination and biofilm formation are required. Proper control of the above conditions may maintain bacterial densities on meat after the fabrication process to as close to initial levels of contamination as possible.

2. Poultry

a. Live bird

Although freshly laid eggs rarely contain microorganisms, eggs and ultimately the developing embryo can be

contaminated through two possible routes; by vertical (transovarial) or horizontal transmission of microorganisms. Transovarial transmission occurs when bacteria infect the hen's ovaries or oviducts resulting in possible contamination of the egg during its formation (7,40,41). Of major concern is the vertical transmission of *Salmonella* Enteritidis (42). The more common route of microbial contamination of eggs, however, is via horizontal transmission. This occurs when the natural defenses of the egg, which include the cuticle layer, shell, and outer and inner membranes, are penetrated resulting in contamination of the internal contents of the egg (43,44). Microorganisms contaminating the egg after it has been laid originate from the intestines when the egg passes through the cloaca, nest materials, litter or incubator surfaces (42,45,46).

Newly hatched chicks from uninfected eggs are microbiologically sterile but are readily contaminated with microorganisms present in their environment, for example, from contaminated eggshells, fecal matter, fluff from infected newly hatched chicks, and walls and floors of the incubator (47,48). Healthy chickens carry millions of microorganisms in their intestines and on their skin (49). Sources of microorganisms on the rearing farms are contaminated feed and water, soil, litter, dust and air. Insects, rodents, wild birds, reptiles and other small animals may also act as reservoirs and vectors of microorganisms (41).

During transportation of birds from growing houses to slaughter facilities, contamination and cross-contamination with fecal material may occur. Stress conditions during transport may lead to more frequent excretion of fecal material and cecal contents (50,51), and thus an increase in the level of contamination. Since transport crates become heavily contaminated with fecal material, they need to be thoroughly cleaned and disinfected before being reused to prevent cross-contamination of other flocks (52).

b. Slaughter and processing

Incoming birds are the principal source of most microorganisms found on poultry carcasses. Similar to red meat animals, healthy birds carry extensive microbial contamination on their feathers, skin and intestinal tract (3,49,53). In general, transfer of this contamination to the carcasses occurs during all processing steps including stunning, bleeding, scalding, defeathering, evisceration, washing and chilling (50).

As birds are hung and bled, the flapping of wings may generate dust and aerosols which distribute contamination onto nearby birds or carcasses. After bleeding, poultry carcasses are scalded by submerging in a warm waterbath (scald tank) at temperatures between 50 and 60°C. The accumulation and survival of microorganisms in the scald tank is influenced by the temperature of water and the rate at which fresh water is added (54). The pH of the scalding water and the presence of organic matter are also important for bacterial survival since they affect the rate of inactivation of microorganisms (55). It is obvious that from a hygienic point of view scalding is a hazardous operation. Attempts to avoid the use of immersion scalding have led to the development of alternative methods including spraying systems and division of the scald tank into several smaller ones (56). Although under experimental conditions these methods improve the hygiene of the scalding process, their commercial implementation is, however, limited because most of them have yet to be fully adapted to commercial requirements.

After scalding, the carcasses pass through a series of mechanical plucking machines which remove the feathers. The defeathering process may spread contamination between carcasses or from the defeathering equipment (56). The level of cross-contamination during defeathering is very high since one contaminated bird can cross-contaminate hundreds of others as they pass through the pluckers (50).

Evisceration of poultry carcasses is carried out in several stages including head removal, opening of the body cavity, removal of intestines and cleaning of the carcass. As with red meat animals this process is associated with contamination of the carcass with microorganisms originating from intestines, including pathogens. Contamination during evisceration may occur by bacterial transfer from carcass to carcass by knives, eviscerating implements and worker's hands. The automated transfer of carcasses to the different stages of the evisceration process significantly reduces product handling and potential cross-contamination. However, contamination may still occur due to improper cleaning of the machines involved in the process.

Poultry carcasses are washed and chilled immediately after evisceration. Washing of carcasses removes the organic matter and some of the contaminating microorganisms. Chilling aims to limit multiplication of spoilage bacteria and restrict the growth of pathogens. The two most common chilling methods for poultry carcasses are water (immersion) and air chilling. Carcasses destined for the frozen market are normally water chilled, while fresh, non-frozen carcasses can either be water or air chilled and marketed as 'wet' or 'dry,' respectively (56). Water chilling is almost exclusively used in the U.S. poultry industry, while European processors commonly use air chilling. Water chilling has a washing effect on the carcasses, but if not properly maintained and operated, has the potential for allowing cross-contamination of carcasses with spoilage bacteria, indicator organisms and pathogens. In-plant chlorination of the chiller water at levels >25 ppm reportedly controls or reduces cross-contamination of carcasses with Gram-negative spoilage bacteria and salmonellae (57). Chlorine levels do not normally exceed 50 ppm, and at this level, microbial loads on carcasses are only reduced by 1 log unit (58). Factors affecting the efficacy of chlorine include the initial bacterial load of the water, the water level, organic load, temperature, pH and

trace minerals in the water (59). In some European countries, chlorine addition to the chiller water is prohibited because of the theoretical link to carcinogenesis (60). Other chemicals used or tested in the poultry processing industry to reduce microbial contamination of carcasses during washing and water chilling steps of processing include chlorine dioxide, trisodium phosphate, acidified sodium chlorite, organic acids (lactic and acetic acids), ozone, cetylpyridinium chloride and hydrogen peroxide (59). These are discussed in more detail in a subsequent section of the chapter.

Air chilling of poultry carcasses is basically a dry process, where cold air is circulated, either in a chill room or air-blast tunnel, to chill the carcasses. In order to enhance cooling, the chilling process may be combined with evaporative chilling, which involves the intermittent spraying of carcasses with water, so that the water absorbs heat as it evaporates (61). The latter process is said to minimize carcass weight loss, which contrasts with the weight gains resulting from water chilling (60). In a U.K. study where these three poultry chilling systems were compared, water chilling resulted in a reduction of microbial contamination of carcasses, while air chilling had little effect on microbial numbers recovered from the skin. Microbial levels of the body cavity, however, were reduced by approximately 1 log unit when the dry chilling process was used. Conversely, evaporative cooling through the use of water sprays that were not in-plant chlorinated led to a large (1–2 log units) increase of pseudomonads in the body cavity of the carcasses (61).

After chilling, carcasses are either packaged whole, or are cut into portions, placed in bags or on trays, weighed, and chilled, or more often frozen. The product is thus exposed to extensive cross-contamination through handling and contact with equipment surfaces such as knives, conveyor belts, and weighing and packaging equipment.

C. Type and Extent of Contamination

1. Red Meat

The type and extent of meat carcass and product contamination depends on sanitation, hygienic practices and handling during harvesting and processing, and conditions of storage and distribution. Red meat carcass contamination after processing is usually variable and may consist of 10^1–10^7 aerobic mesophiles per cm^2 (Table 52.1) depending on plant, carcass and site on the carcass sampled (62,63). In general, contamination of pork carcasses is higher than beef (Table 52.1). A nationwide baseline carcass contamination study carried out by the Food Safety and Inspection Service (FSIS) of the United States Department of Agriculture (USDA) found the mean level of aerobic plate counts of carcasses after chilling to be 3.69 log cfu/cm^2 for market hogs, 3.05 log cfu/cm^2 for cows and bulls and 2.68 log cfu/cm^2 for steers and heifers (64–66). In an additional study incorporating seven U.S. beef packing plants (four steer and heifer; three cow and bull), mean aerobic plate counts of carcasses after 24 h of chilling was 2.55 log cfu/cm^2 (67). Baseline carcass contamination data from Australia showed mean total viable counts of 2.4 log cfu/cm^2 for beef carcasses (68) and 3.6 log cfu/cm^2 for sheep carcasses (69).

The microflora of fresh red meat carcasses usually consists of Gram-negative rods and micrococci including *Pseudomonas* spp., Enterobacteriaceae, *Acinetobacter* spp., *Alcaligenes* spp., *Moraxella* spp., *Flavobacterium* spp., *Aeromonas* spp., *Staphylococcus* spp., *Micrococcus* spp., coryneforms and fecal streptococci (49,70). In addition, lactic acid producing bacteria, *Brochothrix thermosphacta*, *Bacillus* and *Clostridium* spores, and enteric viruses may be present in lower numbers (49,70). Yeasts and molds rarely contribute to the microflora of fresh meat, and, generally, may be detected only during extended storage and when the surface of the meat becomes dry, which limits

TABLE 52.1
Aerobic Plate Count Distribution on Raw Beef and Pork Carcasses

	Steers and Heifers		Cows and Bulls		Hogs	
Range (cfu/cm^2)	Number of Samples	Percent of Total	Number of Samples	Percent of Total	Number of Samples	Percent of Total
<1	25	1.2	8	0.4	0	0

$>10^7$	0	0	2	0.1	5	0.2
Total	2,089	100	2,112	100	2,112	100

Source: Refs. 64–66.

bacterial growth and allows yeasts and molds to dominate. They include *Torulopsis, Trichosporon*, *Candida, Rhodotorula, Cryptococcus, Penicillium, Aspergillus, Geotrichum*, *Mucor, Rhizopus, Monillia, Alternaria, Thamnidium* and *Chaeotostylum* (6,70–72).

The prevalence and levels of pathogenic bacteria on red meat carcasses depends on a number of factors including the origin of the animal, sanitation procedures and hygienic practices employed during handling and processing of the product, application of decontamination interventions, and conditions of storage. Based on baseline data collected by FSIS, 14.6% of steers and heifers and 27.2% of cows and bulls are contaminated with one to three different pathogenic bacteria (Table 52.2) (64,65). The baseline data also showed that the prevalence of pathogens on pork carcasses was higher since 52.4% of market hogs were contaminated with one to five different pathogenic bacteria (Table 52.2) (66). The most important pathogens associated with red meat included salmonellae, *Staphylococcus aureus*, verotoxigenic *E. coli, Clostridium perfringens*, *Campylobacter jejuni/coli*, *Listeria monocytogenes, Yersinia enterocolitica* and *Aeromonas hydrophila* (Figure 52.1). Depending on the factors mentioned above the concentration of pathogens on meat carcasses can vary from 1 to >30 most probable number (MPN)/cm^2 (Figures 52.2 and 52.3). Some of these pathogens are more commonly associated with meat from one animal species rather than another. For example, *Y. enterocolitica* (73) and *C. jejuni/coli* (66) are more commonly associated with pork carcasses. In the U.S., the reported prevalence of *C. jejuni/coli* on beef carcasses is ten times less than on pork carcasses (Figure 52.1). *E. coli* O157:H7, on the other hand, is more commonly associated with beef carcasses since cattle and other ruminants have been identified as major reservoirs of this pathogen (11,74,75). The prevalence of pathogens can also differ within the same species. For example, the prevalence of *Salmonella* for cow and bull carcasses is reportedly higher

than for steer and heifer carcasses (67,76,77). The season of the year can also affect the prevalence of pathogens on carcasses. Studies carried out on cattle in North America have shown an increased prevalence of *E. coli* O157 during the summer and early fall (11,78).

The extent of contamination and the variety of contaminant types increase with product handling and comminution (70). Comminuted meats present a higher contamination than carcass meat due to an increase in the level of cross-contamination from grinders and utensils, spreading of contamination, and the greater surface area of the trimmings. The mean level of total aerobic mesophiles of ground beef reported in the U.S. during the years 1993–1994 was 3.90 log cfu/g (Table 52.3) (79) compared to 2.68 log cfu/cm^2 reported for beef carcasses.

2. Poultry

The microbial contamination associated with poultry carcasses at the end of processing is a combination of the natural population found on the carcass skin, the transient population that is associated with the skin and feathers at the time of slaughter and the population that is acquired as a result of processing (41). The microbiological condition (numbers and types of microorganisms) of poultry carcasses immediately after processing is thus dependent on factors such as the level of contamination on the live incoming birds, the efficiency of the processing methods, the level of cross-contamination during processing, temperature control, and sanitary and hygienic practices in the abattoir (80). Typically, the number of aerobic mesophilic bacteria associated with

carcasses at the end of processing range from 10^3 to 10^5 cfu/cm^2 (49). Studies in the U.S. and Canada during the last decade showed that the total aerobic mesophiles of chicken and turkey carcasses ranged from 10^2 to 10^6 and from 10^0 to 10^6, respectively (Table 52.4). The reported mean total aerobic mesophile levels on chicken and turkey carcasses were 2.60 log cfu/cm^2 and 2.47 log cfu/cm^2, respectively, in the U.S. and 2.32 log cfu/cm^2 and 2.20 log cfu/cm^2, respectively, in Canada (81–83). Bacterial populations associated with carcasses at the end of processing are predominantly Gram-negative, and include *Acinetobacter*/*Moraxella* spp., Enterobacteriaceae, *Flavobacterium* spp. and *Pseudomonas* spp. (84–88).

Human pathogens that are associated with poultry carcasses are *Salmonella* serotypes, *C. jejuni*, *S. aureus*, *L. monocytogenes*, *C. perfringens*, non-O157:H7 Shiga-like toxin-producing *E. coli*, *Aeromonas* spp. and *Y. enterocolitica* (Figure 52.4) (41,89–94). Poultry meat represents the single most important source of foodborne salmonellosis, with the most common serotypes implicated in outbreaks being *S.* Enteritidis and *S.* Typhimurium (70,95,96). Prevalence levels of *Salmonella* associated with poultry carcasses at the end of processing or at the retail market are reportedly as high as 100% (57,97). The level of *Salmonella* contamination on live birds entering the processing plant is reportedly low, but subsequent cross-contamination during processing procedures results in an increase in the *Salmonella* contamination of carcasses. In a FSIS study, a *Salmonella* incidence level of 3 to 5% was found on live birds entering a processing plant, which increased to 36% on carcasses at the end of processing (98). During the period 1998–2002, the prevalence of *Salmonella* in broiler carcass samples from federally inspected establishments in the U.S. was reduced from a baseline prevalence of 20.0%, to 10.9% (available at: http://www.fsis.usda.gov/OPHS/haccp/ salm5year.htm).

III. MICROBIAL EFFECTS IN MEAT AND MEAT PRODUCTS

A. SPOILAGE

Only 10% of the microorganisms present initially on a muscle food will grow at refrigeration temperatures, and only a fraction of those will eventually spoil the product by means of their biochemical attributes (99,100). A muscle food is characterized as spoiled when it exhibits an offensive appearance and/or has an off-odor or off-flavor. Off-odors are detected first when bacterial numbers exceed 10^7 cells/cm^2, while bacterial slime becomes evident when numbers reach 10^8 cells/cm^2 (101); bacterial colonies coalesce to form slime when the water activity of the product is approximately 0.99 (41). The spoilage microflora that develops during storage is determined by the initial number and types of microorganisms contaminating the product, the processing the product may undergo, the storage temperature and gaseous atmosphere, and composition of the product (102). The types of bacteria that are normally involved in the spoilage of meat and poultry products are *Pseudomonas* spp., psychrotrophic Enterobacteriaceae (*Serratia liquefaciens*, *Hafnia alvei*, *Enterobacter agglomerans*), *Brochothrix thermosphacta*, lactic acid bacteria (*Lactobacillus*, *Carnobacterium*, *Pediococcus*, *Streptococcus*, *Lactococcus* and *Leuconostoc* spp.), *Moraxella* spp., *Psychrobacter* spp., *Acinetobacter* spp., *Aeromonas* spp. and *Shewanella putrefaciens* (70,101). Yeast and mold spoilage of muscle foods can also occur but only under conditions where bacterial competition is reduced (103), such as exposure to ionizing radiation, reduced water activity, the presence of preservatives or antimicrobial treatments (104).

Microbiological spoilage occurs in the aqueous phase of meat (105). Spoilage microorganisms within this phase

catabolize glucose, lactic acid, certain amino acids, nucleotides, urea and water-soluble proteins (106–108). Table 52.5 shows the substrates utilized by some of the predominant spoilage bacteria and the order in which they are attacked, under aerobic and anaerobic conditions. Spoilage of meat and meat products packaged in air or under modified atmosphere is discussed in the following sections.

1. Spoilage under Aerobic Conditions

Organoleptic changes brought about by aerobic spoilage microorganisms include green, brown or gray discolorations, off-odors and off-flavors, surface slime and taint. Off-odors and slime production may be detected after 10 or 5 days of storage at 0 or 5°C, respectively (109). Off-odors have been described as dairy/buttery/fatty/cheesy at levels of 10^8 bacteria/g, and as sweet/fruity and putrid at levels of $>10^9$ bacteria/g (110).

Meat and meat products stored under aerobic, chill conditions generally succumb to spoilage by strictly aerobic, Gram-negative bacteria, which exhibit faster growth rates under these conditions. *Pseudomonas* spp., and specifically *P. fragi*, *P. fluorescens* and *P. lundensis*, usually predominate (normally >50%) on meat stored at chill temperatures. The pseudomonads preferentially metabolize glucose, resulting in organoleptically innocuous end products. When, however, the diffusion gradient of glucose from the underlying tissue to the surface of the meat can no longer meet the demands of the large numbers of

spoilage bacteria ($>10^8$ cfu/g), amino acids (cysteine, cystine and methionine) and proteins are degraded which result in the formation of ammonia, amines (cadaverine, putrescine, spermidine, spermine, histamine and tyramine) and sulfides (hydrogen sulfide, methylsulfide and dimethylsulfide) (111,112).

Facultative anaerobes belonging to the family of Enterobacteriaceae can also form part of the aerobic spoilage microflora. Like the pseudomonads, these bacteria preferentially metabolize glucose, and some utilize glucose-6-phosphate followed by amino acids. The slower growth rates of the Enterobacteriaceae under chill conditions, however, prevent them from predominating on aerobically stored muscle foods (111). The Gram-positive, facultative anaerobe, *B. thermosphacta*, also usually forms a minor component of the spoilage microflora on aerobically stored meat. Psychrotrophic Enterobacteriaceae and *B. thermosphacta*, however, seem to be more prevalent on lamb and pork, especially on the fat surfaces, and when the meat is stored at 5°C and not 1°C (101,113). Other bacterial groups implicated in the spoilage of meat under aerobic conditions are *Acinetobacter* spp., *Psychrobacter* spp. and *Moraxella* spp. These strict aerobes tend to form a higher proportion of the spoilage microflora on meat of higher ultimate pH (pH >5.8), or when the meat is stored at ambient temperature (114). Unlike pseudomonads, most of these strict aerobic bacteria do not metabolize hexoses, but attack amino acids directly (102).

Meat of high ultimate pH (pH >6.0) and low glucose concentration, like dark, firm, dry (DFD) meat, undergoes spoilage more rapidly than meat of normal pH (pH 5.5 to 5.8). Dark, firm, dry beef stored aerobically at 6°C produced off-odors after 2 days of storage while beef of normal pH produced off-odors after 4 days (115). *Pseudomonas* spp. degrade amino acids on DFD meat without delay and thus onset of spoilage is simply dependent on the time required to accumulate bacterial metabolites responsible for off-odors; this occurs at bacterial levels of $>10^6$ cells/cm^2 (116).

2. Spoilage under Vacuum

The predominant spoilage organisms of meat stored under vacuum and refrigeration conditions are lactic acid bacteria, which are able to metabolize glucose to produce lactic, isobutanoic, isopentanoic and acetic acids (100,117). *Carnobacterium* spp., *Lactobacillus* spp. and *Leuconostoc* spp. are reportedly the dominant lactic acid bacteria isolated from meat and meat products, where levels of 10^7/cm^2 may be reached (118,119). Spoilage is normally characterized by a sour/acid/cheesy odor (101). Growth of *B. thermosphacta*, *Pseudomonas* spp. and Enterobacteriaceae may also occur at levels of 10^3–10^6/cm^2, but is dependent on the oxygen permeability of the packaging film, storage temperature, pH and initial contamination levels (120,121). Higher numbers of *B. thermosphacta* and Gram-negative bacteria are more commonly found on vacuum packaged pork and lamb than on vacuum packaged beef (113,122). The shelf life of vacuum packaged pork and lamb is also reportedly a few weeks shorter than that of beef. Blixt and Borch (123) compared the shelf life of vacuum packed, cold-stored minced pork and beef and found high correlations between intrinsic factors of the two types of meat, such as initial pH values, fat and L-lactate, respectively, and the rate of spoilage. Almost 70% of the variation in the rate of spoilage was explained by changes in the pH and concentrations of L-lactate and glucose-6-phosphate during storage, and not by whether the meat was pork or beef.

Spoilage of vacuum packaged DFD meat occurs within 3 to 6 weeks of storage at 0°C and is characterized by an offensive putrid odor (115,124). The spoilage flora is dominated by *S. putrefaciens*, Enterobacteriaceae and species of *Lactobacillus.* spp. *Shewanella putrefaciens* causes a characteristic green discoloration of vacuum packaged DFD meat which results from the production of hydrogen sulfide from cysteine or glutathione. The green pigment (sulfmyoglobin) is formed by the hydrogen sulfide reacting with the meat myoglobin (125,126).

Certain psychrophilic and psychrotrophic species of *Clostridium* have been characterized as spoilage organisms of vacuum packed meat (beef, lamb, venison and dog rolls) that was stored between −1.5 to 2°C and that exhibited extensive gas production and gross pack distension within 4 to 6 weeks of storage (127–129). Species linked to 'blown pack' spoilage include *C. laramie*, *C. gasigenes*, *C. frigidicarnis, C. estertheticum* and *C. estertheticum*-like strains (128–132). Using restriction fragment length polymorphism analysis of the 16S rDNA genes and 16S–23S rDNA internal transcribed spacer analysis, Broda et al. (132) showed that the source of these organisms on chilled vacuum packed venison was most likely soil particles attached to the hide or present in the feces of the animals.

3. Spoilage in Modified Gas Atmospheres

Lactic acid bacteria and/or *B. thermosphacta* are the predominant spoilage flora of beef, pork and lamb stored in modified atmospheres (133–138). Enterobacteriaceae and *Pseudomonas* spp. reportedly compete more effectively under modified atmosphere packaging conditions than in vacuum packed meat, especially pork that is stored at approximately 5°C and has undergone prior conditioning in air (101). A CO_2 concentration of 100% can be used to extend the storage life of meat of normal and high pH to more than 3 months when stored at 0 to 1°C (101). Pork stored at 0 and 4°C reached total bacterial populations of 10^6 to 10^7 per cm^2 and exhibited off-odors in 119 and 40 days, respectively, with *Lactobacillus* spp. dominating at both temperatures (139).

4. Spoilage of Processed Meats

Chilled comminuted products, including ground meats, burger-type products and raw sausages, in general, have a short aerobic shelf life of 3 to 5 days at 2 to 4°C, due to high initial loads of bacteria (140). The spoilage flora of ground beef stored in air or under modified atmosphere (20% CO_2/80% O_2) is composed of *Pseudomonas* spp., lactic acid bacteria, *B. thermosphacta*, Enterobacteriaceae and yeasts; however, under aerobic conditions *Pseudomonas* spp. are dominant, while under modified atmosphere lactic acid bacteria and *B. thermosphacta* dominate (141,142). The dominant spoilage flora of fresh sausages is dependent on the meat type, storage temperature, gaseous environment, and the presence of preservatives, but in general, it resembles that of ground meat (100).

In general, spoilage of cooked, uncured meat products (whole and restructured joints and poultry, and ready-to-eat meals) is a result of post-processing contamination (100). Gram-negative psychrotrophic bacteria are the main spoilage organisms of aerobically chill-stored sliced cooked meat, while lactic acid bacteria and *B. thermosphacta* predominate on vacuum packed and modified atmosphere packed products (41). Spoilage of meat pies is a result of molds, including *Mucor*, *Penicillium*, *Rhizopus* and *Aspergillus* spp., which usually contaminate the product during cooling (49).

Microbial spoilage of raw, cured meats, like Wiltshire-style bacon, is characterized by surface slime, discoloration, off-odors and off-flavors (143). Major spoilage populations associated with these products are Micrococcaceae, halophilic *Vibrio* spp., lactic acid bacteria, coryneforms and yeasts, which are tolerant to salt and sodium nitrite (113,143). Factors influencing the composition of the spoilage flora are concentration of additives (salt, nitrite and nitrate), temperature, pH and water activity (100).

Cooking of cured meat products inactivates vegetative bacteria but recontamination occurs during post-cooking steps, like slicing, portioning or skinning. Spoilage of these products (cooked ham, corned beef, emulsion-type sausages, luncheon meats) stored at cold temperatures and packed under vacuum or modified atmosphere is predominantly by lactic acid bacteria (99,144–146). *Lactobacillus* spp. (*Lactobacillus sake* and *Lactobacillus curvatus*) and *Leuconostoc* spp. are the main spoilage organisms of cooked, cured meats (99,146–148). Spoilage is characterized by a sour odor and flavor, greening, gas production and slime formation (99,149). The growth rates and identity of the spoilage lactic flora are found to differ depending on the product composition (salt content, nitrite concentration, pH and water activity), processing method, storage temperature and gaseous atmosphere (99,150). The growth of lactic acid bacteria was more delayed in smoked meats (pork loin, bacon, pariza, mortadella and frankfurters) than in non-smoked, boiled whole meats (cooked ham and turkey fillets) (146). Furthermore, characterization of the predominant spoilage lactic acid bacteria showed that the *Lactobacillus sake/curvatus* group predominated on the smoked meats, whereas *Leuconostoc mesenteroides* subsp. *mesenteroides* predominated on the cooked ham and turkey fillets (146).

Canning or commercial sterilization of uncured and cured meats results in a shelf stable product due to the complete elimination of microorganisms. Spoilage rarely occurs due to underprocessing, loss of package integrity and leakage of microorganisms into the package post-processing (4).

Molds are generally responsible for the spoilage of unsmoked, air-dried fermented sausages, some of which may have the ability to produce mycotoxins while growing on the sausage. Furthermore, molds have been reported to grow on the surface of frozen meat stored at temperatures as low as –8 to –10°C (113).

5. Spoilage of Poultry

Poultry spoilage follows the same principles as those involved in the spoilage of red meat products. The bacterial groups most frequently implicated as the main causes of spoilage of refrigerated poultry are *Pseudomonas* spp., and to a lesser extent, *Acinetobacter* spp., *Moraxella* spp. and *S. putrefaciens* (85,151). The *Pseudomonas* population reportedly may increase from $<$10% before storage to 93% of the total carcass bacterial population at the time of spoilage, following storage at 1 to 5°C (84,85,152). The type of spoilage bacteria as well as their growth rate is affected by the numbers and types of spoilage microorganisms present on carcasses at the end of processing, the type of packaging material and the composition of the atmosphere surrounding the packaged product, the storage temperature and the muscle type and pH (85). Poultry leg muscle has a pH of 6.4 to 6.7 while that of breast muscle is 5.7 to 5.9 (153). Spoilage populations of the breast muscle are thus essentially the same as those found on red meat of normal ultimate pH, while populations of the leg muscle mimic those found on DFD meat (126). Poultry leg meat thus spoils more rapidly than breast meat (41).

B. Foodborne Illness

Current estimations indicate that microbially contaminated food causes approximately 76 million illnesses, 325,000 hospitalizations and 5,000 deaths in the U.S., per year. Bacterial agents are responsible for 30% of these illnesses, while viruses and parasites cause 67% and 3% of the illnesses, respectively. The total percentage of deaths caused by each of these agents, however, is the highest for foodborne illnesses caused by bacteria (*ca.* 72%), followed by those of parasitic (*ca.* 21%) and viral (*ca.* 7%) origin (154).

The U.S. Centers for Disease Control and Prevention (CDC) Emerging Infections Program Foodborne Diseases Active Surveillance Network (FoodNet) collects data on 10 foodborne diseases in nine U.S. site areas, equivalent to 37.4 million people. According to preliminary data for 2002, 16,580 laboratory-diagnosed cases were identified, with *Salmonella* (16.1 cases/100,000 population), *Campylobacter* (13.4 cases/100,000 population) and *Shigella* (10.3 cases/100,000 population) having the highest incidence (155). An equivalent network in Australia (OzFoodNet), consisting of seven sites and encompassing 68% (12.9 million) of the Australian population, and monitoring eight foodborne diseases, reported a total of 22,999 cases of foodborne infections for the year 2001, with *Campylobacter* (125.0 cases/100,000), *Salmonella* (34.1 cases/100,000) and *Shigella* (2.6 cases/100,000) again having the highest incidence (156).

During the period of 1993–1997, a total of 2,751 outbreaks of foodborne disease were reported to the CDC, causing a reported 86,058 persons to become ill (157). Bacterial pathogens were responsible for the largest percentage of cases (86%); however, 68% of the reported outbreaks were of unknown etiology (157). Foodservice establishments (restaurants, cafeterias and delicatessens) were responsible for the highest percentage (43%) of the outbreaks, followed by private residences (21%). Contributing factors to the outbreaks during this period were improper holding temperatures (34.1%), poor personal hygiene (17.8%), contaminated equipment (14.5%), inadequate cooking (10.0%) and food from an unsafe source (5.6%) (157). Beef, chicken, turkey, other/unknown meat, pork, ham and sausage accounted for 6.8, 3.1, 2.3, 2.3, 1.4, 1.2 and 0.2%, respectively, of the total number of outbreaks where the vehicle of transmission was known (967 outbreaks). The respective percentage of cases where the vehicle of transmission was known (58,908 cases) for each of the above meat products was 5.4, 1.9, 1.3, 1.1, 1.1, 0.5 and 0.1%, respectively (157). These products thus accounted for 17.3% of the total outbreaks and 11.4% of the total cases of known etiology during the period of 1993–1997. Bacterial pathogens that were involved in the outbreaks through consumption of meat and meat products during this 5-year period were *Bacillus cereus*, *Campylobacter*, *C. botulinum*, *C. perfringens*, pathogenic *E. coli*, *Salmonella*, *Shigella*, *S. aureus* and *Y. enterocolitica* (Table 52.6) (157).

Other documented or suspected bacterial pathogens of potential concern in meat and meat products are *L. monocytogenes* and *Aeromonas hydrophila*, as well as *Arizona hinshawii*, *Bacillus anthracis*, *Brucella* spp., *Chlamydia psittaci*, *Coxiella burnetii*, *Erysipelothrix rhusopathiae*, *Francisella tularensis*, *Leptospira* spp., *Mycobacterium* spp., *Pseudomonas* spp. and *Streptococcus* spp. (158). As it is beyond the scope of this chapter to go into extensive

detail about each of the etiologic agents involved in foodborne illness (159), a few of the important bacterial agents have been chosen and are discussed briefly. They have been separated into common and emerging bacterial pathogens.

1. Common Bacterial Pathogens

FoodNet data for the year 2002 showed that *Salmonella* was responsible for causing the highest total number of cases of gastrointestinal illness among the bacterial agents (155). The *Salmonella* genus comprises two species: *Salmonella enterica*, which is divided into seven subspecies groups (I, II, IIIa, IIIb, IV, VI and VII), and *Salmonella bongori* (160). There are approximately 2,600 serotypes of *Salmonella*, of which *S*. Typhimurium and *S*. Enteritidis are the most prevalent in the U.S. These serovars cause disease in humans, cattle, poultry, sheep, pigs, horses and wild rodents (161). The emergence of the multi-drug-resistant strain, *S*. Typhimurium DT104, has been the cause of widespread concern regarding the use of antimicrobial agents in agriculture (162). Raw meat, and especially poultry, is frequently contaminated with *Salmonella*, which originates from the intestinal tract or fecal material found on the hair, feathers, feet and skin of the animals. Processed meats and ground products reportedly have the highest prevalence of *Salmonella* (162).

Staphylococcal intoxication is one of the most common types of foodborne disease worldwide caused by the ingestion of food contaminated with one or more preformed heat-resistant enterotoxins produced by *S. aureus* (163). This organism is ubiquitous in nature and can be found in the nasal passages, throat and skin of humans and most warm-blooded animals, including food animals; in fact, 30–50% of humans are carriers of *S. aureus* (163,164). The primary source of contamination of foods implicated in foodborne illness are food handlers. Foods are normally contaminated post-processing and then stored at warm temperatures for adequate time to allow for significant growth and production of enterotoxin by the organism (163,164).

Clostridium perfringens forms part of the normal flora of the gastrointestinal tract of humans and animals. Ingestion of $>10^8$ vegetative cells of this organism followed by the production of enterotoxins during sporulation in the small intestine leads to a toxicoinfection (165,166). Cooked meat and poultry that have been cooled over a long period of time at ambient or warm temperatures are common vehicles of foodborne illness (166).

Clostridium botulinum produces neurotoxins which are considered to be the most toxic of all natural substances (164). Seven types (A through G) of *C. botulinum* are currently recognized, based on the antigenic specificity of the toxins. The organism is further divided into four distinct groups based on their DNA homology and reactions to specific substrates (167). Group I includes all of type A and the proteolytic strains of types B and F; Group II includes the nonproteolytic strains of types B and F, and all of type E strains, all of which are able to grow at refrigeration (3.3°C) temperatures; Group III includes all the strains of type C and D; Group IV includes all the strains of type G, which based on their biochemical properties are proposed to form a new species, *C. argentinense* (167,168). The spores of the proteolytic strains (Group I) are more heat resistant than those of the nonproteolytic strains, a fact that led to the development of the 'botulinum process' or '12-D cook' for low acid canned foods (167).

Different types of *C. botulinum* appear to predominate in different parts of the world; for example, the main cause of *C. botulinum* outbreaks in the U.S., China and Argentina is type A, while in central Europe, type B is responsible for most outbreaks. Furthermore, type A is mainly associated with vegetables, while type B is often linked with meats (169). There are different clinical forms of botulism; foodborne, infant, wound and a fourth classification currently called 'adult infectious botulism.' In foodborne botulism, illness is caused due to ingestion of food that has been undercooked or improperly stored or reheated, resulting in toxin production due to growth of the organism (170). With regards to infant and adult infectious botulism, spores that are ingested or inhaled germinate, in the absence of competition in the intestine, resulting in toxin production (167).

2. Emerging Bacterial Pathogens

Outbreaks involving *C. jejuni* are relatively uncommon (157). However, this organism is believed to be one of the most commonly diagnosed causes of sporadic cases of gastroenteritis in the U.S. and other industrialized countries. *Campylobacter jejuni* and other *Campylobacter* spp. are estimated to cause an annual 14.2% of the total foodborne illnesses in the U.S. (154). The infectious dose of *C. jejuni* is low, ranging from 500 to 1000 cells (171). The main vehicle of foodborne illness by *Campylobacter* is poultry, either due to handling raw or eating undercooked poultry, and especially through cross-contamination of other foods. Other sources include raw milk, water, pork, beef, lamb and seafood (172). Of great recent concern is the emergence of fluoroquinolone-resistant strains of *C. jejuni* isolated from patients in Western Europe, shortly after the approval of fluoroquinolones for veterinary use (173).

Escherichia coli is the dominant Gram-negative facultative anaerobe in the gastrointestinal tract of humans and other warm-blooded animals and is generally considered harmless (174). Pathogenic strains of *E. coli*, however, also exist which can cause distinct syndromes of diarrheal disease (159). Currently, at least six categories of pathogenic *E. coli* are recognized; they include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli*

(EHEC), enteroaggregative *E. coli* (EAEC) and diffusely adherent *E. coli* (DAEC) (175–177). Unlike most foodborne pathogens, diarrheagenic *E. coli* are tolerant to acidic environments and have been shown to be resistant to acetic, citric and lactic acids applied at concentrations as high as 1.5% (159). More information about each of these diarrheagenic groups can be found in book chapters and reviews by Levine (175), Doyle and Padye (176), ICMSF (164), Donnenberg and Nataro (178), Fratamico et al. (177) and Bacon and Sofos (159).

Enterohemorrhagic *E. coli* causes the majority of the most severe outbreaks associated with pathogenic *E. coli* in the U.S. and other developed countries (177). This group includes *E. coli* serotypes that share the same clinical, pathogenic and epidemiologic features as *E. coli* O157:H7, which is responsible for the greatest proportion of *E. coli*-associated diarrheal disease cases in North America and the U.K. *E. coli* O157:H7 is estimated to cause approximately 73,000 cases of foodborne illness in the U.S. each year (154). Serotypes belonging to the EHEC group produce Shiga toxins, otherwise known as Shiga-like toxins, verotoxins or verocytotoxins, and are associated with hemorrhagic colitis and hemolytic uremic syndrome. Non-O157:H7 EHEC serotypes seem to be more important in some countries in the southern hemisphere like Argentina, Australia, Chile and South Africa (174). *E. coli* O157:H7 was first identified as a pathogen in 1982 when it was epidemiologically linked to the consumption of undercooked ground beef in the U.S. (179). Since then numerous outbreaks associated with this serotype have been documented in Canada, Japan, the U.K. and the U.S. (180). The largest reported outbreak occurred in Japan in 1996, with a total of 9,578 reported cases and 11 deaths, which were linked to the consumption of radish sprouts (181).

Cattle have been identified as a major reservoir of *E. coli* O157:H7. It has been isolated from the oral cavity (13), rumen contents (182), the hide (11,13) and feces (11,13,183,184) of cattle. A study conducted in the U.S. showed that *E. coli* O157:H7 is present in 28% of fecal samples taken from cattle in slaughterhouses during the summer months (11). It is therefore not surprising that undercooked ground beef is implicated in a large number of the cases linked to *E. coli* O157:H7 infection. The FSIS has declared *E. coli* O157:H7 as an adulterant in ground and other non-intact beef products. Results from a FSIS testing program to enforce this regulation showed that 0.78 to 0.86% out of 6,374 to 7,026 samples tested during the period of 2000 to 2002 were positive for this pathogen. Besides foods of bovine origin, outbreaks due to *E. coli* O157:H7 have been linked to raw milk, water, apple cider, mayonnaise, cantaloupe and lettuce (178).

Listeria monocytogenes is the causative agent of approximately 0.02% of all foodborne illnesses in the U.S., annually. Its associated illness, listeriosis, however, accounts for approximately 28% of deaths due to foodborne illness (154). There are two variants of the disease: invasive and non-invasive listeriosis. The invasive form mainly affects specific segments of the population, including the elderly, neonates, pregnant women and immunocompromised individuals (185,186). The non-invasive variant has been recently described and causes febrile gastroenteritis. Among the foods identified as causes of non-invasive listeriosis are cold corn salad, tuna fish and cold-smoked rainbow trout (187,188).

Listeria monocytogenes is widely distributed in nature, including soil, decaying vegetation, animal and human feces, sewage, silage and water. It is a psychrotroph and can grow at temperatures as low as –0.4°C and up to 45°C. Furthermore, it can grow at pH levels of 4.4 to 9.4, a_w levels of >0.92 and NaCl levels of 10% (189). Survival of the pathogen, however, has also been reported at levels of 25.5% NaCl in trypticase soy broth for 24 days at 22°C and >132 days at 4°C (190). Furthermore, *L. monocytogenes* can survive freezing and drying, as well as low or oxygen-free and elevated carbon dioxide atmospheres encountered in MAP (189).

Foods implicated in outbreaks of listeriosis include milk and dairy products, seafood products, vegetables, coleslaw and ready-to-eat meat products (186,191). According to a FSIS monitoring program for ready-to-eat products conducted at FSIS-inspected establishments during the period of 1990 to 1999, *L. monocytogenes* prevalence rates were 5.16% for sliced ham and luncheon meats, 3.56% for small diameter cooked sausages such as franks, 3.25% for fermented sausages (data were only collected from 1997 and onwards), 3.09% for cooked beef, roasted beef or cooked, corned beef, 3.03% for salads and spreads, 2.12% for cooked poultry products, 1.31% for large diameter cooked sausage, and 0.52% for jerky (192). In a more recent study, analysis of 31,705 samples belonging to eight different categories of ready-to-eat foods from retail markets in Maryland and California showed the prevalence of *L. monocytogenes* to be 1.82%, with prevalences ranging from 0.17 to 4.7% among the product categories (193). Furthermore, Wallace et al. (194) found 1.6% of 32,800 packages of frankfurters to be positive for the pathogen. Contamination of ready-to-eat products with *L. monocytogenes* occurs primarily during post-processing steps like slicing, dicing and packaging. Of particular concern is the establishment of virulent strains of the pathogen in the food processing environment which can potentially contaminate multiple lots of product over days or months of production (191). For example, the strain involved in the 2000 multistate outbreak of listeriosis in the U.S. (serotype 1/2a), where turkey deli meat products were implicated, reportedly had persisted in the processing environment for more than 10 years (186,195). Of the 13 serotypes of *L. monocytogenes* that can cause disease, three serotypes (4b, 1/2a and 1/2b)

account for 89 to 96% of the sporadic and outbreak cases of human listeriosis that occur worldwide (196). The most publicized outbreaks in the past 20 years in North America and Europe have involved serotype 4b (186).

In view of the high mortality rate of *L. monocytogenes* (154), as well as outbreaks associated with the consumption of contaminated ready-to-eat meat and poultry products (195,197,198), the FSIS has published an interim final rule to control this pathogen in these products (199). Briefly, according to this regulation, establishments that produce ready-to-eat meat or poultry products that support growth of the pathogen and are exposed to the environment after lethality treatments are required to include in their HACCP plans, or in their sanitation operating procedures or other prerequisite programs, one or more validated measures that prevent product adulteration with *L. monocytogenes*. Three alternative methods to prevent or control *L. monocytogenes* during post-lethality exposure of products are proposed in the regulation: (i) application of both a post-lethality treatment and an antimicrobial agent or process; (ii) application of either a post-lethality treatment or an antimicrobial agent or process; and (iii) require no application of a post-lethality treatment or process, but instead require the combination of a sanitation program with microbiological testing of food contact surfaces to hold products when positive results are obtained (199).

Bacillus cereus causes two types of intoxications: one is diarrheal and the other emetic. In Japan, the occurrence of the emetic syndrome is reportedly ten times that of the diarrheal syndrome. Conversely, in North America and Europe, the diarrheal type is more common (200). Foods usually implicated in the diarrheal syndrome are meats, vegetables, sauces and puddings, while foods containing rice are associated with the emetic syndrome (201). The number of cells of the organism needed to cause illness is $>10^5$/g.

Yersinia enterocolitica is an infrequent cause of foodborne illness; however, it can cause severe foodborne infection and pseudoappendicitis (4,159). Pigs are regarded to be the main reservoir of *Y. enterocolitica* bioserotypes that are pathogenic to humans (164). The most common bioserotypes involved in foodborne illness are O:3, O:8, O:9 and O:5, 27. *Y. enterocolitica* is a psychrotroph and is able to proliferate at temperatures of 0 to 45°C (159). Storage of food at refrigeration temperatures, therefore, should not be considered an effective way to control this pathogen.

3. Viruses and Parasites

Foodborne transmission of viruses has in recent years been recognized as an important cause of foodborne illness. More than 9 million cases of viral foodborne illness of known etiology are estimated to occur annually in the U.S. (154). According to data collected in the U.S., however, outbreaks of viral foodborne illness due to the consumption of land muscle foods are rare (157). Viruses reported to cause foodborne illness include, among others, hepatitis A, Norwalk and Norwalk-like (now known as norovirus), rotavirus, astroviruses and enteroviruses (159,202). In general, transmission of these viruses occurs due to inadequately cooked foods, cross-contamination before consumption and poor sanitation (4,159).

Parasitic agents, on the other hand, are estimated to result in more than 350,000 cases of foodborne illness of known etiology in the U.S. annually (154). Parasites of concern in foods of meat origin include, among others, *Toxoplasma gondii*, *Sarcocystis* spp., *Trichinella* spp. and *Taenia* spp. (203). Treatments that inactivate parasites in foods include proper cooking, freezing, salt, chemicals and ionizing radiation (4,159).

IV. METHODS FOR CONTROL OF MICROORGANISMS IN MEAT AND MEAT PRODUCTS

A. General

Meat and poultry products are highly perishable foods, and, if not properly handled, processed and preserved, may support growth of spoilage and pathogenic microorganisms (4). The major technologies that are employed to preserve the quality and microbiological safety of these and other food products include (204):

a) Procedures that prevent or minimize the access of microorganisms to the product.
b) Procedures that reduce initial contamination by removal or inactivation of microorganisms which have gained access.
c) Procedures that inactivate microorganisms on products.
d) Procedures that prevent or slow down growth of viable microorganisms which have gained access and have not been inactivated.

Procedures that restrict the access of microorganisms include mainly sanitation and hygienic procedures or packaging technologies such as the aseptic packaging of thermally processed foods. Procedures that reduce initial levels of microorganisms, which have gained access to the food, include decontamination technologies such as washing, application of hot water, steam, acids or other chemicals, and their combinations. Procedures that inactivate microorganisms remaining on products include heat or thermal processing, ionizing radiation, high hydrostatic pressure and electric shock treatments. Despite their ability to remove or inactivate the microorganisms, some of the above technologies may also result in the inhibition of microbial growth during storage. Preservation technologies that slow down or

prevent the growth of viable microorganisms rely on the control of factors affecting microbial growth. Microbial growth on meat and poultry products, or other foods, is affected by the type and extent of initial contamination and by factors intrinsic or extrinsic to the product (70). Among these, the most important ones, especially for fresh products, are extrinsic factors such as storage temperature and gas atmosphere, while intrinsic factors such as pH, water activity and antimicrobials become more important in processed products. Major preservation technologies based on the inhibition of microbial growth include temperature control, decreased water activity (curing, drying), acidification, vacuum and modified atmosphere packaging, fermentation-biopreservation, and addition of preservatives. In addition to the extreme modification of a single factor, inhibition of microbial growth is often achieved with a combination of preservation technologies at individually sublethal levels that interact to yield the multiple 'hurdle' effect (205–207). In the next paragraphs the most important traditional and emerging preservation technologies applied to meat and poultry carcasses or products are discussed. The discussion is focused on current technologies and new developments of decontamination and preservation methods including animal carcass decontamination (physical, chemical and combinations), emerging decontamination or preservation technologies (irradiation, high hydrostatic pressure, pulsed-field electricity, ultrasonic energy, UV light, oscillating magnetic fields, controlled instantaneous decompression), preservative packaging (modified atmosphere packaging, active packaging) and biopreservation. Traditional processing and preservation technologies are briefly discussed.

B. Decontamination Technologies

Highly publicized outbreaks of foodborne disease associated with meat and poultry have increased consumer concerns and interest in the safety of these products. In response, the industry is implementing decontamination interventions to improve the microbiological quality of fresh meat and poultry (4,20,208–210). Decontamination treatments can roughly be divided into three types (208): chemical, physical and combinations of the two. Physical treatments are based on the use of knives for removal, by cutting of visually soiled tissue, cold or hot water (wash, rinse, spray), vacuum and/or steam, high hydrostatic pressure, irradiation, pulsed-field electricity, ultrasonic energy and UV light (the latter technologies apply more to processed products than animal carcasses). Chemical decontamination includes treatments with chlorine, organic acids, inorganic phosphates, bacteriocins, organic preservatives and oxidizers. Decontamination treatments may be applied at different stages of production and processing including animal (before slaughter), carcass, primal cuts and final product.

1. Animal Cleaning

As has been mentioned, live animal contamination, in addition to environmental plant contamination, is considered as the most significant source of carcass and meat contamination. One approach to potentially reduce the external animal contamination and subsequently carcass contamination is to clean or wash the hide of the animal with water or chemical solutions before slaughter. There are, however, concerns related to preslaughter washing of animals since fecal material and the microorganisms associated with it may be more readily spread through wet animals. Bell (211) indicated that carcass contamination resulting from contact with a clean hide (i.e., a hide with no visible evidence of fecal contamination) was appreciably lower than that following contact with a fecally soiled hide that had undergone preslaughter washing. Furthermore, a higher contamination level was found on lamb carcasses derived from preslaughter washed animals than on unwashed animals (212,213). In another study carried out in Ireland, it was shown that preslaughter washing of pigs with cold water did not lead to significant changes in total viable counts of the live animals, but *Salmonella* incidence was reduced from 27% on live animals prior to transport to the abattoir to 10% after washing (214). Furthermore, a significant reduction of hide fecal contamination with *E. coli* O157:H7 was obtained on cattle that were washed with a power-hose for 3 min before the slaughter process; a lower recovery of the organism was also found on the resultant carcasses (215). In general, the effectiveness of animal cleaning and washing on the microbiological quality of the carcasses have been variable, while application of these procedures is often difficult due to climate, type of animal and the availability of facilities (20). Preslaughter animal washing has been applied for sheep in New Zealand (212), and for cattle in Australia and by some plants in the U.S., especially in recent years. A means of minimizing accidental transfer of contamination from the exterior of animals that have undergone preslaughter washing to the carcass surface and plant environment is to reduce slaughter speeds, and to modify the steps or the equipment involved in hide removal (15,216,217).

An additional hide decontamination process is chemical dehairing; a patented process (218) for cattle early during slaughter to remove hair, mud, manure and other external contaminants and thus, to minimize carcass and plant contamination from these sources (15,20,217). Application of this process to artificially contaminated beef hide samples resulted in significant reductions of inoculated meat pathogens such as *E. coli* O157:H7, *Salmonella* and *L. monocytogenes* (219,220), and in 1995, FSIS approved commercial trials for testing of the chemical dehairing process. Schnell et al. (221) studied a commercial application of chemical dehairing in a beef

slaughterhouse. Although these authors reported that chemical dehairing resulted in a reduction of the visible contamination of cattle compared to the conventional process, the microbial loads were not significantly different between the two processes. It needs to be noted, however, that in the latter study both dehaired and nondehaired animals were processed in the same facility during the same day and thus the weak effectiveness of chemical dehairing could be attributed to the contamination of the plant environment by the nondehaired animals. In an additional study carried out in a commercial beef slaughtering facility, however, chemical dehairing was found to significantly reduce bacterial levels of carcasses immediately after hide removal (pre-evisceration) by approximately 2 logs (222). Furthermore, carcasses that had undergone chemical dehairing had a significantly lower prevalence of *E. coli* O157:H7 (1%) than carcasses that had not received the chemical treatment (50%) (222).

2. Carcass Decontamination

In general, carcass decontamination technologies in the U.S. are applied immediately after hide removal but before evisceration, as well as at the end of the dressing process, before carcass chilling. Decontamination technologies are based on treatments with water of various temperatures and pressures and other chemical solutions. The effectiveness of these treatments in reducing microbial contamination is affected by a number of factors including water pressure, temperature, chemicals used and their concentration, time duration of exposure (which depends on speed of slaughter and length of the application chamber), method of application and time or stage of application during slaughter and processing (20,217). Decontamination technologies that have been proposed, applied or tested for their effectiveness on the reduction of carcass microbial loads include treatments with water or steam (hot water, steam pasteurization, steam-vacuum), and chemical solutions, mostly organic acids (lactic, acetic and citric), as well as chlorine and chlorine dioxide, trisodium phosphate, acidified sodium chlorite, peroxyacetic acid, cetylpyridinium chloride, hydrogen peroxide, ozone, sodium bisulfate, sodium hydroxide, sodium chloride, and protein compounds such as lactoferrin (15,20,208,210). Today, in the U.S., decontamination systems are approved by FSIS if the agents used: i) are 'Generally Recognized as Safe' (GRAS), ii) do not create an 'adulterant' situation, iii) do not create labeling issues (i.e., added ingredients), and iv) can be supported with scientific studies as being effective (15). Among the agents that have been approved for use in foods by FSIS are acetic, lactic, peroxyacetic, citric, malic, propionic and tartaric acid, chlorine, trisodium phosphate, acidified sodium chlorite, hydrogen peroxide, ozonated water and lactoferrin (available at: http://www.fsis.usda.gov/OPPDE/rdad/FR Pubs/88-026F.htm; http://www.fsis.usda.gov/OPPDE/rdad/FSISDirectives/7120.1.htm). Some of these are extensively used in commercial plants in the U.S. In contrast, no chemical or physical treatments of meat and poultry carcasses are allowed by European Union regulations (208).

a. Spot carcass and pre-evisceration decontamination

Under the 'zero tolerance' policy of the U.S., knife-trimming is required to remove visible contamination on carcasses before any washing or other decontamination treatment is allowed. As an alternative, in 1996, FSIS approved the use of steam-vacuuming for removal of fecal and ingesta contamination spots of <2.5 cm in diameter on carcasses, through the use of a hand-held piece of equipment. This method uses hot water and/or steam to loosen soil and inactivate bacteria, followed by removal of the contaminants through application of a vacuum; this process, thus, has a combined effect of removing and/or inactivating surface contamination (15,20,223,224). Kochevar et al. (224) reported that application of steam-vacuuming to beef carcasses resulted in reductions of 1.7–2.0 log cfu/cm^2 in aerobic plate counts and 1.7–2.2 log cfu/cm^2 in total coliform counts. After the approval of the two commercially available steam-vacuuming systems, and as a result of their relatively low cost, steam-vacuuming units became very popular in U.S. slaughterhouses as an alternative method to knife-trimming to remove accidental visible carcass decontamination (20). However, the effectiveness of both knife-trimming and steam-vacuuming in reducing carcass contamination depends on employee diligence of application and the operational status of the equipment (20).

As soon as the hide is removed, whole carcasses are sprayed with water and possibly organic acid solution to remove microbial contamination that may have been acquired during the hide removal stage. In general, water and acid treatments applied soon after slaughter (before evisceration) appear to be effective since bacteria have not yet become firmly attached to the muscle (225–227). This is supported by a study by Cabedo et al. (227), where it was found that the number of bacteria removed or inactivated by the application of different spray-washing treatments decreased, as the length of time between contamination of beef carcass tissue and application of the treatments increased. Pre-evisceration washing of carcasses may also reportedly lead to an alteration of the surface physical characteristics (e.g., contact angle and surface free energy) of the carcass tissue, resulting in less attachment of microorganisms (228). Final washing and decontamination of carcass sides with water, organic acids and other treatments are discussed in the following sections.

b. Water

Water sprays of various pressures are used to remove bone dust and to clean and wash carcasses that have passed the

'zero tolerance' for visible soil inspection at the end of the dressing process in the U.S. Water is also used as a carrier of chemical or physical energy when carcasses are decontaminated with chemical solutions, hot water or steam. The use of hot water as a meat decontamination technology has been studied extensively during the last 30 years. Both laboratory scale and commercial plant evaluation studies have found hot water (74°C) to be an effective method of carcass decontamination (223,224,229–231). The application of hot water for meat decontamination may involve immersion or dipping, deluging, rinsing at low pressures and spraying at higher pressures. Each of these approaches has advantages and disadvantages (20). In all cases, however, the effectiveness of the method is strongly dependent on water temperature. Davey and Smith (232) found a linear relationship between water temperature and *E. coli* numbers on beef carcasses decontaminated with hot water by spraying. In general, effective temperatures exceed 74°C and become more effective as they approach 80–85°C (232,233). Gorman et al. (234) reported that spraying of beef carcasses with hot water at 74°C resulted in higher microbial reductions compared to chemical interventions, while at lower temperatures (16–35°C) chemical decontamination was more effective than water treatment.

Another form of hot water decontamination involves exposure of carcasses to pressurized steam (223,235,236). Davidson et al. (235) reported that exposure of whole and cut-up chicken meat to steam at 180–200°C for 20 sec resulted in 1–3 log reductions in aerobic plate counts and in 50% reduction in *Salmonella* contamination. Morgan et al. (236) applied an ultra-high temperature, ultra-short time steam pasteurization process on beef, pork and chicken samples and found a 4 log reduction in inoculated *Listeria innocua*. A patented steam pasteurization process for carcass decontamination developed by Frigoscandia and Cargill, Inc. (The Frigoscandia Steam Pasteurization System™) has been approved for use in the U.S. (237). Phebus et al. (238) and Nutsch et al. (239) evaluated the Steam Pasteurization System™ using *cutaneus truncii* muscles from steers and beef sides, respectively, and reported significant reductions in aerobic plate counts, *E. coli*, coliforms and Enterobacteriaceae, and inoculated *L. monocytogenes, E. coli* O157:H7 and *S.* Typhimurium. The advantages of using steam rather than water for decontamination purposes are the efficiency of heat transfer, lack of residues, and the reduced water and energy usage (20). However, steam pasteurization requires a major capital investment and may present difficulties in application in a continuous production process.

c. Organic acids

In recent years the use of organic acids such as acetic and lactic, for meat and poultry decontamination, has received considerable attention mainly due to their antimicrobial properties and their characterization as GRAS substances (15,217,226,240–242). Decontamination with organic acid solutions of 1–2% may significantly reduce the bacterial load of meat and poultry carcasses (208,224,243). In addition to the immediate microbial reduction, acid decontamination results in a residual antimicrobial effect during storage, which has been attributed to the residual acids remaining on the meat after treatment as well as the sublethal injury of bacteria caused by the acid treatment (244–246). The effectiveness of acid decontamination can be augmented by increasing the temperature of the solution and the time of application. The stage of processing selected for the application is also important, as mentioned previously. The efficacy of the acid treatments may be further influenced by the type of surfaces to which the bacteria are attached. For example, acid treatment of lean meat surfaces results in higher microbial reductions than on fatty tissues (247).

Organic acid decontamination of carcasses has also been shown to reduce pathogen populations (246,248–250). Decontamination of beef surfaces with 2% lactic or acetic acid resulted in 2–3 log cfu/cm^2 reductions of *S.* Typhimurium DT104 and *E. coli* O157:H7 (250). *Salmonella* is generally more sensitive to organic acid decontamination than *E. coli* O157:H7 (251). This was also shown in a study by Samelis et al. (252), where *S.* Typhimurium DT 104 was found to die off after 2 days incubation, at 4 or 10°C, in lactic acid (pH 2.4) and acetic acid (pH 3.1) fresh beef decontamination runoff fluids (washings), while *E. coli* O157:H7 and *L. monocytogenes* survived in lactic acid washings for at least 2 days, and in acetic acid washings for at least 7 and 4 days, respectively, with better survival at 4 than at 10°C (252). Although decontamination with organic acids has been shown to reduce prevalence and concentration of *E. coli* O157:H7 on meat carcasses (251,253), the potential increase in the acid resistance of the pathogen remains an important concern (254–258), and is discussed in a subsequent section. The potential ability of *E. coli* O157:H7 to resist acidity (254,259) has been attributed, among other mechanisms, to binding of the pathogen to collagen of the meat tissue (260). Recent studies have shown that the latter problem may be reduced by spraying the carcass with a non-ionic surfactant such as Tween 20 prior to spraying with the organic acid (261).

In addition to the microbiological point of view, another important issue regarding the use of acid decontamination on meat and poultry is its effect on the quality of the products. Depending on the concentration and intensity of application, acid treatments may sometimes result in undesirable effects in color and/or flavor of the products. Such effects, however, should be only slight and reversible at acid concentrations below 2% (262,263). Discoloration problems can also be prevented by using buffered acids (264). In general, organic acid (lactic or acetic) spraying finds extensive use as a beef carcass treatment after hot water or steam decontamination.

d. Other chemical solutions

Several non-acid chemical solutions have been tested, and in some instances approved and used in the decontamination of meat and poultry (15,20,208,210,217). Chlorine is a common sanitizing agent used in process water during meat and poultry processing. Application of chlorine (20 ppm) reduced *Salmonella* contamination on chicken carcasses (265,266) while chlorine spray-washing (800 ppm) of beef carcass tissue resulted in a mean reduction of 1.3 log cfu/cm^2 of *E. coli* O157:H7 (267). Chlorine dioxide (ClO_2) has been proposed as an alternative to traditional chlorine sanitizing agents. However, the use of ClO_2 (1.33 mg/l) to control *Salmonella* in poultry chiller water did not result in any significant reduction (<0.5 logs) in bacterial counts on the poultry skin (268). Similar results have been reported by Cutter and Dorsa (1995) who found that spraying beef tissue with ClO_2 (20 ppm) for 10 sec at 520 kPa was no more effective in reducing fecal contamination than spraying with water alone. Mullerat et al. (270) applied Salmide®, a commercial complex mixture of chlorine-based components, and reported that it can reduce the levels of *Salmonella* on poultry skin. Although chlorine has been approved for meat and poultry decontamination in many countries, there are some safety concerns regarding its use related to corrosion of metals and formation of harmful chemical reaction products with organic residue materials (20).

Trisodium phosphate (TSP) has also been approved for treatment of beef and poultry carcasses in the U.S. A patented solution of TSP (AvGard™, Rhone-Poulenc, France) has been shown to reduce both spoilage and pathogenic bacteria including *Salmonella, L. monocytogenes*, *E. coli* O157:H7, *S. aureus* and pseudomonads on meat and poultry tissues (234,271–274). Cabedo (275) reported that TSP may inhibit bacterial attachment and thus allow easier bacterial removal by washing. Studies on the effect of TSP on the sensory characteristics of beef and chicken samples have indicated that a 10–12% solution of TSP does not cause any undesirable sensory effects that are detectable by consumers (276–278).

Acidified (citric acid activated) sodium chlorite (ASC) is another antimicrobial that has received approval from the U.S. federal government for use in beef carcass decontamination systems. Spraying of beef carcass surfaces with ASC, at a concentration of 1,200 mg/l, in combination with a water wash, resulted in a 4.5 log cfu/cm^2 reduction of inoculated (5.5 log cfu/cm^2) *E. coli* O157:H7, compared to a 2.3 log cfu cm^2 reduction obtained with a water wash only (279).

Hydrogen peroxide and ozonated water are also among the chemical agents proposed and tested for meat and poultry decontamination (20), and have recently received approval by FSIS for use on meat and poultry products. The antimicrobial effect of hydrogen peroxide is mainly based on the formation of radicals that damage nucleic acids, proteins and lipids. Treatment of beef and lamb carcass tissue with a hydrogen peroxide solution (5%) has been shown to reduce mean bacteria counts by 1–2 logs (224,227,234). Similar microbial reductions have been observed after spray-washing of beef carcasses with ozonated water (227,230,234). As in the case of chlorine, the use of hydrogen peroxide and ozone, despite their bactericidal effect, may be of concern due to their oxidizing effects on fat and muscle pigments.

Decontamination with cetylpyridinium chloride (CPC) has been shown to be effective in reducing levels of pathogens on meat and poultry carcass tissues. Kim and Slavik (280) reported that CPC spraying or immersion of poultry skin reduced the numbers of *Salmonella* by 0.9–1.7 logs and 1.0–1.6 logs, respectively. Cutter et al. (281) showed that spray washing of beef fat with 1% CPC resulted in significant reductions of *E. coli* O157:H7 and *S.* Typhimurium. In an additional study, 0.5% CPC was shown to reduce *E. coli* O157:H7 levels by 4.8 and 2.1 log cfu/cm^2 on beef carcass surfaces and lean tissue, respectively (282). In a study on the effect of CPC on the sensory characteristics of beef trimmings, the authors indicated that treatments with 0.5% CPC did not affect instrumental color or other sensory characteristics of the samples (278).

Peroxyacetic acid has been recently recognized as an effective chemical agent for meat decontamination. A commercial peroxyacetic acid-based solution (Inspexx 200™, Ecolab Company, St. Paul, MN) for pre-chilling application of carcasses has been approved in the U.S. Ransom et al. (282) reported that 0.02% peroxyacetic acid was effective in reducing the bacterial load of beef samples; however, under the conditions of that study, which did not reflect those recommended by the manufacturer, it was found less effective compared to lactic acid (2%; heated to 55°C).

Naidu and Bidlack (283) reported that lactoferrin, an iron binding protein, presents strong antimicrobial activity and can be used as an alternative to other chemical antimicrobial agents. Activation of bovine lactoferrin, which can be extracted in commercial quantities from skim milk or whey, yields a potent bactericidal peptide that has been shown to inhibit and/or inactivate a wide range of meat pathogenic and spoilage bacteria including *L. monocytogenes, Salmonella*, *Campylobacter* spp., *Pseudomonas* spp. and *Klebsiella* spp. (284). The patented process of producing activated lactoferrin involves immobilization of milk lactoferrin, via its N-terminus region, on a food-grade glycosaminoglycan (e.g., galactose-rich polysaccharide or carrageenan), solubilized in a precalibrated citrate/bicarbonate buffer system containing sodium chloride and an excess of unbound lactoferrin (284). The resultant activated lactoferrin reportedly acts as a microbial blocking agent that is able to (i) interfere with the adhesion or colonization of microorganisms to biological surfaces (ii) detach viable or non-viable cells from biological surfaces, (iii) inhibit microbial growth,

and (iv) neutralize the activity of endotoxins (284). The U.S. Food and Drug Administration (FDA) recently accepted activated lactoferrin as GRAS while FSIS approved the compound for use on fresh beef (284).

A variety of other chemical compounds such as polyphosphates, benzoates and propionates, sodium hydroxide, sodium bisulfate, etc. have been tested with various rates of success for the decontamination of meat and poultry (15,20,208,210,217). Application of these or other chemicals as meat and poultry decontaminants in the future will depend on their efficacy, safety, effects on quality and cost (20).

e. Carcass decontamination with multiple processes

The use of more than one treatment may lead to synergistic or additive decontamination effects (20) and could be considered as a multiple hurdle approach (206). In fresh meat decontamination, the multiple hurdle decontamination approach may involve the simultaneous application of treatments (e.g., warm acid solutions) or the sequential application of treatments (e.g., hide cleaning, steam-vacuuming, pre-evisceration washing, hot water or steam treatment, organic acid rinsing). Several studies on the comparison between the effectiveness of single and multiple decontamination treatments have reported that the latter result in significantly higher microbial reductions (Table 52.7) (10,285,286). Bacon et al. (10) studied multiple-sequential decontamination interventions including carcass washing, steam-vacuuming, hot water and organic acid rinsing before and after evisceration in commercial beef slaughter facilities. The authors reported that *E. coli* counts were reduced from an initial range of 2.6–5.3 log cfu/cm^2 to a final range of 0.9–1.3 log cfu/cm^2 after carcass chilling. Graves Delmore et al. (287) used various technologies and interventions to decontaminate beef adipose tissue samples and reported that a higher reduction in *E. coli* counts was achieved by a series of four processes including pre-evisceration washing, warm-water washing and two steps of acetic acid rinsing. In addition to the number and intensity, the sequence of treatments can be very important in a multiple decontamination process (Table 52.7). For example, Castillo et al. (286) reported that a lactic acid rinse, following hot water washing, was more effective than their use in the opposite order. Overall, when the appropriate number and sequence of hurdles are selected, the multiple hurdle decontamination approach can be a very effective tool for improving the safety of meat and poultry carcasses, and may minimize the potential for resistance development and cross protection (258).

f. Concerns of decontamination technologies

Despite the generally accepted effectiveness of decontamination technologies in reducing numbers and prevalence of pathogenic and/or spoilage bacteria on meat and poultry carcasses, there are a number of concerns associated with their use. Application of spraying/rinsing treatments to carcasses may lead to spreading and redistribution of bacteria over the carcass or penetration into the tissue (20). These problems, however, can be avoided by appropriate selection and adjustment of the factors affecting the efficacy of the decontamination treatment. For example, the issue of bacterial redistribution may be addressed by using decontamination interventions that may inactivate (hot water, steam, chemical solutions) rather than remove contamination. As mentioned previously, the period of time before decontamination has an important effect on bacterial attachment and biofilm formation; thus, decontamination treatments applied before evisceration will be more effective since bacterial attachment is still weak.

Another important concern associated with the use of decontamination technologies is the potential development of stress-resistant pathogens (20,242,252,258,288). Heat or acid resistance are important physiological characteristics that may contribute significantly to the behavior of pathogenic microorganisms during meat processing, cooking or in host systems (gastric secretions, phagocytosomal vacuoles) where acidity is the final barrier that the pathogen must overcome before pathogenesis. The potential concern for development of stress-resistant pathogens can be attributed to the 'stress hardening' phenomenon which refers to the increased tolerance of a pathogen to a specific lethal stress after adaptation to the same or a different sublethal stress environment (258,289). Several studies have demonstrated that adaptation of pathogenic bacteria such as *L. monocytogenes, E. coli* O157:H7 and *Salmonella* to a mild

TABLE 52.7
Mean Log Reduction (log cfu/cm^2) of *Salmonella* Typhimurium, *E. coli* O157:H7, Aerobic Plate Count (APC), Total Coliforms and Enterobacteriaceae on Beef Carcass Surfaces as Affected by the Type of Decontamination Treatment

Treatment	*Salmonella* Typhimurium	*Escherichia coli* O157:H7	APC	Total coliforms	Enterobacteriaceae
Water wash	2.3	2.4	1.6	1.8	1.7
Water wash + hot water	4.2	4.0	3.2	4.0	3.8
Water wash + lactic acid	>4.9	4.6	4.6	4.5	4.3
Water wash + hot water + lactic acid	>4.5	4.9	3.6	>4.6	>4.7
Water wash + lactic acid + hot water	4.4	4.4	4.1	>5.0	>4.9

Source: Ref. 286.

stress environment results in increased survival under stress conditions that would be lethal for non-adapted cells (288–293). In addition to increased stress resistance, adaptation may lead to mutations with enhanced virulence (294) since microorganisms may sense the unfavorable conditions as a signal for the expression of virulence factors (295). It needs to be noted, however, that the majority of the studies on the 'stress hardening' phenomenon have been performed in laboratory media and thus more research is needed on the investigation of stress adaptation in actual foods. Nevertheless, an evaluation of the contribution of decontamination interventions to food safety improvement should take into account the potential development of stress-resistant pathogens. It should be stressed, however, that irrespective of potential stress adaptation inducement on survivors, decontamination treatments are highly effective in reducing microbial contamination of carcasses and thus, allowing meat operations to meet regulatory performance standards and industry specifications (15,20,217,258). Proposed strategies to control stress resistance of bacteria involve the continued application of lethal levels of preservatives, or optimization of decontamination interventions, in type, intensity and sequence, to maximize microbial destruction and minimize resistance development (258,296).

C. Meat Processing and Preservation

Processing and preservation technologies involving physical, chemical and biological factors are used by food processors to ensure the safety and stability of foods by inactivating or inhibiting growth of spoilage and pathogenic microorganisms. Physical preservation methods include refrigeration, freezing, heating, drying, smoking, packaging and irradiation. Addition of antimicrobial agents or preservatives to meat products, including sorbates, benzoates and lactates, or curing agents such as sodium nitrite or salt, as well as treatment of products with acidifying agents like acetic and lactic acid, all constitute methods of chemical preservation. An example of biological preservation, or biopreservation, is fermentation where lactic acid bacteria may be used to inhibit the growth of spoilage and pathogenic microorganisms by the production of inhibitory metabolites by the lactic acid bacteria (297). Details of these processing and preservation methods are excellently reviewed by Claus et al. (298), van Laack (299) and Pearson and Gillett (300). Combination of these preservation technologies, applied individually at sublethal levels (hurdle technology), can result in a product that is more microbiologically stable and safe, as well as of higher nutritive and sensory quality (207).

Before discussing some of these technologies, however, another important aspect that can greatly affect the quality and safety of the final product is the cleaning and sanitation operations of a food-processing establishment.

1. Cleaning and Sanitation

During food processing procedures, equipment surfaces and the surrounding environment inevitably become soiled and require cleaning. Failure to effectively remove the soil from these surfaces may result in the soil becoming a niche for microorganisms. These organisms then have the potential to attach to the surface and form biofilms, which upon detachment may cross-contaminate foods. An effective sanitation program includes cleaning and disinfection; however, to ensure good sanitation and to maximize the effectiveness of the cleaning operation, the design and layout of the processing area and food plant are of primary concern (301). The importance of factory design and food processing equipment are described by Forsythe and Hayes (302). According to the same authors, there are three steps involved in cleaning and two steps in disinfection (sanitation). Cleaning involves removal of gross soil or dirt, removal of residual soil with detergent, and rinsing of the cleaned surface to remove detergent and soil; while sanitation, which often follows cleaning, involves the use of an antimicrobial agent to inactivate microorganisms, followed by rinsing off of these agents. Removal of soil normally involves the use of hot or cold water and cleaning aids such as brush bristles. The type of detergent used is important and ideally should be able to disperse insoluble materials, emulsify and saponify fats, rinse well, remove or inactivate calcium and magnesium salts dissolved in hard waters, and should not be corrosive to equipment surfaces (301,302). Detergents may be classified into inorganic alkalis (e.g., sodium hydroxide, sodium carbonate), inorganic and organic acids (e.g., phosphoric and citric acids, respectively), surface-active agents (e.g., synthetic detergents which are either anionic, cationic, non-ionic or amphoteric), and sequestering agents (e.g., sodium polyphosphates and EDTA). Modern detergent formulations contain a mixture of different chemicals, each of which contributes to the desired properties of the detergent (302).

Application of the sanitizer follows rinsing of the detergent from the surfaces. The sanitizer should ideally be able to rapidly inactivate Gram-negative and Gram-positive bacteria, be stable in the presence of organic residues, be able to work in a wide pH range, water hardness, and temperatures, and should be readily soluble in water and readily rinsable. Sanitizers used in the food industry can be classified into chlorine releasing compounds, quaternary ammonium compounds, iodophors and amphoteric compounds (301,302).

2. Processing for Microbial Destruction

Application of heat, or thermal processing, is one of a few preservation methods that result in the inactivation of microorganisms, with time and temperature of cooking determining the number of organisms destroyed. Furthermore, thermal inactivation of microorganisms is

dependent on the level, type and heat resistance of the organisms, as well as the environment (moisture and fat content, pH, salt, nitrite) (298,299). Most spoilage and pathogenic bacteria are sensitive to heat and are destroyed due to inactivation of bacterial enzymes, protein denaturation and increased membrane permeability (299). Most heat labile organisms, like micrococci, pseudomonads and Enterobacteriaceae are inactivated after several minutes at 65°C; destruction of certain spores, however, may require heating to at least 115.6°C for extended periods of time (298). Thermal processing may be classified as 'pasteurization' or 'sterilization,' based on the level of destruction of bacteria and spores. Pasteurization results in the destruction of vegetative cells of pathogenic bacteria; however, heat-resistant spoilage organisms and spores may survive during this process. Commercially sterile products are processed to be free of detectable microbial contaminants, but may contain spores of thermophilic bacteria that do not germinate below 43°C (299). The internal temperature reached in commercially sterile meat products is generally at least 107.2°C, but depending on the salt and nitrite content of the product, the temperature can be as low as 101.7°C (300). These products remain stable and safe even after long-term storage at ambient temperatures in temperate climates.

Other processing technologies that result in inactivation of microorganisms include irradiation and high hydrostatic pressure, and are discussed in a subsequent section.

3. Processing for Microbial Inhibition

As mentioned previously, preservation technologies that inhibit the growth of microorganisms in foods rely on the control of one or more factors affecting microbial growth (e.g., temperature, water activity, pH, antimicrobials). The most important means of preserving fresh unfrozen meat and other perishable meat products is refrigeration at temperatures between –2 and 5°C (299). Although growth of most mesophilic bacteria at these temperatures is prevented, growth of psychrotrophic and psychrophilic bacteria, including pathogens like *L. monocytogenes*, *A. hydrophila* and *Y. enterocolitica*, is only delayed (due to increased lag times and reduced growth rates) (303). Freezing of meat products, however, results in inhibition of microbial growth with some reduction of microbial levels during freezing, and potential increases during thawing (41,299). Preservation of food by drying is brought about by a reduction in the water activity of the product to a level that prevents growth of microorganisms. Drying methods include hot air drying, refrigerated air-drying, freeze-drying and brine-process drying (299,303). Water activity is also reduced with addition of humectants (e.g., salt, sugar) and by freezing. Smoking is also regarded as a preservation method. Many cured meats are smoked, and this process is either carried out directly from smoldering hardwood or hardwood sawdust, or in liquid form that is produced from natural smoke precipitated in water or oil (304). Smoke is composed of many different compounds including alcohol, carbonyls, hydrocarbons and gases; however, the antimicrobial properties of smoke are due to phenols and acids present in the smoke, as well as the heat that is associated with wood smoking (300). Foodborne pathogens, including pathogenic *E. coli* and *S. aureus*, are reportedly inactivated by commercially available liquid smoke products used in processed meats (297).

The use of salt as a preservative serves to inhibit microbial growth by reducing the water activity and increasing the osmotic pressure of the food (70,305). Salt is also the major ingredient, by weight, of curing mixtures; the active curing agent, however, is nitrite, and to a limited extent, nitrate. These curing agents function to stabilize the color of lean tissues, impart the characteristic flavor of cured meat, retard development of rancidity and provide microbial stability by inhibiting the growth of microorganisms, including *Acinetobacter/Moraxella*, *Flavobacterium*, *Pseudomonas*, *Enterobacter*, and *Escherichia* spp., as well as the pathogen *C. botulinum* (49,300,306). The antibotulinal effect of nitrite, however, occurs only in combination with heat, as is the case with canned products. Furthermore, the inhibitory effect of nitrite is reportedly pH dependent, with an approximate tenfold increase of its inhibitory effect for every one pH unit reduction (299).

Addition of antimicrobial agents in meat products is a widely used method of preservation. The use of antimicrobial agents in ready-to-eat meat and poultry products is, in fact, one of the alternatives given to the U.S. food industry by FSIS, as a means to control *L. monocytogenes* in these products (199). Numerous studies have shown the antilisterial effect of GRAS chemical compounds in ready-to-eat meats, including potassium lactate (307,308), sodium lactate and sodium acetate (309–311), sodium diacetate (310,311), and acetic and lactic acid (312). The most widely used chemical preservatives used by the industry, however, are sodium or potassium lactate and sodium diacetate, alone or in combination, at levels of 2% sodium or potassium lactate (on a dry weight basis) and 0.1 to 0.15% sodium diacetate (191). The other alternatives of the final rule for control of *L. monocytogenes* in ready-to-eat meat and poultry products are post-lethality treatments, which may be applied pre-packaging or post-packaging (e.g., radiant heat, hot water or steam pasteurization, high hydrostatic pressure) (313–316) and sanitation measures (199).

4. Preservative Packaging

a. *Modified atmosphere packaging*

Modified atmosphere packaging can be defined as the enclosure of food products in high gas barrier material, in which the gaseous environment has been changed in order to reduce microbial growth and retard enzymatic spoilage, with the intent of extending shelf life (317).

Among the factors limiting the shelf life of meat and poultry products, oxygen can be considered as one of the most important. Consequently, a logical barrier to extend the shelf life of these products is to modify the gaseous atmosphere surrounding them, which is the principle behind modified atmosphere packaging (MAP). A comprehensive list of different gas mixtures and packaging materials with different oxygen transmission rates that have been used to extend the shelf life of different meat types at specific storage temperatures, and the predominant spoilage bacteria isolated from those products can be found in Stanbridge and Davies (138). Four types of MAP can be differentiated by the manner in which spoilage organisms are inhibited (318): (i) in vacuum packaging, the inhibition of aerobic organisms is based on the removal of oxygen from the in-pack environment and the CO_2 production; (ii) In high oxygen MAP, growth of aerobic organisms is inhibited, but not suppressed by moderate concentrations of CO_2; (iii) In low oxygen MAP the low concentrations of O_2 inhibit the growth of aerobic species while the concentration of CO_2 may be sufficiently high to slow down the growth of both aerobic and anaerobic organisms; and (iv) in oxygen-free controlled atmosphere packaging, the absence of oxygen prevents growth of aerobic organisms, while high concentrations of CO_2 inhibit growth of aerobes and organisms tolerant to anaerobic conditions.

b. *Vacuum packaging*

Vacuum packaging is widely used for shelf-ready retail packs of meat products and for primal cuts of raw meat in wholesale storage. Vacuum packaging is not commonly used for display packs of raw meats because the anoxic environments results in a dull, purple color of native myoglobin, which is considered unattractive to the consumers (317,319). The shelf life extension of primal cuts achievable by vacuum packaging can be as long as two- to five-fold compared with aerobic storage depending on their pH, size and film permeability (318,320,321). Beef of pH 5.6 to 5.8, vacuum packaged with film of low oxygen permeability and stored at 0 to 1°C, may have a shelf life of 10 to 12 weeks (144). Growth of *Pseudomonas* under these conditions, where the CO_2 and O_2 concentrations are approximately 20% and $<1\%$ (v/v), respectively, is inhibited.

Vacuum packaging is also applied to cured and other cooked meat (322,323). The major disadvantage associated with the application of vacuum packaging to these products is that both package and meat are subjected to mechanical strain. This may cause product deformations, exudation and even puncture of the pack if bone is present (321). These problems, however, may be overcome with improvements in packaging techniques such as the use of appropriate packaging material, shrink packs, surface sealing and skin packs (4).

c. *High oxygen modified atmosphere packaging*

In high oxygen MAP the gaseous composition is approximately 70% O_2, 30% CO_2 and 0–20% N_2 (318). This type of packaging is used mainly for red meats and it has been introduced to extend color stability and delay microbial spoilage of products on display (319,324). The high oxygen concentration preserves a desirable color by extending the depth of the surface layer of oxygenated muscle tissue while the 30% CO_2 is sufficient to reduce the growth rate of pseudomonads, which dominate the spoilage flora. In general, the storage life of meats in high oxygen MAP can be twice that of meat stored under aerobic conditions. However, spoilage changes of foods stored in high oxygen MAP are comparable to those stored in air, since pseudomonads remain the responsible spoilage organisms.

d. *Low oxygen modified atmosphere packaging*

In low oxygen MAP, the atmosphere is composed almost exclusively of CO_2 and N_2. The exact level of residual oxygen depends on the procedure of air replacement. Without evacuation, oxygen may remain at levels of up to 10% while with evacuation the residual oxygen is about 1% (318). Low oxygen MAP is not commonly used for red meats due to the rapid discoloration of the product. Such packaging is usually applied when product color is not critically dependent on the oxidation state of myoglobin and thus it is more useful for poultry products. The extension of product shelf life achieved with low oxygen MAP can vary significantly depending on the initial atmosphere established in the pack and the extent to which the gaseous composition changes during storage. The spoilage process of low oxygen MAP meats is generally similar to that observed in vacuum packed products since in both cases the limited oxygen concentration inhibits growth of aerobic organisms, and species tolerant to anaerobic conditions dominate the microflora.

e. *Oxygen-free controlled atmosphere packaging*

Oxygen-free controlled atmosphere packaging is based on the complete elimination of oxygen from the package. The strictly anoxic environment may prevent meat discoloration and microbial shelf life may be greatly extended when the air is completely replaced with CO_2 in a controlled-atmosphere package (319). Scientists in New Zealand developed an oxygen-free controlled atmosphere packaging system (Captech system), which is in commercial use with lamb primal cuts and whole carcasses (319,325). The system involves packaging of cuts in heat-shrunk, air-permeable bags, which are then put in a larger pack of highly impermeable film that is flushed with carbon dioxide and sealed. The permeability of the inside packs allows penetration of carbon dioxide during storage and shipment, as well as oxygen after removal from the

external pack and during display for formation of oxymyoglobin, which results in a bright red color. The storage life of such products can be 8–15 times longer than those stored in air depending on their initial contamination, pH and storage temperature. For example, shelf life may be substantially shorter when highly contaminated, high pH products are stored at temperatures above 0°C (318). The success of the packaging method also requires effective evacuation equipment and totally impermeable packaging materials made from aluminium foil laminate with good sealing and puncture-resistant properties. The extended product stability achieved by this type of packaging is likely to ensure its future commercial use with a wide range of meat products.

f. Factors that influence the effectiveness of modified atmosphere packaging

In addition to gas concentration and composition, the packaging material, the storage temperature and the time of MAP application are important factors influencing the shelf life extension conferred by MAP technology (318,321,326–328). Packages are mainly constructed of plastic films, the majority of which are permeable to gases. The extent of gas transmission through a plastic material depends on a number of factors such as type of plastic, thickness of the plastic layer, temperature, humidity and contamination of the plastic material with food components such as fat (318). Thus, proper selection of the plastic film in order to maintain the essential balance of the flushed gaseous atmosphere in the headspace of the pack is crucial. Bacterial inhibition by MAP is also affected by storage temperature. The solubility of CO_2 is inversely proportional to storage temperature and thus low temperatures have a synergistic affect upon its action (327). In addition, the multiple hurdle application (CO_2 and low temperature) leads to a higher inhibition of meat spoilage bacteria (329).

The time of MAP application is another important factor affecting the storage life of the product. If MAP is applied to fresh meat when the spoilage bacteria are still in the lag phase, shelf life may be extended by 50% compared to products stored aerobically, while MAP application during the exponential phase of the spoilage bacteria reduces the shelf life extension to 30% (326). In addition, the effectiveness of MAP is influenced by the extent of contamination at the time of application since high microbial populations result in an increased probability of the presence of some bacteria which are more resistant to the antimicrobial effect of the gaseous atmosphere. In general, the effectiveness of MAP is enhanced with earlier application and lower initial contamination levels.

g. Safety concerns of modified atmosphere packaging

Given that MAP is capable of extending the shelf life of meat products, the major safety concern is whether MAP can inhibit sensory changes by spoilage microorganisms, which ordinarily would warn consumers, while either allowing or promoting the growth of pathogens by limiting the competition with the spoilage flora (321). The impact of MAP on the microbiological safety of meats is not very well defined especially with respect to *C. botulinum*. For example, in sausages and meat sandwiches inoculated with *C. botulinum* (types A and B) and stored at 26°C, toxin was detected at 6 days for aerobically stored sandwiches and at 4 days for anaerobically stored samples (330). The most important observation in the latter study was that anaerobic samples were found organoleptically acceptable when toxic, while the aerobic were not. In a study by Silliker and Wolfe (331), pork cubes inoculated with *C. botulinum* spores and stored at 27°C under MAP were found to contain toxin by day 1 while aerobic samples were toxic by day 2. It is clear that *C. botulinum* may find atmospheric microenvironments allowing growth at highly abusive temperatures and thus the combination of MAP with strict temperature control is of great importance. Even at low storage temperatures, however, it is known that cold-tolerant pathogens such as *Y. enterocolitica, L. monocytogenes* and *A. hydrophila* are able to grow on vacuum-packaged, high pH raw meat (332).

The majority of the available information on the safety of meat and poultry packaged in modified atmospheres is based on traditional inoculation studies. Such data, however, cannot lead to reliable estimations of MAP safety risks since they are not statistically predictive and ignore the relationship between spoilage and pathogenicity. Thus, there is a need for further research information including risk assessment studies in which MAP will be compared against the current distribution and retail practices by taking into account the effect of factors such as temperature, time, pH and atmosphere as well as the relationship between growth of spoilage and pathogenic organisms. Such studies would lead to a better understanding of the action and interaction of the above factors in MAP and identify the potential need for additional antimicrobial hurdles to assure predictable safety.

h. Active packaging

Active packaging is one of the innovative concepts of food packaging that have been introduced as a response to the increasing consumer demands and the continuous changes in market trends. Major active packaging concepts include the use of substances that absorb oxygen, ethylene, carbon dioxide, flavors/odors and substances that release carbon dioxide, antimicrobial agents, antioxidants and flavors (333). Antimicrobial packaging has been characterized as a promising preservation concept for intact meat and poultry products mainly due to the fact that microbial contamination of these products occurs primarily on the surface (334).

The antimicrobial packaging concept is based on the incorporation of antimicrobial agents with polymeric

packaging materials or biodegradable films and coatings. Compared to direct surface application of antimicrobial agents by spraying or dipping, antimicrobial packaging could be more efficient due to the slow release of the agent from the packaging material to the surface of the product, which helps to maintain high concentrations where they are needed. In addition, a long migration period of the antimicrobial agent may extend its activity into all stages of the food chain including transport, storage and distribution.

Non-edible antimicrobial packaging systems may contain different types of food grade additives in their packaging materials. Among compounds that have been proposed and tested in meat and poultry products are organic acids such as sorbate (335), propionate (336) and benzoate (337) or their respective anhydrides, bacteriocins including nisin and pediocin (338,339), enzymes such as lysozyme (340), and natural antimicrobial compounds from aromatic plants (341) (Table 52.8). The antimicrobial activity of triclosan incorporated plastic (TIP) has been recently investigated and the results showed a satisfactory inhibition against both spoilage and pathogenic bacteria associated with meat and poultry products such as *B. thermosphacta*, *S.* Typhimurium, *S. aureus* and *E. coli* (342). Triclosan is a tasteless, odorless and orally non-toxic bacteriostatic agent (343) and its use for food applications has been recently allowed in EU countries. Another interesting application of antimicrobial packaging is the use of polymers with modified surface composition by electron irradiation in such a way that the surface would contain amine groups with antimicrobial activity (344). These surface-bound amine groups have been proven active against pathogenic and spoilage bacteria (345).

Edible coatings and films prepared from polysaccharides, proteins and lipids and supplemented with antimicrobial agents can be considered as another type of antimicrobial packaging application. In this case, however, selection of the active agents is limited to edible compounds. Edible coatings and films with antimicrobial compounds present the following benefits to the meat and poultry industry: (i) inhibit the growth of spoilage and pathogenic bacteria and lead to products with low safety risk and extended shelf life; (ii) help alleviate the problem of moisture loss that leads to texture, flavor and color changes and weight losses; (iii) hold in juices and enhance product presentation; and (iv) reduce the rate of rancidity and brown discoloration caused by lipid and myoglobin oxidation (346). An additional advantage of this application is that the development of films and coatings can be based on the biopolymer by-products of the meat and poultry industry such as gelatin, blood protein and feather keratin.

TABLE 52.8
Applications of Antimicrobial Packaging Tested in Meat and Poultry Products

Product-Substrate	Antimicrobial Agent	Packaging Material
Bologna, cooked ham, pastrami	Acetic acid	Chitosan
Beef muscle	Lactic acid	Alginate
Bologna, cooked ham, pastrami	Propionic acid	Chitosan
Chicken breast	Potassium sorbate	Starch/glycerol
Beef tissue	Lysozyme	Silicon coating
Broiler drumstick skin	Nisin	Polyethylene
Cooked meats	Pediocin	Cellulose

5. Biopreservation

Biopreservation refers to extended storage life and enhanced safety of foods using their natural or controlled microflora and/or their antibacterial metabolic end products (347,348). In meats, lactic acid bacteria (LAB) constitute a part of the initial microflora which develops easily during fermentation processing, chill storage or packaging under vacuum or modified atmosphere conditions. Lactic acid bacteria growth in meat can cause interference against spoilage and pathogenic bacteria through several mechanisms including nutrient and oxygen depletion, and production of a wide range of inhibitory metabolic substances such as lactic and acetic acid, acetoin, diacetyl, hydrogen peroxide, reuterin and bacteriocins.

Biopreservation may be applied to food and meat systems by four basic methods (348–350):

a) Adding a pure culture of LAB. This is an indirect way of incorporating the antimicrobial metabolites of LAB (e.g., bacteriocins) in a food product. The success of the method depends on the ability of the culture to grow and produce the metabolites under the environmental and technological conditions of the product (temperature, pH, a_w, additives, etc.).
b) Adding a crude metabolite-preparation obtained by growing the LAB culture on a complex substrate in order to avoid the use of a purified compound.
c) Adding purified or semi-purified antagonistic substances. By using this method the dosage of the antimicrobial metabolite is more accurate and thus more predictable. However, application of this method is limited due to regulations concerning food additives.
d) Adding mesophilic LAB as a protective culture to be activated in the event of potential storage temperature abuse. In this case LAB should remain at low levels in cold environments while under temperature-abuse conditions they should grow competitively with pathogens and thus reduce the safety risk of the product.

a. Lactic acid bacteria

The use of LAB as starter cultures in fermented meat products shortens the fermentation time, ensures product safety, extends shelf life and results in products with desirable, distinct and consistent quality (351,352). In addition to their inhibitory activity against meat spoilage and pathogenic bacteria, the production of lactic acid by LAB denatures meat proteins and affects product texture. Protein denaturation also results in the decrease of a_w which leads to the microbial stabilization of the transformed product.

The starter cultures used predominantly in fermented meat products include strains of *Pediococcus acidilactici*, *Pediococcus pentosaceus*, *Lactobacillus plantarum*, *Lactobacillus sake* and *Lactobacillus curvatus*. Other bacteria such as *Micrococcus* (*Micrococcus varians*) and coagulase-negative staphylococci are also used, mostly in Europe, and mainly due to their ability to reduce nitrate to nitrite and the production of specific flavors and catalase, which decomposes hydrogen peroxide and prevents quality defects.

In addition to fermented meat products, the use of LAB is permitted in bacon produced with minimal nitrite levels to reduce formation of nitrosamine during frying; the LAB grow and reduce the pH to inhibit *C. botulinum* growth in the absence of higher nitrite levels if the product is temperature abused (353). Inoculation of selected strains of LAB on fresh meat may suppress other LAB that degrade amino acids to undesirable compounds such as sulfides or biogenic amines (354,355) and contribute to the control of meat pathogens such as *L. monocytogenes* (356).

Addition of LAB to meat products, however, may also impart quality or safety problems. For example, heterofermentative LAB can produce undesirable compounds such as diacetyl, hydrogen sulfide and hydrogen peroxide gases, which affect product flavor and color. In addition, the ability of some LAB to decarboxylate the amino acid, histidine, may result in high levels of histamine, which has been associated with several outbreaks of foodborne illness (357). Thus, starter cultures should be screened for absence of metabolic products that cause quality or safety problems.

b. Bacteriocins

Bacteriocins are ribosomally produced polypeptides or proteins that produce, in their mature form, an antibacterial effect against a narrow spectrum of closely related bacteria (358,359). Bacteriocins exert their inhibitory action by formation of pores in the cytoplasmic membrane of sensitive cells. They are effective inactivators or inhibitors of various Gram-positive bacteria including pathogens, while Gram-negative bacteria are protected by their outer membrane, which prevents bacteriocins from reaching the cytoplasmic membrane (360).

Although several meat-borne LAB have been described as bacteriocin producers (Table 52.9) only a few have been studied as biopreservatives in meat systems. The production and antimicrobial activity of certain bacteriocins in laboratory media does not imply their effectiveness in a food system. Bacteriocin activity may be reduced by the binding of bacteriocin molecules to meat components, by the action of proteases and other enzymes or by an uneven distribution in the food matrix (361). In addition, bacteriocins are not only of narrow activity among microorganisms, but there is also strain variation and their activity in foods may be reduced with storage time. Thus, when evaluating a bacteriocin for meat biopreservation, the influence of the product formulation and processing technology on the antimicrobial performance of the bacteriocin needs to be assayed.

TABLE 52.9
Bacteriocins Characterized from Lactic Acid Bacteria

Lactic Acid bacteria	Bacteriocin
Carnobacterium piscicola	Carnocin U149
	Carnobacteriocin (A and B)
Lactococcus lactis	Nisin (A and Z)
	Lacticin 481
	Diplococcin
	Lactococcin (A, B and M)
Lactobacillus sake	Lactocin S
	Sakacin (A and P)
Lactobacillus curvatus	Curvacin A
Lactobacillus johnsonii	Lactacin F
Leuconostoc gelidum	Leucocin A-UAL-187
Enterococcus faecium	Enterocin 1146
Pediococcus acidilactici	Pediocin (AcH and PA-1)

Source: Ref. 413.

The most studied bacteriocins in meat and meat products include nisin A, A, P and K, leucocin A and pediocin PA-1/AcH (350); nisin, however, is the only bacteriocin approved for use in certain food products. Sprayed nisin has been effective for the decontamination of meat surfaces while its combination with nitrite was effective on *Clostridium* and other Gram-positive pathogens such as *L. monocytogenes* and *S. aureus* in frankfurters, pork slurries and raw meat (362,363). In fermented American-style sausages, pediocin production prevented *L. monocytogenes* growth (364). The activity of pediocin PA-1 was not affected by fat or proteins present in the product while a synergistic effect was observed between the effect of bacteriocin and lactic acid.

6. Emerging Preservation Technologies

a. Irradiation

Food irradiation is generally defined as the process in which foods are exposed to ionizing energy from radioactive sources such as cobalt 60 or with machine sources such as high energy electron beams or X-rays. The role of irradiation as an alternative method to ensure hygienic quality of meat and poultry products is increasingly advocated and

used in some countries (365–367). By properly adjusting the irradiation process it is possible to achieve a specific reduction of the level of microbial contamination commonly found on meat and poultry. Depending on the product and conditions of the process, irradiation treatments at doses of 3–7 kGy can effectively eliminate vegetative cells of pathogens including *Salmonella, S. aureus, Campylobacter, L. monocytogenes* and *E. coli* O157:H7 (368,369). The number of cells that are killed by irradiation depends on various factors such as type of microorganism, type of food, irradiation dose, temperature, oxygen presence and water content (368–372). Table 52.10 provides examples of decimal reduction radiation doses (radiation D_{10} values) which have been determined for various non-spore-forming pathogenic bacteria in meat and poultry products (366). In addition to microbial inactivation, sublethal damage to microorganisms taking place during irradiation can increase their sensitivity to other preservative factors and thus synergistic effects of irradiation and other processes applied in food technology can be encountered (373). Among the benefits of irradiation is its applicability to frozen foods without having to thaw them,

TABLE 52.10
Irradiation D_{10} Values of Some Pathogenic Bacteria in Non-Frozen Meat and Poultry Products

Bacterium	Product	Temp. (°C)	Atmosphere	D_{10} (kGy)

and in packed products as a terminal treatment, eliminating the possibility of recontamination before consumption.

The main limitations of radiation decontamination are the effect of the process on the nutritional and sensory characteristics of the product (374) and the consumer acceptability of the process. Irradiation of meat and poultry may result in nutrient losses and changes in product odor, flavor and color depending on the radiation dose, dose rate, temperature, packaging and atmosphere during the process (375). Threshold irradiation doses at which detectable sensory changes occur in meat and poultry products are shown in Figure 52.5 (376). However, irradiation at low doses under low or no oxygen, or in the cured and frozen states for low fat products, has no notable sensory effects. A disadvantage of using irradiation at low doses is that bacterial spores, viruses and microbial toxins are not inactivated. Thus, as with other processed foods, irradiated products must be handled in accordance with good manufacturing practices and require appropriate temperature control.

Irradiation treatment of packaged products as a final processing step is a special case since this may cause cross-linking between the packaging material and the food. Irradiation may result in the decomposition of package components to lower-molecular-weight entities with increased migration characteristics (377). Therefore, the FDA requires that packaging that holds food during irradiation complies with specific regulations (21 CFR 179.45) based on appropriate testing.

The safety and effectiveness of irradiation as a method of food processing/preservation have been recognized by the Codex Alimentarius Commission (378). The FDA and FSIS approved a petition from industry to allow radiation decontamination of poultry and non-frozen and frozen red meats with maximum doses of 3 kGy, 4.5 kGy and 7.0 kGy, respectively (379,380). Despite this legislation, however, only a small fraction of the total amount of meat and poultry products produced in the U.S. is irradiated (381). Production of irradiated meat and poultry products is also limited in the EU, where no agreement has been reached on guidelines for regulating food irradiation (381). The limited application of irradiation of foods could be attributed to the widely held opinion of some national authorities and the food industry that consumers would be apprehensive about foods treated with irradiation because of the perceived association with radioactivity (365). Proper information about the safety and the benefits of irradiated foods could increase the level of understanding and acceptance of irradiated products by consumers and lead to a wider application of the process by the food industry (382). Furthermore, problems with the undesirable sensory effects of irradiation as well as investigations on the appropriate packaging materials for irradiated foods need to be addressed before this technology can be extensively used.

b. High hydrostatic pressure

High hydrostatic pressure (HHP) is an emerging non-thermal processing technology whereby foods are subjected to high hydrostatic pressure, generally in the range of 100–600 MPa, at low or moderate temperatures. It has been characterized as a very promising technology for the preservation of sliced cooked and cured meat products mainly due to its potential for the innovative development of new products of low safety risk with a relatively low energy consumption (383). High pressure application is of special interest in food processing technology since pressure represents an alternative to thermal processing, especially for foods such as meat and poultry whose nutritional and sensorial characteristics are thermosensitive. Indeed, HHP can reduce microbial contamination without markedly altering the taste and flavor or the nutrient content of foods (384–386). However, pressure processing also presents some disadvantages since it induces protein denaturation and texture modifications (385,386).

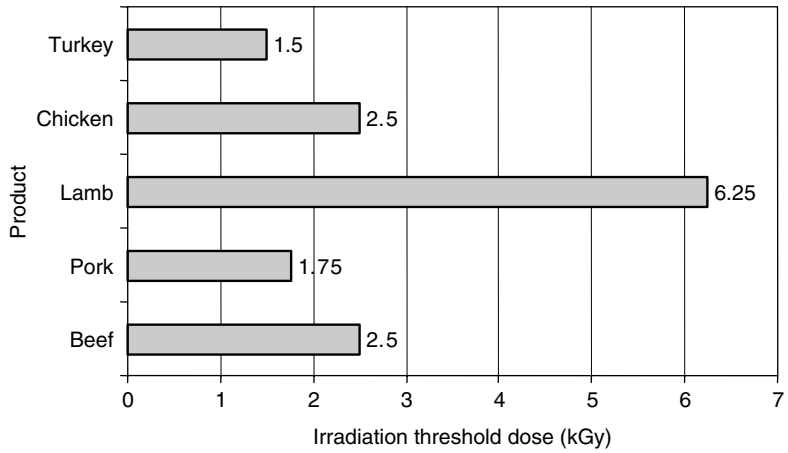

FIGURE 52.5 Irradiation threshold doses of meat and poultry products resulting in detectable sensory changes. (From Ref. 376.)

The mechanisms of inactivation of high hydrostatic pressure can be grouped into cell envelope-related effects, pressure-induced cellular changes, biochemical aspects and effects on genetic mechanisms (available at: http://vm.cfsan.fda.gov/~comm/ift-hpp.html). It has been established that cellular morphology is altered by pressure, and that cell division slows with the application of increasing pressures.

Bacterial spores are the most pressure-resistant life forms known. Thus, unless high hydrostatic pressures in excess of 800 MPa are used, heat in conjunction with HPP is a requirement for effective elimination of bacterial endospores (available at: http://vm.cfsan.fda.gov/~comm/ift-hpp.html). It is well established that the most pressure-resistant pathogen is *C. botulinum*. Spore suspensions of *C. botulinum* strains 17B and Cap 9B tolerated exposures of 30 min to 827 MPa and 75°C (available at: http://vm.cfsan.fda.gov/~comm/ift-hpp.html). Consequently, *C. botulinum* heads the list of most dangerous organisms faced by HPP. Among the vegetative cells, as in the case of other environmental stresses, Gram-positive bacteria are more resistant to pressure than vegetative cells of Gram-negative bacteria. However, there appears to be a wide range of pressure sensitivity among the pathogenic Gram-negative bacteria. Patterson et al. (387) have studied a clinical isolate of *E. coli* O157:H7 that possesses extremely high resistance to HHP.

Microbial inactivation through HHP application on fresh or processed meat has been studied in the last decade (388,389). The results have shown that pressure treatments at 200–600 MPa and 10–25°C for 10–20 min reduced, by at least 5–7 log cycles, the populations of both spoilage and pathogenic bacteria including pathogenic vegetative strains of *E. coli, C. jejuni, Pseudomonas aeruginosa, Y. enterocolitica, S.* Typhimurium*, S. aureus* and *Pseudomonas fluorescens.* The extent of inactivation, however, depends on several parameters such as the type of microorganism, the pressure level, the process temperature and time, and the pH and composition of the product. For example, pressure resistance of vegetative organisms increases at high (35 or 50°C) or low (4°C) temperatures and with decreasing water activity (386,390). Furthermore, the endogenous meat microflora, including *Pseudomonas* spp., appeared to be more resistant to pressure than the artificially inoculated organisms (390). The effect of HHP on microbial inactivation can be increased by combining it with other preservation treatments such as moderate heating or cooling, pH modifications, use of additives or various pretreatments. It may also be of special interest to apply HHP to ready-to-eat, packed products, as a terminal treatment in order to reduce microbial contamination originating from portioning, slicing or comminuting (386).

Other issues related to the application of HHP to meat products are associated with the effect of pressure on meat enzymes and proteins. For example, meat pressurization soon after slaughter usually results in a rapid pH decrease and an intense contraction. This greater rate of pH decrease has been related to changes in the activity of key meat enzymes involved in the regulation of glycogen breakdown. The above issues are considered significant since they may change important quality characteristics such as meat tenderness and structure. The effect of HHP on enzyme activity and meat proteins is extensively discussed in the study by Cheftel and Culioli (386).

Clearly, the benefits of HHP in terms of safety, storage life and quality can be applied to many high-value and heat-sensitive meat products and meat-based, ready-to-eat meals. At present, commercial HHP finds some applications in processed meat products for control of post-processing contamination with *L. monocytogenes*. The high cost of HHP technology and its limitation in terms of capacity could lead to the conclusion that HHP will not replace the conventional preservation and processing technologies. In the future, however, HHP is expected to find its position in the growing market of high-quality, high-priced foods (391).

c. Other technologies

Processing treatments with possible application in the meat industry include pulsed-field electricity, ultrasonic energy, UV light, oscillating magnetic fields (ohmic heating, dielectric heating, microwaves) and controlled instantaneous decompression (208,383,392,393, available at: http://vm.cfsan.fda.gov/~comm/ift-hpp.html). Pulsed field electricity, which is currently used in the meat industry for the electrostimulation of beef carcasses, can also lead to a reduction in the microbial load and extension of the lag phase of bacterial growth (392,394). Ultrasonic energy can be applied to small carcasses such as poultry when they are immersed in water. Research has shown that sonication can reduce the microbial contamination of the carcass especially when combined with appropriate adjustment of pH and temperature or with chlorination (395,396). The use of UV light in meat storage rooms and processing areas may control the bacterial load of the atmosphere (208).

All the above technologies aim at energy saving and being environmentally friendly. They have the same goal of being mild for food and reducing pathogenic and spoilage microorganisms. However, in most countries, these technologies are not approved and thus their application is limited at the present time.

V. MANAGEMENT OF PROCESSES FOR THE MICROBIOLOGICAL SAFETY OF MUSCLE FOODS

Traditionally, the microbiological safety of foods was heavily reliant on end product testing to determine the presence of a pathogen in a batch of product, and in so doing, determine the acceptance or rejection of a specific food lot (397). Limitations are, however, associated with

finished product testing since foodborne pathogens may be distributed sporadically and unpredictably and/or occur at a low incidence within the product (397,398). Thus, the number of samples tested from a specific lot may be insufficient to provide meaningful information, and furthermore, the results obtained may provide a false sense of security (399). A more effective means of ensuring food safety than end product testing is the implementation of food safety management systems that incorporate the principles of good manufacturing practices (GMP), prerequisite programs and hazard analysis critical control point (HACCP) (400–403). To develop an effective HACCP system, a systematic approach is used to identify, evaluate and control food safety hazards. GMP, however, constitute the foundation needed before implementation of HACCP is possible in a food processing operation (403). Prerequisite programs and GMP differ from HACCP in that the former deal indirectly with food safety and are, in general, applicable to the whole processing plant. On the other hand, the sole purpose of HACCP *is* food safety and is product- or line-specific (404). Since its inception, many food industries have adopted HACCP. Countries like the U.S., EU, Canada, Australia and New Zealand have made HACCP compliance mandatory in some or all of their food sectors (405,406). The seafood (since 1997), meat and poultry (phasing in began in 1998), and juice (effective in 2002) industries are currently mandated to implement HACCP in the U.S. (404).

A relatively new concept recommended for adoption into food safety management systems by the International Commission on Microbiological Specifications for Foods, is the food safety objective (FSO) (403,407). The FSO is proposed as a tool to link information from risk assessment and risk management processes with the implementation of measures to control the identified risk(s) (403,407). The FSO refers to the maximum level of a microbiological hazard in a food considered acceptable for consumer protection (403). Once it has been determined that the FSO is technically achievable through the application of HACCP and GMP, the next step is to develop and document strategies to satisfy the FSO, including quantifiable and verifiable performance, process or end product criteria (403). Microbiological criteria differ from FSOs in that they determine the acceptability of a specific food lot. These criteria specify the microorganisms of concern and/or their toxins or metabolites, the sampling plan to be used (number of samples, method of sampling and handling, size of analytical unit), the analytical method to be used, microbiological limits and the number of analytical units required to conform to the limits (403). Sampling plans should be based on statistical probability, and in so doing, provide confidence during interpretation of the results (408).

Microbiological testing programs are thus a necessary part of food safety management systems. The main purpose of testing in a properly implemented HACCP system is to identify hazards and critical control points, and to validate and verify process control measures, and not as a means to assure the microbial safety of the final end product (397–399,401,409,410). As mentioned previously, testing for pathogens during meat and poultry processing operations provides very little information of use for the implementation and maintenance of HACCP systems, since they are generally found infrequently, unpredictably and in low numbers on the animals, and are usually detected rather than enumerated (397). A negative result for the presence of the pathogen could, therefore, be due to process control or simply due to the pathogen being absent at that particular time in that particular sample of product. Testing for pathogens that are found at a low frequency would require larger sample numbers and would thus be costly, and still would not guarantee the safety of the product. Testing for indicator microorganisms, which are indicative of process control, may be more appropriate, as it is generally assumed that the absence or low numbers of an indicator microorganism is a sign of process control and thus a lower likelihood of the presence of the pathogen, with which the indicator microorganism is associated (397,403). Examples of indicator microorganisms that have been used to assess meat plant processes include aerobic bacteria, coliforms, Enterobacteriaceae and *E. coli* biotype I (397,403,411). It should be noted, however, that no microorganisms that can serve as direct indices for pathogens are known. In the U.S., the Pathogen Reduction-HACCP System's Final Rule issued by FSIS in 1996 (400) requires meat and poultry slaughter establishments to conduct microbial testing for generic (biotype I) *E. coli* at regular intervals. Microbial testing for *E. coli* biotype I aims to verify that the establishments' HACCP-based process controls are adequate in preventing and removing fecal contamination, which is also the primary route of contamination of meat and poultry with pathogenic bacteria, like *E. coli* O157:H7, *Salmonella*, and *Campylobacter* spp. (400). Another requirement of the Final Rule is for establishments that produce raw ground products to meet pathogen reduction performance standards for *Salmonella*. These performance standards were issued in order to verify that plant HACCP systems are effective in reducing contamination with pathogenic microorganisms (400). It is expected that improvements in process control that lead to reductions in *Salmonella* will also result in reductions of other enteric pathogens of concern. Reasons for selecting *Salmonella* as the target organism include that it is a major pathogen of concern in the meat and poultry industry, and furthermore, is present in detectable numbers which can be easily tested for with current methodologies, on all types of raw products. Performance standards set by FSIS are based on the most recent U.S. baseline prevalence levels for *Salmonella* (400). Thus, by implementing the requirements of the 1996 Final Rule (sanitation, standard operating procedures, HACCP-based process control, microbial testing and pathogen reduction standards), meat

and poultry establishments are expected to significantly reduce contamination of their products with pathogenic bacteria, which ultimately will reduce the risk of foodborne illness.

53 Microbiology of Marine Muscle Foods

Paw Dalgaard
Danish Institute for Fisheries Research, Technical University of Denmark

CONTENTS

I. INTRODUCTION

This chapter discusses the microbiology of finfish, crustaceans with a chitinous exoskeleton, and molluscan shellfish with a calcareous shell. Bivalve (two-shelled) molluscs are filter-feeding and during this process they concentrate microorganisms from water, which may lead to specific safety issues. Marine muscle foods, or seafood, are produced from a large number of aquatic species that live in habitats as differrent as (i) permanently cold seawater with 3–4% NaCl, e.g., in polar or deep-sea regions, (ii) warm shallow or surface seawaters in the tropics, (iii) estuarine waters or (iv) freshwater of different temperatures. In addition, aquatic animals are captured or reared by different methods and this also influence the microflora of seafoods. The majority of the microorganisms on aquatic animals have no recognized importance in marine muscle foods but spoilage and disease, i.e., infection or intoxication are caused by specific microorganisms.

Spoilage can be considered as any change that renders seafood unacceptable from a sensory point of view. Degradation of lipids by enzymatic hydrolysis or chemical oxidation can result in spoilage of fresh fatty fishes, frozen and dried products as well as fish-oil containing products. However, microbial activity is responsible for spoilage of most fresh and lightly preserved seafood. Globally, the post-harvest losses of food have been estimated to be as high as ~25% due to microbial activity alone (1). At the same time, the world's annual production in capture fisheries has not increased but remained at ~90 million tonnes during the last decade. Only aquaculture production in marine and particularly in fresh water has increased; if reached 35 million tonnes in 2000 (2). Despite the limited increases in fisheries production, international trade in seafood has increased and optimal utilization of available aquatic food resources and prevention of losses during distribution are more important than ever. Historically, seafood spoilage has been inhibited by processes like salting, drying and smoking, developed without knowledge about the microorganisms present in the aquatic raw materials. Today, the interest in fresh and lightly preserved foods is increasing (3) and this represents a challenge

where detailed information about microorganisms in seafoods becomes important to reduce losses due to spoilage and to ensure products are safe at the time of consumption.

This chapter describes the microflora and microbial spoilage of marine muscle foods. The concept of specific spoilage organisms (SSO) is presented and it is shown how it can be applied to determine, predict and extend the shelf life of fresh and lightly preserved seafood. Several previous overview articles concerned the microbiology and microbial spoilage of seafoods. Shewan (4–6) summarized early studies on microbial spoilage, particularly of chilled and aerobically stored fresh fish. Later, Shewan (7) and Liston (8) reviewed the microflora of seafood from different geographical regions. Ashie et al. (9) summarized information on shelf-life extension whereas Dalgaard (10) described the SSO concept and its application with modified atmosphere packed (MAP) seafood. Gram et al. 2002 (11) discussed the importance of microbial interaction in food spoilage. Compared to previous reviews this chapter includes new information on the occurrence and importance of luminous bacteria in marine muscle foods.

Consumption of seafood can result in food-borne human diseases but the more exact numbers of outbreaks and cases are uncertain. In fact, it has been estimated that as little as 1% of the actual cases of food-borne diseases is reported; see (12). The U.S. and the U.K. have well-established reporting systems and some of their epidemiological data from the 1990s are included here to illustrate the importance of marine muscle foods in food-borne disease. In the U.S. finfish and shellfish were responsible, respectively, for 5.1% and 1.7% of the outbreaks and 0.8% and 2.2% of the cases of food-borne disease. For cases due to finfish, the main etiological agents were histamine fish poisoning (47%), ciquatera fish poisoning (24%), salmonellae (18%), *Clostridium botulinum* (3%), *Vibrio cholerae* (2%), *Cl. perfringens* (2%) and viruses (2%). The corresponding agents and figures for molluscan shellfish were viruses (66%), *Vibrio parahaemolyticus* (22%), salmonellae (6%), paralytic shellfish poisoning (3%) and *Cl. perfringens* (2%). In the U.K. cases due to finfish were caused by histamine fish poisoning (70%), salmonellae (16%) and viruses (4%) whereas cases due to molluscan shellfish resulted from viruses (91%) and salmonellae (4%) (12–15). Compared to amounts consumed and relative to other foods the number of cases of seafood-borne disease is high and should be reduced.

This chapter presents information about histamine fish poisoning, *Vibrio* species, *Clostridium botulinum*, *Listeria monocytogenes*, *Salmonella* and viruses. Recent overview articles concerning safety of seafood include (12, 16–18) and these or other chapters in the present volume should be consulted for information about aquatic biotoxins, parasites, toxic algae, and veterinary drugs as well as industrial and environmental contaminants which are hazards of importance in some marine muscle foods but not included in this chapter, which focuses on microbiology.

II. MICROFLORA OF AQUATIC ANIMALS FROM DIFFERENT HABITATS

The microflora of finfish, crustaceans and molluscs depends to a large extent on the microflora of the water in which they live. Microorganisms are found on outer surfaces (e.g., skin, gills and intestine) whereas the muscle tissue of healthy animals is sterile. The concentration of culturable microorganisms is variable and in general 10^2–10^5 cfu/cm^2 are found on skin, 10^3–10^7 cfu/g in gills and $10 - >10^8$ cfu/g in the intestinal content. The variable concentrations of intestinal microorganisms is related to the aquatic animal's intake of food (8, 19, 20). Higher temperatures typically correspond to higher concentrations of culturable microorganisms in water and on aquatic animals. For example, shrimps from cold water harbored 10–10^3 cfu/g, whereas shrimps from warm water had 10^6 cfu/g (8). Similarly, in Japan, seasonal temperature changes had some effect on the total concentration of microorganisms in river, lake and seawater (21–23) and in the intestinal content of wild salmon but no effect was observed for cultured salmon (21). Water salinity has little effect on the total concentration of microorganisms but influences the composition of microbial species in aquatic animals, as discussed in the following section. Organic matter, particularly sewage and land run-off, increases the load of microorganisms, including potentially pathogenic species in water and aquatic animals. Finally, catching methods have an effect; for example, trawled finfish may have 10–100 times higher concentration of microorganisms on skin and gills than similar fishes caught by long line (5).

Heat-labile and sodium-requiring microorganisms are common in sea- and brackish waters as well as on seafood. Thus, for enumeration of microorganisms pour plating with ~45°C hot agar must be avoided as this procedure may kill a major part of the microflora (10). The concentration of microorganisms in deep-water pink shrimp (*Parapenaeus longirostris*) was, for example about twenty times higher when determined by spread plating as compared to pour plating (24). In this respect it may be relevant to note that even in tropical regions where surface seawater is above 25°C, psychrotolerant and heat-labile microorganisms like *Photobacterium phosphoreum* can be present in seawater and aquatic animals at depths below 50–100 m (25–28). Microorganisms on seafood frequently require sodium for growth and although standard plate count agar without NaCl is recommended for many foods this medium is obviously inappropriate for seafood. In addition, bacteria on marine fishes may be fastidious (29) and rich enumeration media are required. For various fresh and lightly preserved seafoods spread plating on pre-chilled plates of Long & Hammer's agar,

modified to contain 1% NaCl, and incubated aerobically during 5–7 days at 15°C have been appropriate for enumeration of the dominant microflora (10, 30). Strictly anaerobic microorganisms are found in low concentrations on skin and gills of newly caught aquatic animals but in some cases these or not-yet-cultured microorganisms dominated the intestinal microflora of marine and freshwater fishes (31–35). In contrast, direct microscopy and both aerobic and anaerobic techniques determined similar concentrations of microorganisms in the intestine of several commercially important fish species (30). Although they may only be important in specific situations, anaerobic or not-yet-cultured microorganisms in the intestinal content of aquatic animals merits further study using culture-independent techniques as increasingly applied within microbial ecology in general.

A. Microflora on Skin, Shell and Gills

The genera or groups of microorganisms found on skin, outer shell and in gills of newly caught or harvested finfish, crustaceans and shellfish have been determined in numerous studies and summarized in several overview articles (8, 17, 19, 20, 31, 36). The dominant groups of Gram-negative bacteria were (i) *Acinetobacter*, *Moraxella* and *Psychrobacter*, (ii) *Pseudomonas* and *Shewanella*, (iii) *Flavobacterium* and *Cytophaga*, (iv) *Vibrio* and *Photobacterium*, (v) *Aeromonas* and (vi) Enterobacteriaceae. The dominant groups of Gram-positive bacteria were cocci primarily *Micrococcus,* coryneforms and rods including *Bacillus*, *Clostridium* and lactic acid bacteria. In some studies the percentage distribution of bacteria in seawater corresponded to the distribution of species on the surface of fish (31). Nevertheless, when data from many studies are compared (8, 17, 19, 20, 31, 36) surprisingly little can be concluded about the effect of water temperature and salinity or about the type of animal, for example dermersal or pelagic on the percentage distribution of genera/groups of microorganisms. However, for animals in freshwater the sodium-requiring species of *Vibrio* and *Photobacterium* are very rarely present whereas *Aeromonas* and Enterobacteriaceae are relatively more important in those habitats. Also, the *Flavobacterium-Cytophaga* group seems less dominant in marine animals. Furthermore, the percentages of *Bacillus*, *Micrococcus* and Enterobacteriaceae tend to be higher in tropical than in temperate regions. Greater differences between the microflora on aquatic animals from warm and cold water could be expected and, as noted by Liston (8), fungi are common on plankton but rarely found on the surface of fishes. Aquatic animals may prevent growth or attachment of microorganisms by antimicrobials like lysozyme in their surface slime, but this area remains little studied. However, the apparent lack of difference between groups of microorganisms on aquatic animals from various habitats may also result from the use of simple identification schemes relying on relatively few phenotypic characteristics. In an attempt to elucidate this problem this chapter will focus on the occurrence of bioluminescent bacteria. Due to a unique ability to glow, these microorganisms have been enumerated and identified in aquatic animals even when they did not quantitatively dominate the microflora. In addition, simple keys for identification of several species of luminous bacteria have been available since about 1970 (37, 38). Luminous bacteria can dominate the microflora in the intestinal content of many aquatic animals; therefore they are discussed in detail in the following section.

B. Intestinal Microflora and Luminous Bacteria

Seafood can be produced from gutted or whole ungutted animals, e.g., products of herring, mussels, oysters, sardines and shrimps. Due to the high concentration of intestinal microorganisms, contamination of seafood during processing of both gutted and ungutted animals is practically impossible to eliminate and the gut microflora has a very direct influence on the microbiology of many seafoods.

Intestinal microorganisms are mainly found in the gut content, although some may be attached to epithelial cells, and concentrations can be orders of magnitude higher than in water, food, skin and gills. This indicates microbial growth within the time it takes food to pass through the digestive tract and under conditions with acid in the stomach and bile, low oxygen and possibly elevated carbon dioxide concentrations in the gut (39, 40). Data from several studies (19, 20, 41) showed Enterobacteriaceae, *Aeromonas* and *Pseudomonas* dominated in the intestinal content of freshwater species, whereas *Vibrio/Photobacterium*, *Pseudomonas* and Enterobacteriaceae dominated in marine species. However, *Acinetobacter/Moraxella*, lactic acid bacteria, yeast and strictly anaerobic microorganisms, including *Bacterioides* and *Clostridium*, can occur in high concentrations. In addition, a *Mycoplasma* phenotype was recently determined in salmon by a culture-independent approach relying on extraction and amplification of 16S rDNA (31, 34, 42–44).

It has been debated if fish has a specific intestinal microflora as found in warm-blooded animals. Sera and Ishida (45) suggested marine fish with a developed digestive tract have a specific gut microflora consisting of marine vibrios, i.e., sodium-requiring species of *Vibrio* and *Photobacterium*, whereas fish with a simple digestive tract, including immature individuals, have more complex intestinal flora that reflect the microflora in water and food. Salmon that return from seawater with an intestinal microflora dominated by marine vibrios can retain this dominating microflora even after three months in freshwater (46) or after migrating 1228 km away from the marine environment up the Yukon River in Alaska (47).

Thus, marine vibrios are either associated with the gut or growing so fast that they avoid 'wash-out.'

In Japan, luminous and non-luminous marine vibrios dominated the intestinal flora of ten commercially important marine fish species including mackerels and tunas (48). In fact, marine vibrios, particularly luminous species of *Vibrio* and *Photobacterium*, frequently dominate the intestinal microflora of marine aquatic animals. The luminous or bioluminescent bacteria are fascinating and they have been extensively studied, but controversy remains about the influence of luminous bacteria on eating quality, shelf-life and safety of marine muscle foods. For example, J. M. Shewan from Torry Research Station in Scotland concluded in an overview manuscript that luminous bacteria were "…of little real importance to the practical fish technologist…" (6) and the opinion that luminous bacteria do not compromise the safety or eating quality of seafood is common. However, it has now been shown that luminous bacteria are responsible for spoilage of different marine muscle foods and due to biogenic amine production may cause histamine fish poisoning (see Sections III and IV).

The luminous marine bacteria occur in light organs in symbiosis with host animals, in seawater and on skin, shell and gills of animals, but, quantitatively, the major habitat is the intestinal content of marine animals where from <10 to $>10^8$ cfu/g can be found (38, 49). At least thirteen species of bacteria contain luminous variants, but only some are important in seafoods. *Photobacterium phosphoreum* and *Vibrio logei* are psychrotolerant bacteria growing at 0°C and are typically inactivated above 25–30°C. *P. leiognathi* and *V. fischeri* grow between ~4°C and 35–37°C, whereas *V. harveyi* grow from 5–10°C and up to ~40°C. Other luminous bacteria include *V. orientalis*, *V. splendidus* biotype I, *V. cholerae*, *V. vulnificus*, *V. salmonicida*, *Shewanella hanedai, Sh. woodyi* and the terrestrial insect pathogen *Photorhabdus luminescens*, but these are less common in seafood (50–53). *P. phosphoreum* dominate in the intestinal content of aquatic animals in cold seawater at ~0°C to ~15°C (28, 29, 54). In coastal waters in California, *V. fischeri* was the dominating luminous bacteria in gut content and in seawater of ~15°C; however, between June and October the water temperature was ~20°C and *V. harveyi* became dominant in both habitats. Interestingly, these studies showed the intestinal microflora of a single fish species in a given location to be dominated by *V. harveyi*, *V. fischeri* or *P. phosphoreum* depending on changes in the water temperature (55, 56). *V. harveyi*-like and *P. leiognathi*-like luminous bacteria dominated in the intestinal flora of a large number of fish species from the Gulf of Oman (57). In the same way, *P. leiognathi*, *V. harveyi* and *V. fischeri* were present in high concentrations and dominated the gut microflora of commercially important crabs from India (58). *V. harveyi* (75–80%) and *V. fischeri* (20–25%) also dominated the intestinal flora of fladhead mullet and sea catfish from India, but the luminous bacteria disappeared when water salinity decreased from 2.17–3.23% to 1.7–1.8% during the monsoon (59). It seems luminous bacteria in aquatic animals are selected by temperature and salinity. Thus, species of luminous bacteria are not specifically associated with intestines of aquatic animals in general, but all luminous marine vibrios are chitinolytic and may contribute to the digestion of the chitin-containing exoskeleton of crustaceans eaten by various marine animals (59–61). Species of non-luminous microorganisms are likely also to be selected by temperature and salinity and the apparent similarity of the dominant microflora of seafoods from different habitats (discussed in section II A) may reflect identification of major groups of microorganisms like *Acinetobacter/Moraxella* or Enterobacteriaceae rather than specific species.

Contamination of seafood with luminous bacteria from the intestinal content is difficult to avoid during processing. *V. harveyi* (80–90%) and *V. fischeri* (10–20%) dominated the luminous microflora on the surface of white seabream caught in the Mediterranean Sea in July but during aerobic storage at 5°C the dominant luminous microflora became *P. phosphoreum* and *V. fischeri* (62). Luminous variants of *P. phosphoreum* and *V. logei* can grow to high concentrations during normal chilled storage of fish and squid from different parts of the world (62–66). In a few studies it has been attempted to measure the light produced by luminous bacteria on seafood. At 10°C and 25°C changes in bioluminescence may be used as an indication of product spoilage, but at 5°C and below bioluminescence in fresh fish was too weak to be useful as an indicator of spoilage (62, 63). From 1989 to 1998 the U.S. Food and Drug Administration (FDA) registered and evaluated 23 luminous seafoods. The majority of the products were cooked and peeled shrimps and imitation crab or lobster meats but glowing red snapper fillet, raw Pacific rockfish, raw herring and raw shrimps were also reported. The dominant luminous bacteria isolated from these products were *P. phosphoreum* and *V. logei* (67). Both *P. phosphoreum* and *V. logei* are heat labile and their presence in cooked seafood must be a result of recontamination. However, bioluminescence of *P. phosphoreum* and *V. logei* is stimulated by the low level of NaCl typically added to cooked shrimps and imitation shellfish products [see Figure 53.1 (38)] and this may explain why processed products have been reported luminous more often than raw fish. In any case, light produced by bacteria in marine muscle food is weak and only visible in a dark room where electric and sunlight are excluded. Thus, common use of refrigerators with inferior electric lights probably masks the bioluminescence of many seafoods. Nevertheless, when glowing seafood is observed it should not be consumed as it is likely to be of poor sensory quality and may be toxic due to histamine formed by luminous bacteria (see Sections III and IV). Finally, when discussing the

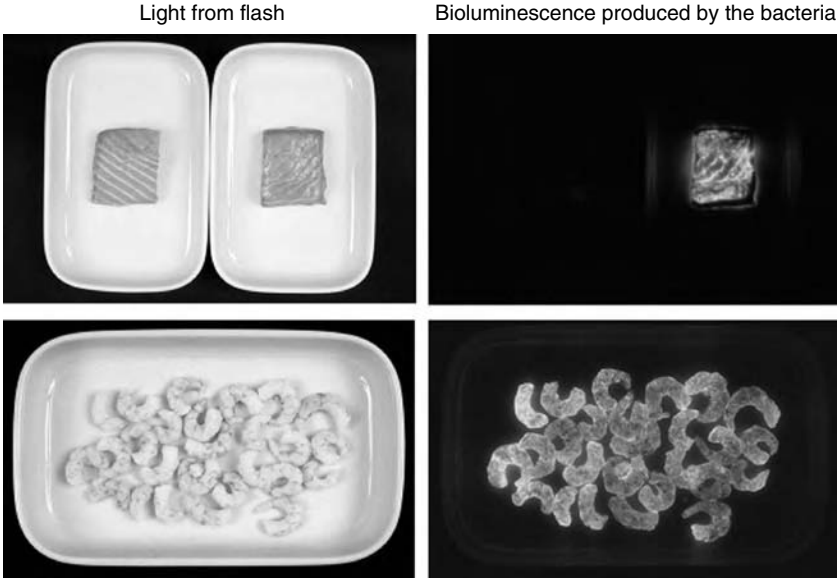

FIGURE 53.1 Bioluminescence by *Photobactrerium phosphoreum* in two pieces of salmon (*Salmo salar*) and in cooked and peeled shrimps (*Pandalus borealis*). Samples were inoculated, incubated aerobically during three days at 5°C and photographed with artificial light (left) and without artificial light (right). One of the two pieces of raw salmon was supplemented with 2% NaCl (w/w) to illustrate how this stimulates bioluminescence. The cooked and peeled shrimps contained 1.5% NaCl which is typical for this product (71).

occurrence and importance of luminous marine bacteria it must be mentioned that non-luminous variants exist for all species of luminous bacteria and the importance of these species of bacteria may be underestimated by enumeration of luminous bacteria only (30, 38, 68–70).

C. Microflora of Farmed Aquatic Animals

The microflora of cultured finfish, crustaceans and shellfish does not as such differ from those of wild aquatic animals. However, cultured aquatic animals are closer to land and human activities than those in the wild and this may influence their environment and microflora. *Listeria monocytogenes,* a psychrotolerant bacteria pathogenic to humans, is absent from clean open waters but found in decaying plant material and indigenous to the general environment. Thus, animals reared in near-shore areas can be contaminated by run-off waters from land and must be expected to contain low levels of *L. monocytogenes* (12). Particularly in Southeast Asia ponds used for shrimp farming may be fertilized by animal excreta and this may result in contamination with *Salmonella, Escherichia coli* and viruses. In warm tropical water the bacteria may persist or even grow and shrimps from some, but not all, areas in Southeast Asia have been contaminated with bacteria potentially pathogenic to humans (72). Mortality of cultured aquatic animals can be a major problem and various diseases are due to bacterial infections. To overcome these problems, antibiotics can be used therapeutically to cure diseases or, on a daily basis, to prevent diseases. Use of antibiotics, particularly prophylatic use in sub-therapeutic concentrations, is problematic because various bacteria develop resistance and the resistance may be transferred by plasmids to other bacteria and thereby reduce efficacy of antibiotic treatment for human and animal diseases. *Vibrio* and *Aeromonas* species, pathogenic to different aquatic animals, have been resistant to several antibiotics and this can make it impossible to control disease in cultured aquatic animals. In Southeast Asia, infection of farmed shrimps by antibiotic-resistant *V. harveyi* has caused so-called luminous vibrioses resulting in significant economic losses during the last 10–20 years. Antibiotic-resistant potential human pathogens, including *Salmonella, V. cholerae*, *Aeromonas hydrophila* and *Plesiomonas shigelloides*, have also been reported in relation to aquaculture production. Human infections by antibiotic-resistant pathogens are most problematic and changes in the use of antibiotics in some aquaculture-producing regions are required. In salmon farming, the use of antibiotics has to a large extent been replaced by vaccination. However, for crustaceans and shellfish with less-developed immune systems, this may not be possible (72–74).

III. MICROBIAL SPOILAGE OF MARINE MUSCLE FOODS

Newly caught fish and shellfish typically have a species-specific flavor that disappears after a few days of chilled storage. Further storage results in development of off-flavors which are often ammonia-like, sulphurous, malt-like or rancid. The off-flavors are typically caused by

microbial metabolites and they increase in intensity during storage resulting in spoilage as determined by sensory methods. The importance of microbial activity in seafood spoilage has been established by comparing off-flavor development in muscle pieces that were (i) sterile, (ii) inoculated with specific microorganisms or (iii) naturally contaminated. Knowledge about spoilage microorganisms facilitates the development of methods to determine, predict and extend product shelf-life and this is particularly important due to the short and variable shelf-life of seafood (10, 75). The short shelf-life of many seafoods is explained by some unique product properties. First, many aquatic animals live in cold waters and their natural microflora include psychrotolerant species able to grow in chilled seafood at temperatures above –2°C. To illustrate the importance of this, it can be mentioned that shelf-life of tropical white-fleshed fish typically is 18–35 days at 0°C, whereas similar coldwater fish spoil after 12–18 days. Second, many finfish, crustaceans and molluscs contain trimethylamine-oxide (TMAO) that stimulates microbial growth and activity. In general, animals from freshwater contain less TMAO than those from seawater, but considerable variation exists between species in both habitats (76, 77). *Aeromonas, Alteromonas,* most Enterobacteriaceae, *Shewanella* and *Vibrionaceae*, including all marine luminous bacteria, reduce TMAO to trimethylamine (TMA) and this anaerobic respiration facilitates their growth under oxygen-limiting conditions, e.g., in vacuum-packed or modified atmosphere-packed products (69, 78–80). TMA contributes to the typical ammonia-like and fishy off-odors in spoiled seafoods, particularly in products with pH above ~6.5 (10). Third, the *post rigor* pH of finfish, crustaceans and molluscs is high compared to beef and pork. White-fleshed dermesal finfish and crustaceans have pH of ~6.5 to above 7, whereas pelagic, dark-fleshed fish like tuna, mahi-mahi, mackerel and garfish, have pH as low as ~5.8. Molluscs have pH similar to finfish, but contain much more carbohydrate (2.5–5.0%) compared to <0.5% for finfish and crustaceans. Consequently, a fermentative type of spoilage with decreasing pH is typical for molluscs but most unusual in other seafoods unless carbohydrates are added (16, 81–84). Finally, high concentrations of free amino acids are present in seafoods and metabolized by spoilage microorganisms, e.g., arginine in shrimps and histidine in dark-fleshed pelagic finfish (85, 86).

Only some of the numerous species of microorganisms in seafoods are important for spoilage and during storage a pattern of microbial growth and activity is frequently observed (Figure 53.2). This pattern is known as the specific spoilage organism (SSO) concept (10). On newly processed, fresh or lightly preserved seafood the SSO are usually present in very low concentrations and constitute only a minor part of the total microflora. During storage and at particular conditions of temperature, atmosphere,

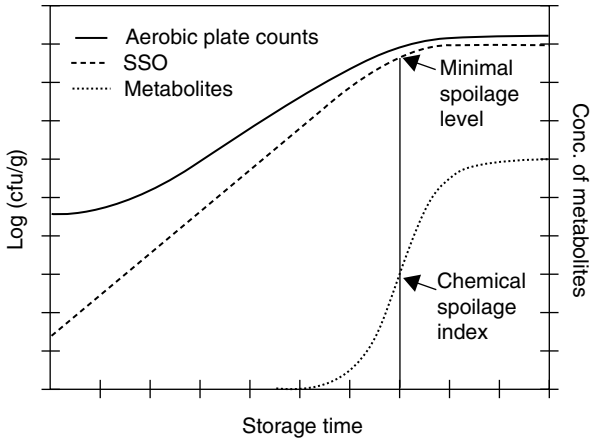

FIGURE 53.2 Specific spoilage organism (SSO) concept. Typical changes in aerobic plate counts, specific spoilage organisms (SSO) and metabolites produced by SSO during storage of fresh seafood (87).

NaCl, a_w, preservatives, etc., SSO, which is often a single microbiological species, grow faster than the remaining microflora, produce metabolites responsible for off-flavors, and finally cause sensory product rejection (Figure 53.2). SSO are typically present in levels of about 10^7 cfu/g when products become sensory spoiled. The importance of an SSO is closely related to its spoilage domain, i.e., the range of environmental parameters within which it is responsible for product spoilage. In contrast to SSO, the spoilage microflora, i.e., the microflora found at the time a product becomes sensorily rejected, can be a mixture of many microbial species, some of which are not important for spoilage.

Identification of an SSO relies on comparison of spoilage characteristics for a naturally contaminated product with those of isolates from the spoilage microflora. Initially, spoilage potential is frequently determined qualitatively as the ability of isolates to produce off-odors and metabolites, e.g., ammonia, TMA or H_2S. This screening technique has been used for decades to separate isolates from spoiled products into potential "spoilers" and "non-spoilers" (88). Isolates of *Shewanella putrefaciens* and *Pseudomonas fragi* often have a strong spoilage potential in seafood. To evaluate if the actual concentration of a microorganism in a product at the time of sensory rejection enables this microorganism to cause spoilage, a quantitative evaluation is required, i.e., determination of the spoilage activity. Yield factors can be used to evaluate if the concentration of cells and metabolites in a seafood corresponds to the spoilage activity of an isolate from the spoilage microflora, i.e., if the isolate is likely to be the SSO (69, 89, 90). The yield factor approach was used to identified *P. phosphoreum* as the SSO in chilled MAP cod fillets and showed this SSO to produce 10–100 times more TMA/cell than *Shewanella putrefaciens.* Despite a strong spoilage

TABLE 53.1
Specific Spoilage Organisms (SSO) in Groups of Fresh and Lightly Preserved Seafoods

Seafood	Typical SSO	Metabolites Produced	Selected References
Fresh chilled products stored in air:			
Various species, particularly those containing TMAO and with pH above ~6;	*Shewanella putrefaciens*-like[a]	TMA, H_2S and other sulphur compounds, hypoxantine	(97–99)
various species, including some with little or no TMAO and low pH ~6	*Pseudomonas* spp.	NH_3, esters, sulphur compounds but not H_2S	(86, 90, 100, 101)
Fresh, chilled products in modified atmosphere packaging:			
TMAO containing species from seawater at temperatures below ~15°C;	*Photobacterium phosphoreum*	TMA, hypoxantine, alcohols and ketones	(24, 69, 92)
species from warmer waters, particularly species with little or no TMAO;	Lactic acid bacteria and *Brochothrix thermosphacta*[b]	Acetic acid, NH_3, tyramine, acetoin, diacetyl, H_2S	(102, 103)
species from tropical freshwater	*Aeromonas* spp.	?	(104)
Fresh and lightly preserved products stored at ambient temperature	*Aeromonas* spp.	TMA, sulphur compounds, biogenic amines	(105, 106)
	Vibrio spp./*Photobacterium* spp.		
	Enterobacteriaceae	NH_3, acetic acid, acetoin, diacetyl, tyramine	(107)
	Enterococcus faecalis		
Lightly preserved and chilled products: Brined, spiced/gravad and smoked products including fish roe	Lactic acid bacteria[c] and *Brochothrix thermosphacta*	Acetic acid, NH_3, tyramine, acetoin, diacetyl, sulphur compounds	(89, 108–113, 130)
	P. phosphoreum, Vibrio and Enterobacteriaceae[d]	TMA, biogenic amines, alcohols, aldehydes, sulphur compounds	

[a] *Shewanella putrefaciens, Shewanella baltica* and other closely related H_2S-producing Gram-negative bacteria.
[b] *Brochothric thermosphacta* is important for products in oxygen-containing modified atmospheres.
[c] Include *Lactobacillus curvatus, Lactobacillus sake* and *Leuconostoc* spp.
[d] Include *Enterobacter agglomerans*, *Hafnia alvei*, and *Serratia liquefaciens*.

potential, *S. putrefaciens* had low spoilage activity and was not important in sensory rejection of MAP cod fillets (Table 53.1). Furthermore, SSO in seafood may be identified by comparison of (i) the profiles of metabolites produced in naturally contaminated products with similar profiles produced by isolated microorganisms and (ii) by evaluating the effect on spoilage when growth of a suspected SSO is specifically inhibited in a seafood (91, 92).

It is well established that many microorganisms from seafoods, including bacteria, yeasts and several SSO (Table 53.1), produce extracellular proteolytic enzymes (93, 94). Nevertheless, seafood spoilage microorganisms typically produce off-flavors from substrates in muscle extractives and proteolytic activity is not important for spoilage of fresh and lightly preserved seafoods (95, 96). The importance of microbial proteolytic enzymes was primarily evaluated for fresh fish, and further research, including lightly and semi-preserved seafoods, seems justified.

A. Specific Spoilage Organisms (SSO) in Groups of Seafoods

Spoilage of fresh chilled and aerobically stored seafood is primarily caused by *Shewanella putrefaciens*-like species and *Pseudomonas* spp. This is well established (Table 53.1), but the taxonomy of these Gram-negative and non-fermentative rods has been changing (114–116). Frequently, *Pseudomonas* were not identified at the species level, but strains similar to *Ps. fragi*, *Ps. fluorescens* and *Ps. putida* seem common in seafood and recently *P. lundensis* dominated the spoilage microflora of chilled aerobically stored marine fish from Greece (114, 117, 118). *Pseudomonas* spp. are unable to reduce TMAO and growth is considerably reduced under oxygen-limited conditions. As an example, *P. fragi* spoiled different species of warm water shrimps stored in ice but spoilage was due to *S. putrefaciens*-like species when shrimps from the same lots were kept in an ice/water slurry (86, 101). Other bacteria may also influence spoilage of fresh chilled and aerobically stored seafood. Lipolytic *Psychrobacter immobilis* can dominate the spoilage microflora in both marine and freshwater fish and, despite a low spoilage potential, they may increase the rancid spoilage of sardines (119, 120). In 1974, van Spreekens (30) suggested *P. phosphoreum* was important for TMA production in iced cod and whiting. More recently, *P. phosphoreum* dominated the spoilage microflora of gutted saithe and plaice (70) and seemed responsible for TMA formation in iced cod fillets and squid (66, 121).

For fresh seafood in modified atmosphere packaging (MAP) with CO_2, luminous and non-luminous variants of *P. phosphoreum* are important spoilage microorganisms

(Table 53.1). Not all studies have detected this SSO in fresh MAP seafoods and in some studies inappropriate enumeration methods and experiments with previously frozen raw material are likely reasons why luminous and non-luminous variants of *P. phosphoreum* were not observed. *P. phosphoreum* is rapidly inactivated by freezing and absent in thawed products (92, 122). The relative importance of *P. phosphoreum* and *Shewanella putrefaciens*-like species in vacuum-packed fresh chilled seafoods probably depends on the initial concentration of the two spoilage bacteria. For shucked bivalve molluscs, i.e., mollusc meat removed from the shells, spoilage is fermentative when stored under vacuum or otherwise with reduced access to oxygen, but the microorganisms responsible remain to be identified (81, 84, 123). Spoilage of chilled MAP seafood from freshwater or products without TMAO need further study, e.g., with respect to identification of lactic acid bacteria and the importance of *Aeromonas* spp. (Table 53.1). High concentrations of *Aeromonas* spp. were found in chilled MAP seafood from tropical regions and they are likely to be the SSO (Table 53.1).

Low dose irradiation changes the spoilage microflora of chilled seafood and *Moraxella* spp. become dominant and probably responsible for spoilage (124). For sous vide cooked and chilled cod fillets, *Clostridium sardiniense*, an anaerobic spore-forming bacteria, caused a most unpleasant type of spoilage due to production of different volatile sulphur compounds (10).

Spoilage of chilled lightly preserved seafoods has been extensively evaluated within the last decade (Table 53.1). In general, lactic acid bacteria seemed to be the most important group of spoilage microorganisms. However, identification of the SSO responsible for spoilage has been complicated and variation in product characteristics, including the initial microflora, NaCl, pH, smoke components, chemical preservatives and packaging, is probably responsible for the various spoilage patterns observed. Thus, the spoilage domain of SSOs identified in several chilled lightly preserved seafood is unclear (Table 53.1), although, with sun-dried tropical fish, the spoilage domains of *Staphylococcus xylosus*, *Halobacterium salinarium* and molds were suggested as a function of temperature and water activity (125). For fermented and semi-preserved seafoods little is known about SSOs, but lactic acid bacteria, yeasts, molds and strict anaerobes seem important in some products.

The SSO concept embodies the hypothesis that in any given product a single species/group of microorganisms is responsible for spoilage. Microorganisms in seafoods interact in several ways, including substrate competition and metabolite inhibition. When the dominating microflora in food reach their maximum population density, i.e., inhibit their own growth, then other groups of microorganisms are frequently inhibited. This has been named the Jameson effect irrespective of the underlying mechanism being substrate competition, bacteriocins, siderophores or other metabolites (126). There is no conflict between the simple SSO hypothesis (Figure 53.2) and the Jameson effect as long as the SSO reaches a high concentration and causes product spoilage before it is inhibited by the dominant microflora. This is typically the case with fresh seafood (Table 53.1). The metabolism of one group of microorganisms may also stimulate the activity of another group and this so-called metabiosis can limit the usefulness of the simple SSO concept for evaluation of microbial seafood spoilage. In cold-smoked salmon, putrescine production by arginine deiminase/decarboxylase negative Enterobacteriaceae increased 10–15 times by co-culturing with arginine deiminase positive lactic acid bacteria. The Enterobacteriaceae and the formed putrescine, however, had little influence on product spoilage (89). In contract, Joffraud et al. (111) found mixtures of spoilage isolates from different microbial species formed stronger off-odors and higher concentration of specific metabolites than mixtures of strains from individual species. The importance of such interactions on spoilage and shelf-life of seafood merits further study.

B. Determination, Prediction and Extension of Shelf-Life

Indices of freshness or spoilage of seafood have been extensively studied and it is generally accepted that there is a poor correlation between remaining shelf-life, as determined by sensory methods, and aerobic plate counts. However, much closer correlations have been observed between remaining shelf-life and concentration of SSOs in different products. Data have been summarized for (i) H_2S-producing bacteria, e.g., *S. putrefaciens*, in different chilled and aerobically stored fish, (ii) *P. phosphoreum* in chilled MAP cod fillets and (iii) *B. thermosphacta* in chilled MAP red mullet and sea bream from Greece. Correlation coefficients between –0.929 and –0.975 were obtained in all cases (102, 127, 128). For several chilled lightly preserved seafoods a close correlation between remaining shelf-life and concentration of any specific group of microorganisms or any specific metabolite has not been determined. Nevertheless, Jørgensen et al. (129) identified a multiple compound quality index (MCQI) to relate sensory quality of sliced and vacuum packed cold-smoked salmon (SVP-CSS) with the product's pH and cadaverine, histamine, putrescine and tyramine content. Furthermore, Leroi et al. (130) related remaining shelf-life of SVP-CSS at 5°C with the products concentration of *Lactobacillus* spp. and concentration of total volatile nitrogen (TVN). Microbiological criteria relying on mesophilic aerobic bacteria in concentrations between 10^5 and 10^6 cfu/g are included in EU Directives [(12), pp. 195–203]. Due to the frequent dominance of heat-labile spoilage bacteria in seafood, it must not be expected that such criteria correspond to sensory spoilage.

Increased transportation of seafood at both national and international levels makes shelf-life prediction important to prevent rejections of products and disappointed consumers. Kinetic models can be used to predict the effect of product characteristics and storage conditions on growth of SSO, but the range of the environmental factors in the models must be within the spoilage domain of the SSO. In fresh seafoods, SSOs often grow without a lag phase and this facilitates shelf-life prediction (Figure 53.2). In fact, kinetic models to predict growth of *B. thermosphacta*, *P. phosphoreum,* psychrotolerant *Pseudomonas* spp. and *S. putrefaciens* as a function of temperature or both temperature and CO_2 concentration in MAP seafoods have been developed. In addition, the models have been incorporated in user-friendly application software and thus the effect of product temperature profiles can be evaluated by electronic time-temperature integration [see (75) for a review or www.dfu.min.dk/micro/sssp/ where the Seafood Spoilage and Safety Predictor (SSSP) software is available]. Other microorganisms, including species of *Aeromonas,* Enterobacteriaceae, lactic acid bacteria and *Vibrio*, are also important in seafood spoilage (Table 53.1) and for these SSO, kinetic models remain to be developed and/or validated in relevant seafoods. Kinetic models are available for some species of Enterobacteri-aceae and lactic acid bacteria (131), but evaluation and validation, particularly with lightly preserved seafood, is lacking. Predictive microbiology is an active research area and in the near future it is likely that more extensive kinetic models can be developed from different existing models and from easily accessible results collected in databases like ComBase (www.combase.cc). Clearly, evaluation of these models' ability to predict growth in specific seafoods will become important. Another and more ambitious future challenge is to predict the species of microorganisms that become SSOs when (i) new product are formulated, (ii) seafoods are processed by a new technology or (iii) seafoods are stored under conditions not previously evaluated. Data obtained within the last decades (Table 53.1) clearly demonstrate that knowledge about the microbial ecology in seafood has been insufficient to make such predictions.

Developments in classical and emerging technologies to extend shelf-life of seafood are numerous and only the effect of a few aspects will be mentioned here. The targeted inhibition of SSOs is interesting as product shelf-life may be extended by mild preservation methods, selected depending on properties of a particular SSO. Mesophilic motile *Aeromonas* spp. spoil Nile perch at ambient temperature and experiments in liquid media showed this SSO could be inhibited by combinations of NaCl, sorbate and smoke components. Relying on this information, a lightly preserved fish product with marked shelf-life extension was developed (132). Other examples include inhibition of *P. phosphoreum* in chilled MAP cod fillet by oregano essential oil (133) or inactivation of this SSO by freezing (92, 122).

IV. MICROBIOLOGY AND SAFETY OF MARINE MUSCLE FOODS

The safety records and etiological agents vary considerably between groups of seafood and between products from different geographical regions. This section includes information concerning the effect of raw material origin, processing, product characteristics, storage conditions and seafood preparation prior to consumption, which are the most important hazards (Table 53.2).

A. Histamine, Biogenic Amines and Histamine Fish Poisoning (HFP)

HFP is a mild disease that occurs rapidly after intake of seafood containing above 500–1000 ppm of histamine. The toxic effect of histamine is probably potentiated by other biogenic amines in seafood, i.e., agmatine, cadaverine, phenylethylmine, putrescine, spermidine, spermine and tyramine. Alone, tyramine may cause migraine headaches in susceptible individuals. Symptoms of HFP can be cutaneous (e.g., rash or inflammation), gastrointestinal (nausea, vomiting, diarrhoea), neurological (e.g., headache, burning or itching) or circulatory (hypotension). Once formed in seafood, biogenic amines are heat stabile and will not be destroyed by cooking, baking or even canning (135–138).

Not all seafoods cause HFP and it has long been know that a high content of free histidine, growth of histidine decarboxylase-producing microorganisms to high concentrations and high activity of microbial histidine decarboxylases are prerequisites for histamine production in significant amounts and thereby HFP. Fish with a sufficient content of free histidine to cause HFP include anchovy, bluefish, bonito, herring, mackerel, mahi-mahi/dolphinfishes, marlin, saury/garfish, swordfish, tuna and yellowtail (135–137). Storage temperature is important for histamine formation and, as a general rule, little histamine is formed below 5–7°C whereas above 7–10°C toxic concentrations are frequently produced. However, toxic concentration of histamine have been observed at 0–4°C, e.g., in mackerel (139), saury (139), sardines (139–141) and tunas (142).

Numerous microorganisms produce histamine but only some species of Enterobacteriaceae, *Vibrionaceae*, and lactic acid bacteria (LAB) can grow to above ~10^7 cfu/g and produce toxic concentrations of histaming in seafood. Some Enterobacteriaceae are strong histamine producers, e.g., *Enterobacter aerogenes*, *E. cloacae*, *Morganella morganii*, *Proteus vulgaris* and *Raoultella planticola.* It seems *Klebsiella* spp. do not produce histamine and that, e.g., strains of *Klebsiella pneumoniae* and *K. oxytoca* previously reported to do so may subsequently have been identified as *Raoultella* spp. (143, 144). Below 7–10°C Enterobacteriaceae did not produce toxic concentrations of histamine (145) but histidine decarboxylase

TABLE 53.2
Seafood Associated Hazards and their Prevention;

Hazard	Safety Concern	Preventive Measures
Histamine and biogenic amines	Microbial formation of >500 ppm histamine in products; of primary concern are Enterobacteriaceae in temperature-abused seafoods and *P. phosphoreum* and possible other bacteria in chilled products	Reduce microbial growth and activity by storage of fresh seafood at <2°C and lightly preserved products at <5°C; critical histamine formation may precede sensory spoilage and storage times should be established accordingly (134)
Vibrio species, primarily hemolysin producing *V. parahaemolyticus,* cholera toxin producing *V. cholerae* and *V. vulnificus*	Growth to high levels in live molluscs, in fresh seafood from warmer waters and in cross-contaminated, ready-to-eat products	Avoid storage of live molluscs and fresh seafood at abusive temperature conditions and avoid consumption of improperly cooked seafood, particularly bivalve molluscs
Clostridium botulinum Group I: Proteolytic, particularly toxin type A and B	Growth and toxin formation in products	Inactivate bacteria and spores by canning (>2.4 min. at 121°C) or prevent growth by chilling (<10°C), acidification (pH <4.5) or salt curing (>10% NaCl)
Group II: Non-proteolytic and psychrotolerant, particularly toxin type E	Growth and toxin formation in ready-to-eat (hot-smoked and fermented) products from temperate or cold regions	3.5% water phase salt prevents toxin formation during 4 weeks storage at 4–5°C
Listeria monocytogenes	Growth in ready-to-eat seafoods	Limit contamination by good hygiene practices, reduce growth through controlled product characteristics and limited product shelf-life *L. monocytogenes* is inactivated by normal cooking
Salmonella spp.	Contamination, even by low levels	Avoid direct or indirect faecal contamination of products; inactivate the bacteria by normal cooking
Viruses, primarily Norwalk-like virus (Noroviruses group I and II) and hepatitis A virus	Presence in seafood particularly in bivalve molluscan shellfish consumed raw or lightly cooked	Avoid harvest of bivalve molluscan shellfish from contaminated waters; avoid consumption of improperly cooked seafood, particularly bivalve molluscs

produced at ≥10°C may remain active after chilling to 0–5°C (146, 147). The quantitative effect of this merits further study in seafoods. Mesophilic *Vibrionaceae*, including *Vibrio alginolyticus* and *Plesiomonas shigelloides*, produce histamine but not in important amounts in seafood. In contrast, the psychrotolerant *P. phosphoreum* (previously N-group bacteria and gut-group vibrios) and the mesophilic *Photobacterium damselae* subsp. *damselae* (previously *P. histaminum* and C-group bacteria) have been important in chilled and temperature-abused seafood, respectively (139). *P. phosphoreum* can produce toxic histamine concentrations at 0–4°C [(148) and unpublished data from the laboratory of the author]. However, the temperature history of seafood causing outbreaks of HFP and the microorganisms responsible for histamine formation typically are not known. Further research, and particularly quantitative studies, e.g., including yield factors (89), are needed to determine the importance of psychrotolerant histamine-producing microorganisms and the risk of HFP from appropriately chilled seafoods. LAB do not produce toxic concentrations of histamine in chilled seafood, whereas formation of tyramine is common, e.g., by *Carnobacterium* spp. (149). A mesophilic LAB, *Tetragenococcus muriaticus*, occurs in salt-fermented fish sauce. At 30°C and with 5–15% NaCl it produced >400 ppm of histamine and the production was markedly increased when pH was reduced from 7.6 to 5.8 and by growth under oxygen-limiting conditions (150). At 20°C, *Lactobacillus buchneri* formed >500 ppm of histamine in herring and tuna salad (151). Interestingly, the optimum pH for histamine production by Enterobacteriaceae, *Vibrionaceae*, and LAB is 5–6, which is much lower than their pH optimum for growth, but similar to the pH in many of the dark-fleshed fish where toxic concentrations of histamine are formed.

EU regulations indicate histamine concentrations in specific seafoods must not exceed 100–200 ppm, whereas the U.S. FDA uses a defect action level of 50 ppm. These relatively low values reflect the fact that histamine concentrations in seafood vary considerably and that a low concentration in one sample suggests a toxic concentration may be present in a different sample from the same lot (137, 152). To control histamine formation in seafood, chilling and storage time are the most important factors (Table 53.2). Freezing can inactivate histamine-producing bacteria but histidine decarboxylase is active during frozen storage and products of dubious freshness should not be frozen. Recently, molecular methods were suggested to identify and detect histamine-producing microorganisms (144, 153). However, quantitative, sensitive and robust methods to enumerate histamine-producing microorganisms in seafood are lacking. This is also

the case for methods to predict histamine formation, although a few simple models to assess the effect of time and temperature on histamine formation in skipjack tuna are available (154, 155) and a semi-quantitative risk assessment tool has been suggested (156).

B. *Vibrio* Species

Within this genus, the most important seafood-borne human pathogenic species are *Vibrio parahaemolyticus*, *V. vulnificus* and *V. cholerae*, but *V. alginolyticus*, *V. fluvialis*, *V. hollisae* and *V. mimicus* have also caused seafood-borne gastrointestinal disease. In Japan, Asian countries and the U.S. outbreaks are common, whereas they are rare in Europe. Disease is primarily due to consumption of temperature-abused raw or inadequately cooked seafood (Table 53.2). Raw fish like sushi and sashimi is increasingly consumed in Europe but this has not yet resulted in outbreaks caused by *Vibrio* spp. Analysis of *Vibrio* spp. is important in Europe and their occurrence has been a major reason to reject seafood imported into the EU (12, 18). As for the luminous vibrios discussed in Section II, occurrence of mesophilic human pathogenic species in water and aquatic animals depends on temperature and salinity. Both their concentration in seawater and outbreaks of seafood-borne disease are highest during in the warmer months of the year. *V. parahaemolyticus* and *V. vulnificus* are typical marine vibrios that grow optimally with 2.0–2.5% NaCl, whereas *V. cholerae* does not require NaCl and growth is optimal with 0.2–0.5%, corresponding to its natural habitat in estuarine waters (12, 157–159).

V. parahaemolyticus causes a gastrointestinal disease characterized by diarrhoea abdominal cramps, nausea, vomiting and headache. Antibiotics, e.g., tetracyclines, can reduce prolonged infections. For clinical isolates, >95% produce a thermostable direct hemolysin (TDH) (causing a positive Kanagawa reaction) or a TDH-related hemolysin (TRH). For seafood isolates, <1–5% contain genes for TDH and/or TRH and the large majority of *V. parahaemolyticus* in seafoods are non-pathogenic (159–161). Pathogenic variants of *V. parahaemolyticus* can be detected by molecular methods, including various PCR approaches, and further development in this area can be expected also for other pathogenic *Vibrio* species (161–164). The infectious dose for *V. parahaemolyticus* is ~10^6 pathogenic cells and growth in seafood is required for disease to occur. In relation to risk assessment activities, there have been attempts to model the effect of water temperature and salinity on the concentration of *V. parahaemolyticus* in live oysters. Furthermore, inactivation in chilled and growth in temperature-abused live oysters have been quantified (157). For processed seafoods, a mathematical model is available to predict the effect of product storage temperature and water activity on growth of *V. parahaemolyticus* (165).

V. vulnificus is an invasive species that may cause septicemia. Symptoms include high fever, chills, nausea and hypotension. The disease can be fatal, with mortality rates as high as 50%, and prompt antibiotic treatment is required. Individuals with liver disorder are particularly at risk and they should never consume raw seafood. Virulence factors and infectious dose remain uncertain for *V. vulnificus* and in contrast to *V. parahaemolyticus*, a high percentage of *V. vulnificus* isolates from oysters seems to be pathogenic (166). *V. vulnificus* is particularly associated with oysters in seawater at above 15°C and models to predict the effect of water temperature and salinity on the concentration in live oysters at harvest and growth at high distribution temperatures post-harvest have been suggested (157, 167, 168).

V. cholerae causes the notorious gastrointestinal disease cholera with severe watery diarrhoea that results in dehydration and can be fatal. For *V. cholerae,* the two serotypes O1 (including the biotype O1 El Tor) and O139 produce cholerae toxin (CT) and they have been responsible for epidemics. However, *V. cholerae* non-O1/non-O139 have also caused sporadic cases of milder gastrointestinal disease and 10–17% of environmental *V. cholerae* non-O1/non-O139 isolates has been found to contain genes for CT production (169). The infectious dose of *V. cholerae* is ~10^6 cells depending on the food matrix (160). Water contaminated with sewage is the major reason for *V. cholerae* O1/O139 in seafood and improved sanitation is the key to solving the problem. *V. cholerae* non-O1/non-O139, however, occur naturally in estuarine waters. In the U.S. 14% of freshly harvested oysters were contaminated with *V. cholerae* non-O1 (18) and *V. cholerae* non-O1/non-O139 were found, e.g., in French mussels (170). In South America, *V. cholerae* 01 was not reported until a major outbreak in the early 1990s caused >400,000 cases and 4,000 deaths. A lightly preserved seafood *ceviche* consisting of raw fish, lime juice, vegetables and salt, was a possible vehicle for *V. cholerae* 01 (171).

Depuration of oysters may not reduce concentrations of pathogenic *Vibrio* spp. and above ~20°C they may even grow. Fortunately *Vibrio* spp. are sensitive to many types of seafood preservation including chilling at 0–5°C, resulting in slow inactivation, and freezing, which inactivates the bacteria more rapidly. The pathogenic *Vibrio* species are heat sensitive and inactivated by normal cooking (12). Recently, high-pressure processing at 250–300 MPa has been used commercially to inactivate *Vibrio* spp. in sucked oysters and concentrations of *V. parahaemolyticus*, *V. vulnificus* and *V. cholerae* were found to be efficiently reduced (83, 172, 173).

C. *Clostridium botulinum*

Cl. botulinum is a botulinum neurotoxin (BoNT) producing Gram-positive, anaerobic spore-forming bacteria.

After consumption of seafood with BoNT, symptoms of botulism initially include nausea and vomiting, later double vision, inability to focus, difficulty swallowing and speaking and loss of muscular coordination that can lead to death by respiratory paralysis or cardiac arrest. Onset of symptoms after 12–36 hours is typical and without treatment death after 3–6 days is likely. In fact, mortality has been as high as 50–75%, but treatment with antisera and respiratory aid has reduced mortality to 10–15% (174, 175).

The biochemical and phylogenic variability of *Cl. botulinum* isolates does not correspond to a single microbial species (176) and strains have been divided into four groups (I–IV). Based on antigenic properties, seven types of BoNTs have been identified (types A to G). *Cl. botulinum* group I are proteolytic, halotolerant and mesophilic with minimum growth temperature ~10°C. They produce heat-resistant spores ($D_{121°C}$ = 0.21 min) and BoNTs of type A, B and F. Group II consist of non-proteolytic and psychrotolerant strains with minimum growth temperature as low as ~ 3°C. They produce spores that are relatively heat sensitive ($D_{82.2°C}$ = 0.4–2.4 min) and BoNTs of types B, E and F. *Cl. botulinum* group III and IV are not related to food-borne disease, but some strains of *Cl. butyricum* produce BoNT type E and may cause food-borne disease. BoNTs have a very low lethal dose and they are resistant to low pH and NaCl. Fortunately, the proteins are sensitive to heat and pH above 7–7.5 and can be inactivated by 20 min at 79°C or by 5 min. at 85°C (12, 174). BoNTs can be detected by mouse bioassays or enzyme-linked immunosorbent assays (ELISA), whereas enrichment procedures, selective plating media and PCR methods are available for detection of vegetative cells and spores of *Cl. botulinum* (174, 177). *Cl. botulinum* group I occurs frequently in soil, but is also found on aquatic animals, primarily in warm waters. In contrast, group II is found frequently in sediments, water and aquatic animals from freshwater and seawater environments in temperate or cold regions. In agreement with this, numerous studies have found low concentrations of spores of particularly *Cl. botulinum* type E in newly caught or processed seafood. Typically <0.1 spore/g was found, but higher concentrations have been found for pond-raised freshwater fishes. Although seafood is frequently contaminated with *Cl. botulinum*, outbreaks of botulism have primarily been associated with fermented/salted and hot-smoked products (174, 175).

For fresh seafood stored aerobically, vacuum-packed (VP) or modified-atmosphere-packed (MAP) growth and toxin formation by *Cl. botulinum* have been extensively studied. Below ~10°C products become spoiled before toxin can be detected, but with substantial temperature abuse toxin formation is more critical and these storage conditions must be avoided. In general, oxygen delays toxin formation by *Cl. botulinum*, but aerobic storage or modified atmospheres with oxygen cannot totally prevent toxin formation as anaerobic microenvironments are formed in the products (17, 178). Cooking prior to consumption can, to some extent, inactivate BoNT and this may have contributed to the excellent botulinum safety record of fresh seafood irrespective of its storage atmosphere.

The psychrotolerant and non-proteolytic *Cl. botulinum* (group II) is able to grow and produce toxin at ~3°C, with <5% NaCl and at pH > 5.0, but combinations of these parameters are inhibitory, which is most important for the safety of several lightly preserved seafoods. It is generally accepted that 3.5% water phase salt (WPS) is sufficient to prevent toxin formation in seafood during 4 weeks at 4–5°C (175). However, BoNT formation in some seafood was inhibited by considerably lower NaCl concentrations. From a sensory point of view, less than 3.5% WPS is often desirable and further studies to identify product characteristics that may contribute to inhibition of BoNT formation in chilled lightly preserved seafoods is relevant. Mathematical models have been developed to predict the effect of temperature, NaCl, pH, CO_2 and spore concentration on growth or BoNT formation by C*l. botulinum*. These models may assist in identification of safe storage conditions for some types of seafoods (131). Proteolytic *Cl. botulinum* are much more NaCl resistant than the non-proteolytic, but conditions to prevent their growth and BoNT formation in seafood by heating, salt curing or acidification are well established [Table 53.2 (12)]. In fact, recent association of botulism with seafoods has resulted from poorly managed heat treatment or fermentation conditions (174).

D. *Listeria monocytogenes*

Occurrence of *L. monocytogenes* in seafood is a considerable problem with respect to trade, but fortunately it is very rare that seafood consumption results in listeriosis. *Listeria* is Gram-positive, non-spore-forming, motile rods that biochemically resemble lactic acid bacteria. *L. monocytogenes* is typically invasive and causes disease in people who are elderly, pregnant or have predisposing health conditions like organ transplants, diabetes or AIDS. The incubation time can be long (weeks to months) and this complicates tracing of sporadic outbreaks back to the implicated foods. *L. monocytogenes*, however, may also cause a non-invasive febrile gastroenteritis in otherwise healthy people. If diagnosed, listeriosis can be treated with antibiotics, e.g., ampicillin but mortality rates of untreated listeriosis have been high (~30%) and this is a major reason for the extensive studies of *L. monocytogenes* during the last 20 years.

As mentioned in Section II.C, *L. monocytogenes* is indigenous to the general environmant and frequently found in low concentrations on newly caught aquatic animals and in fresh and lightly preserved seafoods (12, 179). Low concentrations of *L. monocytogenes* in seafood are not an important risk to human health and the main safety concern is growth in ready-to-eat products [Table 53.2, (180)]. More than 1000 *L. monocytogenes* per gram or ml

have been found in foods that caused listeriosis (181). Despite this fact, some countries, including the U.S., require absence of *L. monocytogenes* in 25-g samples of products. This zero tolerance is a frequent reason for import refusal of seafood by the U.S. FDA (12).

L. monocytogenes is able to grow between ~0°C and ~40°C, with <10% NaCl corresponding to $a_w > 0.92$, at pH above ~4.5 and it is problematic to control growth in some types of seafoods. In fact, a recent risk assessment found smoked seafood and cooked ready-to-eat crustaceans to be of high risk on a "per serving basis" and of moderate risk when evaluated per annum for the total U.S. population (180).

Models to predict the effect of, e.g., temperature, NaCl/a_w, pH, organic acids, nitrite, smoke components, atmosphere and microbial interaction on growth, survival or inactivation of *L. monocytogenes* have been extensively studied. Some models are included in application software to facilitate prediction of growth in foods (131, 182). However, predictive models developed in liquid laboratory media may not be appropriate for use with seafoods. Thus, users of models should verify that a model has been successfully validated for seafoods with microbial ecology similar to the product to which it will be applied.

L. monocytogenes is inactivated by normal cooking of seafood ($D_{60°C}$ = 2–4.5 min) and inhibited by the high concentrations of acetic acid (~2.5%) used in several semi-preserved seafoods, like marinated herring. However, processing of a number of ready-to-eat seafoods, including cold-smoked products, does not include critical control points for *L. monocytogenes.* To prevent growth to high concentrations the following parameters are of major importance: (i) good hygiene practices with careful cleaning and sanitation of known or likely niches in the processing environment, (ii) controlled product characteristics and (iii) limited shelf-life at specified temperature conditions. Modified atmosphere packing with CO_2-containing atmospheres reduces but does not prevent growth of *L. monocytogenes.* The combined effect of 1–2% lactate and 0.1–0.2% diacetate reduces growth of *L. monocytogenes* in different meat products and use of these organic acids in seafood deserves further study. Addition of lactic acid bacteria can to inhibit *L. monocytogenes* in lightly preserved seafood (183, 184), but this type of biopreservation has not yet been used at industrial scale.

E. Salmonella

Salmonella is responsible for a significant number of the cases of disease caused by finfish and shell-fish, both in the U.S. and in the U.K. (see Section I). In contrast to the etiological agents discussed above, *Salmonella* originate from the human/animal reservoir and therefore good hygienic practices, with focus on clean water and personal hygiene, are essential to control occurrence in seafood.

Salmonella is a mesophilic member of the Enterobacteriaceae family that grows at above ~5°C, pH > 3.8 and with <6% NaCl. The genus consists of only two species: *Sal. enterica* and *Sal. bongori.* The former is divided into six subspecies and the genus includes more than 2400 serovars (185). The infectious dose of *Salmonella* is frequently ~10^6 cells, but it can be much lower (10–100 cells) when the bacteria is protected against stomach acid, e.g., by fat (12). Typhoid and paratyphoid strains can lead to enteric fever syndrome salmonellosis with watery diarrhoea, fever, abdominal pain, headache and nausea occurring 7 to 28 days after intake of the strains. In contrast, symptoms caused by nontyphoid strains appear rapidly after exposure (8–72 hours) and include nausea, abdominal cramps, diarrhoea, fever and vomiting (185). When symptoms disappear, people continue to excrete *Salmonella* for up to several months and this is a potential risk for seafood contamination during processing.

Salmonella is rare in temperate waters, but can be found in tropical estuaries and coastal waters as well as in aquatic animals from these habitats. Compared to other types of foods, seafood has caused relatively few, and no major, outbreaks of salmonellosis, but occurrence of *Salmonella* in seafood has been a major reason to reject products at port of entry into both the EU and the U.S. (12, 185).

Mathematical models to predict growth or inactivation of *Salmonella* as a function of temperature, NaCl, pH and essential oils are available (131) and can be used to facilitate assessment and management of the risk caused by the pathogen in seafoods. *Salmonella* is heat labile ($D_{60°C}$ of 1–3 min) and inactivated by normal cooking and, for example, hot-smoking. Thus, focus on post-processing contamination and reduced consumption of raw seafood are important to limit salmonellosis in seafoods (Table 53.2).

F. Viruses

Viruses cause a higher number of seafood-borne diseases than any other microbial hazard. This is particularly due to filterfeeding molluscan shellfish consumed as raw or lightly cooked products. Seawater contains numerous indigeous viruses in high concentrations but seafood-borne diseses are caused by human enteric viruses and particularly Norwalk-like virus (NLV, also referred to as Noroviruses group I and group II) and to a lesser extent hepatitis A virus (HAV). NLV and HAV do not grow in the environment and the main concerns with respect to seafoods are (i) sewage or faecal contamination of aquatic habitats, particularly shellfish growing areas, where molluscan shellfish through their filtration of water to obtain food can accumulate viruses from the water to concentrations that are infectious to humans and (ii) fecal contamination of seafood during processing as a result of poor personal hygiene (186, 187). Seafood-borne disease due to virus in molluscan shellfish is much more frequent than

due to virus in finfish (Section I), suggesting contamination of aquatic habitatsis relatively more important than contamination during processing.

NLV is a genetically diverse group of virus strains divided into two genogroups (188). NLV causes gastroenteritidis with diarrhoea, vomiting and possibly abdominal pain, nausea and fever. Incubation time is ~24 hours and duration of symptoms ~2 days. The infectious dose is estimated to be low but lack of sensitive enumeration methods has prevented more exact determination (186). Recently, oysters with >1000 virions each were shown by a most-probable-number-reverse-transcriptase-PCR approach to cause an outbreak (189). HAV causes infectious hepatitis with jaundice (yellow coloring of skin and eyes), fever, headace, nausea, malaise/vomiting, diarrhoea and abdominal pian. The disease is occasionally fatal. The incubation period is 2–6 weeks and symptoms can last 2 months (186). Both NLV and HAV contain RNA genomes and a protein cover (capsid).

Viruses, in contrast to bacteria, cannot be cultured in simple laboratory media and NLV and HAV from seafood cannot even grow in cell cultures. In faeces, where high concentrations are precent, virus can be detected by electron microscopy and immunoassays, but the detection limit of these techniques is too high for enumeration of NLV and HAV in seafood. Lack of sensitive methods for detection and enumeration have greatly limited our understanding of the occurrence and ecology of viruses in seafoods. However, application of molecular methods including various PCR approaches is now changing this situation (186, 190–192). Further developments, particularly of sensitive and quantitative PCR-based methods, must be expected in the near future although the genetic variability of NLV and the specific detection of active viruses that cause disease represent challenges. Difficulties with virus detection are reasons why both U.S. and EU use legislative standards for live shellfish that rely on enumeration of faecal coliforms or *Escherichia coli*. In fact, numerous studies have found poor correlation between contamination of shellfish with virus and the coliform indicators of faecal contamination and there is a need for updated standards (186, 191).

To control the presence of human enteric viruses in seafood several options are available. Preventing harvest in contaminated waters is an obvious but not always easy solution. If, e.g., a shellfish harvesting area is contaminated by sewage after heavy rainfall, the virus can remain for a long time in seawater. The decimal reduction time of HAV is 671 days at 4°C and 25 days at 25°C (193). However, overboard disposal of faeces by personnel working in a shellfish harvesting area caused an outbreak of NLV disease. This type of contamination should be easy to prevent (186). Depuration of shellfish by circulation of non-contaminated water for 1–7 days is common and can reduce virus concentrations in the animals but faecal coliforms are eliminated more rapidly and virus removal may require weeks (186, 194). To prevent virus contamination during seafood processing it is important that NLV is shed by a person two days after onset disease whereas HAV is shed in faeces ~2 weeks prior to symptoms and 1–2 weeks after of the disease. In appropriate periods after NLV, and HAV-related disease, seafood industry personnel should not handle products.

RNA has limited stability but viruses seem relatively resistant in seafood although the resistance of pathogenic strains in the low concentrations actually found in seafood merits further study. 90°C during 1.5 min has been recommended for inactivation of virus in seafood (186). High-pressure processing of oysters at 250–300 MPa may reduce levels of NLV but will probably have little effect on HAV (195).

V. CONCLUDING REMARKS

Many aspects of the microbiology of marine muscle foods have been extensively studied and the information obtained has been valuable in the management of product quality and safety. However, occurrence of microbial seafood spoilage and seafood-borne disease remains unacceptably high and further research is needed to improve this situation.

The development and distribution of antibiotic-resistant microorganisms in aquatic animals and seafood needs further study. Concerning SSOs, research is particularly needed for lightly/semi-preserved and fermented seafoods where combinations of several preserving parameters influence microbial growth and activity. It is also relevant to evaluate spoilage caused by mixed groups of microorganisms (metabiosis) and to evaluate how information about SSOs can be used to determine, predict and extend the shelf-life of lightly and semi-preserved seafoods. As a part of this work development of sensitive, specific and rapid methods to detect SSOs is relevant and it seems appropriate to evaluate quantitative PCR approaches. Concerning seafood-borne disease, more precise information is needed to understand the occurrence and inactivation of viruses in seafood. The importance of psychrotolerant histamine-producing microorganisms is not yet completely understood. Finally, improved methods to control the growth of *L. monocytogenes* in lightly preserved seafoods are required.

54 Microbial Analysis of Foods

Mieke Uyttendaele and Johan Debevere
Department of Food Technology, Chemistry, Microbiology and Human Nutrition,
Ghent University

CONTENTS

I. INTRODUCTION

Microbial analysis of foods is important in food safety control. It can be done for many reasons (legislation, trend analysis, outbreak analysis, etc.) and by many participants (governmental agencies, food processors, etc.) (1). An overview of the various categories of microbial testing is given in Table 54.1.

TABLE 54.1
Microbial Testing in Food Microbiology

Categories of Microbial Testing	Definition	User/Purpose
Acceptance/rejection testing	Testing for presence/absence of pathogens in defined amount of sample or determination of plate counts of indicator organisms based on agreed specifications and sampling plans (3)	International trade
End product testing	To document that a batch of food meets legal or internal quality standards	Food producer
Trend analysis	Accumulate data to measure changes in the product rather than in the batch, to verify that the application of HACCP keeps the process under control	Food producer
Statutory testing	To control whether a batch of food meets the legal requirements; duplicate samples are made available for independent analysis by the food producer/outlet	Control authorities
Investigative sampling	To determine the source of contamination of a product by pathogens or spoilage organisms	Food producer
Outbreak analysis	To determine the food which could have caused a problem of food-borne illness	Control authorities
Environmental and hygiene monitoring	To determine the hygienic status of the food plant: swabs or scrapings and agar contact plates from food production infrastructure and equipment	Food producer

The major incentive for testing is legislation. Microbial analyses of end-products are specified and mandatory for specific food categories, especially for foods of animal origin. End-product testing is performed by control authorities to check whether a batch of food meets the legal requirements for such food. Although the limitations of end-product testing of foods at the port-of-entry or elsewhere in the food chain to ensure microbiological safety was recognized, numerous end-product testing is still widely performed. However, the overall framework for microbiological testing and interpretation of results is slowly changing. End-product testing has shifted to a system where the focus is verification of preventive approaches based on the use of good manufacturing practices (GMP) in combination with the Hazard Analysis Critical Control Points (HACCP) systems as more reliable means of assuring product safety in the modern food industry (2). In contrast to original expectations, introduction of HACCP did not lead to a reduction of the number of microbial analyses performed. Effective implementation of HACCP requires knowledge on the incidence of pathogenic bacteria in foods, and the organism's response to conditions in foods. Microbial testing programs have been elaborated by manufacturers to acquire in-house knowledge on the prevalence, persistence and behavior of pathogens in a specific food commodity/production site. In addition, the microbiological analysis of ingredients, half-fabricates and end-products as well as of environmental samples are often part of the monitoring program. Although microbiological analyses included in legislation are especially directed towards investigation of pathogenic bacteria and/or indicator organisms, microbial testing of foods is not restricted to these groups of microorganisms. Microbial analysis is an economically relevant parameter. Many food commodities have a limited shelf life because of microbial proliferation during storage. Microbial analysis to determine the composition and the level of the initial microbial flora is essential to predict typical spoilage patterns and to monitor shelf life in foods.

The present chapter will give an overview of the problems associated with microbial food testing, the classical culture-based methodology available for enumeration, detection and identification of food- and water-borne microorganisms, the microbial parameters under consideration for microbial testing and the conventional applied methodology. For discussion of rapid analysis techniques in food microbiology, the reader is referred to Chapter 55 of this handbook.

II. PROBLEMS ASSOCIATED WITH FOOD ANALYSIS

A. Sampling Plans

The quality and safety of a food product cannot be guaranteed by end-product control. While acceptance or rejection of a food is ideally decided by inspection of 100% of the items of a lot, this is too laborious, time-consuming, costly and destroys the lot. Testing of representative samples has to be undertaken instead. When a batch of food is composed from separate units, a selection of units has to be taken from this lot at random. The sample units so drawn will, after examination, yield results which are compared with defined criteria to reach a decision as to whether the entire lot should be accepted or rejected. The particular choice of sampling procedure and the decision criteria is called the 'sampling plan.' A sampling plan states the number of units required to be randomly collected from a lot and lists the acceptance and rejection criteria. As an example, consider that a lot $N > 1000$ units is to be analyzed for coliforms per gram and a unit is to be called defective if it has ≥ 100 coliforms per gram (rejection criterion) and to be called acceptable or nondefective if it has < 100 coliforms per gram (acceptance criterion). A sampling plan is necessary to define the number of units (n) to sample where the number of defectives (c) equals zero. A sampling plan of $n = 30$ and $c = 0$ may be chosen,

however, unless all units are sampled there is always a probability that a 'bad' lot, when offered, will be falsely accepted (consumer's risk). For each sampling plan (definition of n and c) the probability of lot acceptance in relation to lot quality (usually expressed as percent defective units) can be calculated. Using the above mentioned sampling plan (n = 30, c = 0) the chance (consumer's risk) of accepting a lot with one defective unit out of 40 will be about 50%. With regard to food-borne pathogens, large numbers of samples must be found free of target organisms before any significance can be attached to negative results. No feasible sampling plan can ensure complete absence of a particular organism, e.g., if 60 samples were taken and analyzed there is still one chance in two of being accepted for lots in which 1% of the sample units carry a pathogen. Moreover, the above calculation is based on the assumption that the organisms sought are homogenously distributed in the food. In the vast majority of foods**,** microorganisms are randomly distributed. This makes clear that end-product control alone cannot control the production process but can only help in verification of the good functioning of the preventive modern quality assurance systems, including HACCP. For more information on specific proposals for sampling and sampling plans the reader is referred to the ICMSF publication (3) or to the website www.dfst.csiro.au/icmsf/publications.htm.

B. Dynamic Biological Population

Microbial populations of foods have a dynamic character. Often there is an increase or decrease in numbers of viable cells during processing, storage and distribution. The outcome of a microbiological analysis or a typing method reflects the microbial quality of the food or the type of pathogen present at that particular time of sampling. The microbial condition of the product should not change during sampling. Appropriate measures should be taken to prevent any contamination of the sample units and any microbial growth or death within the sample units during collection, transport to the laboratory and subsequent storage and handling of the samples. Sampling should be performed in an aseptic way using clean, dry, sterile materials. Microbiologically unstable products should be transported and stored at a temperature below 4°C and, in general, the period between sampling and analysis should not exceed six hours. Specific rules for the preparation of test samples are to be found in the ISO 6887 series.

C. Sub-Lethal Damage and the Resuscitation of Damaged Populations

Microorganisms occurring in foods are frequently impaired by sub-lethal injury as a result of having been exposed to adverse conditions. This may be due to processing by mild heat treatment or non-thermal inactivation methods. Exposure to adverse intrinsic conditions including low a_w and pH, or to extrinsic factors such as low temperature, oxidizing agents and modified atmospheres may also lead to sub-lethal injury. Such cells may pose problems of detection because they fail to grow on selective media. An increased lag phase duration in injured cells and difficulty in isolating especially low numbers of stressed cells have been demonstrated (4, 5). However, these sub-lethally injured organisms may be capable of repair in certain food products and may possess the potential for pathogenicity, thus posing a potential public health risk. New improved protocols have been proposed for recovery of injured cells. For enumeration procedures some authors have included a resuscitation step on a solid non-selective medium for a few hours, plates being then overlaid with selective agar. For detection procedures, enrichment broths differed significantly in the ability to detect injured cells. The addition of various components to the media, including sugars, yeast extracts, egg yolk, salt, osmoprotectants, cations, reducing agents and antioxidant enzymes (6), may aid in the recovery of sub-lethally damaged cells.

However, one of the main problems remains the dilemma of promoting resuscitation of injured cells whilst avoiding overgrowth by the competitive microflora. In microbiological food control laboratories the use of sufficiently selective media may even be necessary and give better recovery results when food contains high levels of competing background flora.

D. The Need for Highly Selective Procedures

Raw food products harvested or processed under GMP and under applications of well-functioning quality assurance systems such as HACCP are in general of good microbial quality calling for methods allowing assessment of levels of the order of 100 per gram for indicator organisms to 10^4–10^6 per gram for total viable count depending upon the type of product. Several food-borne pathogens are highly infective and often low numbers of pathogens (0.1–10 cfu per g) are present in a ratio of 10^{-4} amongst physiologically similar organisms. These low numbers may not go undetected in these foods. An example is the enforcement of detection of one to ten colony forming units (cfu) of salmonellae amongst some 10^4–10^5 other Enterobacteriaceae. The detection of low numbers of pathogens amongst high numbers of background flora demands highly selective enrichment and isolation procedures. If the presence of injured cells is suspected prior incubation under non- or less selective conditions may be necessary.

III. MICROBIOLOGICAL BASIC ENUMERATION TECHNIQUES

For more information on basic microbial techniques and modifications thereof the reader is referred to the

Compendium of Methods for the Microbiological Examination of Foods published by the American Public Health Association (7).

A. The Colony Count Method

In the colony count method the total number of bacteria in a product is determined by inoculating dilutions of suspensions of the sample onto the surface of a growth medium that has been solidified by agar-agar (spread-plate method) or by mixing the test portion with the liquefied agar medium in Petri dishes (pour plate method). Enumeration is performed after incubation for fixed periods at temperatures varying from 7 to 55°C in an aerobic, microaerophilic or anaerobic atmosphere. During incubation each individual cell will multiply into a colony that is visible to the naked eye. If several cells are physically connected (e.g., by adsorption to a particle of suspended matter) this will also result in one colony. The result of the viable count technique is therefore expressed as the number of cfu per unit volume. Appropriate dilutions of the food samples should have been made in order to enable counts reported from plates in the range of 25–250 colonies for pour plates and 15–150 colonies for spread plates. The principle of microbial enumeration by the conventional culture-based method is illustrated in Figure 54.1.

B. Culture Media

The culture medium used to cultivate microorganisms contains all necessary components for the growth of the microorganisms. Each medium consists of the following components: water, nitrogen compounds (peptones, amino-acids, etc), an energy source (carbohydrates, proteins, anorganic salts) and sometimes additional growth factors (yeast extract, vitamins, etc.) for nutritionally demanding microorganisms.

By addition or removal of certain components a medium can be made selective. Selective compounds frequently employed in culture media are antibiotics, chemicals (bile salts, azide, selenite, tellurite) and dyes (brilliant green, crystal violet) (Table 54.2). In addition certain extrinsic factors, e.g., increase or decrease of temperature or changes in redox potential can often be used to enhance the selectivity (8).

Designing adequate selectivity into a medium becomes more difficult as the proportion of interfering organisms increases and almost impossible when the background association is more robust than the organisms to be counted or detected. Shigellae, for example, are easily overgrown by other bacteria present in the food. Many of the enterococci are also resistant to many inhibitors used in selective culture media and may pose a seriously interfering background flora. It is often necessary, therefore, to use so-called diagnostic or elective media. Using these, the organisms sought can be distinguished from the background flora on the basis of a specific metabolic activity, e.g., dissimilation of lactose visualized by the incorporation of a pH indicator monitoring acid production, dissimilation of aesculine to aesculitin, iron salts which result in a black precipitate upon production of H_2S by the target organism from a sulphate-containing substrate. For more information on the composition of culture media and their selective and diagnostic agents the reader is referred to the catalogues of the suppliers of these media.

1. Semi-Solid Media

Semi-solid media are media which differentiate microorganisms on the basis of their motility. Due to the low incidence of non-motile *Salmonella* strains, the use of motility enrichment has been found effective for rapid detection and isolation of *Salmonella* (9). As a combined enrichment-isolation medium for *Salmonella*, modified semi-solid Rappaport-Vassiliadis (MSRV) medium compares favorably with standard protocol using RV broth followed by isolation on a selective agar and gives results

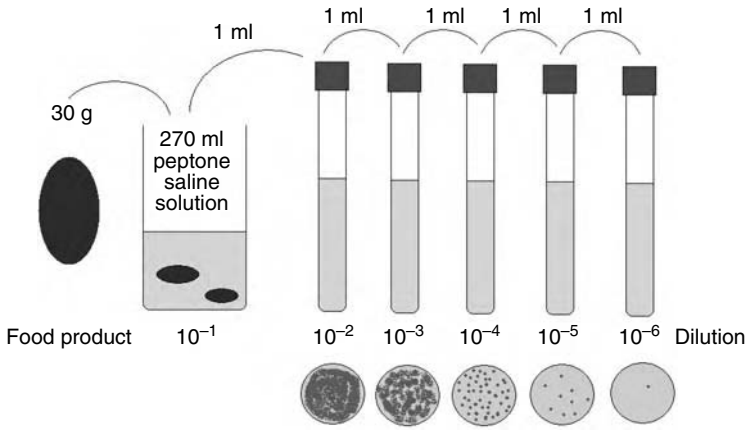

FIGURE 54.1 Lay-out of the conventional procedure for a colony count method.

TABLE 54.2
Review of Selective Agents used in Selective Culture Media

Category of Selective Agent	Examples	Inhibitory Towards	Example of Application in Culture Media (Microbial Parameter)
Dyes	Brilliant green	Gram-positives	Brilliant green agar (*Salmonella*)
	Crystal violet	Gram-positives	Violet red bile glucose agar (Enterobacteriaceae)
Surface active agents	Bile salts	Non-enteros	Violet red bile glucose agar (Enterobacteriaceae)
	Tergitol-7	Gram-positives	Tergitol-7 agar (coliforms)
Inorganic salts	Potassium tellurite	Gram-negatives	Baird-Parker agar (*Staphylococcus aureus*)
	Lithium chloride	Enterococci	(demi)-Fraser broth, Oxford agar (*Listeria monocytogenes*)
Antibiotics	Acriflavine	Gram positive cocci	(demi)-Fraser broth, PALCAM agar (*Listeria monocytogenes*)
	Cycloserine	Broad spectrum	TSC (*Clostridium perfringens*)
	Novobiocin	Gram positives	DIASALM, MSRV (*Salmonella*)
	Oxytetracycline	Broad spectrum	OGY (yeast and molds)
	Polymyxin	Gram negatives	MYP (*Bacillus cereus*)
	Ticarcilline	Broad spectrum	ITC (*Yersinia enterocolitica*)
Anti-fungal agents	Cycloheximide	Moulds	Preston broth, Karmali agar (*Campylobacter*)
	Amphotericin	Moulds	Bolton broth, mCCDA (*Campylobacter*)

one day earlier. Diagnostic semi-solid (DIASALM) agar uses a saccharose/bromocresol purple indicator to observe migrating salmonellae as a pink zone within a green medium. Addition of nitrofurantoin to DIASALM agar favors the isolation of *Salmonella* Enteritidis from poultry samples. In a typical application, three drops of pre-enriched BPW are inoculated in one spot into the center of a semi-solid medium. After incubation, plates are examined for a motility zone. A loopful of the motile zone which is the farthest from the sample inoculum is subsequently subcultured and confirmed as *Salmonella*.

2. Chromogenic and Fluorogenic Media

Chromogenic and fluorogenic media are culture media which have the ability to detect the presence of a specific exclusive enzyme using suitable substrates, a fluorogenic or chromogenic enzyme substrate. The introduction of these media has led to development of improved methods for the identification of microorganisms even in primary isolation media.

Chromogenic and fluorogenic media are well established for detection of indicator organisms but have recently also been accepted in standard methods for detection of food-borne pathogens such as *Escherichia coli* O157:H7 and *Listeria monocytogenes.*

The definition of coliforms is the possession of the β-D-galactosidase gene which is responsible for the cleavage of lactose into glucose and galactose by the enzyme β-D-galactosidase. The determination of β-D-galactosidase can be accomplished by using the chromogenic substrates o-nitrophenyl-β-D-galactopyranoside (ONPG), 6-bromo-3-indolyl-β-galactopyranoside (Salmon-Gal), 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal). The β-D-galactosidase cleaves the chromogenic substrate and the released chromophore causes distinct and easy-to-read colored colonies, respectively, yellow, red and blue colonies for ONPG, Salmon-Gal and X-Gal.

The new generation of media use β-D-glucuronidase (GUD) as an indicator for *E. coli*. GUD activity is measured by using different chromogenic and fluorogenic substrates such as p-nitrophenyl-β-D-glucuronide rendering yellow colonies or 5-bromo-4-chloro-3-indolyl-β-D-glucuronide (X-Gluc or BCIG) rendering blue colonies. TBX agar is a modification of Tryptone Bile agar to which the substrate BCIG is added. TBX agar complies with the ISO standard 16649 for the enumeration of *E. coli* in food and animal feeding stuffs. The fluorogenic substrate 4-methylumbelliferyl-β-D-glucuronide (MUG) has been incorporated into various liquid media for most probable number detection of *E. coli*. MUG is hydrolyzed by GUD yielding 4-MU, which shows blue fluorescence when irradiated with long-wave UV-light (366 nm).

Commercially available media have been developed which permit rapid simultaneous enumeration of *E. coli* and coliforms in water and foods by their distinctive coloration. These media contain a variety of enzyme substrates for detection of β-D-galactosidase (presence of coliforms) and β-D-glucuronidase (presence of *E. coli*).

For more information on the development in chromogenic and fluorogenic media the reader is referred to Ref. 10.

C. Modifications of the Colony Count Method

Modifications to the format of colony count techniques have been introduced in order to decrease the detection limit (membrane filtration, most probable number method), to decrease the workload (Petrifilm™, spiral plate method) or to monitor environmental contamination (surface contact methods).

1. Membrane Filter Method

For liquid foods, the membrane filtration method enables testing of large volumes by passing them through a bacteriological membrane filter (usually of 0.45 μm pore size) and placing the filter on the growth medium. The method is especially useful for samples that contain low numbers of bacteria. Membrane filtration is the basis of the standard methods for indicator organisms in water analysis.

2. Most Probable Number (MPN) Methods

In this method dilutions of food samples are prepared as for the plate count method. Three serial aliquots or dilutions are then transferred into 9 or 15 tubes of appropriate medium for the three- or five-tube method, respectively. Specific groups of organisms can be determined by use of appropriate selective and differential media. After incubation, the number of positive tubes for each dilution is counted. To confirm the growth in questionable tubes, a loopful of the medium from the tube is transferred to an appropriate culture medium and incubated. On the basis of the number of positive tubes for each dilution a MPN in the original sample is determined by use of standard MPN tables and taking into account the dilution factor. The method was introduced by McGrady in 1915. It is statistical in nature. Unlike the viable count, the MPN does not provide a direct measure of the bacterial count. In addition, the MPN is more variable than the viable count and tends to yield a higher result. Nevertheless, it produces estimates of bacterial concentrations that are below the detectability of most current direct measurement microbiological methods. MPN methods are often the method of choice for detection of low numbers of indicator organisms or pathogens in foods (11).

3. Hydrophobic Grid Membrane Filter (HGMF)

The HGMF can be used to enumerate all or specific microorganisms from a variety of foods. The method employs a specially constructed filter that consists of 1,600 wax grids on a single membrane filter that restricts growth and colony size to individual grids. On one filter, from 10 to 9×10^4 cfu can be enumerated by an MPN procedure, and enumeration can be automated. The procedure consists of pre-filtering homogenized food samples, which traps food particles larger than 5 μm. The sample is then filtered through the membrane followed by placing the filter on a suitable agar medium for incubation, to allow colonies to develop. The grids that contain colonies are enumerated and the MPN is calculated. The method has been given AOAC approval for total coliforms, faecal coliforms, salmonellae and yeast and molds (12, 13).

4. Petrifilm™ Plate Method

An alternative to plating to agar-agar media in Petri dishes is the Petrifilm™ plate method (3M). The Petrifilm™ plate count consists of two plastic films. The bottom film is coated with adhesive, powdered standard methods nutrients, and a dehydrated cold water-soluble gelling agent. The upper film is permeable and fosters oxygen diffusion, although it retains gas formed by, e.g., coliforms during lactose fermentation. An indicator dye, triphenyltetrazolium chloride (TTC), is included. The major advantage of Petrifilm™ is that colony counts can be taken on these small and sample-ready Petrifilm™ plates, without the need for the preparation of culture media. The indicator stains the colonies red and facilitates counting. The Petrifilm™ plate occupies small volume for storage, incubation and disposal and is a user-friendly method to control the microbiological quality of foods (14). The Petrifilm™ plate Aerobic Count method for the enumeration of aerobic bacteria in foods and dairy products has regulatory approval, certification or official recognition in a number of countries. Petrifilm™ products are also available for yeast and mold counts, coliforms, *Escherichia coli*.

5. Spiral Plate Method

Traditional colony count methods are laborious and do not allow for efficient management of numerous samples. The spiral plate method is a variation of an agar spread plate method which automates the sample dilution and agar inoculation steps and provides savings in time and effort. A known volume of sample is dispensed onto a rotating agar plate in an Archimedes spiral. The amount of sample decreases as the spiral moves out toward the edge of the plate. A modified counting grid, which relates the area of the plate to sample volume, is used to count colonies on an appropriate area of the plate and enables the colony count for the sample to be calculated. The primary advantage of this method is that one inoculation can enumerate bacterial densities of, for example, 500–500,000 cfu/ml, depending on the manufacturer. Within that range no additional dilutions are needed and thus savings on materials (pipettes, Petri dishes) can be made. The biggest disadvantage of the spiral plate method is the tendency of food particulates to plug the inoculation stylus. The small volume of sample plated also limits the sensitivity of the method. The spiral plate count is accepted for total enumeration by the U.S. Food and Drug Administration and is an AOAC International Official Method for food testing. The spiral plate method has also been used to test milk samples (15).

6. Surface Contact Methods

An environmental monitoring program may be necessary to assess the microbial contamination of the processing equipment and the plant itself (16) and to verify the effectiveness of cleaning and disinfection cycles. Swab procedures and replicate organism direct agar contact (RODAC) plates are the methods of choice for sampling of surfaces (17).

Swab techniques should be used for flexible, uneven and potentially heavily contaminated surfaces on equipment and utensils. The swab will be more effective than the RODAC plate in recovering organisms from these sites. The swab methods use either cotton or calcium alginate swabs. If one wishes to examine given areas of surfaces, templates may be prepared. The sterile template is placed over the surface, and the exposed area is rubbed thoroughly with a moistened swab. The exposed swab is returned to a test tube containing a suitable diluent and stored under refrigeration until plated. Sponge swab procedures are useful for sampling large areas of food processing equipment and environmental surfaces.

The RODAC procedure should be used only on flat, firm and nonporous surfaces that are relatively easy to clean and disinfect. The RODAC method employs special Petri plates which are poured with an appropriate plating medium resulting in a raised agar surface. When the plate is inverted, the solidified agar makes direct contact with the surface. Plates are incubated under the appropriate time and temperature regime for the microorganism in question and enumerated. Samples taken from heavily contaminated areas will result in overgrowth of the plates.

IV. METHODS FOR IDENTIFICATION AND CHARACTERISATION OF FOOD BORNE MICROORGANISMS

A. Identification Based on Morphological, Physiological and Biochemical Characteristics

Isolates obtained from a food product can be broadly categorized to a group depending on characteristics such as Gram stain, colony characteristics (pigmentation, mucoid colonies, swarming or pin-point), cell morphology (shape, size, motility and flagellar patterns, endospore formation, inclusion bodies), relation to oxygen (aerobic, facultatively anaerobic, anaerobic, microaerophilic), catalase activity, oxidase activity, ability to dissimilate glucose and the type of metabolism (oxidative or fermentative). Most often further identification is based on a number of diagnostic characteristics (18):

- Physiological features such as growth at different temperatures, pH values, salt concentrations, growth in the presence of various substances such as antimicrobial agents
- Biochemical features such as activity of various enzymes, metabolism of carbohydrates

It is essential to start from a pure culture for identification of an organism. Determination of phenotypic characteristics is prone to experimental error. Rigorous standardization of phenotypic methods is of the outmost importance to obtain reproducible results. The results of physiological and biochemical tests may vary depending upon the size of the inoculum, the incubation temperature, length of the incubation period, composition of the medium and the criteria used to define a "positive" or "negative" reaction. Therefore it is advisable to include reference strains, available from culture collections for comparison with, when using a phenotypic identification scheme in order to check the performance of the test under the conditions employed in one's own laboratory.

Several commercial identification kits have been developed to simplify and automate the identification of individual microorganisms, e.g., API galeries (bioMérieux, Marcy-l'Etoile, France), Biolog microplates (Biolog Inc., Hayward, CA, U.S.A.), the BBL Crystal ID system (Becton Dickinson, Meylan Cedex, France). In microbial analysis of foods often a complete identification is not required but only a confirmation of the suspected colony based on a restricted number of typical characteristics which are easily determinable and enable good differentiation between competitive closely related strains. However, miniaturized identification systems are increasingly used because the saving in time (e.g., media preparation, ease of reading) is significant and results are comparable to conventional tests.

B. Identification Based on Chemotaxonomic and Genetic Methods

Phenotypic testing is often insufficient for correct identification of species especially if the taxonomy of the organism is complex, e.g., *Bacillus* spp., lactic acid bacteria. Also the paucity of phenotypic characteristics, in particular bacterial groups, can cause problems for identification, e.g., thermophilic campylobacters.

Chemotaxonomy is the application of chemical and physical techniques to elucidate the chemical composition of whole bacterial cells or parts of cells (19). Amongst the techniques, which can be applied for identification of these difficult taxonomic groups, are comparisons of the fatty acid methyl ester content (FAME) or comparison of the whole-cell protein patterns obtained by highly standardized sodium dodecyl-sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). These techniques are based on the comparison of patterns/fingerprints with a database. FAME makes use of the variability in chain length, double-bond position and substituent groups of the cellular lipids and lipopolysaccharides and has proven to be very useful for the characterization of bacteria, e.g., *Aeromonas* species (20) and *Bacillus* species (21). The comparison of SDS-PAGE profiles has proven to be extremely reliable for comparing and grouping large numbers of closely related strains, e.g., lactic acid bacteria and campylobacters (22, 23) SDS-PAGE yields discriminative information at or below the species level.

The accumulation of bacterial DNA sequences and the introduction of user-friendly PCR protocols provide

the tools for the use of molecular techniques in bacterial diagnostics. For a well-studied genus or species, genus or species-specific primers from the 16 S rDNA sequence may be selected to construct a PCR for identification purposes with the advantage that it is feasible to examine many strains and acquire a rapid reliable identification. PCR assays are useful for correct identification of *Listeria monocytogenes* (24) and thermotolerant *Campylobacter* species (25). Ultimately, identification of strains may be performed by partial or complete sequencing of the 16 S rRNA gene using comparative sequence software and a database. Strains sharing more than 97% of 16S rRNA sequence homology belong to the same species.

For more information on identification of bacteria based on phenotypic and genetic characteristics the reader is referred to Uyttendaele et al. (26).

C. Typing of Food-Borne Microorganisms

Discrimination of strains below the species level is performed in academic and governmental research institutes to assemble epidemiological data on the transmission routes and distribution of food-borne pathogens (27). Moreover, typing of food-borne pathogens is essential to establish the role of a contaminated food as the responsible agent for a food-borne outbreak (28). Typing in microorganisms may also assist in the identification of critical control points of a food manufacturing process by tracking down the sources of product contamination during processing of the food in the manufacturing plant (29).

The relatedness of bacterial isolates may be determined by testing for one or several phenotypic markers using methods such as serotyping, phage typing, biotyping, antibiotic susceptibility testing, bacteriocin typing. These are still the conventional methods for typing of the major food-borne pathogens such as *Salmonella*, *Escherichia coli* 0157, *Listeria monocytogenes* and thermotolerant campylobacters. However, the analysis of DNA by molecular typing methods offers advantages over traditional techniques. DNA can always be extracted from bacteria, thus all bacteria should be typeable. In addition, the discriminatory power of DNA-based methods is greater than that of phenotypic methods. These methods do not require specialized reagents and can be readily performed in molecular biology laboratories (30). Several types of molecular typing techniques can be distinguished: typing techniques based on chromosomal restriction fragment length polymorphism such as PFGE (pulsed field gel electrophoresis) and ribotyping, PCR mediated typing techniques such as RAPD (random amplified polymorphic DNA) and typing techniques combining restriction digestion with selective amplification such as AFLP (amplified fragment length polymorphism). The various molecular typing techniques differ in their simplicity of performance, their reproducibility and their resolution; the latter are sometimes pathogen-dependent. The techniques, which are characterized by their high reproducibility and resolution, are largely also the most complex and laborious ones (PFGE, AFLP). They also tend to be more expensive (cost of reagents and specialized equipment). On the other hand, RAPD is a rapid and simple technique with a good discriminatory power (if a suitable RAPD primer is found) but it often lacks reproducibility (inter- and intra-laboratory). Ribotyping is open to automation and reproducible patterns with a reasonable number of fragments are obtained but it is not as discriminatory as some of the newer molecular methods.

For more information of molecular typing of food-borne pathogens the reader is referred to Heyndrickx et al. (31).

D. Toxin Detection

Apart from establishing the presence of pathogens in foods, it is of concern to determine whether bacterial toxins are produced in the food or if the pathogen is a potential toxin-producing strain. The major food intoxications are caused by *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens* and *Clostridium botulinum*. The characteristics and detection of the major bacterial toxins are reviewed in Table 54.3. The immunological methods are still the method of preference for detection of the enterotoxins of *S. aureus*, *Cl. perfringens* and *B. cereus* in foods (Table 54.4) (32). The ELISA (enzyme-linked immuno-sorbent assay) methods use a solid support to which the antibodies are attached. The samples (which may contain the toxin serving as an antigen) are put into contact with the solid support and allowed to react with the antibodies. After the reaction the samples are removed and the plate or strip is washed. The enzyme-antibody conjugate is added and allowed to react with the enterotoxin-antibody complex. The plate or strip is again washed before the substrate is added and subsequently the colorimetric or chemiluminescent reaction is measured. RPLA (Reversed Passive Latex Agglutination) tests are also available. The RPLA technique involves the use of sensitized (antiserum to enterotoxin-treated) latex beads that are exposed to serial dilutions of the extracted enterotoxin. The agglutination titer is determined after overnight incubation. Enterotoxin controls and blanks are included in the test kits. Some kits allow the identification of the type of enterotoxin present, others are limited to demonstration of the presence of enterotoxin (without further indicating the type). For the emetic toxin (cereulide) of *Bacillus cereus* no immunological method is available (no antigenic property assigned to the small cereulide molecule). Cell cultures (33) or a boar spermatozoa test (cytotoxicity) are used to assess the presence of the enterotoxin (34). As an alternative, animal assays may be applied. The mouse lethality assay is still employed as the reference method for botulinal toxins in foods. Immunological

TABLE 54.3
Characteristics and Detection of Toxins Produced by *S. aureus, B. cereus, Cl. perfringens* and *Cl. botulinum*

Staphylococcus	*Staphylococcus aureus* Emetic Toxin	*Bacillus cereus* Diarrheal Toxin	*Bacillus cereus* Diarrheal Toxin	*Clostridium perfringens* Neurotoxin	*Clostridium botulinum*
Toxin type	Enterotoxin (single chain polypeptide, with cystine-lus) MW 26–34 kDa	Enterotoxin Cereulide (cyclic dodecapsipeptide)	Enterotoxin a) Haemolysin BL: tripartite protein complex B, L_1, L_2 b) Non-haemolytic tripartite protein complex	Enterotoxin Single chain protein with MW 36 kDa	Neurotoxin Protein with MW 150–170 kDa complex with non-toxic proteins
Formation of toxin	In the food, during vegetative growth	In the food during the late exponential or stationary phase	During vegetative growth in the food or in the intestines after ingestion of high numbers of cells	In the intestines after ingestion of high number of cells; toxin formed during sporulation	In the food during vegetative growth
Effect of proteolysis	Resistant	Resistant	Activity loss	Increased activity after treatment with trypsin	Activation
Heat stability	Resistant to 100–120°C	Resistant to 90 min at 121°C	Inactivation by 5 min at 56°C	Inactivation by 15 min at 60°C	Inactivation by a few minutes at 75–80°C
Symptoms	Nausea, vomiting (sometimes diarrhea)	Nausea, vomiting	Cramps, diarrhea	Cramps, diarrhea	Gastro-enteritis, trouble vision and finally paralysis
Incubation period	1–5 h (recovery after 24–48 h)	1–5 h (recovery after 6–24 h)	8–16 h (recovery after 12–24 h)	8–24 h (recovery after 24–48 h)	12–36 h (deceased after 3–6 days)
Toxicity (LD_{50})	LD_{50} (monkeys): 25 µg/kg dose causing symptoms in humans: 100–200 ng	Unknown	100 × more toxic than *Cl. perfr.*	1.5 µg for a 20 g mouse	25 pg for a 20 g mouse
Detection methods	Immunological detection (Oxoïd BCET RPLA, Vidas (Biomérieux), Tecria immunoassay)	No immunological detection method Cytotoxicity Animal feed trials	Oxoïd BCET RPLA (L_2 component Haemolysin BL) Tecra immunoassay (Non-haemolytic protein complex) Cytotoxicity	RPLA en ELISA	Mouse bio-assay ELISA

TABLE 54.4
Present Status of ISO Standards for Indicator Organisms in Food and Animal Feeding Stuffs and Water

ISO Standard	Product Group	Title
DIS 21528-1:2003	Horizontal	Detection and enumeration of Enterobacteriaceae – Part 1: most probable number technique with pre-enrichment
DIS 21528-2:2003	Horizontal	Detection and enumeration of Enterobacteriaceae – Part 2: colony-count method
5552:1998	Meat (products)	Detection and enumeration of Enterobacteriaceae without resuscitation – most probable number technique and colony-count technique
7402:1993	Horizontal	Enumeration of Enterobacteriaceae without resuscitation – most probable number technique and colony-count technique
8523:1991	Horizontal	Detection of Enterobacteriaceae with pre-enrichment
4831:1991	Horizontal	Enumeration of coliforms – most probable number technique
4832:1991	Horizontal	Enumeration of coliforms – colony count technique
5541-1:1986	Milk (products)	Enumeration of coliforms – colony count technique at 30°C
5541-2:1986	Milk (products)	Enumeration of coliforms – most probable number technique at 30°C
9308-1:2000	Water	Detection and enumeration of *Escherichia coli* and bacteria of the coli- group – Part 1: membrane filtration
16649-1:2001	Horizontal	Enumeration of β-D glucuronidase-positive *Escherichia coli* – Part 1: colony count at 44°C by membrane filtration
16649-2:2001	Horizontal	Enumeration of β-D glucuronidase-positive *Escherichia coli* – Part 2: colony count technique at 44°C
CD16649-3:2001	Horizontal	Enumeration of β-D glucuronidase-positive *Escherichia coli* – Part 3: most probable number technique
6391:1997	Meat (products)	Enumeration of *Escherichia coli* – colony count technique at 44°C using membranes
11866-1:1997	Milk (products)	Enumeration of presumptive *Escherichia coli* – Part 1: most probable number technique
11866-2:1997	Milk (products)	Enumeration of presumptive *Escherichia coli* – Part 2: most probable number technique using 4-methylumbelliferyl-β-D-glucuronide (MUG)
11866-3:1997	Milk (products)	Enumeration of presumptive *Escherichia coli* – Part 3: colony-count technique at 44°C using membranes
DIS 7251:2002	Horizontal	Enumeration of presumptive *Escherichia coli* – most probable number technique
7899-2:2000	Water	Detection and enumeration of enterococci – Part 2: membrane filtration

Modified from de Boer (7).

methods have been reported for the botulinal toxin but seem to lack sensitivity in comparison to the mouse bioassay. PCR methods targeting the toxin genes have also been developed.

V. MICROBIAL PARAMETERS IN FOOD ANALYSIS

The bacteriological examination of food products falls into one or more of the following categories: total viable count, indicator organisms, specific spoilage organisms, functional flora and food-borne pathogens.

A. "Total" Bacterial (Colony) Count

The total bacterial count or, better, "colony count," is an attempt to measure the total number of viable microorganisms present in a food sample as an indication of the overall microbial quality of the food product. "Total" is often associated with microscopic counts which also include dead cells, whereas these procedures are actually based on the assumption that each viable microbial cell will form a visible, separate colony when mixed with an agar and permitted to grow.

Since microorganisms in foods represent various populations with many different growth requirements, the optimum conditions for determining the total viable count may vary from one food to another. The conventional aerobic plate count for examining frozen, chilled, precooked or prepared foods uses pour plates of Plate Count Agar (PCA) and incubates plates for 72 h at 30°C (35) or 48 h at 35°C (36). For analysis of milk and milk products PCA can be supplemented with milk powder in order to favor growth of nutritional fastidious organisms such as lactic acid bacteria. Generally, the lactic acid bacteria show delayed growth and smaller colony size (pin point colonies) in normal PCA. On the other hand, when high numbers of a functional flora are expected, as is the case in fermented foods, a nutritional poor agar medium such as peptone agar may be used to suppress the growth of this competing functional flora.

For the determination of the colony count of thermophilic and mesophilic bacteria in, for example, canned food, Dextrose Tryptone agar is recommended incubated respectively, for 48 h at 55°C and 72 h at 30°C. Flat sour bacteria (e.g., *Bacillus stearothermophilus*) which are important spoilers in these types of product are on this agar medium typically surrounded by a yellow zone

because of acid production in contrast to the purple medium (pH indicator is bromocresol purple) (7).

For enumeration of psychrotrophs, the predominant spoilage flora of refrigerated minimal processed foods, incubation for 10 days at 7°C for pour plates has been described. Incubation conditions using shorter times at higher temperatures have included 25 h at 21°C for raw and pasteurized milk using Plate Count Milk agar. Under the assumption that most psychrotrophs are Gram-negative bacteria, a selective medium was recommended that contains crystal violet and triphenyl tetrazolium chloride and is incubated for 5 days at 22°C (7).

Aerobic plate counts of water uses pour plates with Yeast Extract agar incubated either for 48 h at 37°C or for 72 h at 22°C (37).

Anaerobic plate count methods use a medium to favor growth of anaerobic organisms. Although thioglycollate is widely used in anaerobic media to lower the redox potential, it has been reported to be inhibitory to some anaerobes. Shaedler anaerobe agar contains cysteine hydrochloride and glucose as reducing substances and has been shown to successfully recover obligate anaerobes under anaerobic incubation (38).

The mesophilic bacterial spore count is determined by previously heating the primary suspension for 10 minutes at 80°C in order to eliminate vegetative cells and subsequently plating on, respectively, PCA (39) and Reinforced Clostridial Agar with incubation under, respectively, aerobic and anaerobic conditions for 48 h at 37°C for the aerobic and anaerobic spore count. A heat treatment for 30 minutes at 100°C is applied before plating and incubation at 55°C for 48 h to determine the thermophilic bacterial spore count (7).

There is no single set of conditions that will allow growth of the whole spectrum of microorganisms present in a natural sample. Nevertheless, in all of the above-mentioned methods, the selectivity is unintentional and merely a consequence of the choice of time, temperature, atmosphere or nutritional composition of the medium. They all aim to maximize the number of bacteria that may be found in a food product. However, once a procedure for a given food is determined, it should be respected and can be very useful for routine microbial analysis of the food.

B. Indicator Organism Count

Specific organisms are sought indicating the standard of hygiene used in the manufacture, storage and handling of the food products. The presence of indicator organisms in given numbers points to failure to comply with appropriate GMP.

The use of Enterobacteriaceae as indicator organisms has gained acceptance now in several countries. In the monitoring of foods processed for safety, e.g., by heat or by a chemical process like chlorination, Enterobacteriaceae are the indicators of choice since all member of the Enterobacteriaceae are known to be eliminated by these treatments. In the case of milk and dairy products, because of the selection of lactose-positive types by the high levels of lactose in the environment, the coli-aerogenes group or coliform bacteria have been used successfully for safeguarding pasteurized products. However, taxonomically, the coliform bacteria are a rather ill-defined group. In general, all Gram-negative bacteria capable of growing on bile salts-containing media, and which produce acid from lactose, are included in the coliform count. In addition, coliforms are not a good indicator in foods where lactose-negative bacteria dominate the microbial ecology of a food.

The entire group of Enterobacteriaceae is of limited use in the examination of foods that have been possibly involved in outbreaks of disease: tests for properly selected pathogens are required here. There is also very limited scope for using the complete taxon of Enterobacteriaceae as an indicator of faecal contamination as not all genera of the Enterobacteriaceae are of faecal origin. The use of an Enterobacteriaceae test on a large number of samples offers considerable advantages for trend analysis in assessment of the overall hygiene during food processing, however, only on the day of production. When raw meats and poultry or vegetables are examined for Enterobacteriaceae in the frame of hygiene monitoring at sampling times during the shelf life, the psychrotrophic types (which grow during refrigerated storage of these products) should not be included in these counts. An alternative approach is to rely on the thermotrophic population fraction of the Enterobacteriaceae also referred to as the 'faecal coliform' group. However, the 'faecal coliform' group is ill-defined as the coliform bacteria having the ability to grow at 44°C and include coliform bacteria which are not of faecal origin and therefore this is also not an absolute marker of faecal contamination. To demonstrate that faecal pollution in a food may have occurred, *Escherichia coli* should be used as the marker organism. It is a well-defined taxonomic unit and ecological investigations have substantiated that *E. coli* originates from the intestinal tract of man and warm-blooded animals.

The Enterococcus group (formerly Lancefield-Group D Streptococci) can be used as an enteric marker organism in specific situations. All streptococci of this group occur in faecal niches. Nevertheless, enterococci possess a high extra-enteric resistance whereas *E. coli* declines quite rapidly in some non-enteric environments, particularly under conditions of reduced a_w. Streptococci are useful marker organisms in certain foods (dry foods, cooked foods) to demonstrate the elimination of the more resistant pathogens (e.g., *Listeria monocytogenes*), an assurance which cannot be provided by the absence of the more fragile Enterobacteriaceae.

Test methods for indicator organisms are also of the utmost importance in water quality assessment. Under European legislation, treated waters should contain (per

100 ml) no coliforms, no faecal coliforms/ *E. coli* and no enterococci. For more information on the use of indicator organisms the reader is referred to Mossel et al. (40).

Violet red bile glucose agar for Enterobacteriaceae and violet red bile lactose agar for coliforms have been widely used in the last 20–30 years for counting and isolating Enterobacteriaceae and coliforms. Enterobacteriaceae and coliforms are determined by incubation at 37°C, faecal coliforms by incubation at 44°C. In fact no new developments in solid media for these bacteria have appeared recently (Table 54.4). Standardized methods for detection and enumeration of *E. coli* comprise a MPN technique, a membrane filtration method and a direct plate count (Table 54.4). The MPN technique comprises, using lauryl sulphate tryptose broth incubated at 37°C and isolation on a chromogenic medium, namely tryptone bile agar with X-glucuronide agar (TBX-agar), and a substrate for β-D-glucuronidase (GUD) and incubated at 44°C. The membrane filtration procedure uses cellulose membranes on minerals modified glutamate agar incubated for 4h at 37°C for resuscitation and subsequent transfer to TBX-agar and incubation at 44°C for enumeration. If high numbers are present, direct enumeration on TBX agar incubated at 44°C can be performed. The introduction of chromogenic media has enabled detection of β-D glucuronidase-positive *E. coli* without the necessity of colony confirmation steps. Over 95% of *E. coli* strains are positive for GUD. The older methodology for detection of *E. coli* relied on used lauryl sulphate trypose broth and subsequent selective enrichment in EC broth (MPN technique) or isolation on tryptone bile agar (membrane filtration method) or violet red bile lactose agar (enumeration) incubated at 44°C and subsequent confirmation of *E. coli* as the only true faecal coliform by indole production from tryptophan at 44°C (41).

Enterococci are enumerated on Slanetz and Bartley agar medium incubated at 37°C for 24–48 h. Kanamycin aesculin azide medium may be used as an alternative (42).

C. Detection of Specific Spoilage Organisms/Functional Flora

Spoilage organisms are usually associated with taints and off-flavours in stored products. They are the major factor in determining the shelf-life of microbiological unstable food products and are considered to be of more relevance than total viable counts to indicate the microbial quality of the product. For prediction of the shelf-life it is of interest to focus microbial analysis on a selected fraction of the microbial community that contributes to the spoilage of the food defined as the specific spoilage group or organism. This microflora is a function of the raw material flora, the processing, preservation and storage conditions. For more information of the spoilage flora associated with different food products is referred to Chapter? The following microbial parameters are often involved in microbial analyses of foods in order to determine the shelf-life of a particular food product: lactic acid bacteria, yeast and moulds, osmophilic yeasts, lipolytic microorganisms, proteolytic microorganisms, sulfide producing spoilers, thermoduric flat sour bacteria, *Pseudomonas* species, *Clostridium tyrobutyricum*, etc. However, this is not a restrictive list.

In contrast to provoking deterioration of the food product, microorganisms (mainly lactic acid bacteria), are sometimes added as deliberate starters or take part in the fermentation processes as a result of their being natural contaminants of the starting substrates. In addition, lactic acid bacteria, predominantly *Bifidobacterium* spp. and *Lactobacillus acidophilus*, are increasingly used in dairy products as probiotic organisms. Microbial analyses may be performed to determine whether the claimed starter of probiotic cultures is, indeed, present in the quantities claimed (43, 44).

Intentionally selective methods have been elaborated to quantify this defined sub-set of the microbial population. Media formulation for the important group of the lactic acid bacteria and the yeasts and moulds is provided beneath. For description of the culture media and incubation conditions of other spoilers used as an indication of the microbial quality of foods the reader is referred to specialized literature.

1. Lactic Acid Bacteria

The MRS formulation was developed by de Man, Rogosa and Sharpe to encourage the growth of lactic acid bacteria which includes species of the following genera: *Lactobacillus*, *Streptococcus*, *Pediococcus* and *Leuconostoc*. The MRS medium is a complex medium with an acid pH (6.2) and includes high concentrations of glucose and the essential growth factors magnesium and manganese. MRS supports rapid growth of the fastidious lactic acid bacteria resulting in a rapid decrease in pH to 5.0 or less because of the lactic acid production thus further enhancing the selectivity of the medium. Growth of lactic acid bacteria is considerably enhanced by micro-aerophilic conditions. MRS is commonly incubated with an agar overlay for 72 h at 30°C. Selection for lactobacilli can be made by pH adjustment. Acidified MRS to pH 5.4 with acetic acid is, for example, used for enumeration of *Lactobacillus bulgaricus* in yoghurt. Vancomycin and thallium acetate can be added to enhance the selectivity towards *Leuconostoc*. Addition of sorbic acid in combination with low pH inhibits growth of competitive yeasts and moulds. However, upon addition a compromise between the combinations and concentrations of substances used has to be reached between selectivity and productivity of the organism sought (38).

2. Yeasts and Moulds

For determination of yeast and moulds several media are available. In general, an antibacterial compound is added

to the culture medium (oxytetracycline, chloramphenicol) or pH of the medium is lowered (pH 5.7) although the latter approach also allows growth of acidophilic bacteria. Dichloran or rose bengal may be added to inhibit spreading and restrict the colony size (45).

VI. DETECTION OF FOOD-BORNE PATHOGENS

Food infection is caused by consumption of food contaminated with the etiological agent, in other words, the pathogenic microorganism. The pathogen develops in the gastro-intestinal system, accompanied or not by toxin production, causing food infection. Food infection can be caused by low numbers of the pathogen. Low numbers can be expected in foods that are correctly processed for safety and not recontaminated or recolonised subsequently. Often detection of single cell in 25 g is required. Virtually all pathogens in foods are sub-lethally stressed. Therefore the detection method of infectious agents encompasses four subsequent steps (46):

- A *resuscitation* procedure or *pre-enrichment* lasting between a few hours to overnight incubation in a non- or half-selective medium to enable recovery and limited outgrowth (10^2–10^4 cfu/ml) of the stressed target organism. Stressed cells are often particularly susceptible to reactive oxygen metabolites. Thus, anaerobic incubation or the addition of free radical quenching agents may be highly effective in resuscitation. Often incubation for a few hours at a more optimum reduced temperature is applied before exposure to the higher selective temperature of incubation (47).
- A period of *enrichment* in a selective medium to suppress the competitive flora and enabling multiplication of the target organism to attain detectable levels of the order 10^5–10^7/ml (48).
- *Isolation* of the pathogen on a selective differential agar medium. Selective agars are streaked with a loopful of enrichment broth and incubated under appropriate conditions. It must be stressed that the ability to grow on specific selective media does not mean that the organism growing is that for which the medium was developed. Differentiation of typical colonies must be regarded as presumptive and confirmatory tests are required.
- Purification of typical colonies and confirmation using a number of morphological, biochemical, and physiological tests.

A few remarks should be made to this general procedure:

- Enrichment is applied where pathogenic microorganisms are present only in small numbers, particularly if large numbers of competing spoilage microorganisms are present. It is not normally applied where the organism is a common contaminant of foods in low (and harmless) numbers, such as the bacterial food intoxicants *Bacillus cereus*, *Staphylococcus aureus*, and *Clostridium perfringens*. These food borne pathogens are tolerated in the order of 100 cfu/ml or g and only pose a health hazard in numbers above 10^5 cfu/ml or g. In the latter case selective media are used for direct plating without prior enrichment and enumerations may be made.
- Although in many cases enrichment media are used in conjunction with selective plating media, they may be used to enumerate specific microorganisms or groups of microorganisms using the MPN technique. In such circumstances, it is necessary to incorporate a diagnostic (differential) reaction to distinguish the organism being enumerated from other microorganisms, which are able to grow under the imposed conditions. Examples are lactose fermentation in media for 'coliforms' and the 'sulphide' reaction in media for clostridia. Further confirmatory tests are required where reactions are positive.
- The use of culture media with selective agents and the incorporation of an elective system to differentiate the target organism has been discussed above. Numerous selective media are available for the isolation of specific food borne pathogens, and development of media and modification of existing media is a continuous process in microbial food analysis. The choice of media should take into consideration factors such as selectivity and sensitivity of the medium as well as the ease of use. However, another important factor is the type of food for analysis. Food borne pathogens from specific foods may be unusually sensitive to selective agents or competing microorganisms from specific foods may be unusually resistant to selective agents. For example *Listeria monocytogenes* may be sub-lethally stressed and selective agents in enrichment media may interfere with the process of repair in such cells. Consequently, the isolation of stressed *Listeria monocytogenes* from particular types of cheese benefit from a partially non-selective pre-enrichment compared to the completely selective pre-enrichment and enrichment procedure conventionally used (49).

An overview of the recommended procedure according to ISO for detection of the most important pathogenic bacteria implied in food analysis namely *Salmonella* spp.,

Listeria monocytogenes, *Campylobacter* spp. and *Escherichia coli* O157 is shown in Figure 54.2 (a–d). A description of the selective media and recommended confirmation tests for detection of the food-borne intoxicating *Bacillus cereus*, *Staphylococcus aureus* and *Clostridium perfringens* is given in Table 54.5.

For more information on approved protocols for the detection of food-borne pathogens the reader is referred to the different national and international standard organizations.

VII. STANDARD METHODS, VALIDATION OF METHODS AND QUALITY ASSURANCE IN MICROBIOLOGY

Microbiological tests are important in governmental food inspection to enforce legal regulations, in international trade to determine compliance with a microbiological standard, in commercial relationships between trade partners to control on agreed microbiological specifications, in the food industry to maintain quality control and process requirements, in

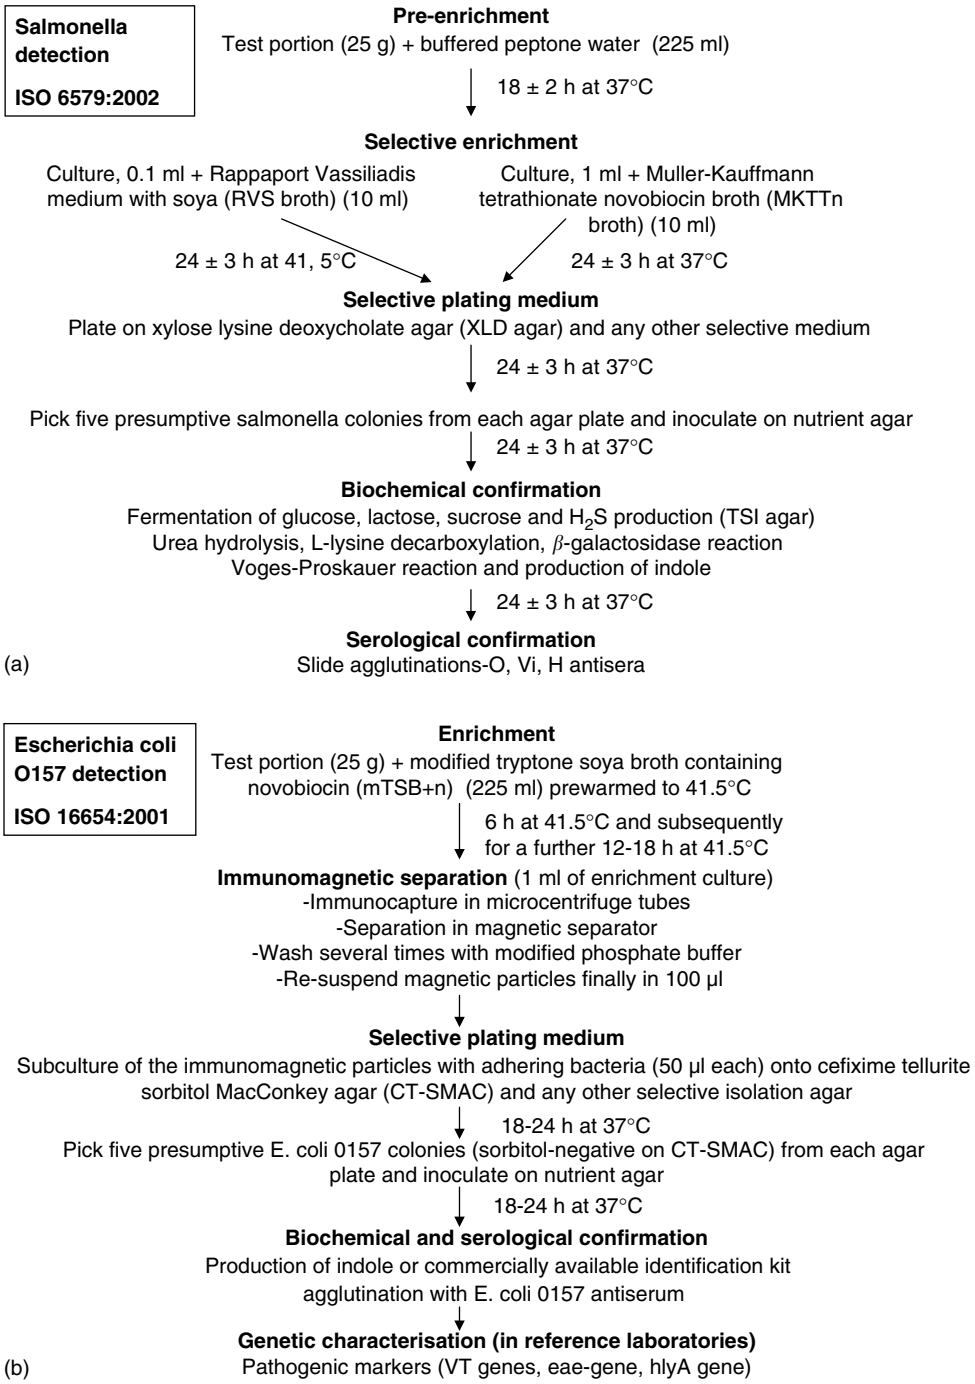

FIGURE 54.2 Schematic lay-out of ISO methods for detection of foodborne pathogens in foods.

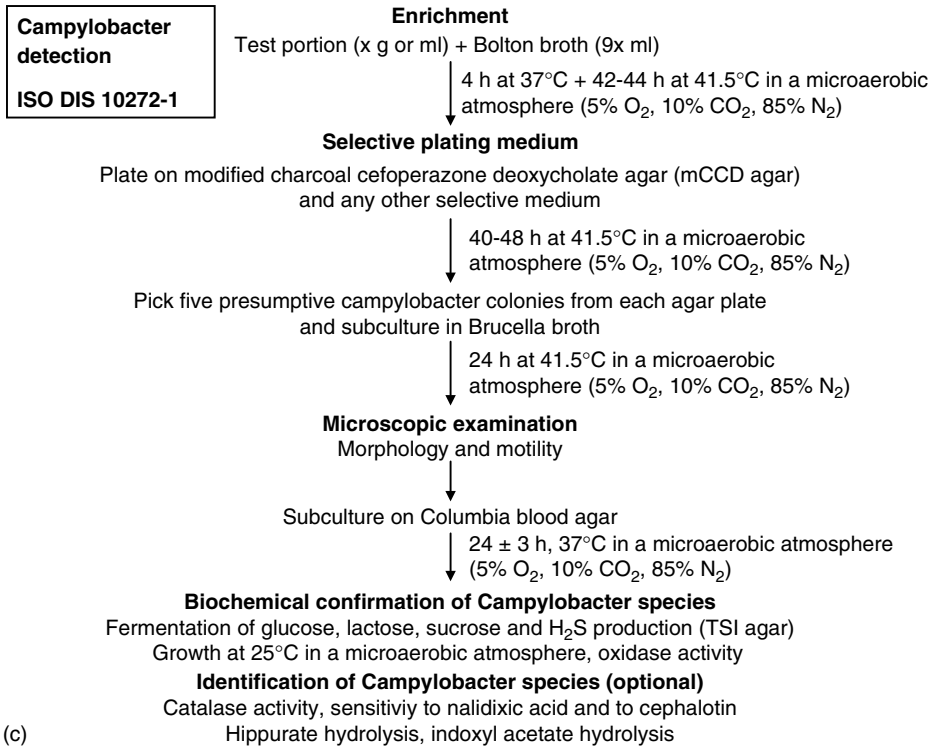

FIGURE 54.2 Continued.

academic laboratories for conducting research, and in reference laboratories to confirm the analyses of another laboratory and to provide surveillance data. The results of these tests should be reliable. It is required that performance characteristics of the method are determined. Apart from these technical characteristics, it is important that all parties involved agree with and accept the methods employed. Mutual recognition of test methods in international trade relations facilitates commerce and exchange of results.

A. Standard Methods

Standard methods have been elaborated by international, national or trade organizations such as ISO (International

TABLE 54.5
Overview of the Standard Media Used for Enumeration of *Staphylococcus aureus, Clostridium perfringens* and *Bacillus cereus* in Foods

	Coagulase-Positive Staphylococci (*Staphylococcus aureus* and Other Species)	*Clostridium perfringens*	Presumptive *Bacillus cereus*
Selective media	Baird-Parker agar medium with egg yolk tellurite emulsion (spread plate)	Egg-yolk-free tryptose-sulfite-cycloserine agar (poured plate + overlay)	Mannitol Egg Yolk Polymyxin agar
Incubation conditions	Aerobic incubation for 48 h at 37°C	Anaerobic incubation for 20 h at 37°C	24–48 h 30°C
Growth promoting compounds	Sodium pyruvate		
Selective compounds	Glycine, tellurite, lithium	D-cycloserine anaerobic incubation	Polymyxin B
Diagnostic compounds	Reduction of tellurite results in gray-black shiny colonies		
	Egg yolk emulsion renders medium yellow and opaque; clear zones around colonies produced by proteolytic action; most strains also form opaque haloes around colonies because of lipase activity	Sodium metabisulphite and ammonium ferric citrate indicate sulphite reduction and produce black colonies	Most strains produce phospholipase C and hydrolyze lecithine in egg yolk resulting in a white precipitate surrounding the colony Failure of *B. cereus* to use mannitol induces alkaline color of the pH indicator phenol red rendering violet/pink background to the rough/dry colonies
Confirmation tests	Coagulase test	Lactose fermentation and gelatine hydrolysis, motility and nitrate reduction	Haemolysis on sheep blood agar and motility
Remarks	Rabbit Plasma Fibrinogen agar (incorporation of rabbit plasma in the basal medium enables direct detection of coagulase-positive staphylococci)	Confirmation in lactose sulfite medium when incubated at 46°C is very specific	
Reference	ISO 6888-1:1999 and ISO 6888-2:1999	ISO/DIS 7937:2002	ISO 7932:1993 and ISO 7392/A1:2002

Standards Organization), AOAC International (formerly Association of Official Analytical Chemists), CEN (Comité Européen de Normalisation), NMKL (Nordisk Metodik-komitté för Livsmeddel), AFNOR (Association Fran-çaise de Normalisation), NNI (Nederlands Normalisatie Instituut), DIN (Deutsches Institut für Normung), IDF (International Dairy Federation), etc. (50).

These standard methods for detection of microbiological contaminants in foods are usually conventional cultural methods. Primarily because the intention is to provide the users of these methods with a reliable and internationally accepted method which enables them to obtain equivalent results in different laboratory settings without having exclusivity of materials related to one manufacturer. Although in essence these standard methods serve only as guidelines for reliable microbial analysis of foods, historically in many countries governmental agencies and trading agencies recommend or accept them as official methods for detection or enumeration of microorganisms in foods (51, 52) they may also recommend their own established methods, e.g., the U.S. FDA compiles its recommended methods in a Bacteri-ological Analytical Manual (US FDA-BAM) (36).

B. Validation of Methods

The confidence in the results produced by a microbiological analytical procedure depends on the reliability of the analytical method. Determination of the performance characteristics of a method by validation will facilitate it to gain acceptance of the test results by international, national or regional regulators and trade partners. Standard methods, which are published by international, national or regional standardization organizations or trade organizations, are considered as validated. In this case the laboratory implementing a new standard method has to demonstrate that criteria for validation indicated in the standard can be achieved. This is done by a systematic research on specific analytical parameters. However, only recently the performance characteristics of six ISO methods, namely *Bacillus cereus* (enumeration), *Listeria monocytogenes* (detection and enumeration), *Staphylococcus aureus* (enumeration), *Clostridium*

perfringens (enumeration) and *Salmonella* (detection), were determined and published in the corresponding ISO methods (53–55). In the present situation, laboratories will have to show that they are capable of performing the standard method of choice correctly on experiments with their own range of samples. This is preferably referred to as a method verification study because it is not a validation study *sensu strictu*. Validation of a method is a formidable collaborative research task that so-called rapid, modern methods are subjected to before they are accepted and will be discussed in Chapter 55. Methods are most effectively assessed with specially designed experiments. Routine analyses usually lack a plan or replications that is are prerequisites for method verification.

For quantitative methods (enumeration) this method verification study should focus on establishment of the trueness (bias) and the precision of the method.

Trueness (*bias*) is defined as the closeness of agreement between the true value or, if not known, the accepted reference value and the mean result which is obtained when the experimental procedure is applied a large number of times (= systematic error) (56, 57). The trueness can be obtained by the analysis of certified reference materials (CRMs), derived from a certifying body (e.g., the Community Bureau of Reference (BCR) of the European Commission (EC)). However, only a limited number of CRMs or stable reference materials from other sources are available for microbiological purposes. The analysis of spiked materials (recovery studies) can be performed as an alternative. Participation in proficiency testing schemes can also help in assessing the laboratory performance for the parameter of trueness.

Precision is defined as the closeness of agreement between independent test results obtained by applying the experimental procedure several times on the same sample under stipulated conditions (= random error) (57, 58). The measure of precision is usually expressed in terms of imprecision and calculated as a standard deviation of the test results. Less precision is reflected by a larger standard deviation. Checks of precision in routinely used methods should be made to ensure that the result does not change with time as a result of changes in reagents, equipment, staff, etc. Distinction is made between:

- Repeatability: indicates the variability observed within a laboratory, over a short time, using a single operator, the same apparatus on identical test material.
- Reproducibility: inter-laboratory reproducibility indicates the variability observed when different laboratories analyse the same sample by use of the same method and may be estimated directly by inter-laboratory study. Intra-laboratory reproducibility relates to the variation in results observed when one or more factors, such as time, equipment and operator, are varied within a laboratory.

For qualitative methods (presence/absence testing) the method verification study should focus on establishment of the detection limit and the specificity and sensitivity of the method.

The *detection limit* is defined as the smallest number of culturable microorganisms that can be reliably detected in the sample. For qualitative methods it can be defined as the smallest number of culturable microorganisms that can be detected on 50% of occasions by the reference method (56).

Both *sensitivity and specificity* relate to the degree to which a method responds uniquely to the specified target organism or group of organisms and relate to the number of false positives and false negatives results that are found with the validated method. Various definitions for sensitivity and specificity are proposed, includig the following (58).

The sensitivity of a method is the proportion of target organisms that can be detected; it can be calculated with the following equation:

$$\text{Sensitivity (\%)} = \frac{\text{number of true positives (P)}}{\text{P + number of false negatives}} \times 100$$

A failure to detect the target when present is a false negative result and will lower the sensitivity of a test. In food microbiology only a very low frequency of false-negative results can be tolerated for safety reasons.

The specificity of a method is the ability to discriminate between the target organism and other organisms; it can be calculated with the formula:

$$\text{Sensitivity (\%)} = \frac{\text{number of true negatives (N)}}{\text{N + number of false positivies}} \times 100$$

A positive result in the absence of the target is a false-positive result and will lower the specificity of a method. For rapid screening methods, a higher false-positive frequency may be acceptable, as positive screening tests are followed by confirmation tests.

In addition to the specificity and sensitivity as described above, the inclusivity and exclusivity of a qualitative method also may be determined, inclusivity being the ability of the validated method to detect a wide range of strains belonging to the target organism, exclusivity being the lack of detection with the validated method of a relevant range of non-target strains (56).

A number of issues need to be addressed in the preparation of a solid method verification scheme. These are listed in Table 54.6.

TABLE 54.6
Considerations in the Preparation of an Experimental Design for Method Verification

Number of food types to be tested	If the method is to be validated for all foods, usually five categories of foods are included
	Food categories are predominantly determined by the origin of the product, e.g., meat products, dairy, fruits and vegetables, etc.
	The modes of processing to increase shelf life may further be used to select food types within a category, e.g., raw, heat-treated, etc.
	The types of food chosen should be relevant to the type of target organism(s) sought and the scope of the laboratory
Number of samples to be analyzed	A sufficient number of samples should be analyzed in order to generate sufficient data to allow the use of appropriate statistics for interpretation
Naturally contaminated food samples versus artificially contaminated food samples	Whenever possible naturally contaminated samples should be used. These represent best real-life encountered samples with the target organism(s) present as a minority (if pathogenic bacteria) in a vast majority of other bacteria and in a non-optimal (stressed) conditions
	When artificially contaminated samples are used, the levels of inoculation and the preparation of the inoculants to achieve this should be similar to those expected to be found in naturally contaminated samples; the background flora also should be representative
The source and number of inoculum strains	Strains that have been isolated from the same type of food product are preferred; if not possible, then inoculants should be fully characterized (reference) cultures
	Cover the recognized range of the target and non-target organism with respect of the geographical distribution, incidence and diversity of the identification characteristics it is biochemical activity, serotype, phage type, etc.

TABLE 54.7
Requirements of the ISO 17025:1999 for the Accreditation of Testing Laboratories

Management requirements	Technical Requirements
Organisation	Personnel
Quality system	Accommodation and environmental conditions
Document control	Test methods and validation, measurement of uncertainty
Review of requests, tenders and contracts	
Subcontracting of tests and calibrations	Equipment
Purchasing services and supplies	Measurement of traceability, control of data
Service to the client, complaints	Sampling
Corrective and preventive actions	Reporting of results
Control of records	
Iternal audits, management review	

By method verification insight is obtained into the possibilities and limitations of the test method under the laboratory's own conditions in the area typically served by the laboratory.

C. Quality Assurance in Microbiology

The performance characteristics of a method are closely related to analyst performance, the equipment and, more generally, the competence of the laboratory to provide accurate, reliable and repeatable test results under controlled conditions. Accreditation of laboratories carrying out microbiological food analysis provides to those relying upon its services the assurance of the reliability of the test results. Accreditation of a laboratory is the formal approval given by a national authorized body (linked by the European co-operation for Accreditation of Laboratories (EAL)) that the laboratory is competent to carry out specific methods of analysis and has a commitment to quality assurance in the lab (59). A detailed account of the requirements that testing labs have to meet is described in ISO 17025:2000 (60) and reviewed in Table 54.7.

It is clear that, to comply with the requirements of the ISO17025:1999, the laboratory should use validated methods which are documented in standard operating procedures and must have a systematic approach of quality control. Of equal importance is the execution of the method by qualified staff with well-maintained and properly functioning equipment and utensils.

55 Rapid Methods in Food Diagnostics

Mieke Uyttendaele and Johan Debevere
Department of Food Technology, Chemistry,
Microbiology and Human Nutrition, Ghent University

CONTENTS

I. INTRODUCTION

The classical procedures for enumeration or detection of microorganisms in foods (Chapter 54) are labor-intensive and time-consuming. Several days are needed to obtain confirmed results. To shorten analysis time, new methods have been developed that can rapidly enumerate or detect low numbers of microorganisms in foods. In this chapter, the term 'rapid' will be used to describe methods which are able to give results within a 24–48 h timeframe, whereas results within 0.5–4 h are considered extremely rapid. In order to allow for immediate corrective action during food manufacturing processes, 'real-time' or 'on-line' detection of microorganisms in foods is sought by manufacturers.

The lack of sensitivity or lack of robustness of most new technologies, however, makes 'real-time' detection in solid foods difficult to obtain. Water and beverages are easier to manipulate and, therefore, more amenable for application of 'on-line' methodology.

A number of instrumental methods have been developed for rapid detection of pathogens using various principles of detection. Direct microscopic methods like DEFT (Direct Epifluorescent Filter Technique) or flow cytometry (FCM) are based on the detection of the actual cells. Indirect methods detect growth and metabolic activity (e.g., conductimetry/impedance) or cellular components (e.g., ATP bioluminescence). Immunological methods have been and still are popular in different formats for rapid detection of pathogens. More recently, nucleic acid-based methods like PCR (Polymerase Chain Reaction) have been advancing rapidly and are promising for rapid screening of foods for presence of pathogens. Finally, the development of biosensors opens new perspectives for 'real-time' or 'on-line' detection of pathogens. Because there are many manufacturers supplying commercially available options for the rapid detection methods discussed and the format in which these techniques are available changes rapidly, no listing of these commercial assays is included. For an up-to-date overview the reader is referred to the internet sites of the manufacturers, or to comprehensive information websites such as http://www.foodhaccp. com or http://www.rapidmicrobiology.com. The present chapter aims to discuss the potential and pitfalls of each of the above-mentioned techniques as a rapid detection method of either spoilage organisms or pathogens in foods. For a discussion of the modified and automated traditional culture-based methods, e.g., spiral plater, chromogenic media, commercial identification kits, etc. the reader is referred to Chapter 54.

II. BENEFITS AND LIMITATIONS OF RAPID METHODS IN FOOD MICROBIOLOGY

Some distinguishing features of both traditional culture-based methods and alternative rapid methods for microbiological analyses of foods are listed in Table 55.1.

Alternative rapid methods are especially cost-effective if large numbers of samples need to be screened for a defined parameter in a short period of time. The reliability of the results is related to the intrinsic performance characteristics of the method and the degree to which operators are trained and familiar with the execution and interpretation of the methods.

Although rapid methods have become increasingly popular in recent years, they also have their limitations:

- Often rapid methods are developed for a specific scope of application (e.g., a defined product group) and linked to strict protocols in order to obtain good performance. They are less flexible than traditional methods which are most of the time horizontal methods that are more amenable to modification depending on the food product to be analyzed.
- Rapid methods may, in many cases, only be able to indicate the presence or absence of target organism(s) but they do not provide an isolated colony, the availability of which may be desirable for epidemiological purposes.
- Novel rapid methods measure parameters (antigen-antibody response, DNA or RNA sequences, metabolic activity) distinct from the classically accepted ones (phenotypic traits). This may complicate the problem of interpretation of the results in comparison studies of the methods.
- Rapid methods that work remarkably well with pure cultures of target organisms fail sometimes when applied to real food specimens which may include inhibitory components. The effect of these may be overcome by previous concentration and purification of target organisms, although at the expense of ease of use and rapid results.
- Often rapid methods still make partial use of the traditional culture-based method. For example, ELISA methods and PCR methods both employ a one- or two-day culture enrichment step to resuscitate sub-lethally damaged cells and enable multiplication of low numbers of pathogens to the intrinsic detection limit of the proper ELISA (10^4–10^6 cfu/ml) or PCR assay (ca 10^2 cfu/ml). As such, these methods do not entirely replace traditional culture-based methods but rather are complementary to the traditional methods in overcoming their lack of speed in reporting results. This also implies that the reliability of the outcome of the ELISA or

TABLE 55.1
Significant Distinguishing Features of Traditional and Rapid Methods

Traditional Culture-Based Methods	Alternative Rapid Methods
Labor-intensive	User-friendly, amenable to automation
Time-consuming	Rapid results
Low investment in apparatus and materials	Often expensive apparatus and consumables needed
Subjective interpretation (linked to personnel observation)	Objective interpretation (print-out)
Moderate reproducible (depends on quality-assurance program in the laboratory)	Better reproducible (quality-controlled reagents, meticulously standardized protocols)

PCR assay not only depends on the assay as such but also on the effectiveness of the enrichment procedure to provide sufficient numbers of the target organism.

III. MICROSCOPIC METHODS

Due to the necessity of incubation to enable multiplication of cells to become visual colonies, the traditional culture-based methods cannot be classified as rapid. Truly rapid methods are based on the detection of target organisms at the single cell level by use of microscopy. In order to visualize cells for microscopical examination, coloring agents are used to provide information on the total level of microorganisms (e.g., acridine orange staining) or specific types of microorganisms (e.g., fluorescent labeled antibodies). In combination with different pre-treatments (e.g., pre-filtration to remove solid particles, enrichment to enhance the number of cells) and detecting principles (epifluorescent microscopy or flow cytometry), microscopic methods have developed into promising rapid methodologies for microbial analysis of particular food categories such as dairy products and beverages.

A. DEFT

DEFT stands for Direct Epifluorescent Filter Technique, a microscopic cell counting method. Originally developed for the determination of total bacterial counts in raw milk, this technique also found application in the fields of meat and fish microbiology. The DEFT procedure consists of four main steps: homogenization and pre-treatment of samples with detergents and proteolytic enzymes, filtration of an aliquot of the sample over a polycarbonate membrane, fluorescent staining of the bacteria retained on the filter and the subsequent microscopic counting of the cells under a fluorescent microscope. This detection can be automated by linking the microscope to an image analyzing system. DEFT differs from conventional light microscopy in that different fluorogenic labels can provide different types of information. Originally, the nucleic acid stain acridine orange was used as the labeling reagent for total bacterial counts. Although it has been said to label viable cells orange and to render dead or impaired cells green, intermediate colors can occur and a clear distinction cannot always be obtained. Alternative fluorescent probes, such as nucleic acid stains like DAPI (4′,6-diamidino-2-phenylindol), indicate total number of bacteria present irrespective of metabolic activity. Viability labels have also been developed, including fluorescein derivatives that are cleaved into intensely green products by viable (metabolically active) cells. Although the actual staining and counting takes less than 0.5–1 h, the total detection time is seriously lengthened by sample pre-treatment steps. The intrinsic detection limit of DEFT is around 10^4–10^5 cells per ml of original sample, and so concentration techniques and enrichment steps usually have to be included in the protocol (1). The inherent lack of specificity in conventional DEFT methodology is a serious drawback in terms of specific pathogen detection. All the above-mentioned fluorescent stains are "universal" ones, incapable of demonstrating specific pathogens. Consequently, fluorescent labeled antibodies are used for specific pathogens in the so-called antibody-DEFT (Ab-DEFT) approach. A protocol using Ab-DEFT has been described for detection of *E. coli* O157:H7 in beef (2).

A novel way of cellular staining in combination with conventional DEFT methodology has been described recently and is termed "oligo-DEFT." It uses the combination of FISH (Fluorescent *In Situ* Hybridisation) with a highly specific oligonucleotide probe for the 16S rRNA, and DEFT. It has been used for the detection of *E. coli* in water, beverages and sprouts (detection limit: 1 CFU per ml) (3).

To conclude, DEFT *in se* allows a near on-line detection of microorganisms, but its practical applicability in food analysis is seriously hampered by the need for sample pre-treatment and concentration/isolation steps. As a result, the 30-min assay time in model systems takes more than 20 h when specific pathogens have to be detected in real food samples.

B. Flow Cytometry

Flow cytometry (FCM) is an optically based method for analyzing individual cells. It comprises the suspension of target cells in a fluid, injection of an aliquot in the detection system (flow cytometer) and the automated real-time analysis by the instrument. Basically, the cells, which can be labeled with a fluorogenic compound prior to the assay, pass a laser beam and scattering of light occurs. The extent and the nature of the light scatter reflects bacterial number, size and shape, and the fluorescence is measured as well by a system of lenses and optical cells (Figure 55.1). The sensitivity of the technique is very high: as few as 10^2 yeast cells and about 10^2–10^3 bacterial cells per ml can be detected with results being obtained in less than 30 minutes. However, as is the case for DEFT, the application in the field of food microbiology is limited by the fact that a homogenous suspension, free of interfering particles, is needed to be injected in the system. This necessitates an appropriate sample preparation method (e.g., enzymatic clearing). As a consequence the application of FCM in food microbiology is mostly limited to the enumeration of total viable counts (TVC) or yeast cells in milk and beverages (4). Flow cytometry is often used in conjunction with the commercially available LIVE/DEAD®BacLight™ bacterial viability kit. The kit was developed to differentiate live and dead bacteria based on plasma membrane permeability. The staining mechanism using LIVE/DEAD kit on bacterial cells is based on the attachment of the non-fluorescent

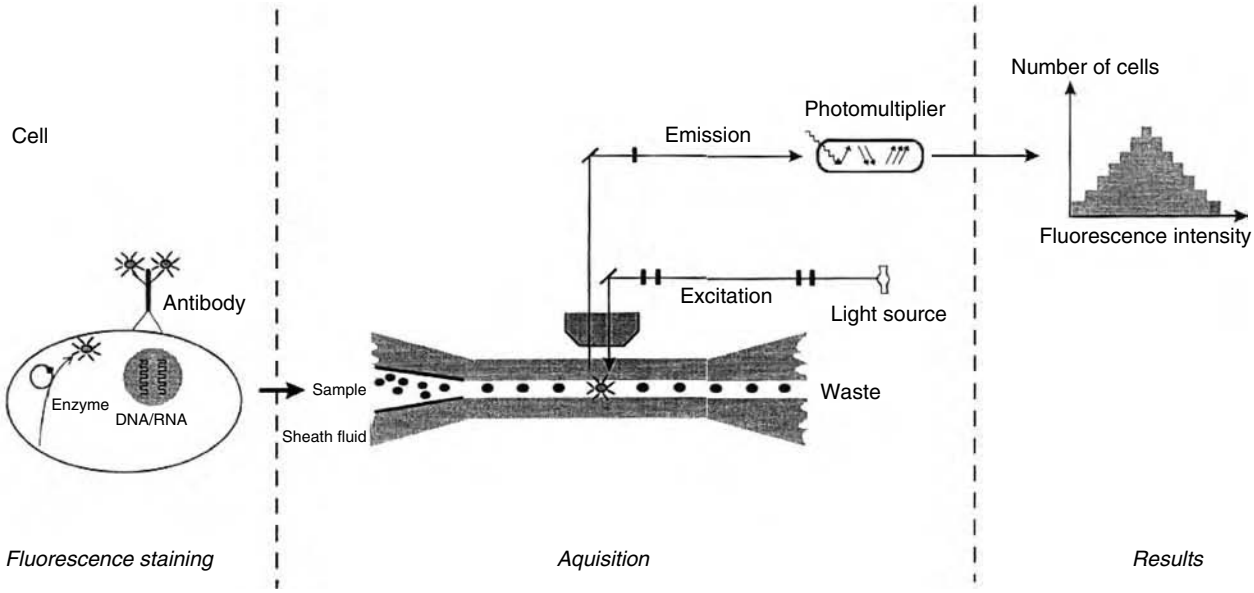

FIGURE 55.1 The principle of flow cytometric analysis. (Ph.D. thesis of C.N. Jacobsen on flow cytometric detection of *Listeria monocytogenes*, courtesy of M. Jakobsen, Dept. Dairy and Food Science, Royal Veterinary and Agricultural University, Denmark.)

agents on nucleic acids. Once the DNA-dye complex is formed fluorescence can be measured. The kit consists of two fluorochromes, which have distinct fluorescent behavior in terms of emission of wavelengths and membrane permeability. The first component is the membrane-permeant stain SYTO9®, which fluoresces green at 530 nm upon excitation at 488 nm. It stains all cells, thus acting as total cell stain. During cell death, accompanied by membrane damage, the second, membrane-impermeant, dye propidium iodide (PI) penetrates into cells and quenches the green SYTO9® fluorescence. PI is able to excite at 488 nm as well and emit red fluorescence at 620 nm. When used in combination, intact cells are labeled green and cells with damaged membranes are labeled red. Raw milk data using LIVE/DEAD staining showed good agreement between FCM and standard plate count methods. The detection limit of the FCM assay was $\leq 10^4$ bacteria per ml of milk. However, this limit is below the level of detection required to satisfy legislation in many countries (5). Sensitivity may be improved by flow cytometry using fluorescein labeled antibodies, or by using immunomagnetic separation as the specific step in combination with a less specific staining such as viability staining for flow cytometric detection of the separated cells (6).

IV. METABOLISM

To permit routine in-process measurements in a production setting to monitor critical control points very rapid methods are needed. ATP bioluminescence and impedance are two methodologies which emerged about a decade ago and that have been extensively evaluated, especially in the dairy and meat industry for fast and reliable microbiological screening of raw material on arrival at the processing plant. Both methods rely on monitoring the metabolic activity of microorganisms. Often, the major drawback of these methods is that the detection limit requires high numbers of bacteria (10^4–10^5 cfu/ml) present in the food matrix because the moment a signal can be measured or detected is in a limited time interval.

A. ATP Bioluminescence

ATP bioluminescence acts by measuring ATP levels in bacterial cells in order to calculate the number of cells. ATP bioluminescence is a natural phenomenon which is responsible for the glowing of fireflies. When the enzyme luciferase and the substrate D-luciferin are added in excess amounts, the light generated is proportional to the ATP present, according to the following reaction.

$$\text{Luciferin} + \text{ATP} + \text{O}_2 \xrightarrow[\text{Mg}^{2+}]{\text{Luciferase}} \text{Oxyluciferin} + \text{AMP} + \text{CO}_2 + \text{PPi} + \text{light}$$

ATP measurements take about 10–15 minutes. There are two major fields for the application of the ATP bioluminescence in the context of food diagnostics (7):

- Measurement of microbial ATP to determine microbial cell counts
- Measurement of total ATP to test the efficiency of cleaning procedures

1. Measurement of Microbial ATP to Determine Microbial Cell Counts

The problem with ATP bioluminescence is that ATP is the primary energy source of all living cells and the food samples themselves (fat cells in milk, blood, muscle cells) will also contain large amounts of this energy source which have to be destroyed before microbial ATP can be measured. An initial step (enzymatic, physical) for the release and destruction of any somatic cell's ATP should be included before bacterial ATP can be measured.

The use of ATP bioluminescence has been evaluated for the counting of microorganisms present in raw milk (8) or on the surface of raw meat (9, 10) upon delivery to the processing plant. In order to predict CFU values from relative light units (RLU) a correlation needs to be established (Figure 55.2) (8), imposing the necessity of an extensive standardization. This correlation is not universal and should be performed 'in-house.' Indeed the RLU that are measured depend on the actual experimental conditions (type of food matrix) and the type of luminometer for ATP measurement. In general, ATP bioluminescence is not recommended for accurate enumeration of CFU but better suited for a good bacteriological grading of the samples. Each interval of RLU may be considered as a cut-off level, an arbitrary boundary that separates defined levels of microbiological quality. ATP bioluminescence can only be used to control microbial contamination when the food to be tested is expected to have a total viable count above the detection limit of 10^4 cfu/g or cm^2. ATP readings only allow conclusions on the levels of bacterial cells present and not on the composition of the microflora. No correlation can be established between ATP readings and the presence of pathogens.

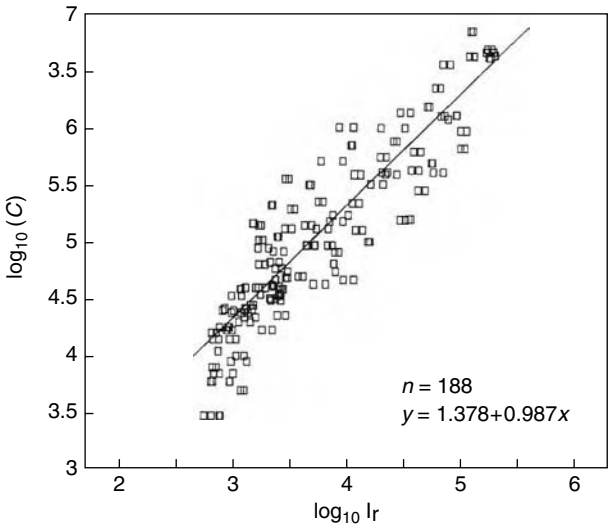

FIGURE 55.2 Relation between relative light intensity, Ir, with an improved ATP filtration method and numerical value of number concentration of bacteria in ml-1, both log-transformed, in 206 raw milk samples. Orthogonal linear regression line calculated for samples with a plate count ≥ 10000 ml-1 (n = 188). (From Reference 8.)

2. Measurement of Total ATP to Test the Efficiency of Cleaning Procedures

Because of the problems described with non-microbial ATP, the measurement of ATP bioluminescence is probably best suited to detect contaminated surfaces on equipment associated with food production. Residues of ATP (microbial or non-microbial) on equipment and working surfaces which have already undergone cleaning procedures suggest insufficient cleaning. As the corresponding tests can be carried out on site with portable luminometers and as results are available within 5 minutes, corrective measures can be taken immediately. Application of ATP determination for hygiene monitoring again necessitates the establishment of cut-off values to be linked to a hygienic standard (dirty, unsatisfactory, tolerable, clean) (Table 55.2) (11). As criteria differ according to the product (e.g., fat remaining in the deep reliefs of the surfaces may produce high RLUs) and kind of surface (e.g., plastic surface yielded higher RLU values than a stainless steel surface), each plant should set its own limits (11).

B. Conductimetry/Impedance

Conductimetry or impedance measurements are based on the detection of electrical current during microbial growth. Changes are caused by bacteria that metabolize uncharged macromolecules in the medium (proteins, carbohydrates, lipids) to mostly charged particles (amino acids, lactate, acetate, etc.), increasing the conductivity of the medium and causing a decrease in electrical impedance. Specially developed media are required for these methods. During the incubation period of the inoculated broth in the instrument, changes in conductance/impedance are measured at regular time intervals. The time taken to reach the threshold value for detection is related to the number of target organisms inoculated in the medium and their subsequent growth. Detection time is inversely related to the bacterial number: the lower the initial content, the longer the detection time (up to 16 h for low numbers ($\pm 10^2$/ml)) (Figure 55.3). The results are presented as a conductance/impedance curve, which is compared with a previously generated calibration curve to estimate the numbers of bacteria. The systems most commonly used to estimate total viable count or indicator organisms include the Bactometer (bioMérieux), Malthus (Malthus Instruments), RABIT (Don Whitley Scientific Ltd.) and Bactrac (Sy-lab). They are fully automated to enable continuous monitoring of changes in electrical current in several samples at the same time. A drawback of

TABLE 55.2
Hygienic Standard of Cleaned and Disinfected Surfaces in Meat Cutting Plants (11)

Material	Dirty RLU/20 cm³	Unsatisfactory RLU/20 cm³	Tolerable RLU/20 cm³	Clean RLU/20 cm³
Stainless steel	>1000	1000-200	199-55	<55
Plastic	>2000	2000-600	599-190	<190

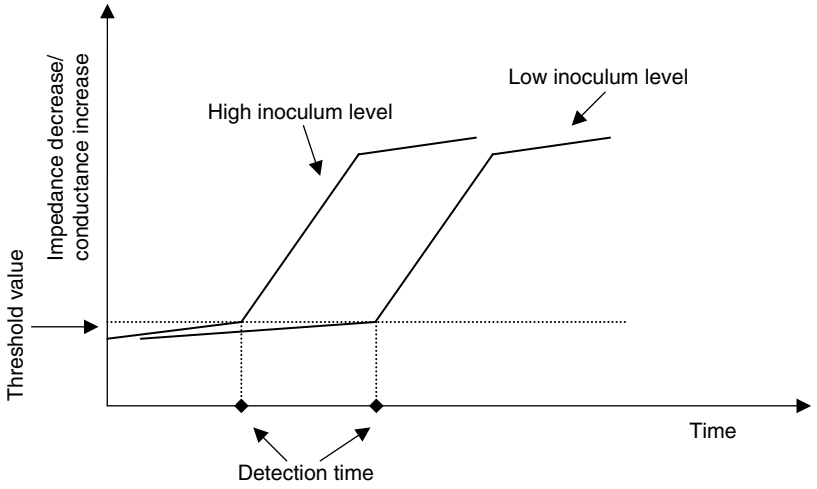

FIGURE 55.3 Graphic presentation of impedance readings, threshold value and detection time.

these electrical measurements is that the food matrix and the degree of sub-lethal stress to which the microflora is exposed may influence the analysis, which necessitates the determination of calibration curves for each food matrix examined.

Indirect conductimetry is based on the production of carbon dioxide by growing microorganisms. The carbon dioxide is absorbed into an alkaline solution and the reduction of conductivity of the solution is measured. This method is suitable for food products with low contamination levels such as juices and beverages, since carbon dioxide formation can be detected much earlier. Specific growth media are not necessary.

Detection of pathogenic bacteria such as *Salmonella* may also be done by the conductance method but usually pre-enrichment is required. Immunomagnetic separation (IMS) to capture and concentrate salmonellae from pre-enriched broth prior to inoculating the impedance medium has been evaluated. Additionally, a reduced pre-enrichment period was proposed since salmonellae from a 6-h pre-incubation period were detected in 5–7 h by impedance. Under these conditions the impedance method can be classified as a rapid method for detection of *Salmonella.*

For more information on the impedance systems available and their use as a rapid method in food microbiology the reader is referred to the reviews of Silley and Forsythe (12) and Wawerla et al. (13).

V. BACTERIAL BIOLUMINESCENCE/ REPORTER BACTERIOPHAGE ASSAYS

Bacterial bioluminescence is a specific bioluminescent assay which shows promise for rapid detection of foodborne pathogens. Many marine microorganisms like *Vibrio* spp. or *Photobacterium* spp. are capable of emitting light due to the presence of so-called *lux*-genes. The introduction of these *lux*-genes into highly specific bacteriophages by genetic engineering has resulted in the development of rapid and sensitive methodologies for pathogens in foodstuffs. Bacteriophages are highly specific for bacteria, usually to the genus level, and as they need host cell machinery to multiply they are good indicators of bacterial viability, too. In the luminescent phage test concept, bacteriophages possessing *lux*-genes infect target bacteria. This infection results in expression of the light-emitting genes which renders the bacteria luminescent upon the addition of an exogenous substrate. Luminescent bacteriophage assays have been developed to detect *Escherichia coli*, *Salmonella* spp. and *Listeria monocytogenes* (14). Loessner et al. (15) described the luciferase reporter bacteriophage A511: *luxAB* to detect viable *L. monocytogenes* in foods, where, without prior enrichment, as few as 500 cells were detected. The presence of less than one cfu/g could be detected within 24 h. Additionally, the assay could detect *L. monocytogenes* cells from naturally contaminated foods, including meat, poultry and various cheeses (16).

Apart from bioluminescent reporter genes, other reporter genes have been implicated in reporter bacteriophage assays. The ability of the *ina*-genes to confer ice nucleation activity on bacteria previously unable to produce ice nuclei, is the basis of a commercially available assay known as the Bacterial Ice Nucleation Diagnostic (BIND) (17). This test uses a genetically modified *Salmonella*-specific phage carrying an *ina*-gene. Due to the synthesis of an ice-nucleating protein *Salmonella*-positive samples will freeze while uncontaminated samples remain in a supercooled liquid state (temperature lowered to −9.3°C or below). It enables the detection of less than 10 *Salmonella* cells per g of food within 2–6 h (18).

The use of reporter bacteriophage assays for the rapid detection of food-borne pathogens is a powerful technique with a strong potential for future applications. Despite this, the technology has not been widely accepted. One potential problem may be the fact that an individual bacteriophage may not possess the host range required to detect all isolates of a bacterial species (14).

VI. IMMUNOLOGICAL METHODS

Over the past two decades, immunological techniques have been developed in a number of different formats for application as rapid confirmation tests (agglutination), as improvements for currently available enrichment and isolation methods (immunomagnetic separation), or as rapid detection methods (ELISA) of food-borne pathogens and their toxins. Immunoassays are based on the specific reaction of an antigen (a specific lipopolysaccharide on the outer cell wall, a protein on the flagella of motile bacteria, or a toxin) with its antibody. Sensitivity and specificity of immunoassays are mainly determined by the antibody used. In this respect the use of well-selected monoclonal antibodies can be of advantage. Each immunoassay may be sensitive to non-specific reactions, for example, *Escherichia hermanni* is known to cross-react with *Escherichia coli* O157 in specific immunoassays. Recognition of false positive results is necessary and supplementary tests such as biochemical tests are recommended to confirm the presence of the target organism.

A. Homogenous Immunoassays

1. Latex Agglutination

Traditional agglutination tests rely on the interaction between soluble antibody (in an antiserum) and a particulate antigen such as a bacterial cell, resulting in visual clumping (agglutination). Agglutination is often used to confirm the serological identity of a pathogenic isolate and is a common test in case of detection of *E. coli* O157 or *Salmonella*.

Latex agglutination uses latex particles to amplify antigen:antibody agglutination reactions. The latex particle is coated with antibody for detection of antigen such as a toxin or a component of a bacterial cell. Upon reaction, cross-linking of the latex particles results in the formation of a lattice structure which is visible to the naked eye as agglutination. If the target antigen is absent or below the detection limit of the test, the lattice structure does not form and the coated latex particles form a homogenous suspension. Latex agglutination for toxins is referred to as Reversed Phase Latex Agglutination (RPLA). Oxoid Ltd (Basingstoke, Hampshire, England) is one manufacturer that provides a range of RPLA kits for the detection of different bacterial toxins.

2. Immunochromatography

Lateral flow immunochromatographic devices were originally introduced, and are now widespread, in clinical diagnosis. They are now being applied for rapid detection of food-borne pathogens. A sample of enrichment culture is added to the sample port of the device. The liquid migrates by capillary diffusion along the surface of a solid support. During this flow, any target organism present reacts with a conjugate (antibody linked to a chromogen) contained in the device. The resulting complex proceeds to move and migrate towards the capture binding protein where it becomes immobilized and forms a visible line in a viewing window (Figure 55.4). For the test to be valid a control line should form in a second viewing window. In an evaluation of rapid methods for detecting *E. coli* O157 on beef carcasses three immunochromatographic methods were compared to the conventional culture method. These assays were all simple and rapid to use, giving a result at least 24 h earlier than culture. However, although one of the assays compared favorably with culture, both other assays lacked the sensitivity of culture and this finding seriously limits their usefulness (19). This was already

FIGURE 55.4 Example of a rapid Listeria test (Clearview™) based on immunochromatography showing test and control lines in the viewing window. (Courtesy of Oxoid, Basingstoke, Hampshire, England.)

mentioned in the study of Johnson et al. (20) who found 18 of the 107 culture-confirmed samples negative with the immunochromatography method for *E. coli* O157. False negatives spanned both high- and low-inoculum subsets.

B. Heterogeneous Immunoassays

The most widely used tests for rapid detection of pathogens, in particular *Salmonella, E. coli* O157 and *Listeria*, in foods are enzyme-linked immunosorbent assays (ELISA) using a sandwich configuration (Figure 55.5). The word 'sandwich' indicates that the assay uses two antibodies which trap or sandwich the target antigen. They use a capturing antibody immobilized on a solid matrix (strip, microtitre tray, dipstick) and enzyme labeling of the secondary antibody to make the primary antigen-antibody reaction detectable. Colorimetric or chemiluminescent substrates are used to visualize the antibody-antigen-antibody sandwich. A range of commercial immunological tests are available in different formats for the common food-borne pathogens. These tests normally require enrichment of the target bacterium to the level of the assay's detection limit (generally 10^4–10^6 CFU per ml). Their dependence on conventional cultural enrichment still remains the most important limiting feature of the majority of these immunoassays. In most cases, a presumed positive result is obtained in approximately 54 h. The magnitude of the resulting reaction will be proportional to the number of bacteria in the broth. However, results are usually converted to a dichotomous scale: results at or above a chosen cut-off value are regarded as positive and results below as negative. A high cut-off value will decrease sensitivity and increase specificity and vice versa. False-positive or false-negative results can be significantly reduced by appropriate antibody selection and preparation. ELISAs are of considerable use in situations where the value of a negative result is high, for example, if a negative is required before a product can be released for distribution or further processing. This explains why these tests are extremely popular for routinely screening food samples following enrichment. In case of a positive ELISA the sample will need to be subjected to further conventional cultural testing to confirm the presence of the pathogen. Many of the ELISAs require the elaboration of a number of steps: capture of the 'target' antigen to the antibody absorbed to the solid phase, washing steps to remove 'non-target' antigens, capture of the secondary labeled antibody (=conjugate), washing to remove excess conjugate, addition of enzyme substrate and reaction which makes the procedure labor-intensive. The introduction of automated plate washers and readers can decrease the hands-on time. Typically these assays take between 1–2 hours, depending upon the format of the test and number and length of incubation steps (21, 22).

Automated immunoassays have also been developed. Vidas (bioMérieux, Marcy-l'Etoile, France) is an automated enzyme-linked immunofluorescent assay (ELFA) based on the detection of specific pathogens using specific antibodies coated on the inner surface of a tip-like disposable pipette which is introduced into the Vidas system along with the Vidas pathogen-specific reagent strip containing the boiled enrichment culture (Figure 55.6). A chemiluminescent substrate is used to visualize the antibody-antigen-antibody sandwich (23, 24). The Vidas system enables high-throughput and rapid screening of large

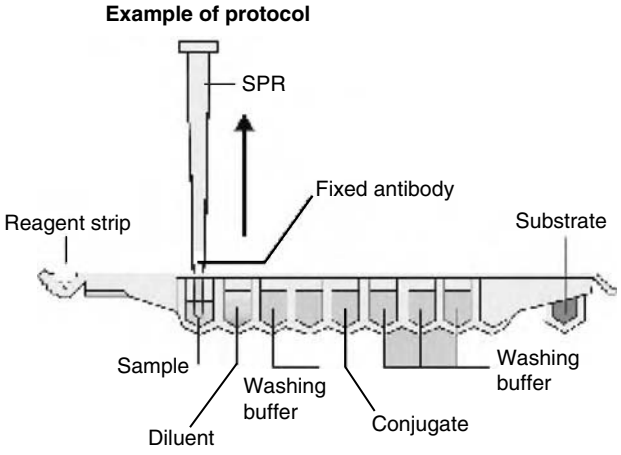

FIGURE 55.5 Principle of ELISA: capturing antibody immobilized in the well of a microtitre tray (a) interacts with target antigen in the sample and enzyme-labeled secondary antibody (conjugate) makes the primary antigen-antibody detectable (b). Washing steps are include to remove unbound conjugate and non-specific sample components (c). Colorimetric or chemiluminescent substrates are used to make the primary antigen-antibody reaction detectable (d).

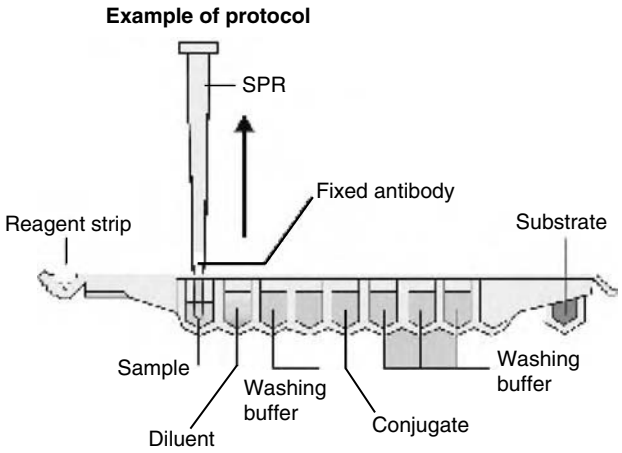

FIGURE 55.6 The Vidas system: an automated ELFA method based on the detection of pathogen-specific antibodies coated on the inner surface of a tip-like disposable pipette which is automatically transferred in the Vidas strip in which the test sample is introduced and which holds the necessary ELISA reagents. (Courtesy of bioMérieux, Marcy-l'Etoile, France.)

number of samples for presence of pathogens. The VIDAS is available for detection of *Salmonella*, *Listeria* spp., *Listeria monocytogenes*, *Campylobacter* spp., *E. coli* O157 and *Staphylococcus aureus* toxins.

C. Immunomagnetic Separation (IMS)

IMS, which employs paramagnetic particles coated with specific antibodies, promises to be a useful tool to remove small food particles from a sample and to selectively enrich and concentrate target bacterial cells by altering the ratio of target to non-target organisms in favor of the target organism. IMS techniques are nowadays widespread in food diagnostics (25). The efficiency and specificity of IMS depends upon the type of magnetic beads, the choice of the antibodies, the target organism, the numbers of the competitive flora and the food matrix. The sensitivity of the IMS technique varies from 10^2–10^4 CFU per ml. In most cases IMS after 24 h pre-enrichment results in an increase in the isolation of the pathogen with concomitant reduction in the number of competitive flora. Thus the use of IMS improves the sensitivity of microbiological tests and eliminates the need for a secondary 24h enrichment, thus reducing the total test time. IMS can be of significant value in conjunction with a number of end-point detection techniques (Figure 55.7). IMS was shown to improve the sensitivity of ELISA, PCR and both used in conjunction enabled detection of *Salmonella* and *E. coli* O157 in foods within 24 h. As such, IMS is an important contribution to the development of a rapid and facile preliminary screening method of food for the presence of pathogens. IMS has become an integral part of the conventional as well as some rapid methods for *E. coli* O157. The use of IMS was shown to increase the isolation rate of *E. coli* O157. The IMS procedure has now been automated (BeadRetriever™, Dynal Biotech Ltd. Wirral, U.K.). Automated immuno-magnetic separation in combination with an enzyme immunoassay complements the conventional culture approach to produce more timely results for the detection of pathogens without significantly increasing the workload of the laboratory (26).

IMS methodology has been coupled to electrochemiluminescence (ECL) detection for rapid detection of *E. coli* O157 or *Salmonella typhimurium* with a commercial immunomagnetic (IM)-ECL sensor. Like other chemiluminescence techniques, ECL offers high signal-to-background ratios and is comparable in sensitivity to radioisotopic methods but has the advantage over other chemiluminescent techniques of being initiated by a voltage potential and thus providing better-controlled luminescence. ECL can be accomplished by heavy metal chelates such as ruthenium(II) trisbipyridal [$Ru(bpy)_3^{2+}$] chelate. Following IMS, [$Ru(bpy)_3^{2+}$]-labeled antibodies were added and after a short incubation period magnetic beads were captured and ECL was measured. The IM-ECL assays were capable of detecting less than 2000 CFU per ml in various food samples (27). The IM-ECL approach proved to be at least 100 times more sensitive than the current ELISA assays and enabled rapid detection (within 24 h) of low numbers (0.05 CFU per g) of *E. coli* O157:H7 in ground beef (28).

An alternative format for IMS, ImmunoFlow, has recently been developed to capture bacteria and eliminates an enrichment step to allow bacteria to be concentrated directly in food and water samples in 30 minutes. ImmunoFlow uses a high-flow-rate fluidized bed with large beads to capture and concentrate bacteria and is volume-independent. Specific antibody is covalently linked to the beads and large beads (>3 mm) are used to prevent sample clogging when testing food samples. Detection of bound targets is done using conventional ELISA protocols. This protocol enabled detection of 10 cells independent of the sample volume (29).

VII. NUCLEIC ACID-BASED METHODS

The application of molecular biological techniques to food microbiology has increased tremendously in recent years. These techniques represent a new generation of rapid methods, based on the primary information contained in the nucleic acid sequences of a particular organism. Indeed, nowadays a bacterial species is defined on

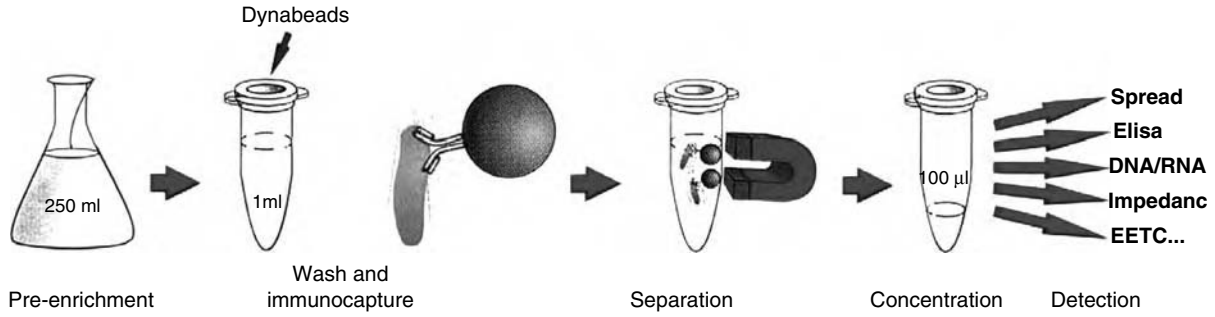

FIGURE 55.7 Immunomagnetic separation uses paramagnetic particles with specific antibodies to selectively concentrate bacterial cells. IMS can be of significant value in conjunction with a number of end-point detection techniques. (Courtesy of Dynal, Oslo, Norway.)

the basis of genetic information combined with a phenotypic description. Detection of pathogens based on specific DNA or RNA sequences thus goes back to the basis of classification of unknown organisms.

A. Oligonucleotide Probes

With the classical DNA probe hybridization assay, microorganisms are collected on a filter, cells are lysed and the liberated DNA or RNA is immobilized in single-stranded form. The nucleic acid is identified by hybridization with radioactively or non-radioactively labeled specific DNA probes. For many pathogens rRNA genes are targeted in hybridization assays. The rRNA gene contains very conserved parts but also variable regions in which specific probes for a certain species can be chosen. In addition, rRNA is present in high numbers in the bacterial cell ($>10^4$/cell). Although all these DNA probes offer good specificity, they are limited in sensitivity. Typically, these assays need about 10^5–10^6 CFU per ml to obtain a reliable result. There are two types of user-friendly nucleic acid probe tests commercially available in routine food laboratories for several pathogens, e.g., *Salmonella*, *Listeria* spp., *Listeria monocytogenes*, etc. The Gene-Trak system (Neogen, Lansing, MI, U.S.A.) uses a dipstick format with a colorimetric detection and is generally applied after 48-h enrichment of the food sample. The AccuProbe test (Gen-Probe Inc., San Diego, CA, U.S.A.) is a chemiluminescent homogenous DNA probe system based on the principle of DNA hybridization protection. It is recommended as a culture confirmation test applied to purified colonies from isolation media, thus providing qualitative results (30).

Recently, PNA probes were developed as an alternative to DNA probes. Peptide nucleic acid (PNA) is a pseudopeptide that binds strongly and specifically to nucleic acids. PNA consists of a non-charged polyamide backbone to which the different nucleo-bases are attached. The neutral PNA backbone confers unique properties on the molecule, relative to oligonucleotides. These include faster hybridization kinetics and the ability to use more stringent hybridization conditions that favor the disruption of the target structure while still promoting strong hybridization of PNA. PNA probes can be used for rapid detection and identification of specific microorganisms (31).

B. Polymerase Chain Reaction

1. Principle and Applications in Food Microbiology

A significant factor in the application of molecular techniques for rapid detection of pathogens lies in the development of the polymerase chain reaction (PCR). Conventional PCR assays incorporate a pair of oligonucleotide primers to amplify by use of the Taq DNA polymerase, a specific gene that is then detected using agarose gel electrophoresis. PCR is based on repetitive cycles of DNA denaturation, primer annealing if they meet a complementary target DNA sequence, and elongation of the primers according to the complementary base sequence given by the target DNA by a thermostable DNA polymerase (Figure 55.8). This results in duplication of the target DNA after each cycle. Thus, during thermocycling, exponential amplification of target DNA occurs. PCR has become an important tool in microbial diagnostics because of the potential for detecting less than 10 copies of a specific gene within a complex sample. However, its sensitivity is also the greatest potential weakness of the method. Cross-contamination with external DNA or carry-over contamination of target DNA produced during prior amplification assays may give false results very easily. Technical improvements (real-time PCR instrumentation, enzymatic decontamination systems), the adherence to careful laboratory procedures and the use of dedicated materials and pre-aliquoted reagents may solve this problem. The reliable identification due to the use of specific DNA or RNA sequences and the intrinsic sensitivity of PCR shows tremendous promise for rapid detection of pathogens in foods. Specific primer sets were developed for almost all established and emerging pathogens in food microbiology (32, 33). Target genes involved for PCR detection of pathogens are numerous:

- rRNA genes or the spacer region between 16 S rRNA and 23 S rRNA genes.
- Virulence genes and toxin genes. Some virulence genes are located on plasmid DNA. A chromosomal location is preferred because of the instability of plasmid during subculturing. By targeting virulence genes (*hlyA*-gene for *L. monocytogenes*, *invA*-gene for *Salmonella*, *eae*-gene for *E. coli* O157:H7, *ail*-gene for *Y. enterocolitica*, etc.) or toxin genes (*vt*-genes for VTEC, *lt*-genes and *st*-genes for ETEC, *ct*-genes for *Vibrio cholera*, BoNT for *Cl. botulinum*, etc.), potential pathogenic strains can be discriminated from non-pathogenic strains belonging to the same species.
- A specific sequence with a known function, e.g., flagellin genes for *Campylobacter*, beta-D-glucuronidase gene for *E. coli,* IS 200 element for *Salmonella*, etc.
- A specific sequence with an unknown function, often derived from species-specific bands in DNA fingerprinting patterns.

Multiplex PCR uses multiple primer sets to amplify two or more target loci in a single reaction. It was described for simultaneous detection of *Listeria* spp. and *Listeria monocytogenes* in poultry products and dairy samples, *Salmonella* spp. and *Shigella* spp. in mussels, *Salmonella* strains and *Escherichia coli* O157 in meat,

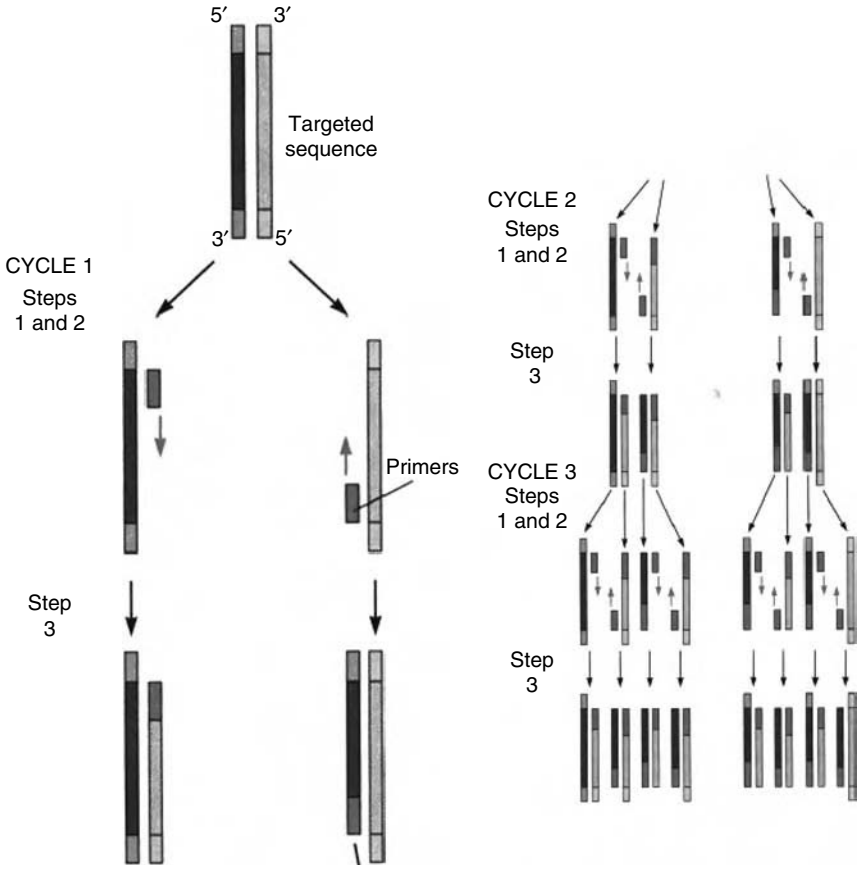

FIGURE 55.8 Principle of PCR. PCR is based on repetitive cycles of DNA denaturation and primer annealing if they meet a complementary target DNA sequence (steps 1 and 2), and elongation of the primers according to the complementary base sequence given by the target DNA by a thermostable DNA polymerase (step 3). This results in duplication of the target DNA after each cycle.

Campylobacter jejuni and *Arcobacter butzleri* in a range of food products (1).

PCR methods are of particular importance in two areas in the field of food microbiology:

1. In the context of rapid detection of food-borne pathogens.
   In accordance with immunoassays, PCR provides a rapid screening method for the presence of pathogens. If a specific primer set is chosen, amplification conditions well optimized, appropriate sampling protocols are applied and proper controls are included, PCR assays may be developed that are highly specific and provide a reliable detection of pathogens in the food sample under examination in a 24-h time period.
2. As a complementary technique in the identification of pathogens where the conventional cultural methodology lacks accuracy.
   Usually, phenotypic characteristics such as morphological, physiological and biochemical features are applied as confirmation tests for food-borne pathogens. However, sometimes the development of simple and restricted confirmation schemes may not be feasible to provide a reliable identification of the pathogenic organism, especially for particular genera or species with a difficult taxonomic position, e.g., identification of *Bacillus cereus* s*enso stricto* being part of the *B. cereus* group including *B. cereus*, *B. anthracis*, *B. mycoides* and *B. thuringiensis* may be accomplished by a PCR method based on the *gyr*B-gene. In the case of emerging pathogens, e.g., pathogenic strains of *Escherichia coli* for which pathogenicity is associated with the presence or absence of certain virulence genes, PCR is an essential part of the full characterization of the strain. For the genus *Campylobacter*, which is characterized by its biochemical inertness, detection of the hippuricase gene by PCR provides a more useful test for confirmatory identification of *C. jejuni* because wrong identification may occur due to non-expression of the gene when

only relying on the hippurate hydrolysis phenotypic confirmation test (34).

Although user-friendly PCR formats are available now, the technique still requires a significant amount of labor with regard to sample preparation and subsequent detection of PCR amplicons.

2. The Necessity of Sample Preparation in PCR-Based Pathogen Detection Systems

Any PCR-based detection system, while potentially very sensitive, must still confront a number of challenges inherent with sampling complex substrates such as food samples. PCR is an *in vitro* enzymatic reaction which only takes place under well-defined conditions of pH and ionic strength and is very susceptible to interfering factors which may be co-extracted from the food sample. If the complexity of the samples adversely impacts the assay, causing reduced amplification efficiency or complete inhibition of the enzymatic reaction, then a negative result may in fact be caused by lack of sensitivity to detect a given pathogen at the minimum concentration that is known to cause health risk. Thus sample preparation needs to be well designed: how much sample is processed, the efficiency of pathogen isolation, the efficiency of nucleic acid extraction, and the effect of co-factors that inhibit PCR. In the context of food diagnostics the following points need to be considered:

1. The PCR technique has the intrinsic sensitivity to achieve the required detection limit for pathogens in food (approximately 5–10 CFU per PCR reaction). However, direct detection of the pathogen in food samples by PCR presents a number of technical difficulties. The relative low levels of pathogens are present in a large amount of food (1–30 g used for food analysis) while only a small sample size (normally one ml of food homogenate) is used for nucleic acid isolation and only a small portion of the DNA extracted (2–10 μl) can be used in the PCR reaction. The pathogen may also be non-uniformly distributed in the food product (35).
2. Several studies indicated the presence of PCR-inhibitory factors in milk (calcium ions), soft cheeses (proteins and fats), red meat (coagulated blood) and various other foods (36, 37). The inclusion of proper controls makes it possible to develop and apply PCR methods for reliable and rapid detection of pathogens in routine laboratories. A positive control (in a separate tube) should be taken along in each PCR run and preferentially an internal control is co-amplified with the target DNA in each PCR tube to check on inhibitory compounds in the sample.
3. From a food safety point of view, care must be taken in interpreting results generated by PCR analysis since this technique cannot distinguish between viable and non-viable organisms. The precise correlation of cell viability with detection of DNA was shown to be poor, with DNA persisting in actively killed cells for significant periods of time (38). The detection of dead cells has to be considered.

The above-mentioned problems can be solved by the execution of PCR after a short enrichment period. Most commonly, the food sample is homogenized in a broth and the number of bacteria is increased *in vivo* by enrichment in order to obtain a sufficient number in a small volume while at the same time diluting out inhibitory components of the food. In addition, previous culture also ensures that only DNA from viable cells is detected (39). Prior enrichment also enables the use of rapid and simple protocols for lysis of bacterial cells and DNA purification. The commercially available PCR systems, the BAX™-assay (DuPont Qualicon, Wilmington, DE, U.S.A.) (20), the Probelia™ assay and its real-time format, the iQ Check PCR assay (Bio-Rad Laboratories, Marnes-la-Coquette, France) (40, 41) and the Taqman™ assay (Applied Biosystems, Foster City, CA, U.S.A) (42) all recommend the application of PCR after a 16–24 h pre-enrichment step.

The use of a shortened pre-enrichment (4–12 h) should be carefully evaluated. In contrast to fully viable pathogenic bacteria used for artificial contamination, bacterial cells in naturally contaminated foods are subjected to stress. The enrichment time needed for a positive PCR detection of stressed cells will be adversely affected. In this state, the microorganisms require a period of recovery before they regain full growth potential and limitation of the enrichment time could lead to an underestimation of the contamination of the food products (43). Often a technical intervention for further concentration of the bacteria is performed after enrichment to increase the sensitivity of the PCR assay and eliminate interfering food components. These include filtration, centrifugation, buoyant density centrifugation, immunomagnetic separation (IMS), surface adhesion or selective adsorption to metal hydroxides, etc. (1, 44). At present several protocols combining a short enrichment, subsequent bacterial concentration, DNA extraction and PCR analysis for rapid (within 24 h) detection of low numbers of pathogenic bacteria in various foods are described (Table 55.3) (20, 40, 42, 45–55). To reduce the time needed for a PCR result the direct application (without prior enrichment) to food is preferred. It must be considered that for application in routine microbiological analysis the complexity of the procedures should be limited. For fluid food products such as milk a single concentration step such as centrifugation or filtration allowed the detection of 1–10 CFU of *L. monocytogenes* per 25 ml

TABLE 55.3
Some Examples of Nucleic Acid Amplification Protocols for Rapid Detection (within 24 h) of Pathogens in Foods

Micro-Organism	Period of Enrichment	Sample Preparation	Detection	Food Types	Ref.
Escherichia coli O157:H7	6–11 h	InstaGene™ Matrix (Bio-Rad laboratories)	PCR + Molecular Beacon based detection	Pasteurized apple juice and milk (I)	Fortin et al. 2001 (45)
Salmonella	16–20 h	InstaGene™ Matrix (Bio-Rad laboratories) EnviroAmp Kit (PE Applied Biosystems)	Taqman PCR assay	Raw meat and shrimp (I +NC)	Kimura et al. 1999 (42)
Salmonella	16–20 h	Multiple protocols	Taqman PCR assay	Chicken carcass rinses, raw meat, raw milk (I+NC)	Chen et al. 1997 (46)
Salmonella	16–20 h	InstaGene™ Matrix (Bio-Rad laboratories)	Probelia™ PCR assay	Various foods (I + NC)	Fach et al. 1999 (40)
Escherichia coli O157:H7	20 h	BAX lysis reagent	PCR + agarose gel detection	Ground beef (I)	Johnson et al. 1998 (20)
Campylobacter spp.	6–24 h	Surface adhesion to a polycarbonate membrane + phenol:chloroform extraction	PCR + agarose gel detection	Meat and poultry (I+NC)	Cloak et al. 2001 (47)
Salmonella spp.	16 h	IMS + heat treatment	PCR + agarose gel detection	Dairy and egg products (I)	Rijpens et al. 1999 (48)
Escherichia coli O157:H7	6 h	Buoyant density centrifugation + boiling	PCR + agarose gel detection	Raw meat (I + NC)	Lindqvist 1997 (49)
Campylobacter jejuni	24 h	GuSCN lysis + silica-based extraction	NASBA + internal enzyme labeled detection probe	Various foods (I), poultry (NC)	Uyttendaele et al. 1995, 1996 (50, 51)
Escherichia coli O157:H7	0 h	Adsorption to titanium hydroxides + GuSCN lysis and phenol-chloroform extraction	PCR + Molecular Beacon based detection	Skim milk (I)	McKillip and Drake 2000 (52)
Listeria monocytogenes	0 h	Centrifugation + IMS + phenol: chloroform extraction	PCR +agarose gel detection	Ham (I)	Hudson et al. 2001 (53)
Campylobacter jejuni	0 h	Mechanical disruption in the presence of DNAzol	PCR+ agarose gel detection	Chicken carcass rinses (I)	Englen and Kelley 2000 (54)
Miscellaneous	0 h	FTA filters	PCR +agarose gel detection	Fresh produce (I), beef (I), apple cider (I)	Lampel et al. 2000 (55)

I = artificially inoculated, NC=naturally contaminated

(56, 57). To obtain this detection limit the filtration step was combined with a complex DNA-purification protocol.

3. Detection of PCR Amplicons/Real-Time PCR

The location of the primers in the selected gene determines the length of the amplification fragment. The detection of the amplicon is usually performed by agarose gel electrophoresis combined with an intercalating dye (e.g., ethidium bromide) and UV light. Electrophoresis makes it possible to estimate the length of the PCR product and length often serves as a proxy for product identification. However, production of non-specific PCR products is known to occur sometimes as the result of priming at loci that share homology with the target sequence or because of primer artefacts. Confirmation of the identity of the amplification product is recommended either by

- Hybridization with a probe internal to the amplification primers (Southern blots or dot-blots)
- Digestion of the amplicon with a restriction endonuclease
- Generation of an internal fragment using nested or semi-nested PCR
- Sequencing to identify the PCR product

In addition to testing the specificity of the product, hybridization with an internal probe or nested PCR can also improve the sensitivity of the assay system.

The application of fluorescent probes to the detection of PCR amplicons, together with suitable instrumentation capable of combining amplification and detection, has led to the development of real-time PCR methodologies. These assays eliminate the need for gel-based detection and yield data amenable to storage and retrieval in an electronic database. Fluorescent real-time detection uses either the SYBR Green fluorescent dye that binds to double-stranded DNA or specific hybridization of fluorescence-labeled probes to the amplicon (44, 58). For the

latter approach three different chemistries are predominantly applied in food microbiology: Taqman probes (Applied Biosystems, Foster City, CA, U.S.A.), molecular beacons (Bio-Rad Laboratories, Marnes-la-Coquette, France) and the LightCycler hybridisation system (Roche Molecular Diagnostics, Basel, Switzerland). These systems are commercially available for routine detection of pathogens in foods. The application of each of these fluorescent real-time PCR techniques is linked to dedicated suitable instrumentation.

a. SYBR Green DNA binding dyes

SYBR Green binds specifically to double-stranded DNA (dsDNA). The unbound dye exhibits little fluorescence in solution in the presence of denatured DNA, but during elongation increasing amounts of dye bind to the nascent dsDNA. When fluorescence is monitored in real time in every cycle at the end of the elongation step, an increase is observed in fluorescence as the PCR progresses and target DNA is exponentially amplified. This method obviates the need for target-specific fluorescent probes, but its specificity is determined entirely by the choice of specific primers. Thus this assay is no more specific than conventional PCR with agarose gel detection. Additional specificity and PCR product verification should be achieved by the generation of melting curves following amplification. Melting curves are generated by slowly ramping the temperature of the sample to a denaturing level (95°C). As the dsDNA denatures, the dye becomes unbound from the DNA duplex, and the fluorescent signal decreases. This change in fluorescence can be plotted against temperature to yield a melting curve waveform. A characteristic melting peak at the melting temperature (T_m) of the amplicon will distinguish it from amplification artefacts.

b. Taqman probes

The Taqman assay utilizes the 5′-nuclease activity of the DNA polymerase to hydrolyse a hybridization probe bound to its target DNA. This probe (the Taqman probe) contains a fluorescent reporter dye at its 5′-end, the emission of which is quenched by a second dye at its 3′-end when the reporter and quencher dye are close to each other. Intact Taqman probes do not generate fluorescence. During the annealing both the primers and the Taqman probe will anneal to its complementary sequence of the target DNA. However, during elongation, when the Taq DNA polymerase is adding bases to the synthesize specific dsDNA, it will degrade the Taqman probe on its way by its 5′-nuclease activity, the quencher and reporter dye will separate from each other and fluorescence will occur (Figure 55.9). By measuring fluorescence in the PCR tube every cycle, the PCR reaction can be followed up in real time.

c. Molecular beacons

Molecular beacons are DNA hybridization probes that form a stem-and-loop structure; the loop portion of the molecule is complementary to the target nucleic acid molecule and the stem is formed by the annealing of complementary arm sequences on the ends of the probe. On one end of the probe a fluorophore is attached and on the other end a quencher of the fluorophore (Figure 55.10). In the absence of the target PCR product the beacon is in a hairpin shape and there is no fluorescence. However, during PCR reactions and the generation of target PCR products, the beacons will attach to the PCR products and cause the hairpin to unfold. As the quencher moves away from the fluorophore, fluorescence will occur and this can be measured. The measurement can be done every cycle of the PCR during the annealing step as the PCR is in progression allowing real-time detection of target PCR products and thus the presence of the target pathogen in the sample. By using molecular beacons containing different fluorophores, one can detect different PCR products in the same reaction tubes, which enables one to perform multiplex tests of several pathogens.

d. The Light Cycler hybridization system

This method uses two hybridization probes. One of the probes carries at its 3′-end a fluorescent donor which emission spectrum overlaps the excitation spectrum of an acceptor fluorophore that is attached to the 5′-end of the probe. Excitation of the donor results in fluorescence resonance energy transfer (FRET) to the acceptor and thus fluorescence. In solution the two dyes are apart, and because FRET depends on the spacing between the two dye molecules, only background fluorescence occurs. During the annealing step, both probes hybridize to their complementary sequence, specific target DNA, in a head-to-tail confirmation. This brings the two dyes in close proximity to one another, promoting FRET and fluorescence is measured. Increasing amounts of fluorescence are measured proportional to the amount of specific target DNA synthesized during the PCR reaction.

There are three competing instruments on the market to perform real-time PCR: the ABI PRISM® Instruments (Applied Biosystems), the iCycler (Bio-Rad Laboratories) and the LightCycler (Roche Diagnostics). All three are run as closed-tube systems requiring no post-amplification manipulations for detection of amplicons. This avoids problems of carry-over contamination. The entire PCR process is amenable to automatization and can handle large amounts of samples making real-time PCR suited for high-throughput screening applications. Although real-time PCR allows quantification, automated fluorescent PCR methods are predominantly used for qualitative pathogen testing (presence/absence in the food sample). However, the real-time monitoring of PCR reactions by tracking a fluorescent signal at every cycle during PCR thermal cycling demonstrates positive results more rapidly (at the cycle at which fluorescence exceeds the statistically determined fluorescence background threshold) thus decreasing the time to detect a positive sample.

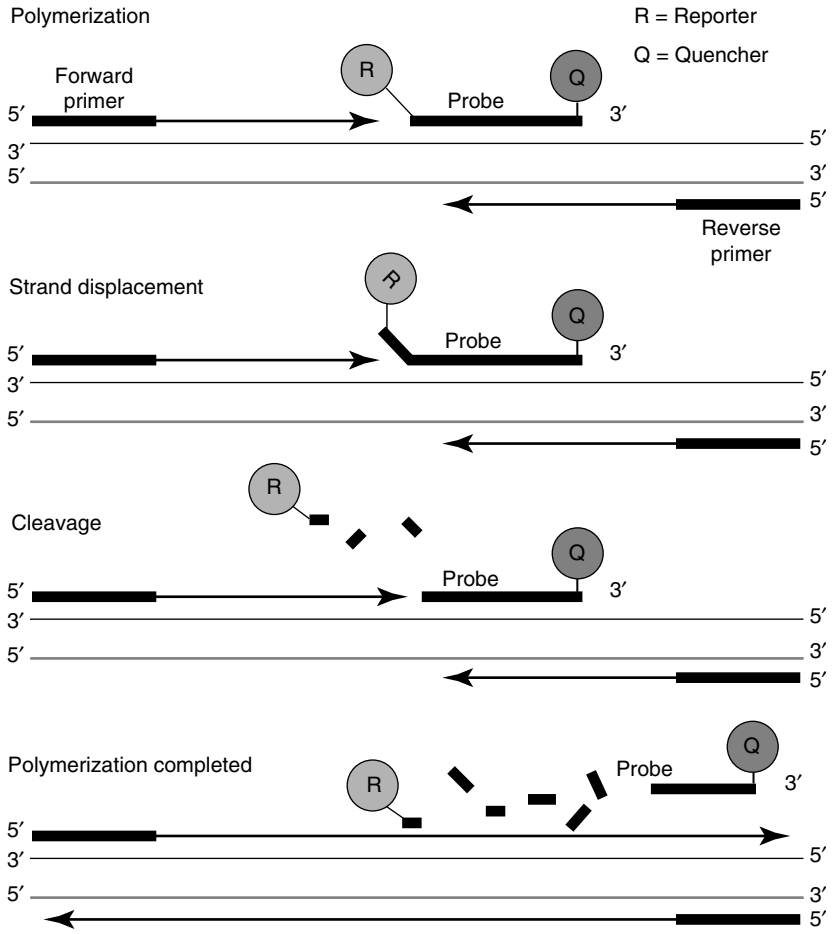

FIGURE 55.9 The Taqman assay utilizes the 5′-nuclease activity of the DNA polymerase to hydrolyze a probe bound to its target DNA. Subsequently, the quencher and reporter dye at the ends of the probe will separate from each other and fluorescence will occur. (Courtesy of Applied Biosystems, Foster City, California, U.S.A.)

4. Quantitative PCR

During real-time PCR, fluorescence values are recorded during every cycle and represent the amount of product amplified to that point in the amplification reaction. The more amplified product appears during PCR amplification, the more fluorescence intensity increases due to hybridization of the fluorescent probe to the PCR product. The instrument-associated software plots automatically during the amplification the RFU (Relative Fluorescent Unit) versus number of cycle which allows the detection in real-time of the PCR product. In the software a baseline for the RFU is calculated as a function of fluorescence noise. When adjusting the graph to have log RFU in Y-axis versus the cycle number in the X-axis it should be verified that the threshold cycle Ct (the cycle at which the fluorescence rises appreciably above background) is located in the linear part of the graph (corresponding to the PCR exponential phase since the scale is in logarithmic units). The combination of a sample preparation method for direct PCR (without cultural enrichment step) with a PCR method using a real-time monitoring fluorescent PCR amplicon detection system allows rapid quantification of pathogens. Quantification is based on the threshold cycle. The higher the level of pathogenic bacteria present in the sample, the higher the input of pathogenic target DNA in the PCR reaction and the faster the threshold cycle is reached. Quantification is performed by an external standard correlating the time to detection to the initial number of pathogens or DNA material used as an input (Figure 55.11). As the real-time quantitative PCR does not use an internal standard but is based on an external scale, quantification demands a good reproducibility of isolation/concentration of bacteria, DNA extraction and PCR. Quantification of *Salmonella, Campylobacter jejuni* and *Escherichia coli* O157 in pure cultures using real-time PCR was reported (59–61). Evaluation of a quantitative real-time PCR for rapid enumeration of *Listeria monocytogenes* showed that log differences in the pathogen added to cabbage could be reliably distinguished. The method produced a linear response over 7 log cycles from 10^2 to 10^9 cfu in 25 g of cabbage (62).

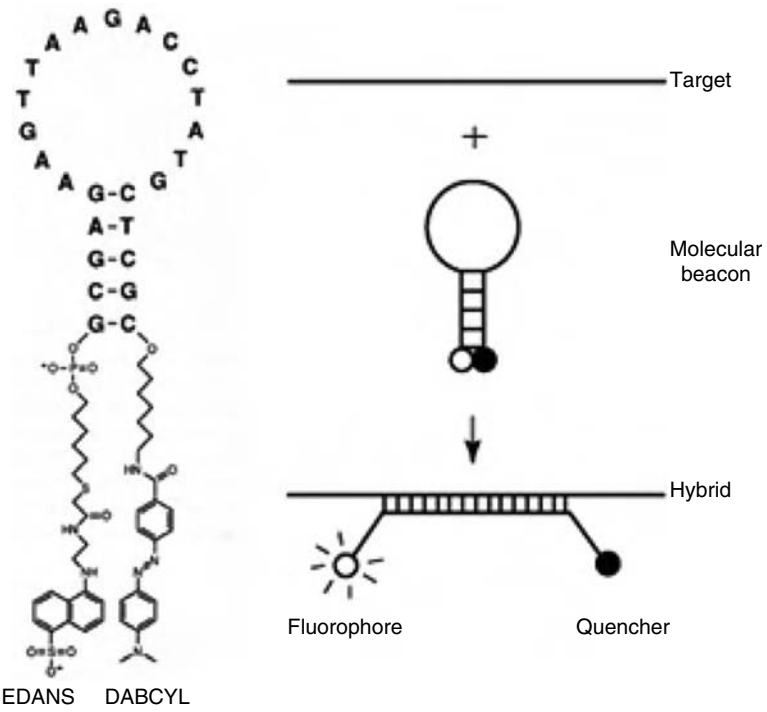

FIGURE 55.10 Molecular beacons are DNA probes that form a stem-and-loop structure. During PCR reactions, the beacons will attach to the PCR products and cause the hairpin structure to unfold. As the quencher moves away from the fluorophore, fluorescence will occur.

5. Microarrays

The recently developed nucleic acid microarray (oligonucleotide microchip) technology has been introduced to enhance the detection capabilities of PCR. In this context, microarrays serve as a system for rapid detection of multiple amplicons resulting from a multiplex PCR. DNA microarrays are in fact a series of reverse dot-blots for which sequence-specific short oligonucleotide-probes are attached to a substrate in a lattice pattern. Probes appear as "spots" in the final image where each spot represents a unique probe sequence. PCR products can deposit on the surface and if these PCR products specific hybridize to complementary probes, it can be visualized using some type of reporter molecule (either a fluorescent label or biotin that permits subsequent detection with a secondary label). This system enables simultaneous detection of the presence of distinct PCR products based on inter-product DNA sequence differences. Multiplex PCR in combination with microarrays have been used for the detection and genotyping (identification of various virulence factors) of enterohemorrhagic *E. coli*. The microarray technology has great potential for use in diagnostic microbiology, by combination of DNA amplification with a universal primer pair with an oligonucleotide microchip with specific probes for several pathogens (63).

6. RNA Amplification Systems

DNA was also demonstrated to persist in a PCR-detectable form in culture negative samples. However, the presence of intact DNA sequences does not give an indication of cell viability. RNA is chemically and biologically more labile than DNA. The type of target RNA, the primer choice, the inoculum level, the inactivation treatment and the holding conditions of the inactivated culture influence the half-life of the target RNA and as a consequence its (in)ability to be amplified. The longer half-life of rRNA and its variable retention following a variety of bacterial stress treatments make rRNA, under many conditions, a less accurate indicator of viability than mRNA. Studies investigating messenger RNA as a target for amplification showed genes with inducible expression (e.g., the *hlyA*-gene of *L. monocytogenes*) not to be suitable; because of the inducible expression, the extraction efficiency of the transcript is variable. The use of housekeeping genes (e.g., the elongation factor) seems a better target as an indicator for viability.

The most commonly used amplification techniques for detecting mRNA are RT-PCR (reverse transcriptase-PCR) or NASBA (nucleic acid sequence-based amplification). RT-PCR is a two-stage process, in which a target messenger RNA sequence is first transcribed into a complementary DNA (cDNA) sequence, either using random hexanucleotide primers or sequence-specific primers. The

FIGURE 55.11 During real-time PCR (in the present example using a molecular beacon-based assay performed in an iCycler), fluorescence intensity increases due to hybridization of the fluorescent probe to the PCR product. When adjusting the graph to have log RFU in Y-axis versus the cycle number in the X-axis the threshold cycle Ct (the cycle at which the fluorescence rises appreciably above background) can be derived. Quantification is performed by an external standard correlating the time to detection to the initial number of pathogens or DNA material used as an input. (Courtesy of Bio-Rad, Hercules, California, U.S.A.)

cDNA sequence may then serve directly as a template for PCR. NASBA is a transcription-based amplification reaction that utilizes three enzymes (avian myeloblastosis virus reverse transcriptase (AMV-RT), ribonuclease H (Rnase H) and T7 RNA polymerase) acting together to mimic retroviral replication. A major advantage of NASBA over RT-PCR is that NASBA is performed isothermally which avoids amplification of double-stranded DNA and enables amplification of RNA from a pool of total nucleic acid.

Both methods have been applied for detection of microbial pathogens in food and water samples. NASBA accomplished rapid detection of food-borne pathogens (*Listeria monocytogenes*, *Campylobacter jejuni*) in foods after a preceding 24-48 h enrichment period. RT-PCR has been applied for detection of viable *Listeria monocytogenes* in beef and eggs and *Salmonella* Enteritidis in beef (64, 65) (Table 55.3).

RNA amplification methods offer in many instances the best means of detecting food-borne enteric viruses

(hepatitis A virus, rotaviruses, Norwalk-like virus); other methods such as ELISA or cell culture are too inefficient or slow (66, 67).

7. International Acceptance

Despite rapid advances in the field of molecular-based methods, there is no doubt that the complexity of the food samples will continue to challenge further these rapid detection methodologies. Nucleic acid-based diagnostics, such as PCR, are very young compared to traditional detection methods and although well-established in research laboratories, still need to gain general acceptance as reliable methods in routine food diagnostics. However, it is considered that PCR can be established as a routine reference method, alongside traditional techniques within the next decade. Currently, there are international collaborative efforts to produce PCR-based methods for food-borne pathogens which are suitable for standardization, and thereafter adoption as routine diagnostic procedures. The framework of these efforts is based on three principal steps: demonstration of primer specificity, evaluation of the method through collaborative trial and, finally, proposal to an international standardization body such as CEN (Commission Europeén de Normalisation) (68). At the same time ISO Technical Specifications are under development to formulate some general definitions and recommendations on the requirements for sample preparation, the performance criteria for thermocyclers, and the requirements for amplification and detection in order to control the overall reliability of the PCR methods executed in food diagnostic laboratories.

VIII. BIOSENSORS

Biosensors are defined as analytical devices which combine biospecific recognition systems with physical or electrochemical signalling. The architecture of a generic system comprises three components: the biospecific reaction, the signal emitted when the target is bound, and the platform, which transduces the binding reaction into a machine-readable output signal. Recently new concepts have begun to yield biosensors aimed at addressing pathogen detection in the food industry. They consist of immobilized biologically active material (e.g., enzymes, antibodies or antigens, nucleic acids) in close proximity to a receiving transducer unit. Target recognition results in the generation of an electrical, optical or thermal signal which is proportional to the concentration of target molecules. However, the application of biosensors to the on-line detection of food pathogens is seriously hampered by problems of stability, sterilizability, sensitivity and matrix interferences. Some current papers have reported the detection of common food-borne pathogens like *E. coli, Salmonella* or *Listeria* in model systems within minutes. Only very few papers, however, deal with their direct detection in food samples. Given the complexity of the different types of biosensors and their limited application in food pathogen testing, we refer to excellent reviews by Ivnitski et al. (69) and Hall (70) for further reading.

IX. VALIDATION OF ALTERNATIVE (RAPID) METHODS

In the past, different countries have developed different validation schemes. Several standardization organizations such as AOAC, IDF, AFNOR, NMKL, etc. have expanded their activities and started up a validation protocol for alternative methods. This has frustrated kit manufacturers, as they have to undertake a number of different validations in different countries, in order to get widespread acceptance of their test. There is a need for harmonization in validation schemes. In 2002, the European Standard "Protocol for the Validation of Alternative Methods" was accepted by the CEN. Through the CEN/ISO "Vienna agreement," this European Standard will also be adopted as an ISO standard (ISO 16140) and agreements have been made with AOAC International for mutual recognition of the different validation schemes. A European certification organization named MicroVal for independent validation and approval of alternative methods based on the European standard is set up and pilot validation studies are ongoing. The proposed ISO 16140 standard for validation of alternative methods describes a technical protocol for the validation of qualitative methods and a technical protocol for the validation of quantitative methods which both include a method comparison study and an interlaboratory study. Specific recommendations are given relating to the experimental setup of the measurement protocol and the calculation and interpretation of the data obtained using appropriate statistics. Nevertheless, the acceptance criteria are not clearly defined in the protocol. Results of the alternative method should be 'comparable' to those of the reference method. The actual criteria will depend upon the type of method and the circumstances under consideration.

In the U.S. but also worldwide, AOAC International, which has a long tradition in validation of methods, is the expert organization for validation of alternative (rapid) methods. The collaborative study forms the essence of the AOAC validation process. In this study, competent, experienced analysts, working independently in different laboratories, use a specified method to analyze homogeneous samples for a particular microorganism. An Associate Referee, under the guidance of the General Referee and assisted by a statistical consultant, is responsible for the actual development of the protocol for the collaborative study which should be approved through the Methods Committee on Microbiology and Extraneous Materials. The Associate Referee also conducts ruggedness testing

and a pre-collaborative study to determine the applicability of the method for detection of the target organism(s) in a wide range of food matrices and conditions. The Associate Referee is required to be an expert in a particular target organism or a particular type of method or a food matrix or a combination of these. The General Referee must be a recognized authority in the field of interest (71). For the parameters taken into consideration to evaluate the performance of alternative (rapid) methods the reader is referred to Chapter 54.

X. CONCLUSIONS

Improvements in the field of instrumentation and data processing, immunology and molecular biology have led to the development of rapid (within 24–48 h) methods for the detection of food-borne pathogens. The introduction of these methods for 'real-time' detection of specific bacteria is hampered by the complexity of the food matrix and the low numbers of pathogens present in the sample. One of the most challenging problems is sample preparation. More research is needed on techniques for separating microorganisms from the food matrix and for concentrating them before detection. The potential of combining different methods should be further exploited. Results obtained from alternative (rapid) methods should be carefully interpreted because positive tests are not necessarily linked to biological activity and should be supported by classical cultural methods which are still the reference methods whereas negative test results are only representative for the absence of the pathogen in the sample taken at that time. Anyhow, it should be kept in mind that microbiological monitoring of foods as such cannot control entirely microbiological quality or food safety. It is only a tool to verify the well functioning of preventive measures taken to eliminate, reduce or prevent the contamination from spoilage or pathogenic microorganisms.

ACKNOWLEDGMENTS

Mieke Uyttendaele is indebted to the Fund for Scientific Research, Flanders, for a position as a postdoctoral research assistant.

CONTENTS

I. INTRODUCTION

A. Definition of Consumer Acceptance Research

Consumer acceptance research is the field of study that examines the perceptual, cognitive, social, and attitudinal factors that influence liking of and behavior toward a food product or concept. It involves the study of the intrinsic and extrinsic product factors that influence liking, choice, purchase, or consumption of foods and beverages, utilizing untrained people who are representative of the ultimate users of the product.

B. Importance and Purpose of Consumer Acceptance Research to the Food Industry

The importance of consumer acceptance research to the food industry is reflected in the large number of R&D professionals who are employed by food companies all over the world to conduct consumer-based, sensory research for food product development, optimization, shelf stability analysis and quality control. In addition, another broad range of consumer research activities is performed within marketing research departments in these companies. Considering the cost involved in successfully bringing a new product to market, food manufacturers realize that it is essential to obtain consumer information as early as possible in the product development cycle in order to screen out potential product failures from potential successes. Consumer acceptance research, along with many of the other sensory testing techniques described in Chapter 57, can provide critically important information to decision makers in order to maximize the likelihood of both product and business success.

Since consumer testing is ordinarily more expensive and time consuming than non-consumer sensory testing, it would be inefficient to have consumers evaluate products that have not been previously evaluated by in-house or trained panels to either characterize their sensory properties or to ensure that the samples to be compared differ significantly on some sensory dimension. However, for most of the trained panel techniques discussed in Chapter 57, consumer testing of the liking/disliking of the product(s) will be a necessary follow-on activity. This is especially true, since knowledge about a product's sensory characteristics or the fact that it is discriminably different from another product does not tell the product developer whether it will have any meaningful effect on consumer liking/disliking of the product(s). Without this latter information, product managers risk making decisions that are very costly in time, resources, and money, but without any evidence of their likely impact on consumer liking or purchase. In addition, one of the most important uses of consumer acceptance testing is for product optimization. Without reliable and valid measures of liking/disliking, it is not possible to develop useful relationships between sensory and/or physical variables of the product and consumer acceptance, so that a set of optimum product characteristics can be achieved.

C. Consumer vs. Non-Consumer Sensory Research

1. Differences in Test Populations: Consumers vs. Trained Panels and Experts

The primary difference between consumer research and other sensory research is the test population that is used. A necessary element of consumer acceptance research is the use of untrained people who represent the target population for which the product is intended. This reliance on untrained individuals contrasts with other types of sensory research that is conducted for the purposes of descriptive analysis of products, quality control, sensory-instrumental correlations, and other specialized purposes within specific food commodity areas. The latter research often utilizes trained or expert panels. *Trained panels* are groups of individuals who have been selected for participation on the basis of objective criteria related to their ability to perceive differences in basic sensory attributes and who are trained in specific sensory evaluation techniques and/or the use of a standardized lexicon. *Expert panels* are groups of individuals who have extensive formal experience with the product or the product category, but who may or may not have received training in a specific descriptive methodology. Expert panels are often made up of in-house authorities within an organization. Trained and expert panels should not be used to assess the affective (liking) aspects of foods (1) or to evaluate any aspect of the suitability of the item for its intended purpose. The reason for this is

that the members of these panels are not necessarily the users of the product or product category. In addition, due to their training and experience, these individuals may well have different perceptions of the sensory properties of the product (2), different liking of the products (3), or biased opinions of its suitability for the average consumer. For these reasons, trained and expert panels should not be used in consumer research.

Although it is agreed that consumer research must be conducted using naive users of the product, the extent to which naive consumers can be used to provide descriptive or other, non-affective, sensory data is more controversial (4). Due to the historical evolution of sensory science within the food industry, where commodity experts and highly trained professionals were often employed to perform sensory analysis, the use of consumers to make analytic sensory judgments was often deemed inappropriate. However, as a result of the influence of the fields of psychology and psychophysics, both of which have long relied on the use of naïve subjects to make sensory and perceptual judgments of complex stimuli, a wider acceptance of the use of consumers to make discriminative and descriptive evaluations of products has emerged. In fact, the method of "free-choice profiling" (5, 6) has been developed for the specific purpose of utilizing consumers and consumer terminology for the descriptive evaluation of food products. The pros and cons of the use of consumers for non-affective sensory analysis have recently been debated (7–11) and the utility of having consumers rate descriptive attributes of products in order to segment them on the basis of sensory preferences has been documented (12, 13). At present, it is best said that a consumer panel should be used when affective (liking) data are being obtained or when sensory data are to be generalized to a consumer population. Trained panels should be used when there is a need to maximize sensitivity to differences in the product or when detailed descriptive information is required.

Although trained panels and consumer panels provide different types of sensory data, it is often useful to be able to relate the two. For this purpose, a number of multivariate statistical approaches have been developed. These include multiple regression techniques, principal component analysis, response surface methodology, internal and external preference mapping, and a variety of data clustering techniques. Details and examples of the application of these techniques to consumer acceptance issues can be found in a variety of books and papers on the topic (14–25).

2. Differences in Independent and Dependent Variables

Another common difference between consumer and non-consumer sensory research is the types of variables that are studied. As noted previously, the independent variables of interest in consumer testing include factors that are both intrinsic and extrinsic to the product. Although intrinsic variables, e.g. ingredients, processing variables, and storage conditions, are also studied using non-consumer sensory techniques, the extrinsic properties of the product, e.g. price, packaging, labeling, and product information variables, along with the demographic and psychographic variables of the user, are unique to consumer research. Similarly, while the dependent variables of non-consumer sensory research typically focus on the perception of the product's sensory attributes (its appearance, odor, taste and texture), the dependent variables used in consumer research typically focus on affect (liking or preference), choice, purchase, or consumption of the product.

II. QUANTITATIVE TEST METHODS: MEASURES OF PREFERENCE AND LIKING

A. The Psychological Construct of Affect: Liking and Preference

One of the major dependent variables of interest in consumer research is *affect*, the emotional response or "feeling" toward some object. In operational terms, affect is commonly assessed through judgments of the "hedonic" or liking dimension of a food or through judgments of the relative preference for one item over another. The word hedonic means, "having to do with pleasure" and derives from "hedonism", the philosophy that views pleasure as the ultimate good and the goal of all human behavior.

The affective or hedonic dimension of a food is separate and distinct from its sensory dimensions. It is a conscious experience that accompanies the somatic (physical) effects of emotions. Thus, when someone states that they *like coffee*, this is *not* a descriptive statement regarding anything intrinsic to the coffee itself. Rather, it is an evaluative statement, based on an emotion that is elicited in the observer when he/she drinks coffee. This contrasts with the statement that *the coffee is bitter*, which is a descriptive statement about the sensory properties of the coffee. Descriptive statements can be said to be "objective", i.e. they tell us something about the object's outward manifestations. However, evaluative or affective statements are "subjective", i.e. they tell us something about the subject's private experiences. It is relatively easy to get agreement among individuals about descriptive statements, but it may be impossible to get common agreement about evaluative or affective statements. Similarly, it is sometimes possible to get independent corroboration of descriptive statements through physical tests performed on the food, whereas no such tests are available to corroborate evaluative or affective statements.

In spite of the differences in the underlying nature of sensory versus affective responses, in many ways, affective responses manifest themselves in the same way as sensory

responses. For example, they both have psychological magnitude and duration. They both adapt over time and recover after deprivation. They are both subject to contrast and order effects, and they both can show bipolarity. These similarities between sensory and affective dimensions have led to the development and use of similar methods and approaches for their measurement (26).

B. Measuring Affect

1. Measurement Levels and Scale Types

Measurement is defined as the assignment of numbers to objects according to rules. This definition applies to the measurement of both the physical and psychological attributes of objects, and by extension, to their sensory, cognitive and emotional dimensions. In a classic paper, S.S. Stevens (27), a mathematician and psychophysicist, defined four different levels of measurement and corresponding measurement scales. The four levels of measurement that he identified were *nominal*, *ordinal*, *interval*, and *ratio*, each defined by the rules used to assign the numbers to objects and the allowable transformations of the numbers that keep the scale form invariant.

The most rudimentary form of measurement is nominal measurement. It refers to the use of numbers to name objects, e.g. the numbers appearing on the jerseys of football players or the designation of the symbol "4" to sets of objects containing four elements. Nominal scaling is rarely used in sensory or consumer science, except when simple counts of the number of consumers who like or dislike a product are made. In the latter case, the proportion of consumers who like the product is referred to as the "acceptor set size", and this measure can sometimes be an important measure in food marketing decisions (28).

The second level of mathematical measurement is ordinal measurement. It refers to the assignment of numbers to reflect the *order* of objects along some dimension, e.g. the numbers assigned to the finishing places of racehorses. Ordinal measurement is often used in consumer sensory testing when food samples are compared or ranked for preference (see section IIB2). However, these tests are usually conducted only when a crude measure of the differences among test samples is needed. Most of sensory science, whether consumer or non-consumer oriented, has come to rely on the last two levels of mathematical measurement — interval and ratio measurement.

Interval scaling refers to the measurement of objects in such a way that the differences between adjoining numbers on the scale represent equal intervals along the dimension being measured. Common interval scales include the Fahrenheit and Celsius scales of temperature and the 9-pt hedonic scale for assessing food liking/disliking (29, 30) (see section IIB3a). Although interval scales afford a meaningful degree of quantification along the measured dimension, they lack the precision and mathematical sophistication of ratio scales.

Ratios scales represent the highest level of mathematical measurement and are defined by the fact that the ratios among the numbers reflect the ratios of the magnitudes among the test objects. In order to achieve this, ratio scales require a *true* zero point. [Note that neither the Fahrenheit nor Celsius scales of temperature are ratio scales, because the zeroes on these scales do not represent a true absence of thermal energy and, therefore, 20 degrees Fahrenheit (or Celsius) does not reflect twice as much thermal energy as 10 degrees Fahrenheit (or Celsius)]. Common ratio scales include metric measurements of line length, the Kelvin scale of temperature, and, in sensory science, magnitude estimation and labeled magnitude scales (see section IIB4).

2. Ordinal Methods: Paired Preference and Ranking

a. *Paired preference tests*

The simplest method for assessing the difference in liking associated with two or more food items is to have consumers directly compare the samples and indicate their preferences. The term *preference* refers to the choice of one sample over another. A paired preference test is used when two samples are to be compared. The two samples are presented either sequentially or simultaneously, depending on the test objectives. The order of presentation of the samples is balanced either temporally (sequential test) or spatially (simultaneous test) in order to avoid order and position biases. The task for the consumer is to choose which sample he/she prefers. The test is typically run as a forced-choice task; that is, the consumer *must* choose one sample or the other. The number of consumers who prefer one sample over the other can then be compared to statistical tables found in standard sensory texts (1, 31, 32) in order to determine whether a statistically significant difference exists in consumer preference between the two samples. There has been a recent discussion in the literature concerning the advantage of having a no preference choice for the consumer, since this represents a real possibility; however it has not found wide use by sensory scientists. (33)

b. *Multiple paired preference tests*

When more than two samples are to be evaluated, either a multiple paired preference test or a ranking test can be performed. In a multiple paired preference test, all possible pairs of the samples are presented in a series of paired preference comparisons. If a large number of samples is to be evaluated, a subset of the possible pairings can be used that focuses on comparing one or two samples, e.g. controls, with all of the other samples. The data and conclusions to be drawn from such an iterative set of two-sample comparisons are similar to those that would be obtained

using a ranking test. However, the multiple paired comparison test minimizes the complexity of the choices for the consumer and can produce greater sensitivity when differences among samples are small. The reader is referred to standard texts on sensory analysis to read further about these methods and the statistical procedures that apply to the data (1, 31, 32, 34).

c. *Preference ranking tests*

A ranking test is the most direct way to determine the order of consumer preferences for more than two samples. However, for reasons related to panelist fatigue and memory limitations, the maximum number of samples that should be tested is 5–6 (35). In a ranking test the samples are usually presented simultaneously to the subjects, in order to minimize the variability contributed by memory effects. The samples are presented in a balanced, random order and the consumer assigns numerical ranks to the samples to indicate the order of his/her preferences for the samples. The data can then be then analyzed by nonparametric statistical tests (Friedman's) and appropriate multiple comparisons to determine if a difference in preference exists among the samples, and if so, which samples differ from one another. Alternatively, rank sum statistics can be found in published tables (36–38).

3. Interval Methods: Rating Scales

Ordinal preference testing methods have several limitations. First, they require at least two samples in order to collect the data. Second, they do not provide information about absolute levels of liking or disliking. In a paired preference test showing that Sample A is preferred to Sample B, one still does not know if both samples are liked, if both samples are disliked, or if one is liked and the other disliked. Lastly, paired preference and ranking methods do not provide information about the degree of difference among samples on the affective dimension. In order to obtain information about the absolute level of liking/disliking for a single sample, a rating scale with specific verbal language that addresses the intensity of the liking-disliking dimension is required. In addition, in order to make statements about the degree of difference in liking/disliking between samples, an interval level of scaling is required.

a. *Category rating scales*

Verbal hedonic scales

Perhaps the most common and best-known method for measuring consumer liking/disliking of foods is the 9-pt hedonic scale (30). This scale, shown on the left side of Table 56.1, is designed not merely to determine preferences among samples, but also to index the degree to which the consumer likes or dislikes the sample. The 9-pt hedonic scale was developed at the U.S. Army Quartermaster Food and Container Institute in Chicago in the years immediately following World War II (see (39) for a review of the contributions of this laboratory to consumer research). The goal of the laboratory's research was to maximize the consumption and nutritional intake of soldiers by identifying and/or developing foods that soldiers would readily consume. In order to develop fast and efficient means for predicting the foods that soldiers would eat, the 9-pt hedonic scale was developed.

TABLE 56.1
The 9-Point Hedonic Scale (30) and Geometric Mean Magnitude Estimates of the Semantic Meaning of Each Category Label (48)

9-Point Hedonic Scale	Geometric Mean Magnitude Estimate
• Like Extremely	476
• Like Very Much	360
• Like Moderately	232
• Like Slightly	72
• Neither Like Nor Dislike	0
• Dislike Slightly	−66
• Dislike Moderately	−199
• Dislike Very Much	−347
• Dislike Extremely	−472

Although the 9-pt hedonic scale is commonly treated as an interval scale, this assumption is unwarranted. The scale is simply an ordered metric scale of liking. The reason for this is that the 9-pt hedonic scale represents a scale type frequently used in consumer research and known as a "category scale". A category scale consists of a set of verbal labels that define different "categories" along a measurement dimension. These verbal categories are often assumed to represent equal-sized intervals along the dimension. However, several analyses of these scales have shown that this is rarely the case (see section below).

The 9-pt hedonic scale is only one of many different types of category scales that can be used to assess food liking. Such scales can have varying numbers of categories (typically 3–10), may be unidirectional or bi-directional, and may use variants of the terms "liking and disliking", e.g. "pleasant" and "unpleasant" or variants of the intensity modifiers, e.g. "somewhat", "a little", etc. In one extension of the use of verbal category scales, a scale consisting of a set of verbal labels relevant to children, i.e. "super good", "really bad"; was developed (40). Most category scales of liking may be used to index either overall liking of the product or liking of one of its specific attributes, e.g. its flavor, texture, etc. (see (31) for examples of a wide range of balanced and unbalanced category scales of liking).

Facial hedonic scales

Although the 9-pt hedonic scale is the most commonly used scale for measuring liking, it is often difficult to use with children, with individuals who have reading difficulties, or with the visually or cognitively-impaired. For these

special classes of consumers, facial category scales are often used that place a lower cognitive demand on the respondent. Such scales consist of a set of faces depicting frowns or smiles. Figure 56.1 shows a consumer ballot that uses a 5-pt facial hedonic scale. This ballot was used to assess the liking of foods served in the U.S.D.A. school lunch program (41). Similar facial scales have been developed using either three (42, 43), five (44, 45), or seven points (46), while others have used animal cartoons (47) and adult faces (31).

Limitations of category scales

In spite of the diversity in the nature of category scales and their widespread use in the food industry, all category scales have the same basic measurement properties and all suffer from the same limitations. As stated previously, empirical evidence indicates that the points on the 9-point hedonic scale do not represent equal subjective intervals, i.e. the difference in acceptability between two products rating "1" and "2" on the scale is not the same as the difference between two products rating "4" and "5" on the scale or "8" and "9" on the scale. The right column of Table 56.1 shows data from a study in which a magnitude estimation procedure was used to scale the semantic meaning of the verbal labels of the 9-pt hedonic scale (48). As can be seen, the data show that the differences between points on the scale are not equal. For example, the psychological distance between "like extremely" and "like very much" is larger than the psychological distance between "like moderately" and "like slightly." Other investigators (49–51) have also demonstrated this nonequivalence of scale intervals using similar techniques.

Another problem with category scales is that respondents tend not to use the extreme categories, because they fear that if they use these categories to rate a food item, but a more extremely liked (or disliked) item is presented subsequently, they will have no appropriate category left to assign to it. This central tendency or regression effect means that the 9-point hedonic scale effectively becomes a 7-point scale of liking/disliking. Also, many category scales have a neutral point. The use of a neutral category decreases the efficiency of the scale (52) and may encourage complacency in judgments by providing the consumer a "safe" category into which foods that engender only mild liking or disliking can be placed (53,54).

Rating foods vs. food names

Since the inception of the study of consumer food research, investigators have applied a variety of methods to obtain an index of the liking or "acceptability" of a tasted food. However, for certain practical purposes in the food industry, such as for menu planning, it is often desirable to index consumer liking for a wide array of foods without presenting the actual foods for evaluation. For this purpose, the same methods of analysis used to evaluate the liking/disliking of real foods can be applied to *food names*. Under these circumstances, the term "preference" is sometimes used to describe the nature of the data that are obtained (55). Although many investigators reserve the term *preference* for methods that require the consumer to choose one sample over another (e.g. paired preference methods), the word *preference* is also defined as an underlying "psychological continuum of affectivity" (56). It is in keeping with this latter usage that the word "preference" is often used to refer to affective ratings of food names (a liberal perspective).

Since a food name is not the same as any particular preparation of that food, the correlation between liking/disliking ratings of foods and their corresponding food names is quite variable. In one study where subjects rated both their liking/disliking for food names and for tasted preparations of the same foods, correlations ranged from .02 to .61 across food items (57). This study also showed that "acceptance" ratings of real foods are characterized by a regression toward the mean relative to "preference" ratings for the corresponding food names.

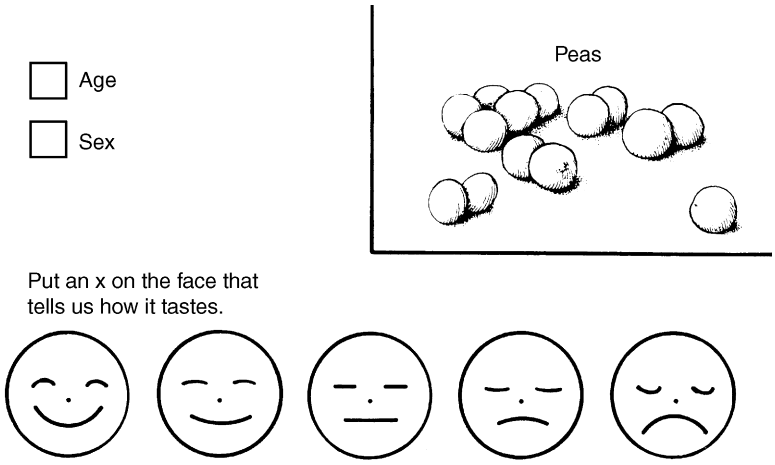

FIGURE 56.1 Facial hedonic scale ballot used to assess food liking/disliking in school lunch programs (41).

That is, foods that are rated as very highly liked, based on ratings of their names, are generally rated lower when actually tasted; whereas, foods that are rated as very disliked on the basis of their names are rated more positively when tasted. This has led to the conclusion that consumers' stated preferences for foods based on their rating of food names reflect a quintessential or idealized image or memory trace of the food, and that actual preparations of the food item are never as good or as bad as this mental image (57).

From a practical standpoint, ratings of affect are also often used to predict future consumer behavior toward a food, e.g. purchase or consumption of it. In a lengthy set of studies conducted by the U.S. military from 1950–1980, soldiers' ratings of liking/disliking in response to food names accounted for 25–50% of the variability in the consumption of these foods (see (57) for a review of these data). More recent studies looking at the relationship between affective ratings of tasted foods and consumption have shown approximately the same degree of predictability (58–65). Although food preference and acceptance measures obtained from affective attitudinal judgments are relatively poor predictors of consumption, this has not interfered with the widespread use of these measures in both industrial and academic settings to predict consumer behaviors toward food. In many cases, affective ratings in response to a tasted food have become the *sine qua non* of consumer behavior toward foods and are used to guide product development, product improvement, and quality assurance throughout the food industry. The continued use of the 9-point scale is a function of its ability to order the liking of both potential new products and products undergoing quality control testing, rather than because it is an accurate predictor of food consumption.

b. Line scales

A different method for measuring the liking and disliking of foods that is not dependent on the use of verbal or pictorial categories is line scaling, also known as linear graphic scaling or visual analogue scaling. A linear graphic rating scale consists of an unbroken horizontal or vertical line that is anchored on both ends with a verbal label. Such a scale may also be anchored in the middle or elsewhere. Figure 56.2 shows a typical linear graphic rating scale used to assess consumer liking. Although line scales have been used to evaluate food quality since World War II (66), they were popularized in the early 1970's due to their use in the procedure known as Quantitative Description Analysis (QDA) (67).

Linear graphic rating scales have been used in a number of studies to rate liking/disliking of foods (68–70). When presented without instructions, linear graphic rating scales are presumed to be interval scales. However, Lawless (71) used a linear graphic rating scale with ratio instructions in order to scale both sensory intensity and affect in response to taste and odor stimuli. In order to enable extremely large ratings of magnitude, Lawless allowed subjects to "extend" the end-point of the line beyond its terminal point. Line scales have also been combined with verbal labels whose semantic meaning have been quantified using direct ratio methods in order to construct a labeled magnitude scale of liking (see below). The latter scales have been shown to produce data comparable to those of ratio methods (48).

FIGURE 56.2 Typical linear graphic rating scale for assessing liking/disliking.

4. Ratio Methods

a. Magnitude estimation

In the 1950's, S.S. Stevens developed a variety of "ratio" methods to permit subjects to make ratio judgments of the attributes of food and other stimuli. The most widely known of these methods is magnitude estimation (72). It was originally applied to sensory stimuli to establish psychophysical functions relating physical intensity to perceived intensity. Magnitude estimation was probably first applied for the scaling of consumer food liking by Moskowitz and Sidel (49). These authors argued for the practical importance of magnitude estimation as a "supplement" to category scaling, suggesting that a category scale could be used to *label* the perceptual categories of acceptance, but that magnitude estimation should be used to refine the *degree* of acceptability. Later, in several papers and books, Howard Moskowitz, a student of S.S. Stevens, championed the use of magnitude estimation for wide scale use in sensory evaluation of foods (50, 73, 74).

When using magnitude estimation, respondents rate the liking of one product relative to another. If one product is liked twice as much as the other, it is assigned a number twice as large. If it is liked one-third as much, it is assigned a number one-third as large, etc. In one study in which magnitude estimation was used to rate whiskey sour beverages (75), it was found to be more sensitive than the 9-point hedonic scale. However, other studies have found the hedonic scale to be more reliable (76), although both scales were observed to be linearly related to one another. Other investigators (77, 78) have found only minor differences between the two scales. A collaborative study sponsored by the American Society for Testing Materials (ASTM) was carried out to compare the 9-point hedonic scale with both unipolar (only positive numbers) and bipolar (positive numbers are used for liking; negative numbers are used for disliking) magnitude estimation (79). This study found all three scales to rank the test stimuli in the same order, with very similar spread of ratings. Very similar degrees of precision and sensitivity were also found in differentiating samples. Reliability of the category

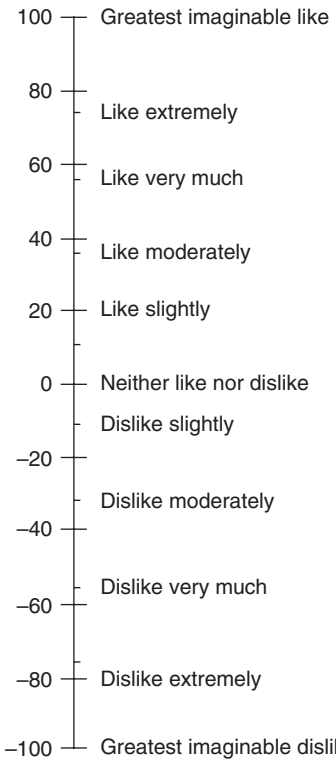

FIGURE 56.3 The Labeled Affective Magnitude (LAM) Scale (48).

scale was higher than for either form of magnitude estimation, although high reliability could be obtained with larger sample sizes. An ASTM method for conducting magnitude estimation has now been published (80).

b. Labeled magnitude scales

Although, magnitude estimation provides valid and reliable data on the sensory and hedonic attributes of food, in practice, it is difficult to use due to the complexity of instructions that are required and certain data analytic demands. This has limited its wide scale use. However, recent work in the development of labeled magnitude scales has combined the practical simplicity of category scales with the quantitative sophistication of ratio scaling for rating both the intensity and affective attributes of tasted stimuli. Green et al. (81) developed the first labeled magnitude scale of oral sensation by placing verbal labels of expressed intensity along a linear numerical scale at specific locations that reflect the numerical ratios among their perceived intensities, as obtained by a magnitude estimation procedure. A critical characteristic of this scale is the presence of a phrase involving the "maximal", "strongest imaginable" or "strongest possible" sensation. The use of this phrase is assumed to serve as a fixed end-point of sensation that places judgments of different subjects on a common sensory "ruler", a scale characteristic that is considered critical for valid sensory results (82–84). Subjects can quickly look at the verbal labels and corresponding numbers, and then place a mark (/) through the line scale to indicate the perceived strength of their sensation. The resulting data have been shown to have ratio properties (81).

More recently, Schutz and Cardello (48) have extended the use of labeled magnitude scales to ratings of consumer liking/disliking. Using the same approach as Green, et al. (81), Schutz and Cardello scaled the semantic meaning of verbal phrases used to describe the liking/disliking of foods. By locating these phrases along a visual analogue scale in accordance with their determined semantic meaning, they created the LAM (Labeled Affective Magnitude) scale of liking (Figure 56.3). As can be seen in Figure 56.3, the non-linearity in the scale is most evident in the middle and at the ends of the scale. During numerous applications of this scale, it was shown that consumers can use this scale to rate the affective aspects of stimuli with equal or better sensitivity, greater reliability and equivalent ease of use as the 9-point hedonic scale (48).

III. QUANTITATIVE TEST METHODS: OTHER AFFECTIVE MEASURES

A. Expected Liking Ratings

Another measure that has become popular in consumer acceptance research on foods, because of its usefulness to understanding the psychological factors that influence consumer food behavior is *expected* liking. Expected liking ratings consist of prospective judgments of the affect that is likely to be associated with a food or beverage. It differs from an affective rating made to a food name, which is primarily retrospective in nature, i.e. past experiences with the food are used to arrive at the liking judgment for the food name. In the case of expected liking ratings, the consumer is asked to assess his/her likely affective response to a food, usually in the context of some information that is presented about the food, e.g. its appearance, brand name, method of processing, etc. Expected liking ratings have often been made using the 9-pt hedonic scale, but any type of affective rating scale can be used. The application of expected liking ratings to consumer food behavior is discussed in section VIIC.

B. Relative to Ideal and Absolute Ideal Ratings

In certain product development situations, it is desirable to know how closely some sensory attribute of a food comes to being the "ideal" level for that product. Such a judgment requires the consumer to integrate an affective evaluation of liking with a sensory judgment of the intensity of the attribute of interest. In such cases, a relative-to-ideal or "just right" scale may be used. Figure 56.4 is an example of a relative-to-ideal scale that one might use to determine if a new formulation of lemonade has the appropriate sweetness

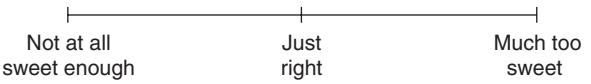

FIGURE 56.4 Relative-to-ideal or "just-right" scale for sweetness.

for consumers. Rather than have consumers rate the sweetness and liking of the product independently in two separate tests, the scale shown in Figure 56.4 can be used. As can be seen, the consumer rates the product from 'not at all sweet enough' to 'much too sweet' on either a linear graphic (shown) or other rating scale. The midpoint of the scale is labeled 'just right'. Such a scale implies that the respondent has an internal ideal for the product against which he/she can compare the sample of interest. Due to the need to have an internal "ideal" for the product, "relative to ideal" scales can only be used for well-established products. It is not possible to use such a scale to assess the ideal level of an attribute for a new or novel food.

A number of researchers have used relative to ideal scales (85–87) and studies have shown good agreement between these scales and hedonic scales. The breakpoint in the hedonic function, i.e. the point at which responses shift from increasing liking to decreasing liking, is highly correlated with the just-right point. Shepherd, et al (88) have argued that relative-to-ideal scales are 'unfolded hedonic scales', i.e., they represent the amount of liking of the product attribute in either direction from the just-right or "bliss" point of the scale. The bliss point in hedonic functions has been documented and studied since the time of Beebe-Center (89), and some investigators (90–92) have formulated psychological theories of food quality that focus on the deviation of sensory attributes from their ideal or bliss-point levels.

It is also possible to have consumers directly rate the ideal levels of all the sensory attributes of a product. In order to discern differences between this "ideal" product and a test product, difference scores are calculated for the attributes of interest. Absolute ideal ratings have been used successfully by a number of investigators (93–95), and strategies for their effective use have been reviewed (96).

C. Multiattribute Preference Ratings: Conjoint Analysis

A common market research tool that has recently been found to have many important applications in consumer acceptance research is known as conjoint analysis (97, 98). Since consumers respond to a combination of variables and levels of variables in making purchase decisions, this procedure allows consumers to make judgments of liking or purchase interest to a "bundle" of attributes. Consumers are presented with a number of conceptual products comprised of different combinations of selected variables and levels (a computer-selected main effects model is ordinarily used to keep the total number of judgments to a manageable level). Consumers rate the product concept on the dependent variable and statistical procedures are then applied that yield both a measure of the "importance" of each variable to the consumer and a measure of the "utility" contributed by each level of the variables. The resulting information allows predictions to be made concerning which product, packaging or other aspect of the product should receive the most attention in the product development and marketing processes in order to maximize consumer liking or purchase.

D. Tailored Questionnaire Items for Survey Research

In addition to the types of rating scales described above, consumer liking and other general or specific attitudes toward food are often assessed using a variety of survey questionnaire formats (99–101), e.g. multiple-choice questions, Likert response scales (agree-disagree), open-ended questions, etc. These techniques are more often used in market research to assess consumer opinions toward new food concepts or for exploring consumer food habits. The required considerations for the proper design, development and implementation of survey research include the design of reliable and valid questionnaire items, proper respondent sampling methods, choice of a viable data collection technique (mail vs. mall intercept vs. internet administration), and analysis of the impact of low response rates on survey validity. The details of these procedures can be found in a variety of standard texts (102,103).

IV. QUANTITATIVE METHODS: BEHAVIORALLY ORIENTED MEASURES

A. Food Frequency Ratings

One practical purpose of any measure of food acceptance is to predict consumer behavior toward the food. However, a simple measure of liking may not suffice to predict the behavior. For example, although a consumer may rate chocolate ice cream an "8" and bread a "5" on a 9-point hedonic scale, this does not mean that the consumer wants to eat chocolate ice cream more often than he/she wants to eat bread. Thus, hedonic judgments of the acceptability of foods are not always a useful tool for menu planning or for predicting food choices. For these purposes, consumer judgments of the desired frequency of consuming the product may be more useful.

Schutz (104) developed the first food frequency scale as a supplement to the 9-point hedonic scale. Known as the FACT (Food Action) rating scale, it consists of a series of statements about the desired frequency of eating an item (Table 56.2). By its nature, the FACT scale provides relative frequency estimates. However, absolute frequency

TABLE 56.2
The Food Action (FACT) Rating Scale (104)

- Eat Every Opportunity
- Eat Very Often
- Frequently Eat
- Eat Now and Then
- Eat If Available
- Don't like, Eat on Occasion
- Hardly Ever Eat
- Eat If No Other Choices
- Eat If Forced

measures can also be obtained by having consumers indicate the number of times during a 30-day period that they would like to consume the item (105). High (>.90) group reliability coefficients have been found for both types of scales (104, 106), while individual reliability coefficients for the latter scale range from .58 to .69 (106, 107). In terms of their ability to predict actual consumer behavior, the correlation of ratings on absolute food frequency scales with food consumption has been reported at .59-.66 (108).

B. Situational Appropriateness Ratings

Appropriateness ratings of food were developed to measure the degree to which a food is appropriate or inappropriate for specific situations or uses. Schutz (109, 110) developed the concept of "situational appropriateness" using a simple category scale that ranges from "never appropriate" to "always appropriate". This scale has been used effectively in a variety of survey formats, and more recently has been shown to be a valuable adjunct to laboratory affective testing of foods (111, 112).

The development of a situational appropriateness scale was one of the first attempts to measure the role of context on consumer food behavior. It is often an overlooked fact that people do not consume foods simply on the basis of how well they are liked or disliked. We eat more or less of foods because it is the right time to eat (breakfast, lunch, etc.), because of health reasons, social constraints, or any one of a number of other factors that are related more to the situation and context of the dining occasion than to any intrinsic aspect of the food itself. This is one important reason why liking ratings account for only about 25-50% of the variance in consumption, as previously noted.

C. Satisfaction Ratings

Another type of attitudinal rating commonly used in consumer research on foods is satisfaction ratings. Satisfaction ratings can be obtained using category, linear graphic, labeled magnitude, or other types of rating scales. In practice, satisfaction ratings are used to assess the post-purchase or post-consumption attitude of the consumer toward a product. When applied to food products, the satisfaction dimension integrates the affective response to a broad range of product attributes. These include, not only its taste quality, but also its price, suitability, convenience, nutritional and health benefits, etc. Moreover, satisfaction with the product is considered to be a function of the consumer's expectations about the product and has been shown to be related to the degree of disparity or disconfirmation between the expected characteristics (or liking) of the product and its actual characteristics (113, 114).

In a recent study, it was found that satisfaction ratings for foods were better predicted from a combination of the expected liking of the food, its appropriateness for the eating situation, and the consumer's preference for the food item than by either liking/disliking ratings or actual consumption (55). Based on these data it appears that the concept of satisfaction takes in a wider range of variables influencing the consumer than simple affect and should be used in those situations where the researcher is interested in the effect of the full range of intrinsic and extrinsic variables on consumer behavior.

D. Behavioral Intent Ratings

One of the traditional methods used by market researchers to predict whether consumers are likely to purchase a particular food is to use a form of "behavioral intent" rating (115). These are ratings by the consumer of his/her future likelihood to behave in some way toward the product. A simple form of behavioral intent measure to quantify purchase intent would utilize a probability-like scale, e.g. "I do not plan to purchase" to "I definitely plan to purchase". Another more sophisticated type of behavioral intent method is known as the "constant sum" technique (116). In this method the consumer is asked to distribute some number of points, e.g. 10, among a set of alternative products or product descriptions in order to reflect the likelihood associated with purchasing each item during their next shopping trip. Unfortunately, neither of these methods is highly predictive of actual purchase behavior. However, they can be used successfully to screen out the best and worst products within a group, and they can serve as a useful adjunct to affective ratings of the products.

E. Purchase Behavior

A more direct behavioral measure of the degree to which a consumer likes or dislikes a product is whether or not he/she actually buys it. Purchase behavior is an important index of liking/disliking for a product, with special relevance to food marketers. Purchase measures include dollar sales, unit sales, and market share. Dollar sales reflect total revenue to the manufacturer and those in the distribution chain, while unit shares index the number of items that consumers have purchased. Market share is a relative index of the manufacturer's sales volume relative to that

of competitors. Of course, pricing heavily influences all purchase indices, so that a very well liked item may not be purchased if it is priced too high, whereas a product that is only slightly liked may be purchased over the highly liked item if it is priced sufficiently low. For this reason, purchase behavior can only serve as a rough approximation of how well liked is the item. The reader interested in measures of purchase behavior should consult standard sales and marketing texts (103, 117).

F. Consumption

Perhaps the most meaningful index of whether or not a consumer likes or dislikes a product is whether or not he/she eats it and how much of it he/she eats. Unfortunately, food consumption measures are difficult, time-consuming, and costly to obtain. To measure food consumption requires that the amount of food eaten by the consumer be quantified by weighing the total amount of food served to the individual, the amount that is left after eating (plate waste), and then subtracting the latter from the former. Less exacting methods require that a visual estimate be made of the amount eaten (as a percent of total served) or that food diaries be maintained. The latter methods are fraught with problems associated with the accuracy of self-reported data. In addition, the hunger or satiety level of the individual influences all consumption measures. Very well liked items will not be consumed if the consumer is full, whereas relatively disliked items may be consumed when the individual is very hungry. As such, consumption measures only serve as an approximation of how well liked or disliked is a food item. It was exactly because of the great difficulty involved in measuring human food consumption that early researchers opted to develop attitude measures to assess liking/disliking of food (30) and to use these measures as predictors of food consumption. Readers interested in further discussion about measures of food consumption are referred to several recent reviews of the topic (118–121).

V. QUALITATIVE CONSUMER TEST METHODS: INTERVIEWS, FOCUS GROUPS

In addition to the quantitative measures described above, a number of qualitative consumer techniques have been developed for use in food acceptance and marketing research. These methods primarily address issues of a creative nature and the motivational factors that drive consumers' purchase behavior. They may be considered exploratory in nature as compared to the confirmatory nature of quantitative consumer research methods, and often allow the investigator to explore more deeply the factors that underly consumer behavior.

A. Personal Interviews

Borrowing from the discipline of psychology, in-depth, personal interviews with consumers can yield valuable information about consumer attitudes and dispositions toward foods. However, this technique has low external validity because the time and effort involved in personal interviews usually results in small numbers of respondents and is unlikely, therefore, to provide representative data about the consumer population to which the investigator would like to generalize. However, personal interviews can be used quite effectively to generate hypotheses that can later be tested using large-scale, quantitative surveys. Recently, personal interview techniques have seen somewhat greater use in consumer acceptance research, due to their use in "laddering" techniques (122) that seek to uncover the cognitive structures that underlie consumer perceptions and behaviors toward foods. Such factors as the use of standardized questionnaire protocols and interviewer training and consistency will affect the reliability and validity of interview information. However, personal interviews do allow for a level of detailed questioning and understanding that is not practical or possible with other, more quantitative techniques, such as written surveys.

B. Focus Groups

Focus groups are a form of group interview. Ordinarily from 8–12 respondents are selected from the community representing some relevant component of the marketplace, either demographically and/or on the basis of product usage. The sessions are held either in homes or in central testing facilities that are designed with one-way mirrors and sound/video recording equipment. A moderator or facilitator who has been trained in group dynamics and who leads the group discussion according to a predetermined script of topics leads the sessions. A typical focus group lasts from 1–2 hours.

Information from focus groups can be used to develop and/or evaluate product packaging concepts, advertising themes, and to help develop appropriate questions for quantitative surveys. Focus groups can also be conducted as a follow-up to a quantitative survey in order to help understand the results (this is typically done using respondents who represent those consumers who either liked or disliked the tested product). The interested reader should refer to other published papers for further details on the use of focus groups in consumer food research (123, 124).

VI. CONDUCTING CONSUMER TESTS: WHO, WHERE, AND HOW

A. Locations for Testing

The location for performing a consumer test ranges widely, from the laboratory to central locations (churches,

shopping malls, etc.), field sites (especially for institutional foodservices), and even the homes of consumers. The choice of which location to use is partly a function of cost and partly a function of the research objective of the study, i.e. whether the objective is exploratory or confirmatory in nature. For simple exploratory or research guidance tests using a small number of respondents, the laboratory is an appropriate choice. As the need for greater external validity arises, such as when significant resources are to be expended based on the results of the study, it is important to have a location that allows for a greater number of respondents and for more normal consumption conditions. As might be expected, as one moves from the laboratory to the field, the opportunity for controlling testing conditions diminishes, making the need for a larger number of respondents necessary to reach statistically significant findings. The appropriate tradeoff is a management decision that must be made during the test-planning phase.

B. Control of Sample Presentation

The presentation of samples in consumer tests should be made in such a way as to minimize the bias produced by the order of testing. This ordinarily means that samples are presented unlabeled, in a random or balanced order, and identified with a non-biasing, e.g. random three-digit, blinding code. The size and temperature of the samples presented is a function of the amount of product that is available, the total number of different products, and the degree to which the researcher wishes to simulate actual eating situations. Ideally, a normal serving size and temperature would be used. However, the problems of sensory adaptation, post-consumption satiety, and practical time constraints usually lead to compromises, so that interpretation of the results must take into account the specific nature of the serving conditions. The location of testing heavily interacts with these decisions, since what is feasible in the laboratory or in the home will argue for one type of presentation over another. In general, it is only possible to approximate the actual consumption conditions, since samples are rarely presented as part of a meal situation. If only food concepts are to be evaluated, such as in conjoint analytic studies, computer presentation can also be utilized.

C. Control over Ambient Conditions

As with sample presentation, control of ambient conditions is dependent upon the testing location. In the laboratory a great deal of control can be gained over lighting, temperature, noise, etc. Figure 56.5 shows a typical laboratory consumer testing situation, in which a consumer is seated in an individualized sensory testing booth that is light, sound and temperature controlled. Food samples are presented to consumers through openings from a kitchen area, which minimizes cooking odors and any visual bias from preparation procedures. The consumer has access to rinse water and a computer terminal/keyboard for viewing questions and entering responses. Of course, less control is possible in central location sites, and control may be minimal in home-use tests or in actual field locations. The consequences of this lack of control will vary depending on the nature and differences among the products evaluated. However, in all cases, it is appropriate to exercise as much control as possible over testing conditions to maximize the likelihood of finding statistically significant and meaningful differences among products. Again there is a tradeoff between being sensitive to possible differences and representing actual eating situations. (The reader is referred to Chapter 57 for further details on sensory testing facilities, controls and procedures.)

FIGURE 56.5 Consumer panelist judging the liking/disliking of foods in a computerized sensory testing booth.

D. Selection of Respondents

The ideal test population for most consumer research is a cross-section of marketplace consumers of the product within the geographical area in which the product is marketed. However, in practice, this target population may be difficult to access. In general, the most common types of consumer groups utilized in testing are 1) shoppers in supermarkets or malls in the geographical area of interest, 2) residents of the local community who volunteer to test products at home or at central test locations and who have been screened to meet certain demographic, psychographic or use criteria, and 3) random samples of employees working in a research or manufacturing facility where the testing is to be conducted. Such consumer samples may be highly stratified and selected to match exacting norms of the target population, e.g. age, gender, education, income, geographic residence, ethnic origin, religious affiliation, or employment, or they may be simply convenience samples, chosen for their ease of access and their presumed similarity to the target population.

Lists of respondents may be obtained from commercially available compilations, telephone directories, and random telephone numbers. Whatever source or method is used, limitations on true randomness or representativeness should always be considered in evaluating the results of a consumer test. Also, in all cases, the individuals must be untrained in sensory methodology and users of the product or product category being tested. A minimum of 50 consumer panelists is required for most consumer testing applications, although the number may be considerably larger when important decisions are to be based on the obtained data (125). The choice of respondents also depends in part on the location of the test. It is not uncommon to simply have a convenience sample in a shopping mall intercept study. In some instances a quota sampling procedure is used so that the number of respondents in each category of interest is represented in a predetermined fashion.

E. Internet-Based Testing

For the evaluation of product concepts, use of the Internet has recently become quite popular (126). Respondents can be obtained from a variety of commercially available sources. Important considerations in the conduct and interpretation of data collected in this manner is the length of time subjects will be willing to spend and the possible non-representativeness of those who have internet access and who volunteer for such testing.

VII. FACTORS INFLUENCING CONSUMER ACCEPTANCE

A. Situation and Context

The study of consumer food acceptability is complicated by the fact that foods are typically eaten within a specific situation and context. The situation and context may include a variety of environmental factors, e.g. where and under what physical conditions the food is eaten, social and cultural factors, e.g. with whom and for what purpose the food is being consumed, and other factors related to the meal context, e.g. what other foods and beverages are being consumed at the time. Such influences can have a profound effect on consumer ratings of the acceptability of foods. Almost all laboratory studies of the consumer responses to food attempt to limit these influences by exerting great control over these "extraneous" variables. This historical approach of conducting sensory consumer research in a sterile laboratory environment has led some investigators to call for more testing of foods in realistic contexts and situations (127, 128).

One obvious factor that can influence consumer liking of foods is the ambient environment in which the food is presented. A cold beverage on a hot day seems to taste better than the same beverage on a cold day. This phenomenon is often explained as being the result of "alliesthesia", a theoretical mechanism by which the perceived pleasantness of a stimulus is influenced by its usefulness to the body, as determined by internal bodily states (129). The effects of alliesthesia have been found for taste, olfactory, and thermal sensation (129–131), and the general conclusion to be reached from these studies is that bodily deprivation levels can modulate the perceived acceptability of food.

Consumer researchers have also studied the influence of a number of situational and contextual variables that operate in naturalistic dining situations for their effect on food acceptance and consumption (132–138). These variables have included the physical dining environment, meal variety, meal cost, and the effort required to obtain and consume the food. Almost all such variables influence consumption of the food, while some also influence acceptance. For example, the effort required to obtain food has been shown to have a large effect on consumer consumption (139–142). However, changes in acceptance have been less reliable (142). Changes in price influence both selection rates and acceptance (143). Further studies have identified a major difference in acceptance ratings of foods depending upon where the foods are served, e.g. in institutional or non-institutional foodservice settings. The same foods served in a pleasant sit-down restaurant environment are better liked than those served in a less pleasant environment, e.g. in a cafeteria (144). In the case of food variety, a number of studies have shown dramatic effects on both food acceptance and consumption in cases where food variety is limited (145–148). The general conclusions that have followed from these studies are that food liking and consumption in a natural eating environment are greatly dependent upon "the situational variables which make it more or less *convenient* for us to eat and which signal mealtime" (136).

B. Cultural and Social Influences

Social and cultural influences can also play a significant role in influencing consumer perceptions and liking of food. One only needs to consider the strict dietary avoidance of pork by Jews and Muslims, the avoidance of beef in India, or the avoidance of eggs by certain African tribes (149) to gain an appreciation of the influences of culture on food likes and behaviors. These differences can also be based on regional variations within the same country. For example, brown eggs are preferred in the Northeastern United States, but in few other areas of the country. Other social and cultural factors, such as income level and status in society can also influence liking/disliking toward certain foods, as reflected in the gourmet and health food preferences of many "upscale" consumers. Other social effects on consumer liking of foods derive from the social influences of parents, peers, leaders, and heroes. For example,

mother-daughter and father-son food preferences are much more alike than those of mother – son or father-daughter (150). Other social imitation effects on food acceptance have been well documented (151, 152) and are the basis for the numerous food advertisements that rely on celebrity endorsements of a product.

C. Information

Information can also have a powerful influence on consumer liking and behavior toward food. Such information can take various forms, including brand and label information, ingredient information, nutrition and health claims, information about processing and preservation techniques, and various forms of product advertising. These influences of information are sometimes referred to as "framing" effects, because they are sensitive to the specific context and wording of the information (153, 154). One hypothesis of how information may come to influence affective ratings of food is through their influence on consumers' expectations of liking. This hypothesis is an extension of expectancy — value theories of consumer behavior that posit that value judgments result from a comparison of the expected performance of a product or service with its actual performance. Thus, the degree to which the product or service confirms or disconfirms expectations about it, will determine the degree of consumer affect. In the marketing and consumer psychology literature, there are a number of models to predict the effect of disconfirmed expectations on perceived product performance or satisfaction. These models have been reviewed and extended to issues of food acceptance by Cardello (113) and Deliza and MacFie (114).

Over the past 25 years, the bulk of empirical research on the role of disconfirmed expectations on product performance has supported an assimilation model (155) of these effects (156–159), that is, consumer acceptance increases in those cases where the expectation for the product is high and decreases in those cases where the expectation is low. Support for such a model has been found in several food-related studies. Figure 56.6 shows data from one such study on cola beverages (160) in which subjects were led to expect that they would receive either their preferred brand of cola beverage or a non-preferred brand (as determined in blind taste tests). In some

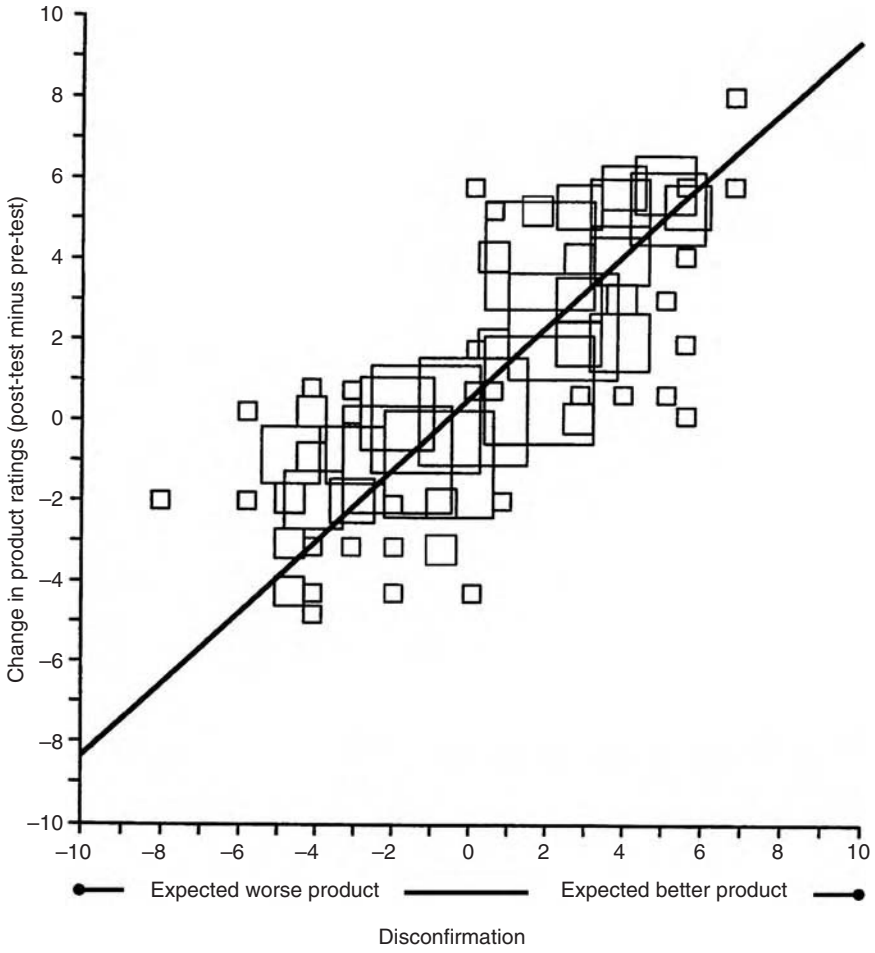

FIGURE 56.6 Consumer data showing how product liking increases as product expectations increase (160). (The size of the boxes reflect the number of data points falling at that location.)

cases, subjects were given the cola that they expected, while in other cases they were given either a *more* preferred or *less* preferred brand. Pre-trial ratings of excepted liking and post-trial ratings of actual liking were obtained from all subjects. Figure 56.6 shows the change in product liking from the baseline level as a function of the direction of disconfirmation experienced by subjects, i.e. whether they expected a better or worse product relative to the one they received. As can be seen, there was a strong linear association ($r^2 = 0.66$) in the data, showing that post-test liking moved in the direction of the expectations. Similar results to these have been found in studies where expectations were manipulated by varying fat-content information (59) and in studies with yogurt (161) and orange juice (162, 163). Similar effects have also been reported using consumption as a dependent measure of product acceptance (164).

D. Perceptions of Risk

With recent advances in food processing techniques, one category of foods for which liking is especially susceptible to the influence of information and other cognitive factors is foods processed by novel and emerging technologies. Like most new products, optimizing the sensory quality of these foods is critical to their success in the marketplace. However, optimal sensory quality, on its own, will not guarantee success. The reason for this is that information about the nature, source, or processing of the food can have a profound effect on consumer liking, choice and purchase decisions. This is especially true when the nature, source or processing of the food is perceived by the consumer to impart some risk to its consumption. e.g. irradiated and genetically modified foods.

The study of consumer risk perception began in the early 1970's with the pioneering work of Starr (165), Fischhoff et al. (166), and Slovic et al. (167). Prior to this time, the risk associated with a new technology was based on expert analyses of risk. These analyses were based on actuarial data related to accidents, fatalities, or losses accountable to the technology. However, this *technical/rational* approach to risk was often found lacking when it came to predicting consumer reactions to novel technologies. Frequently, consumers had great concerns about technologies that had relatively low risk from an objective, i.e. technical/rational, risk analysis standpoint. In response to these discrepancies between consumer perceived risks and expert opinions of risk, researchers adopted a new paradigm for risk perception. This new *normative/value* risk model defined risk as a perceptual construct, one that must be evaluated by lay people on the basis of *subjective* evaluations of risk. In keeping with this focus on perception, the study of risk has adopted many of the same univariate and multivariate psychometric techniques commonly used today to assess consumer perceptions of the sensory qualities of foods.

In a comprehensive study of consumer risk perceptions (168), a factor analytical approach was used to determine the perceived risk associated with a wide range of everyday hazards, including many "technological" hazards. Several of the characteristics found to be important to perceived risk included the degree of control that the consumer has over the risk, whether the risk is voluntary or involuntary, whether the risk is known or unknown, fatal or non-fatal, observable or unobservable, and whether the effects of the risk are immediate or delayed. These hazard/risk characteristics exemplify the kinds of cognitive variables that must be considered when assessing consumer perceptions and acceptability of foods processed by novel or emerging technologies.

E. Consumer Risk Perceptions about Foods Processed by Novel Technologies

Although the mainstream literature on risk perception has served to identify critical variables important to consumer risk perception for many technological and non-technological hazards, consumer perceptions of risk for specific food hazards have been left to other investigators. Over the past several years, numerous investigators have utilized the normative/value approach in surveys and studies that have assessed the perceived risks or "concerns" of consumers toward such specific food safety issues as irradiated foods, genetically engineered foods, foods containing pesticides, foods processed using laser light sources, and microbially contaminated foods (169–188).

In a recently conducted study (189), the effect of consumer concerns and expectations on liking for foods processed by different food processing techniques was examined. In this study, consumers tasted and evaluated chocolate pudding that had been thermally processed. Subjects rated their liking of chocolate pudding (no other information presented) and their level of concern for several different food processing technologies ("irradiation", "high voltage pulses", hydrostatic pressure", "pulsed electric fields", "non-thermal preservation", and "the addition of bacteriocins." Subsequently, they were provided information about the chocolate puddings that they would taste. In one condition, consumers were told that the product they were about to taste had been processed by one of the six food processing technologies, e.g. "this sample was processed by pulsed electric fields". In a second condition, the name of the technology was accompanied by an objective description of that technology, e.g. "in irradiation processing, foods are exposed to a source of ionizing radiation, e.g. cobalt 60, for short periods of time". In the third information condition, consumers were told the name of the technology, given the description of it, and provided a safety benefit statement, i.e. "this process is entirely safe and avoids the thermal damage done to foods by heat pasteurization". After exposure to the information manipulation, consumers rated their expected liking of the product, before and after seeing it, and were then presented the sample to taste and rate for liking.

Results showed a large gender difference, with females showing much greater concern for all the food technologies, than males. Of greater overall importance however, was the fact that correlations of "concern" ratings for the different food processing technologies with expectations of liking for the chocolate pudding that the consumers believed had been processed by that technology were all negative and highly associated for the 3 conditions. These results revealed that as consumers' concerns about the risk of a technology *increase*, expected liking of foods processed by that technology *decrease*. Still more significantly from the perspective of marketing these foods, the diminished expectations were shown to result in systematic decreases in rated liking for the tasted products. On the positive side, this research also demonstrated that factual product and process information, product exposure (merely seeing the product), and a safety/benefit statement all had positive effects on expected liking and acceptance of the tasted product. The data confirm the fact that good communication practices and effective marketing strategies can be utilized to overcome negative images created by risk perceptions or product stereotypes and to significantly improve the probability of consumer market success for foods processed by emerging technologies.

VIII. FUTURE DIRECTIONS IN CONSUMER RESEARCH

As the food industry continues to accelerate its development of novel ingredients, processes and end-uses for foods, so too will the need for new and novel approaches for measuring consumer acceptance accelerate. The dramatic challenges to consumer acceptance that new food processing technologies have raised to date will undoubtedly grow as food science continues to push the frontiers of food processing and preservation. These developments will require new and more powerful methods for assessing the social, psychological, health, and values-based aspects of these new technologies on consumers' liking and willingness to purchase these future foods. In addition, much greater reliance on novel consumer acceptance technologies will likely result from the opportunities that the Internet and other web-based interactive technologies provide for obtaining access to large numbers of consumers with relatively little cost or time-investment. The joint contribution of these influences (advances in food science and web-based testing) will continue to keep an important focus on the theories and methods required to conduct effective consumer acceptance research on foods.

57 Sensory Science: Methodology

Joel L. Sidel and Herbert Stone
Tragon Corporation, Redwood City

CONTENTS

I. INTRODUCTION AND OVERVIEW

Measuring the sensory properties of foods and relating these properties to consumer acceptance is a major objective and accomplishment for sensory evaluation. These achievements are possible as a direct result of advances in the science, development of valid and reliable methods, education of research and application professionals, development of cost efficient and well run sensory programs, and institutions and commercial companies that support these programs. The latter is directly related to the expected and realized commercial benefit of sensory tests.

This chapter provides the reader with an overview of sensory evaluation, its uses and limitations. We highlight important developments, current thinking and the current status of the science. The interested reader will find more detail in several books published on the topic, most notably, Lawless and Heymann (1), Stone and Sidel (2), and Amerine, Pangborn, and Roessler (3).

A. Historical Background

The food industry, similar to other consumer product industries, traditionally viewed sensory evaluation in the context of the technical "experts" who through education (e.g., learning to judge the quality of dairy products as part of dairy science education) and years of accumulated experience were able to describe company products and set standards of quality by which raw materials would be purchased and products manufactured and marketed. Three noteworthy developments led companies to evolve away from reliance on the single technical expert, and to reliance on formal sensory panels and procedures. First, products became more complex, and technical experts were less able to predict consumer acceptance. Second, companies could not wait the 2 or more years for an "apprentice" to assume evaluation responsibilities. Thirdly, the emerging field of sensory evaluation was demonstrating the need for, and value of, formal, unbiased, and statistically relevant procedures for qualifying subjects, evaluating products, and communicating actionable results.

During the 1940s and 1950s, sensory evaluation received additional impetus through the U.S. Army's Quartermaster Food and Container Institute, which supported research in food acceptance for the armed forces (4). It became apparent to the military that adequate nutrition, as measured by analysis of diets or preparation of elaborate menus, did not guarantee food acceptance and consumption by military personnel. The importance of the sensory components of food was acknowledged, and resources allocated to studies for determining how best to measure food acceptability. Several psychologists were hired by the military to develop methods for measuring food acceptance, and this practice was continued when the Army's food research laboratories were moved to Natick, MA in the 1960s. The original group of psychologists chose to not participate in the move to Natick. They disseminated their knowledge and interest in sensory evaluation further into the food industry by joining product companies (e.g., Coca Cola, Pillsbury, and General Mills), contract research organizations (e.g., Battelle Memorial Institute) or founding research companies (e.g., Peryam and Kroll Corporation).

Government and industry interest in sensory evaluation encouraged additional developments. For example, in the 1950s the Arthur D. Little Company introduced the Flavor Profile Method (discussed below), a qualitative form of descriptive analysis that did not rely on an individual expert, and formalized subject screening and training procedures. Private contract research companies continue to play an important role through sponsoring workshops, developing proprietary methods, assisting product companies establish internal sensory capabilities, and conducting research studies.

By the mid-1950s, a few universities were offering a series of courses in sensory evaluation; most notably the University of California at Davis (UCD). Many students from the U.S. and abroad introduced the science into companies, while others went on to teach the science at the university level. Currently, a wide range of universities and technical institutes worldwide offer programs in sensory evaluation, and in 2002 UCD initiated a sensory course online: "Applied Sensory Science and Consumer Testing Certificate Program for Distance Learners."

Also during the era of the 1950s and 1960s, various technical and scientific societies organized activities and published procedures focusing on sensory evaluation and the measurement of flavor. These included Committee E-18 of the American Society Testing and Materials, the Food and Agriculture Section of the American Chemical Society, the European Chemoreception Organization, and the Sensory Evaluation Division of the Institute of Food Technologists.

B. Defining Sensory Evaluation

The Sensory Evaluation Division of the Institute of Food Technologists defined sensory evaluation as "a scientific discipline used to evoke, measure, analyze and interpret reactions to those characteristics of foods and materials as they are perceived by the senses of sight, smell, taste, touch and hearing" (5). This definition emphasizes several important points, including 1) the scientific focus of the discipline, correctly distancing the discipline from art and opinion; 2) although implied and not directly stated, the foods and materials represent physical, rather than cogitative, stimuli; 3) implicit in the definition is the concept of the measurement and analysis of perceptions from information obtained through the five senses; and 4) the definition forwards a distinction between the perceived characteristics of foods and materials and their actual

physical properties. To this latter point, the definition focuses on the importance of perception for understanding the impact of a product's physical properties; implicit in this is the notion that in sensory evaluation "perception is reality." This has enormous implications on determining how subjects are selected, and, when necessary, trained, what sensory evaluation should measure, and the measurement method.

The evolution of sensory evaluation as an independent discipline in the 1940s and 1950s produced unique methods for determining difference. These and other sensory method developments are a reminder that although they have a common lineage, psychophysics and sensory evaluation have very different objectives. Sensory evaluation focuses on measuring the responses of people to products, and application of findings to action-oriented decisions about products. Psychophysics focuses on the measurement process and explaining the behavioral mechanisms behind sensory responses. Both objectives are important, and each has its own criteria for success.

C. Classification of Sensory Methods

There are several sensory methods, differentiated primarily by objective, measurement procedure, subject qualification, and various combinations of these factors; and new methods continue to be developed. As reported in Stone and Sidel (2), sensory tests are classified primarily by type of test in a three-category classification system, which are: discriminative, descriptive, and affective tests. (We view discriminative and descriptive as analytical tests and thus could consider two categories; analytical and affective tests.) There are several different tests within each class, and they are described in greater detail later. Discrimination tests measure whether there is a perceived difference between products, descriptive tests measure perceived attributes and their intensities for a product, and affective tests measure product acceptance or preference. Affective tests are discussed in the current handbook under the topic of Consumer Testing.

D. Sensory vs. Instrumental Testing

The development of instruments to measure food and beverage characteristics such as appearance, aroma, taste, and texture has a very long history, as has research into correlating instrumental and sensory measures. Interest in this relationship in the food and beverage industry is based in part because it represents a potential means of reducing reliance on the human judgment, which some view as variable and subjective. Value, efficiency, and economy are possible where instrumental measures can be effectively substituted for sensory measures. This is especially true in product quality assessment.

An extensive literature is available describing sensory/instrumental relationships for texture measurement, where mechanical devices for measuring texture have been described in the literature for more than a century. Bourne (6) provided an excellent review of the subject describing mechanical devices to measure product changes, particularly the fruit ripening process, or to simulate the chewing process to measure meat tenderness. The interested reader is also referred to the *Journal of Texture Studies*, especially the publications of A.S. Szczesniak and her collaborators. While such mechanical devices have undergone substantive change in terms of sensitivity, measurement, design, etc., the basic principles have remained unchanged, to wit, creating a mechanical device to measure what humans perceive.

The main difficulty in simulating sensory behavior by an instrument is due to the complex simultaneous activity ongoing in the mouth during eating and drinking. The upper jaw remains stationary while the lower jaw is capable of several different motions to hold, bite, tear, and masticate. At the same time, the highly muscled tongue gathers, moves, and compresses stimuli, the salivary glands contribute moisture and lubricant to the process, and swallowing provides control of volume in the mouth while momentarily limiting intake to the mouth. To our knowledge, this multidimensional activity cannot be reproduced with current instrumentation.

The history of odor detection has always included both human and instrument systems. The earliest instruments began with measuring total volatiles. This was followed by development of chromatographic techniques and gas-liquid chromatography (GLC) which enabled separation of chemicals as well as ability to separate specific chemicals at very low concentrations; e.g., ppm (parts per million), ppb (parts per billion) and less, to facilitate their identification. Subsequent developments enabled integration of the chromatographic separation with even more sophisticated instrumentation such as mass spectroscopy to more precisely clarify chemical structure, and so forth. Amerine et al. (3) describe limitations and early efforts to combine GLC with sensory panel results. Volatiles from foods are trapped and collected for sensory evaluation. Later refinements included development of equipment containing multiple odor ports that delivered the separated odorant at prescribed dilutions simultaneously to sensory panel members. Gas chromatography-mass spectrometry are used to analyze perceived odors, and Noble (7) described the use of instrumental analysis for the sensory properties of foods.

During this same time period, Schutz, Veley, and Iden (8) and Wilkens and Hartman (9) described their efforts to devise other systems for the detection of odorants. Schutz and co-workers investigated use of specific enzyme systems associated with olfactory tissue that were reactive to odorants and correlated results with the physical and chemical properties of those odorants. At the time, the constraints of separation technology, enzyme stability, and

related issues impeded further development of this approach. Wilkens and Hartman, on the other hand, took a very different approach to the problem; they devised an instrument, an electronic analog that relied on microelectrodes made from combinations of metallic wires for the detection of odorants. These authors were able to demonstrate differential response sensitivity to various volatile chemicals with just a few microelectrode metal combinations. Today's "Electronic Noses" and "Electronic Tongues" represent significant advances in electrode specificity, sensitivity to individual chemicals, use of computer chip technology for analyses, and in accessing pattern recognition and neural network statistics as an aid in data interpretation (10, 11, 12, and 13). Bleibaum et al. (11) concluded from their research "the electronic tongue and electronic nose, in combination, can be used to predict the sensory characteristics and their relationship to the quality of apple juices measured by consumers." The degree to which these odor and taste detection instruments, or those yet to be developed, are incorporated into routine product development and quality control activities will depend on how well they correlate to important sensory measures, and are economical and safe to operate in those respective environments.

Correlating sensory flavor attributes and chemical measures has become almost routine in research and quality control, as has correlating sensory and Hunter color measures. Instrumental and sensory correlations also have been described for visual clarity and turbidity (14).

Before leaving this topic, we are reminded that sensory information is uniquely different than information obtained from a physical instrument (a point often overlooked when creating a mechanical system to substitute for a physiological system). It represents the relatively simultaneous integration of information from all the senses, in conjunction with cognitive factors that include learning and expectation. In this sense, sensory information is multidimensional whereas instrumental information is almost entirely one dimensional. Although we can instruct subjects to not pay attention to certain attributes, it is false to assume that those attributes do not influence the subject or his response. Instruments can be useful in sensory evaluation when there is a good understanding of the relationship between those measures, sensory perception, and consumer behavior. At present such relationships are the exception, and considerably more needs to be accomplished before instruments represent a practical alternative to sensory measures.

II. SENSORY EVALUATION FACILITIES

The typical sensory evaluation facility in a R&D center consists of separate areas for testing, panel training, and administration. Satellite facilities are sometimes required to accommodate testing that cannot be accomplished in the immediate vicinity of the research center.

A. Testing

A product evaluation area typically consists of the following three functional areas, adjacent to one another and separated by walls and doors for easy communication and passage. This area is best located for its ease of accessibility to the subjects and for its low level of odors, noise, and vibration associated with more intense R&D and manufacturing activities.

1. Reception Area

The reception area is typically a well-lit and comfortable room located off a main corridor, and offering easy access to the test area. It is equipped with a receptionist desk and chair, telephone for contacting subjects, comfortable chairs where subjects are either seated while receiving instructions or where they wait prior to proceeding to an assigned sensory booth. A blackboard or bulletin board is located on a wall near the receptionist desk and identifies the product category and number of products that are to be tested in the session. A table is also provided for those situations where subjects are offered a reward, or "treat" (juice, coffee, cookies, candy, etc.), immediately following participation in a test. The room should allow easy access to, yet visual separation from, the sensory booth area to minimize distraction from early arriving subjects to subjects still seated in the sensory booths. The dimensions for the reception area depend on the number of subjects it has to accommodate prior to their proceeding to the sensory booths.

2. Test Kitchen Area

The test kitchen area and materials used in this area typically represent a well-equipped commercial, or heavy duty home, kitchen. The area must accommodate preparation and cleanup equipment, equipment and supply storage, product preparation, holding and serving activities, and workstations for kitchen staff. One or two large central islands for product preparation, showings, and holding for serving are recommended, and these must allow for unencumbered foot traffic flow around them during product preparation and serving. Airflow from this area is an important consideration, and food preparation aromas from here must be exhausted away from the sensory booths. Serving counters need to be high enough to minimize posture stress during serving, and wide enough to accommodate products, supplies, and scorecards for subjects seated in sensory booths with pass through into in the serving area. All under- and above-counter space should be utilized for storage, and an adjacent storage room is recommended where possible. A door from the kitchen to the reception area will facilitate any needed communication between the receptionist and kitchen staff, and provide easy access to treats and materials needed to clean and maintain the reception area. Telephones in this area should be equipped with a

visual alert, so that the auditory alert may be turned off during testing.

3. Sensory Booths

Individual sensory booths need to minimize visual and other potential distractions to the subjects from one another, from the kitchen, and from the reception area during the evaluation process. Dimensions, surface colors and materials, lighting, ventilation, pass-through structure, expectoration system, signal system, and direct data entry systems must be considered when designing sensory booths for food research. Clean filtered air should flow into the booth area, and air should flow from the booths to the kitchen, and not the reverse. The interested reader will find useful booth design information in several texts, and is directed to Eggert and Zook (15) and Stone and Sidel (2) for additional detail. Most sensory booths are permanent structures; however, temporary booths can be constructed from sturdy coated art board or plywood, and these can be made collapsible or foldable with hinges or fitted slots for portability. Temporary booths can be moved to off site testing locations.

B. Panel Training

Open discussion is required at various times during panel training, and these discussions can be held in a conference room, focus group facility, or a dedicated training room. The room should be proximal to the test kitchen or product preparation area, be readily accessible by subjects and sensory staff, and free from distraction as described above. Sufficient blackboard, wall, or easel space is required to accommodate attribute lists developed by the panel during training. A one-way mirror to an adjacent viewing room, equipped with video and audio taping capabilities, can accommodate observers without distracting subjects during training.

C. Administration

The staff required to support project planning, report writing, data processing, and general administrative functions should be located in a common area accessible from a main corridor and near to the test kitchen. Access to the administrative area should not require passage through the test area.

D. Satellite Facilities

Most sensory tests are conducted in well equipped laboratories as described above and are associated with company headquarters and a main research center. Tests also may be conducted in locations specific to product quality maintenance and production. Such satellite facilities are smaller, as they require less preparation equipment and space, and fewer booths. Regardless of where done, the same general rules for maintaining these locations apply; that is, a clean, quiet, and distraction-free test environment.

III. ORGANIZING SENSORY PANELS

There are several steps to developing and organizing effective sensory panels. Subjects must be recruited and qualified, must participate in tests, be motivated, and have their performance monitored.

A. Recruiting Subjects

Subjects for sensory panels may be recruited from a general population of consumers local to the sensory facility, or from a company's employee list. Because sensory panel membership is performance related, the decision about which group is best to recruit is influenced by factors of convenience, cost and availability. Subjects may be recruited randomly by telephone, mall intercept, or electronically. Alternatively, recruitment notices can be sent to prospective subjects, or posted in locations frequented by them. The recruitment notice should state that people interested in joining a food evaluation panel are being sought, and individuals who qualify will be required to participate for 1 to 3 hours a day for an extended period of time. People responding positively to the recruitment request are screened further for their availability and willingness to evaluate specific food categories that will be tested. To reduce early panel attrition, it is advisable that subjects are likers and users of foods in the category. Twenty-five to thirty interested and qualified subjects should be invited for sensory screening.

B. Screening and Qualifying Subjects

Sensory panels require subjects who are qualified based on their sensory skills and availability. A variety of tests are used to determine sensory skills, with some being method specific (e.g., Texture Profile®). Most popular, but not most useful, screening methods used by sensory professionals are: basic taste and odor thresholds, basic taste intensity ranking, identification of selected taste and odor compounds, texture stimuli for texture-specific panels, and discrimination of simple compounds and more complex finished products. Successful screening, especially when based on the latter procedure, can eliminate poor performing subjects, but does not guarantee successful performance. No evidence has been provided that demonstrates that threshold testing or use of "standards" actually identifies better performing subjects. However, eliminating subjects who cannot discriminate product difference at better than chance has proven to be a good predictor and is sufficient justification for continuing the latter practice. For discrimination and descriptive panels we recommend using discrimination screening tests within the test product

category. Screening should involve at least ten product pairs, given in replicate, covering all sensory modalities and increasing in difficulty from easy (85 to 100% success rate) to very difficult (50% or less success rate).

C. Scheduling Subjects

Subjects should be scheduled to arrive at the sensory facility at the same time, receive their instructions as a group, proceed to their assigned booth, and begin their evaluation. Scheduling avoids conflicts, assures similar instructions and products are given, provides order, and establishes this as a serious professional activity. Allowing subjects to arrive at the facility and begin testing whenever they like introduces potential error from a variety of sources including product stability, extending the session too long, and traffic congestion in the test area. Most testing is done in the morning from 9:00 to 11:30 and in the afternoon from 1:30 to 4:00. Suppliers that use consumers trained for sensory panels may schedule testing for the evening hours until 9:00 or 9:30 pm.

D. Personal Requirements

Subjects should be informed that they are expected to arrive on time at the test location, and to not have consumed food or flavored beverages, or smoked for approximately ½ hour before testing. They are asked to not use fragranced personal care products, perfumes, and so forth, when reporting to the test site, and they are cautioned to not wear clothing that has retained aromas from previous contact with these products. Subjects are discouraged from discussing product tests other than during sessions conducted by the panel leader. In many cases they are required to sign confidentiality agreements, and in tests involving experimental ingredients or processes may be asked to sign release of liability forms.

E. Test Orientation and Instructions

Subjects reporting to a site are provided with a verbal orientation. The orientation informs subjects about the product category, number of products to be evaluated, the evaluation procedure, and any procedural variations that differ from previous evaluations. Written instructions are posted in each test booth, and subjects are encouraged to read those instructions before evaluating the first product, and again during rest intervals between products.

F. Incentives and Motivation

Positively motivated subjects are more likely to follow test rules, have lower panel absenteeism, remain focused on the task, and are less likely to be negative and disruptive. Although positive motivation does not guarantee satisfactory performance, it increases that likelihood, and is beneficial for the other subjects and for the test staff.

Positive motivation begins with informing subjects that the task is important, maintaining an efficient and professional test program, and providing positive reinforcement where possible, without disclosing information that can influence upcoming tests. Following testing, a daily treat, such as a beverage, baked good, confectionery, fruit, vegetable and dip immediately reinforce subject participation. These items need to be thoughtfully presented and fresh. Once they become routine or are leftovers from previous tests, they lose their reinforcing value. Where there is insufficient space for a treats table, or where one would interfere with testing, a coupon of equal value and redeemable at the company cafeteria can be substituted. Holidays provide the opportunity to incorporate a special theme into the daily treat.

Long term incentives include various forms of recognition rewarding participation and attendance rather than skill. A letter of commendation from a senior executive, company newsletter recognition for the "taster of the month," an annual dinner out or panel party, and accumulating points toward a gift or raffle have proved successful. Incentives that reward the subject and publicize the sensory program are always a good idea. Cash payments are usually reserved for non-employee subjects. Employees should not be compensated for their participation.

G. Performance Records

Sensory panels use a small number of subjects; therefore, the performance of each subject is important. Performance records track the number and type of panels on which the subject participates and notes any sub-standard areas of performance. An individual subject's failure to find differences where the panel result is statistically significant is noted in the performance record. The information will help to identify where additional training is required for the subject or the panel, or when a subject needs to be excused from a panel.

IV. APPLICATIONS

The growth and success of sensory evaluation is directly related to its positive contributions and variety of applications to product development and product quality. The following section describes many of these useful applications.

A. Product Development

Product development is an activity that ranges from new product development to several planned activities associated with changes to a product or process.

1. New Product Development

The new product development cycle begins with a product idea generated from consumer research or technical

discovery, and is complete when marketing research demonstrates sufficient consumer interest in the new product. The amount and detail of direction consumer research will provide about the sensory characteristics for a new product will differ based on a company's ability to obtain that information. Trained panel (e.g., QDA) evaluations in these consumer studies will provide an accurate description of product differences and similarities, and when combined with consumer preferences will identify sensory attributes and intensities to optimize consumer acceptance. The sensory description for the optimized product becomes the development target. Trained descriptive panels and qualified discrimination panels are used to determine when one or more products satisfactorily achieve or approximate a sensory optimized target.

2. Pilot Plant Scale-Up

A pilot plant is often used during product development as a means for providing test products and quantities supporting research and development without interrupting manufacturing or requiring production size quantities. At the conclusion of the R&D development process, the pilot test product (i.e., formulation and process) will need to be converted to a production product, using production equipment and processes. Differences between pilot plant and production product usually is unwanted; however, they are not unexpected. The manufacturer needs to determine that there is a perceived difference between the two products, and if there is, what are the implications of that difference. Where possible, sensory discrimination tests are used to determine whether there is a perceived difference between the pilot and production products, and where a difference is found, trained panel descriptive tests are used to describe those differences. Product Development will need to determine formulation or process variables responsible for the difference and make necessary changes. If the production product is different compared to the pilot plant product and cannot be modified further, it's impact on acceptance will need to be assessed. This is achieved either through comparison to an optimization model, if one was developed during the development process, or in a consumer test of the pilot and production product. Where production product cannot be modified further and it does not satisfy the company's action standard for acceptance for new product introduction, the new product may be abandoned.

3. Cost Reduction

Cost reduction is an ongoing activity, and where possible sensory discrimination tests are used to determine whether there is a perceived difference between the control and cost-reduced product. Where no difference is found, the cost-reduced product is accepted to replace the current product. A difference usually results in rejection of the cost-reduced product. Where a difference is found, descriptive tests may describe differences to determine whether the difference is for an important attribute or one that may be readily corrected. Caution is advisable relative to using a series of discrimination tests where a successful cost-reduced product replaces the control. For example, if A is not significantly different compared to B and B is not significantly different compared to C, and so forth, A very well may be significantly different when compared to Z. This transitivity can occur when a series of non-significant differences result in a product that is significantly different from the original control. This possibility can be minimized through the use of descriptive analysis, comparing the descriptive profile of the proposed new control to that of reproduced original control or to the historical profile for the original control.

4. Ingredient/Process Change

Alternate ingredients, new equipment, and process changes may be introduced at any time. All changes should be evaluated to determine their potential effect on product perception; the evaluation strategy is the same as described for cost reduction. In situations where a change is required by the business, even where sensory differences are found, consumer tests are recommended to estimate the impact of the change.

5. Ingredients/Purchase Specifications

Sensory requirements are designed into the purchase specification for many ingredients. For example, a prescribed perceived heat level is required for hot peppers that will be used in processed salsa.

B. Product Quality

The objective is to provide a consistent product of appropriate sensory quality, where appropriate sensory quality is defined during the product development cycle. The following describes important areas where sensory evaluation supports the quality mission.

1. Sensory Specification

A sensory specification describes the acceptable range for the most important characteristics of a product. Specification development requires products selected to represent the broad range of production product and possible variation. Products are evaluated by a trained panel and by consumers. The trained panel provides sensory descriptions (e.g., QDA) for each product, and consumers, qualified as likers and users of the product, provide the liking scores. The data are analyzed to identify the most important acceptance predictors (usually about 10 to 12) and the tolerance

range for each, and these results are used to train quality control panels at manufacturing sites.

2. Production Benchmarking

Once a new product has been accepted for manufacture and distribution, production samples are evaluated by a trained descriptive panel to establish the sensory profile for the product when first released for sale. The benchmarking documentation is used for future comparisons and references to the original product.

3. Manufacture Quality

In a manufacturing facility, subjects are screened and trained to evaluate a product at one or more stages of production (and where permitted according to GMP and HACCP requirements). These evaluations can include ingredient receipt and storage, during manufacture, and finished product. For finished product, trained sensory panels evaluate attributes included in the sensory specification. A sensory professional coordinates the activity but is not a panel participant. Subjects evaluate attribute intensities, and the sensory professional uses that information to determine whether to recommend accept, hold for further evaluation, or reject the product.

4. Shelf-Life and Stability

The sensory quality of products deteriorates over time, and the rate of deterioration depends on factors related to ingredients, packaging, handling, and storage. Several different sensory related criteria are possible for determining when the end of shelf-life occurs, and no one criterion is universally accepted. Using a qualified descriptive or discrimination panel, any statistically significant difference for a sensory attribute compared to a control product is a popular choice for determining end of shelf-life, albeit a conservative one. Where a sensory specification is available, stored product is evaluated to access whether it deviates from that specification. A loss of consumer acceptance is another popular criterion used to determine end of shelf-life.

5. Distribution Product

Products may experience abuse after leaving the manufacturing facility; therefore, many companies audit product quality at the retail level. Results from qualified descriptive and discrimination sensory panels are used to measure differences compared to data from the product benchmark or sensory specification.

C. Marketing

Sensory evaluation supports marketing and marketing research activities beginning with new product development, continuing through tracking product performance, and contributing to special assignments such as developing tests and data to support or challenge advertising claims. We briefly describe the role of sensory evaluation in those activities.

1. Monitor Competition

Discrimination and descriptive panel information are used to provide immediate intelligence about the similarity and differences between competitive products and also for tracking changes and trends over time.

2. Advertising/Claim Support

Sensory claims often appear on television, radio, and in mass media print and trade oriented publications. Most claims are comparative and preference related, others may identify specific sensory differences. In either case, the claims can be challenged and damages assessed where the claim is not substantiated. All phases of the research, including subject recruitment, selection, training, testing and the data analysis are subject to examination and challenge. Therefore, it is important that sensory claims are supported by appropriate research that can be defended in the legal system. The research must demonstrate that it is free of bias that could influence the outcome, and that sound testing principals are used.

3. Category Review

A broad array of products, often between 12 to 24 and representing the competitive and sensory range for a category, are evaluated by a trained descriptive panel and by consumers. Reviews for a rapidly changing product category may be scheduled as frequently as 6 month or 12 month intervals. The information is used to monitor the competitive market on a broad scale and to track changes and trends over time.

4. Product Optimization

This category of sensory research is conducted for the purpose of optimizing consumer liking for a product. Two different approaches are used for selecting products for this research; one is a design of experiments (DOE), and the other is a category review (CR). The DOE limits products to those the researcher modifies according to a prescribed experimental design (e.g., factorial, RSM); the CR includes a range of products having sensory differences representing the product category. A qualified discrimination panel may be used to eliminate redundant products and a trained sensory panel to provide a descriptive analysis of the products. The statistical analysis relates the consumer, trained panel, and analytical (if included) data sets to determine combinations of sensory and analytical

attributes that best predict optimal consumer liking. The descriptive panel is used for the follow-up research to evaluate test products until one or more satisfy the optimized sensory target.

V. DISCRIMINATION METHODS

Discrimination tests are classified as analytical methods, and are used primarily to determine whether there is a perceived difference between products. The tests may be directional, where the attribute of difference is named, or non-directional, where the attribute of difference is not named. Discrimination tests are relatively uncomplicated to administer (most use a simultaneous sample presentation), analyze, interpret, and report. They are used in sensory studies primarily to screen products as a prelude to other types of tests (e.g., descriptive or consumer), or to screen subjects for participation in descriptive and other sensory analytical panels. Discrimination tests are used in quality control and manufacturing to identify non-conforming product. They may not be the method of choice where inherent variability within samples is large.

Discrimination testing dates back to the psychophysics of the 1800s and procedures used for absolute and difference threshold determination. The following section discusses discrimination tests used by sensory scientists to make product decisions, without reference to competing psychophysical theories or models attempting to explain the discrimination process.

A. General Requirements

Following are some requirements for discrimination tests. We are reminded that these tests are sensory analytical tests, and as such use small numbers of screened and qualified subjects. By small numbers, we mean 20 to 25; however, there is no rule that precludes more or fewer subjects.

1. Subject Selection

Subjects for sensory analytical tests are screened for their sensory skill, and for discrimination tests this means for their ability to detect differences between products. Using consumers or other subjects that have not been screened for sensory acuity is not common practice or is it recommended. Unskilled subjects increase the risk of a Type II error (i.e., missing a real difference); large numbers of subjects, typical for consumer tests, increases the risk of a Type I error (i.e., finding a false difference). A previous section provides a detailed discussion about subject screening.

2. Test Design, *N*, and Replication

Balanced design serving orders are typical for discrimination tests within and between product trials, except for those three sample tests where it is prudent to reinforce the sensory characteristics of a control product that is a benchmark. For each trial in this fixed order scenario, two of the three products are the control and the third is the test product.

Sensory analytical tests typically use small numbers of subjects screened for their sensory skills, and the discrimination model is no exception. About 12 screened and qualified subjects are optimal, and together with a recommended replicate trial provide sufficient data for statistical analysis. Replication is recommended for analytical sensory tests, because each subject contributes a large percent of the data and it is important to know which subjects have difficulty replicating their response. An inability of a subject or a panel to replicate responses can provide important information about problems with the subjects, procedure, and products.

3. Data Analysis

Unless noted otherwise below, statistical testing for discrimination data is typically based on expansion of the Binomial distribution. Published tables are available in the literature for determining the number of correct judgments required for statistical significance (2, 15). These tables provide for 1-tail and 2-tail tests and for chance probability values of 0.5 and 0.33.

B. Non-Directional Discrimination Tests

The following tests are classified as non-directional because subjects are not instructed to select the different product based on any specified attribute.

1. A-Not-A Sequential Presentation

Subjects are provided with two 3-digit coded products, one followed by the other, and indicate whether the second product is the same, or different from the first. The first product is removed prior to serving the second to eliminate a direct comparison of the two. This method is used primarily to minimize observation of unimportant visual differences between products, and to control exposure time between products having significant carryover effects. The probability of a correct judgement is 0.50; data analysis is straightforward and based on the binomial expansion, for which there are several published tables. The A not-A method can be expanded to where two or more coded products are given to the subject, one at a time, without reintroduction of the first product. Although this further reduces carryover effects, selection of this serving option must be balanced against unwanted differences in subject's memory skills.

2. A-Not-A Simultaneous Presentation

Subjects are provided with 2 products, side by side, and indicate whether the products are the same or different. They are instructed to try the product on the left first, and

then the product on the right. This design should include an equal number of pairs in which the products are in fact the same, to reduce the impact of false hits from subjects that always respond that there is a difference.

3. Duo-Trio

Three products are presented simultaneously to the subject, where one is coded "R," for reference, and the other two products have unique 3-digit codes. The subject is instructed to select which coded product is most similar to the reference. Similar to the A-not-A method, it does not require selection based on a named attribute or training with that attribute, has a $p = 0.50$, and one can use published tables for the binomial expansion. As we will see, this method requires less re-tasting and consequent potential for carryover effects than does the Triangle method. A sequential procedure can be used to further reduce direct comparisons and carryover effects; however, it introduces unwanted memory skill issues.

4. Triangle

Three 3-digit coded products are presented simultaneously, and the subject is informed that two of the products are the same and one is different. The subject's task is to correctly select the product most different from the other two. The triangle method requires more tasting to reach a decision than does the duo-trio method. This is because the triangle has 3 pairs of unknown products (A vs. B, A vs. C, and B vs. C) compared to two pairs (Reference vs. A, and Reference vs. B) for the duo-trio. The chance probability for the triangle test is 0.33 to reflect that there are three unknowns, and there are published tables available for assessing significance between products.

5. Matching and Sorting Tests

A variety of non-directional discrimination tests are possible for matching unknowns to two or more controls or standards (e.g., dual-standard method), sorting unknowns into similarity groups, or indicating degree of "sureness" that an unknown matches a previous sample. An example of the latter is the *R*-index described by O'Mahony (17). These methods require more tasting than do the methods described above, and for this reason are not routinely used for product evaluation.

C. Directional Discrimination Tests

For directional difference tests, subjects are instructed to make their choice based on a specified attribute.

1. Paired Difference

Subjects are provided with 2 products, side by side, and indicate which product has more of a specified attribute. They are instructed to try the product on the left first, and then the product on the right. The order of tasting is balanced across subjects and replications.

The primary criticisms of this method, and of all directional discrimination tests, is the time and effort required to train subjects to evaluate the specific attribute, and knowing whether subjects actually selected a product based on the specified criteria. Commercial products are often quite complex, where an ingredient or process difference can result in several sensory differences. Limiting the subject's response to a single attribute may result in a correct choice based on incorrect criteria. For example, different sweetener types and amounts for a beverage or baked product may alter visual and textural characteristics. Products scored different for sweetness actually may differ on some other attribute. Several investigators (1,18,19,20) have convincingly argued that, all things being equal, a directional method is superior to an equivalent non-directional method. The problem is, seldom are all things equal. Where attribute information is required, sensory descriptive methods are recommended.

2. *n*-Alternative Forced-Choice

The directional paired difference test can be expanded to include several samples, and the subject instructed to select the product that has the most, or least, of some attribute. As in all discrimination tests, the probability value must reflect the number of samples from which the subject must select. For example, the probability value is 0.33 for a 3-product test, 0.20 for a 5-product test, and so forth. AFC tests are directional and have the same procedural problems described for the paired difference test. They are multisample tests where all the samples for a trial are simultaneously presented, introducing issues of sensory fatigue for many commercial products.

AFC methods are have been popularized most recently by researchers developing theoretical models to explain sensory discrimination behavior (19,20). Signal Detection, Thurstonian, and other competing approaches may well provide answers to important sensory discrimination issues, and their examination is encouraged. To be useful for routine product evaluation, these approaches will need to offer alternate procedures that are practical in a business environment.

VI. DESCRIPTIVE METHODS

Descriptive analysis is the most sophisticated source of information available about the perceived sensory properties of products. It is particularly important because it provides a focus for development efforts. Descriptive analysis provides a basis for measuring the effects on perception of a process or of ingredients; it is used for correlating instrumental measures, and it is essential for correlating

consumer response behavior and for identifying those product attributes that are most important to consumer preferences. Before discussing specific methods, it is necessary to define what is meant here by descriptive analysis. Descriptive analysis is a sensory methodology that provides quantitative descriptions of products based on the perceptions from a group of qualified subjects. Based on the method, it provides information about a specific sensory modality or provides a total sensory description, taking into account all the sensations that are perceived, visual, auditory, gustatory, olfactory, and kinesthetic — when the product is evaluated. The evaluation is usually (but not always) done in a controlled environment, and can include product handling, and, in this sense, it is a total experience. The evaluation also can be done in a home environment when normal preparation, use, and consumption are required over a period of time.

The origins of descriptive information can be traced to early brewmasters, perfumers, flavorists, and other product specialists. These technical specialists described products, made recommendations about the purchase of specific raw materials, and also evaluated the effect of process variables on product quality (as they determined product quality). Companies used that information to determine that a particular product met their criteria for manufacture and sale to the consumer. These early activities were the basis for the foundation of sensory evaluation as a science, although at the time it was not considered within that context. Formal descriptive analysis received its major impetus from "flavor profile," an approach that demonstrated it was possible to select and train individuals to describe the sensory properties of a product in some agreed sequence, leading to actionable results, without requiring years as an apprentice to an expert. The method attracted considerable interest and was a milestone in the development of the science of sensory evaluation. It also was the source of much controversy, and since then other descriptive methods have been developed.

A. Flavor Profile

The Flavor Profile® method described by Cairncross and Sjöstrom (21), Sjöstrom and Cairncross (22), and Caul (23) was developed at the Arthur D. Little Co. and is the only existing formal qualitative descriptive procedure. The method utilizes a panel of four to six screened and selected subjects who examine, discuss, and evaluate product in an open session. Product attributes are scored for intensity in the order of their perception. The intensity scale was: 0 = none,) (= threshold,) (−1, 1 = slight, 1–2, 2 = moderate, 2–3, and 3 = strong. Once agreement is reached on the description of the product, the panel leader summarizes and reports the results without application of any statistical analysis.

Six subjects are selected for training based on technical background and a series of screening tests, including basic taste recognition and intensity ranking, odor identification for selected chemical compounds, and a personal interview to evaluate interest, attitude and availability. Training takes 6 months or more and includes instructional information about the senses, introduction to the components of the flavor profile, and direct experience evaluating selected products. Training also includes threshold determination for the basic tastes, skills having little or no connection with evaluation of products containing mixtures of supra-threshold stimuli. Selected references are introduced to demonstrate specific sensations, and practice profiles obtained for products evaluated by an experienced panel. During training all subjects serve as panel leader until one is selected. The panel leader is key to this method; they coordinate the testing and report results. This individual assumes a leadership role, directing the conversation and providing a consensus conclusion based on the results. The role of panel leader as defined in the method can have significant consequences without some independent controls. Subjects could be led to a conclusion without being aware this had occurred.

The method had considerable appeal because results could be obtained rapidly. Subjects meet, as a group, for about an hour to evaluate a product, reach a consensus about its sensory properties, and provide the requestor with a result. The developers of the method emphasized that there would be confidence based on the collective professional judgment of the panel and this would obviate the need for statistics. The method is unique in that no direct judgement was made concerning consumer acceptance of the product, although most investigators assumed consumer acceptance based on a result. An early recognized shortcoming of the method was its focus on the single sensory modality of flavor. Subsequent methods would extend screening, training, and evaluation to one or more additional modalities.

B. Texture Profile

Chronologically the next descriptive method of importance was the Texture Profile® method developed at the General Foods Research Center (24, 25, 26). The method was based on Flavor Profile, and extended descriptive analysis into a second modality, texture. Brandt and co-workers (24) defined a texture profile as "the sensory analysis of the texture complex of a food in terms of its mechanical, geometrical, fat and moisture characteristics, the degree of each present and the order in which they appear from first bite through complete mastication." Several of the procedures introduced by Texture Profile raise behavioral issues related to panel training.

If the panel is to be used also for flavor assessment, subject screening includes tasks identical to those described for Flavor Profile. Texture screening tests were devised for hardness and viscosity ranking, and for geometric matching. As many as 40 to 50 subjects may be screened, with 10 to 15 selected for training. Full or partial denture wearers were not considered for panel membership.

Texture training included a two week orientation phase, a three month practice phase, and a three month expansion phase. A standard set of references was used to demonstrate taste, aroma and mouthfeel sensations. The concept of the components of flavor profile was extended to include what were described as mechanical, geometrical, and a category of "other" (moisture and fat) characteristics, intensity, and the order of appearance for the texture properties. An effort was made to describe the physical properties of texture and to provide a sensory definition for each described physical property.

Initially, the texture terms and definitions were compiled, sorted, and categorized from both scientific/technical and popular terms, the latter from laboratory or field situations in which common usage terms were used to describe textural sensations. This led to the development of a classification of terms that were believed to encompass texture sensations. Standardized rating scales were introduced for the mechanical and geometrical properties of texture perception, and these relied on commercially available products to anchor each point of each scale. During training, subjects were expected to learn these definitions and their associations. The product evaluation procedure used a Flavor Profile approach with panelists discussing results in order to reach a conclusion.

Although the method was useful for focusing attention beyond flavor and on the relative importance of texture, it had numerous problems of its own. In developing the method, one objective was to eliminate subject variability through use of a standard vocabulary, and standard rating scales and references as part of the training program. There are inherent risks in experimenter-assigned attributes. While they may be meaningful to a chemist, one might question the perceptual meaning of these technical definitions to a subject. Other subjects could ignore a perception because the characteristic was not among those selected for training. Use of products as scale anchors presents their own set of problems. Products are not invariant; they change over time as a function of marketing and other considerations. Another concern is the separation of texture from other sensory properties of a product such as color, aroma, taste, and so forth. As a rule, perceptions are interdependent, and the exclusion of a sensory modality from a scorecard does not eliminate those perceptions. In effect, the subject is likely to use other attributes to acknowledge these perceptions, and the visible manifestation is increased variability and decreased sensitivity. These other perceptions can influence the responses to the textural perceptions and vice versa.

Profile methods and related "expert" systems treat subject differences as unwanted error, and these training programs resort to behavior modification procedures in an attempt to eliminate this source of variance. The panel leader trains subjects to provide what the leader judges to be the correct response to stimuli, and subjects are trained to agree and repeat those responses in the presence of the stimulus. The approach ignores the reality of the situation, and eliminates the opportunity to assess the importance of individual differences for understanding and generalizing results to consumers.

Interest in eliminating subject variability is, on the surface, a reasonable (although not likely or practical) idea but it must not give way to procedures that sacrifice the validity of the measurement system. The human is a living and changing organism, influenced by physiological and psychological conditions that better support a concept of expected variability. Products also are themselves variable. For these reasons, a panel is used rather than a single subject, and replication has become a mainstay in most current descriptive methods.

C. Quantitative Descriptive Analysis (QDA)

Development of the Flavor and Texture Profile methods demonstrated a need for descriptive information and a formalized procedure for screening and training subjects, and for evaluating products. They also stimulated interest and research on alternative descriptive methods that would correct weaknesses previously identified: the extended amount of time to select and train a panel, reliance on model systems (e.g., compounds in water) for screening subjects, an experimenter-derived descriptive language, the types of scales used, qualitative rather than quantitative information, the role of the panel leader, and the type and role of references. The Quantitative Descriptive Analysis (QDA) method, first described by Stone, Sidel, Oliver, Woolsey, and Singleton (27) and taught by the Tragon Corporation, addressed behavioral, measurement, and quantitative weaknesses of the profile methods, reflecting scientific and technical developments in psychology and the consumer products industry.

The QDA method differs from the profile methods on criteria of subjects recruited, screening procedure and materials, subject training, testing, analysis, and reporting for descriptive information.

1. Subjects

Consumer users in the product category are recruited, and test results are then generalized to the consumer population. Experts and others having technical degrees in the product area are avoided as subjects because of the potential for biased responses based on their technical knowledge of the product category, ingredients, and processes. About 25 subjects are recruited, and it is expected that 12 to 15 will successfully qualify and complete training.

2. Screening

Discrimination tests are used, and screening stimuli are selected from the product category rather than the simple stimuli in water solutions popular with the profile methods. The closer the screening stimuli are to the test stimuli, the more likely that successful performance will be obtained in the actual test. About 10 to 15 replicated pairs of product

stimuli are used, increasing in difficulty from the first pair (easy to discriminate) to the last pair (difficult to discriminate), covering all sensory modalities, and including any differences known to be relevant to consumers. Correct selection of the different product in more than about 65% of the trials, and consistency in correct selection across replications are used as a guide for subject selection.

3. Training

QDA training focuses on language development and the evaluation process, and provides subjects experience with the range of products they will evaluate. Language development is a consensus building process. The panel leader's function is to keep the panel focused on developing objective terms (in contrast to attitudinal terms) that can be measured and obtain agreement amongst subjects on the evaluation procedure. A typical QDA scoresheet includes 30 to 50 or more attributes covering all sensory modalities. The language development process contrasts with the profile methods, which teach a preconceived technical language and use a prescribed set of "universal references" derived from the experimenter. QDA uses references selected directly from the product category, and only on an as-needed basis. Consequently, QDA derived attributes and consumer perceptions take less time to obtain, with the entire training process requiring between 5 to 10 hours, rather than several months.

4. Testing

Subjects evaluate each product individually in a facility equipped with test booths or partitions, or, for an extended use QDA, in their own homes following product usage. Subjects typically evaluate 4 to 6 products, and as many as 24 or more when part of product optimization research. Balanced block serving designs are used and each subject provides 2 to 4 replicate evaluations. Subjects use a semi-structured line scale to score the perceived intensity for each attribute for a product. The scale consists of a 6-inch (~15 cm) line, anchored ½ inch (~1.5 cm) from each end to identify the direction (e.g., weak to strong) for each attribute. This type of scale has no numbers and minimizes word bias. It is very difficult for a subject to memorize the location of previous judgements (assuring greater independence of judgements from replication to replication and product to product), and preserves the interval character of the scale for data analysis.

5. Data Analysis

QDA was the first trained panel method to insist on, and provide for, statistical analysis of subject performance and product differences. Line scale responses are converted to numerical values from 0 to 60 prior to analysis. A unique method of graphing the data, QDA "spider graphs," was developed that readily communicated product similarities and differences, and has become a standard in the food industry. A proprietary statistical package was made available for analyzing QDA data, and included in Tragon's training program for panel leaders. The statistical package uses one-way and two-way Analysis of Variance models in prescribed ways to assess subject performance. Current innovations to the package include algorithms for assessing crossover and magnitude interaction, scale use, and multivariate analysis and mapping techniques. QDA data is well suited to the recent advances in statistical analysis and computer technology.

D. Sensory Spectrum Analysis

This method positions itself as a hybrid of the three methods described previously; however, it is primarily an extension of the profile methods. Concepts first introduced for the Texture Profile method are extended back to the recruiting, screening, training, and testing for flavor panels as well. Separate training programs are required for flavor, texture, and each other modality. Training programs are quite lengthy, a common element for all profile methods. Subjects are taught about sensory processes, similar to the orientation programs found in the other profile methods. They also are taught experimenter-assigned attribute vocabulary and rating scales, the latter anchored at multiple points with experimenter-assigned references. Subjects must learn the required response to selected stimuli, independent of their individual perceptions, as an attempt to produce absolute scales. Teaching identical responses, independent of individual perception, is possible; however, skeptics of the method view this as a form of behavior modification and contrary to understanding and predicting consumer perception. QDA concepts included in the Spectrum method include category-specific discrimination tests for subject screening, intensity scales (although more nominal or ordinal than interval here because of the training method), exposure to a broad range of product in the category, evaluation in individual test booths, and application of statistical analysis. The statistics are generic and less specific than those found in QDA and other recent developments in descriptive methods. Curiously, variance data from panels trained in the Spectrum method has not adequately demonstrated the zero result necessary to support a claim of absolute scales or counter the concept of individual differences.

E. Free-Choice Profiling

Williams and Langron (28) described a radically different descriptive method that required no subject screening and training, where each subject could use their own words and scales to describe products. Generalized Procrustes analysis, an iterative type of factor analysis, is used to force fit individual data into a common space. While this type of summary analysis can show differences between very different products, it misses smaller, and possibly

important, differences. The method does not demonstrate any substantially unique advantages and may be better suited to classification and comparison to other consumer procedures than to trained panel procedures.

F. Other Methods

Descriptive information is recognized as important, if not crucial, as a means for providing a comprehensive product assessment. Descriptive panels are used in several venues including, and not limited to, product development, quality control, advertising claim support, and food science education. Different needs have given rise to descriptive panel variations other than the methods described above. Many descriptive methods are generic and retain in varying degree elements of the core methods; a few other methods have established, or attempted to establish, themselves as different. Larson-Powers and Pangborn (29) introduced the use of a reference combined with a difference from reference scale. The method required simultaneously available stimuli, reducing the number of different products that could be evaluated in a session. The developers of the Flavor Profile introduced a new version called Profile Attribute Analysis (30) that included 7-point intensity scales allowing for statistical treatment of the responses. Stampanoni (31) introduced "Quantitative Flavor Profiling" as a hybrid method based on Flavor Profile and QDA.

VII. TIME-INTENSITY SCALING

The temporal aspects of the sensory experience during food and beverage consumption are apparent to even the casual observer. Not unexpectedly, perceptual changes occur as the physical properties of a food change during chewing, or while in the mouth (e.g., ice cream and butter). Perceptual change also can occur when the chemical properties of a stimulus remain constant, as with taste, odor, and certain mouth sensations (e.g., burning sensation from chemical hot stimuli). Early psychophysical research into taste adaptation included time as a variable, measuring changes in taste threshold over time for simple adapting solutions. Hahn's (32) results demonstrated threshold differences based on the concentration of the adapting solution and for the basic tastes measured (salt, sugar, bitter, and acid). The research also concluded that subjects complete recovery to the adapting solutions was not reached within the 30 seconds allowed, and that there were individual differences. Individual differences in time-intensity research continue to be reported; for example, van Buuren (33), using principal components to analyze time-intensity (TI) curves, concluded "TI curves appear to be determined by characteristics that are related to the judge and that may be unrelated to the product." Given that most time-intensity studies involve small numbers of subjects and data are averaged, individual differences are a vexing concern for generalizing time-intensity results to a larger consumer population.

Time-intensity studies have been reported for the taste, aroma, and texture of foods, and for a variety of products including bread, chewing gum, beer, wine, ice cream, chili pepper, gelatin, and chocolate. Commercial interest in synthetic sweeteners in the 1970s prompted significant published and unpublished research into the temporal effects of these sweeteners compared to sucrose.

A. Measurement

Interest in time and intensity relationships in sensory evaluation is evident by the almost universal practice of measuring aftertaste or aftereffect in descriptive analysis and consumer research. Subjects in time-intensity studies typically receive instruction and practice with the test procedure, scale, and any special apparatus used for data collection, and may be screened for their ability to detect differences for the attribute or attributes measured. Under these conditions, the subjects are viewed as a special type of descriptive analysis panel.

The simplest measurement practice involves scoring the perceived intensity for overall aftertaste or aftereffect (i.e., sensation remaining in the mouth), or for a specified attribute, as a last task during routine product evaluation by an ongoing descriptive panel. The panel is instructed to first wait a prescribed amount of time (30 to 60 seconds or more depending on the product) after completing other attribute evaluations. This procedure can be expanded to include intensity measures for several specific attributes obtained at one or more designated points in time during the evaluation. This approach is appealing because it uses an ongoing panel, can measure several attributes at selected points in time, and special data collection equipment is not required. There is a practical limit to the number of attributes that can be measured during a time interval, as it takes time to score attributes. This and related issues should be resolved during training. The primary disadvantage of this approach it that measurement occurs at discrete points in time, whereas, the perceived change may be continuous. Whether the perceived change is different for different subjects is more a data analysis issue than one of data collection.

Continuous measurement of the change in perceived intensity requires an apparatus that simultaneously tracks time and the subject's intensity scores. While providing the advantage of continuous measurement, the apparatus usually limits the number of attributes that can be measured to one or two, and based on the apparatus requires varying degrees of physical involvement by the subject. Pen type strip-chart recorders were among the earliest devices used for continuous measurement in time-intensity studies (34). The recorder moves chart paper at a constant rate and an intensity scale is fixed on the recorder perpendicular to the direction of chart flow. The subject continuously records perceived intensity for the selected attribute by keeping the pen in contact with the chart paper, moving the pen in the direction of increasing or decreasing intensity until the

perceived intensity for the attribute has returned to baseline. Data from early generation strip chart recorders was handled much like that from similar tests using paper ballots. The subject's intensity score at several points in time were hand measured and converted to numerical value for data analysis. This was a labor-intensive process, depending on the number of time points examined.

Desktop computers linked to a joystick (35), or similar device, for measuring perceived intensity introduced significant improvements in the time required to collect, enter, and analyze data, and simplified the subject's task compared to strip chart recorders. These advances and developments in statistical analysis and graphing software that could be used with time-intensity data encouraged greater use of the method for sensory research.

B. Analysis

Time-intensity studies typically involve one or two attributes, and the results are readily graphed on *x-y* coordinates, with attribute intensity on the *y-axis* and time on the *x*-axis. Curves may represent individual data, averaged data for the panel, or group data for subjects having similar results. Measures of central tendency, such as means or medians, are used to construct data points for selected time periods, or data may be otherwise transformed to reduce or eliminate subject differences. Data points are then connected to create a time-intensity (TI) curve. Selected curve parameters or discrete points are compared directly or analyzed for statistical significance. Maximum intensity (Imax), time to maximum intensity (Tmax), and duration (return time to baseline intensity) are popular discrete points used for comparing TI results for different products, and suitable analysis of variance and multiple range tests are then performed to determine significance for the observed differences. An examination of the literature on this topic reveals views espousing and challenging a variety of curve parameters worthy of consideration, such as area under the curve, peaks, plateaus, slopes, and so forth. Several investigators have proposed combinations of these and other measures, and developments are still forthcoming in this area. The interested reader is directed to Lawless and Heymann (1) for additional detail about TI research in sensory evaluation and the different analysis methods proposed for the data.

One of the biggest challenges facing the experimenter is how to deal with a subject's error of anticipation; i.e., providing responses based on the subject's guessing the purpose of the test.

VIII. DATA ANALYSIS

Statistics is an essential part of the sensory evaluation process, providing a means of summarizing information to reach conclusions about subject performance and product difference. For sensory evaluation there are several issues that make the use of statistics especially challenging. First, there are many different statistical procedures from which to choose, and new tests are regularly introduced and described in the literature. Second, statisticians as well as sensory scientists differ in their view about how responses should be treated, which type of analysis is more or less appropriate and useful, the extent of any data transformation, and so forth. Third, software packages and the power of the PC make all methods for analysis easily obtainable in terms of time and cost, but that does not make them appropriate.

This section provides an introduction to the use of statistics as a guideline for making sensory and business decisions about products of interest. The focus is on statistical applications rather than statistical theory and the proofs, or various algorithms that would take far more than the space allocated here for this topic. The interested reader can find that information and worked examples in books covering the general topic of sensory evaluation and other books that focus on statistics for sensory evaluation (17, 36, 37). Sensory decisions based solely on the statistical conclusions are the exception, not the rule. The statistics that we describe will focus primarily on those analyses found to be useful for the behavioral sciences; e.g., variance measures, and will focus less on statistics more typically used in the engineering and physical sciences.

A. Descriptive Statistics

Sensory responses may take the form of discrete or scaled data. An example of discrete data is found in discrimination results where subjects select a product as similar or different compared to one or more other products. An example of scaled data is found where subjects score individual sensory attributes. In this case scoring may be a ranking, or rating on one form or another of an interval or ratio scale. Descriptive data provides a summary of the individual scores, and as such, is more manageable than the original raw data. However, summary statistics by their very nature can also mask or distort information and the sensory scientist must be aware of this potential problem. Descriptive statistics are grouped into measures for central tendency and dispersion, and are often displayed in tables and graphs.

1. Central Tendency

The mean, mode, and median are important measures for summarizing individual data.

a. Mean

The arithmetic mean for scaled data is the sum of all scores divided by the number of scores that have been summed. The arithmetic mean is the most widely used measure in sensory evaluation. It can be distorted by extreme scores, in which case other means such as the harmonic mean or geometric mean may be better choice. Rank means are possible when rank order scales are used.

b. Mode

The mode is the response category that contains the largest number of responses. This measure is not influenced by extreme scores as is the arithmetic mean.

c. Median

The median is the category containing the 50th percentile, dividing an ordered distribution in half. This measure is also not influenced by extreme scores.

2. Dispersion

The range, variance and standard deviation are the three most frequently used dispersion statistics reported in sensory tests.

a. Range

The range refers to absolute difference between the lowest and highest scores of an ordered distribution. The range is easily influenced by one or more extreme scores, and by itself has limited value. It is more informative when combined with measures of central tendency, variance, and a frequency distribution.

b. Variance

The variance provides a measure of deviation or dispersion from a mean. To calculate the variance for a data set requires that each score is subtracted from the mean, each difference from that operation squared (to eliminate negative numbers), these squared differences summed, and then divided by the number of scores minus 1. The calculated variance resulting from this process is displayed as S^2 to represent sample data rather than population data.

c. Standard deviation

The standard deviation is the square root of the variance and displayed as S to represent sample data. As may be expected, the standard deviation will always be a smaller value than the variance, further reducing the impact of extreme scores.

3. Frequency Distributions

Frequency is the number or percent response for each response category. Frequency data are typically displayed as tables or graphs, which provide useful information about how well other measures, such as the mean and range, represent the data. For example, a flat distribution would indicate that the mean value is not a good summary description for the data. Sensory specialists routinely examine frequency distributions for each product and serving order combination, and different groups of subjects to identify important trends in the data. Products having similar shape distributions may readily be included in a variety of statistical significance tests, whereas those with very different shape distributions may not.

B. Inferential Statistics

This category of statistics is used by the sensory researcher to determine the risk associated with declaring that an observed difference in a test represents a real difference that can be generalized to other test populations, or to a larger consumer population. Using appropriate statistics does not eliminate the risk of making a wrong decision; nonetheless such errors can be minimized through proper experimentation and analysis. There is not sufficient space in this chapter to include discussion about probabilities and hypothesis testing; therefore, the interested reader is directed to the aforementioned publications (17, 33, 34). We will limit our discussion to those inference statistics used most frequently by sensory practitioners.

1. Non-Parametric

This category of statistical tests is used when data from groups or products to be compared are in the form of counts (i.e., frequencies), percents, or ranks. These are distribution free statistics, with no constraint regarding the shape (e.g., symmetrical bell shape Gaussian curve referred to as the normal curve) of the distribution. The number of non-parametric tests is too large to discuss here, and the interested reader will find greater discussion and useful references in the sensory statistics literature cited above. We mention only a few of these tests below.

a. Binomial tests

Data from forced choice tests such as those described for most discrimination tests can be analyzed for statistical significance using tables based on the binomial expansion. This has been described previously in this chapter.

b. Chi-square (χ^2)

This is a useful statistic for determining whether the observed number of responses is significantly different from an expected number (derived from the total number of responses). There are several variations of the formula that can be used based on how the data are collected and the number of classifications being compared. In sensory evaluation the chi-square test is often used to determine whether two response distributions are significantly different, and as a preliminary test for isolating and comparing two response categories from among several. It is used more in sensory consumer tests and less so in sensory discrimination and descriptive tests.

c. Other non-parametric tests

The aforementioned texts include useful descriptions for several other non-parametric tests worthy of note for sensory analytical tests. Those statistical tests include, and are not limited to; the McNemar test, Cochran Q test, Wilcoxon test, Mann-Whitney U test, Friedman test, and the Kruskal-Wallis test.

2. Parametric

This category of statistical tests is reserved for data that satisfies the constraints of the normal curve, which includes equality of the scaled intervals. All things being equal, which they seldom are, parametric tests are viewed as more powerful than non-parametric tests. When response data are clearly nominal (e.g., counting and classification data) or ordinal (e.g., ranks), non-parametric tests are recommended. Parametric tests are appropriate when data are clearly interval or ratio. Having said this, the reader is cautioned that most of the scales used in sensory evaluation have sufficient interval characteristics to permit judicial use of parametric statistics. Underlying statistical assumptions and theory is just that, assumptions and theory. In practice, results may be reliable, valid, and useful even if they do not perfectly satisfy underlying assumptions. In this event, it may be more beneficial to modify the theory and assumptions, rather than forgo the application.

a. t-test

The t-test is used to determine whether the means for two products are significantly different. Different formulae are available to accommodate various conditions such as: independent and dependent observations, large and small N, proportions, and equal and unequal number of observations. The t-test is not the best choice for sensory tests where the same subjects evaluate both products, the analysis-of-variance can be substituted and it extracts more from the error variance. The t-test also is inappropriate where more than two products are to be evaluated and statistically compared to one another. This constitutes multiple t-tests of the same data, a common error.

b. Analysis of variance (AOV)

The analysis of variance is the primary statistical test used for scaled sensory data. It is a versatile statistical procedure that readily accommodates multiple products, treatment conditions and groups of subjects. It is used to determine whether an effect is statistically significant, and when a difference noted is followed by a multiple range test to determine which means are different. Several AOV models are extensively used in sensory evaluation; these include the one-way for independent means, the two-way for dependent means, treatment x levels for different treatment conditions (e.g., x-levels of different variables), and split-plot models for different subject groups evaluating the same and different treatments.

The primary challenges for selecting the best AOV model are to select one that is appropriate for the specific test conditions, to accurately account for all the sources of variance in the test, and to select the appropriate error term for testing the significance of an effect. Statistical significance in the AOV is based on a calculated F ratio consisting of an effect variance in the numerator and an error variance in the denominator. Probability tables for the significance of the calculated F are published in most statistics books; most statistical packages for sensory and behavioral data include the AOV analysis and exact probabilities for the calculated F.

c. Multiple range tests

Multiple range tests are used following an AOV to determine from among a set of means for a significant variable which ones are significantly different. Different range tests reflect what is to be compared and the respective authors' preference for controlling the various error rates possible when making multiple comparisons for a single data set. Too conservative a test will make it difficult to find statistical significance and result in more Type II errors, whereas a less conservative test may result in false differences (i.e., Type I error). The sensory scientist is cautioned here that the underlying theoretical assumptions for a multiple range test may not agree with practical experience using that test. Where this is the case, paying attention to the risk one can still proceed cautiously. Frequently used multiple range tests include; Fisher's LSD (least significance difference), Dunnett's test, Duncan's test, some tests by Tukey, the S-N-K (Student-Newman-Keuls) test, the Scheffé test, and the Bonferroni test. Whichever test is selected, the results must be examined to determine whether they agree with the knowledge and expectation the researcher has about the products and the sensory test.

C. Correlation and Regression

Sensory scientists are often interested in the relationships between different sets of data. The interest may be between different groups of subjects, products, attributes, or combinations thereof. Because correlation does not imply causation, summary statistics and graphs depicting association are useful for data reduction, substitution, prediction, and generally improving understanding about variables. As with inference testing, different statistics are used for different levels of measurement (e.g., nominal, rank order, or continuous).

These measures are used to examine and better understand sensory and instrumental relationships, and in optimization research where sensory attributes are used as predictor variables for consumer acceptance.

1. Correlation

To understand a simple two-variable correlation it is best to first graph results as a scatter plot with the data from one variable on the X-axis and data from the second variable on the Y-axis. For example, descriptive scores for sweetness and bitterness for a set of products can be graphed and a correlation for the relationship between the two attributes calculated. The Pearson product moment correlation coefficient is used for continuous scaled data and is depicted by r. Calculated r-values range from -1 to 0 to $+1$. The

closer to 0, the less is the association between the two variables. The minus sign depicts an opposite relationship, whereas a plus sign depicts a directionally similar relationship; unity represents a perfect correlation. Pearson's is useful only for linear data, curvilinear data can produce low values approaching 0, misleading the casual observer to conclude the variables are unrelated. Correlation can be determined for non-continuous scaled data as well; an example is Spearman's rank order correlation coefficient (ρ Greek lowercase rho).

2. Multiple Correlation (R)

Multiple Correlation is used to assess the degree of association between a dependent variable and a set of predictor variables. In product optimization research several sensory attributes (independent variables) may be included as important predictors of consumer acceptance (dependent variable), and the multiple correlation (R) describes the degree of association between the dependent and independent variables. Several books have been published on the topic of Multiple Regression/Correlation (MRC), and the interested reader is directed to Cohen and Cohen (38) for an in-depth discussion.

3. Regression

Regression is a general term applied to equations that fit a line to observed data points. Simple linear, non-linear, and multiple regression are possible, and the resulting regression line is often used to predict values of the dependent variable (y) from values of the independent variable (x). The sensory scientist will use regression equations, for example, to predict perceived intensity for an attribute based on ingredient concentration. In optimization research, multiple regression is used to predict consumer liking from a combination of sensory attributes and their intensities. Analytical measures may also be used as predictor variables for acceptance in optimization, alone or in conjunction with sensory measures.

D. Additional Multivariate Methods

Several tests in addition to those already described are used in sensory evaluation to simultaneously examine multiple variables. Multivariate analysis often provides understanding of important relationships imbedded within the data and not readily observable by other means. The interested reader will find that the book by Dillon and Goldstein (39) offers a useful integration of theory, explanation and illustration for the topic.

1. Multivariate Analysis-of-Variance (MANOVA)

This analysis is used to test the significance of a set of variables. A good example would be descriptive panel data where several attributes are evaluated for a product set.

2. Discriminate Analysis

Discriminate analysis is a methodology for finding linear combinations of the independent variables that can act as scoring functions to estimate to which of several classification categories an observation belongs. Sensory scientists use this and related procedures (e.g., canonical correlation) in optimization research to identify lifestyle, attitude, and classification information that best identify membership in different consumer preference groups.

3. Principle Components Analysis

This data reduction technique transforms the original set of variables into as few linear combinations as possible to explain as much of the total variation in the original data. The linear combinations, identified as the factors or components, are independent from all other factors. The method is often applied to sensory descriptive panel data to reduce the number of attributes, or to identify a smaller set of independent attributes to include as independent variables in developing multiple regression models for optimization research. It is also used in optimization research to identify products that form independent groups based on sensory attributes.

4. Factor Analysis

Similar to principle components analysis, factor analysis is a data reduction technique, except it focuses on that part of the total variation that a variable shares with other variables in the set. Some sensory researchers prefer to build optimization models using factor scores rather than attributes identified through principle components analysis. However, such a result has limited value when applying the information to make product change, for example.

5. Cluster Analysis

This data reduction technique is used to find a smaller number of groups whose members have elements more similar to one another than to members of another group. Cluster analysis is used in sensory optimization research to identify unique consumer preference groups, and it is used in the same way in descriptive analysis to identify unique subject groups. In the latter situation, uniqueness may indicate the need for additional panel training.

IX. VISUAL PRESENTATION

Visual presentations are an important part of understanding and communicating data. They reveal events and trends in data not readily observed any other way, and they simplify results for less technical and non-statistical audiences (40). Increased availability of desktop computers capable of managing large amounts of data has proven to be of great benefit to sensory scientists. The sensory scientist can stretch,

shrink, rotate, organize and reorganize large and small amounts of data with a simple keystroke or two, and in doing so examine countless relationships among subjects, attributes and products. In addition to the large number of generally available analysis and graphing software programs, such as SAS and SAS/JMP (SAS Institute Inc., Cary, NC), S-Plus (MathSoft Inc., Seattle, WA), SPSS and BMDP (SPSS Inc., Chicago, IL), custom programs have been developed by several companies for application in sensory evaluation. For the latter, the interested reader is directed to: Camo, Inc. Corvallis, OR; Compusense, Guelph, Ontario, Canada; Sensory Computer Systems, Lancaster, PA; and Tragon Corporation, Redwood City, CA. A few examples of graphs useful to the sensory scientist are described below.

A. Histograms

Frequency histograms, together with central tendency and variance measures, provide important information about sensory responses to products and how well the data satisfy assumptions required for other statistical tests, and allow for comparisons between products. Figure 57.1 illustrates a different Product by Serving Order distribution for 24 subjects, where each subject evaluated both products (i.e., 12 subjects per serving sequence). The means are lower for both products in the second serving order, demonstrating a possible order bias, a not uncommon finding in sensory studies, and the primary reason for using balanced serving orders. The bimodal distribution and variance

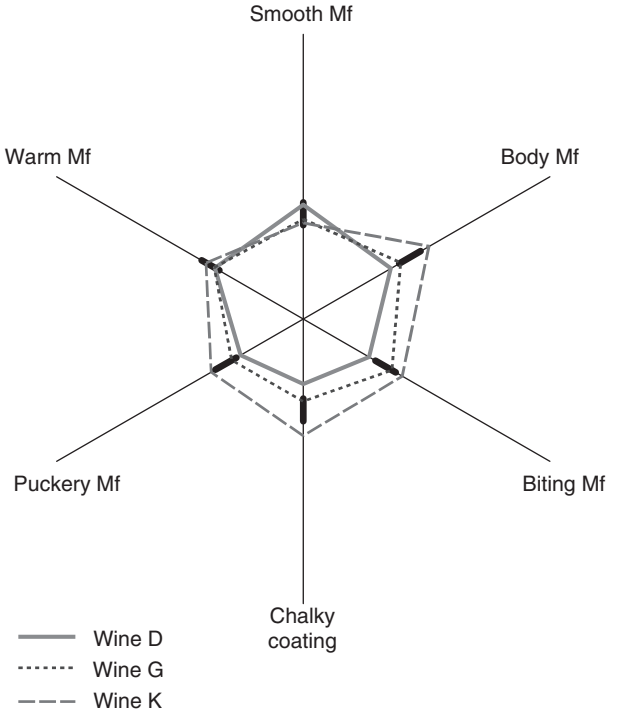

FIGURE 57.2 Typical "spider" plot for selected mouthfeel attributes. Intensity scores are measured from the center out to the point where the product crosses. The attributes are spaced equally around the center point. Bars on spokes represent the magnitude of difference for that attribute to be significant using the LSD test.

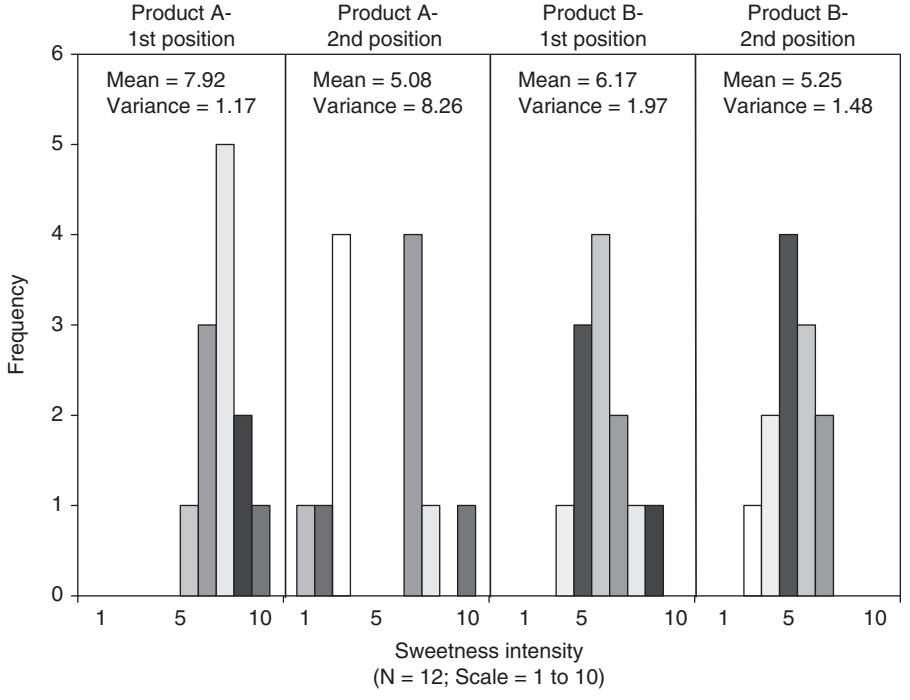

FIGURE 57.1 Illustration of distribution histograms for examining serving order effect. The graph represents 24 subjects that evaluated two products in two serving orders. Twelve subjects evaluated Product A first, and 12 subjects evaluated Product B first.

differences for Product A when served in the second order would alert the sensory researcher that it may be risky, or even inappropriate, to conduct statistical tests for this result if homogeneity of variances is an issue.

B. QDA Spider Charts

Figure 57.2 represents a popular way for graphing descriptive panel results (2,27). Figure 57.2 displays results only for mouthfeel from a study that included additional modalities. Examining Figure 57.2, we readily see product differences for individual attributes, relationships among the attributes, and the overall tendency for a product to score low (Wine D), high (Wine K), or in the middle (Wine G) compared to other products evaluated.

C. Sensory Maps

Mapping is frequently used for displaying results of optimization research involving consumer acceptance and descriptive panel data. The maps often group well liked products together with sensory attributes and consumer information (e.g., lifestyle and attitude) identified as highly related to those product preferences. In the case of descriptive panel data, it is often helpful to visually display products by attribute results. Figure 57.3 is such a graph, and demonstrates how products may differ, or group, based on several attributes across different modalities. Here we see that Wines K and D are scored high for several different attributes; whereas, Wine G falls between the two. We would conclude that Wine K is a strong and high impact product in several areas.

Figure 57.4 is an example of a density map based on a cluster analysis of consumer acceptance scores for a broad range of products of the type typically included in a category review optimization. The cluster map reveals three reasonably unique preference groups embedded within the aggregate population. An appropriate follow-up sensory strategy is to use multiple regression techniques

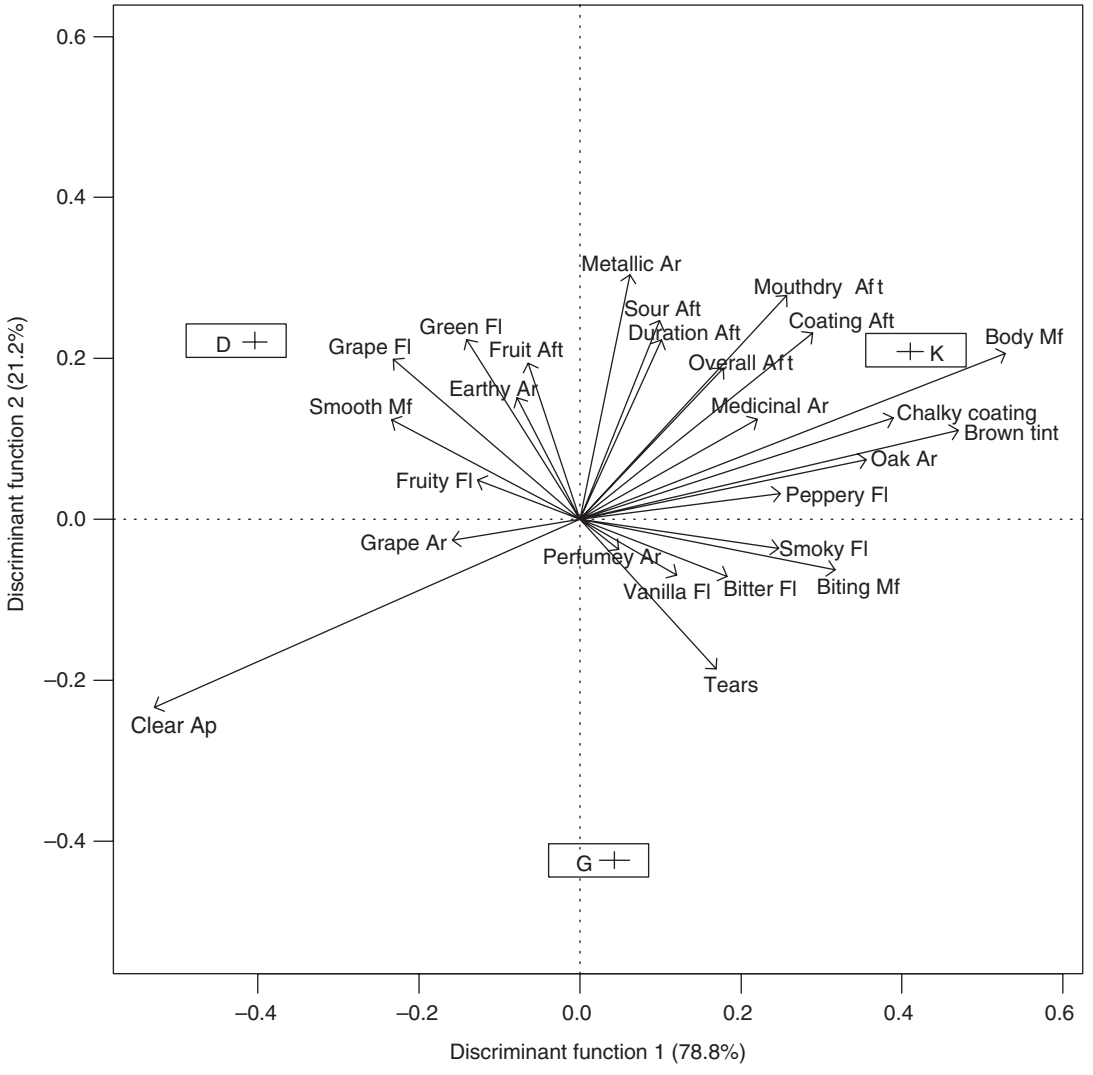

FIGURE 57.3 Attribute factor loading for trained panel evaluation of three wines; D, G, and K.

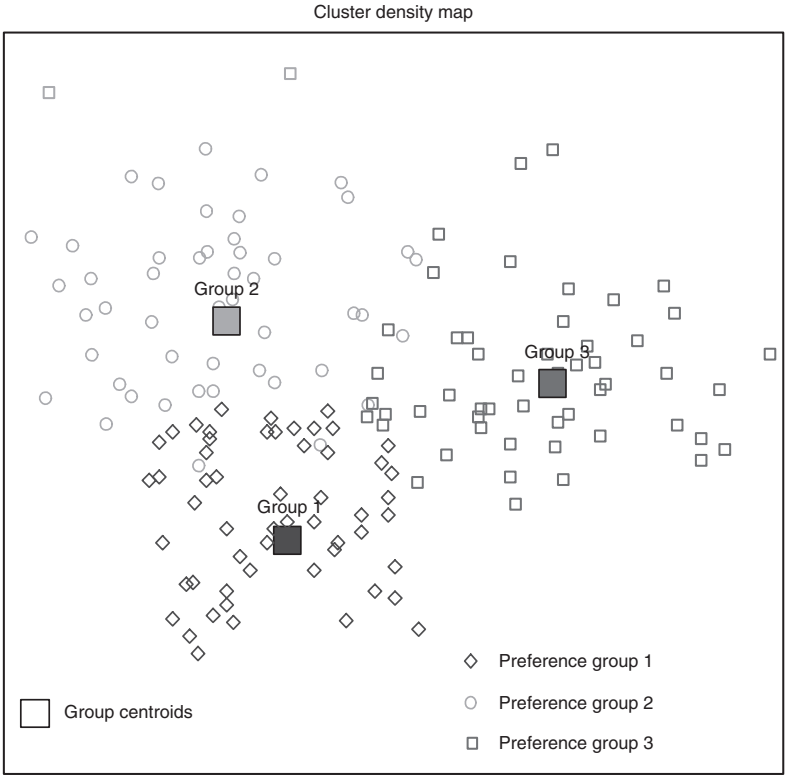

FIGURE 57.4 Cluster Analysis density map for aggregate acceptance scores. Three unique preference groups were identified.

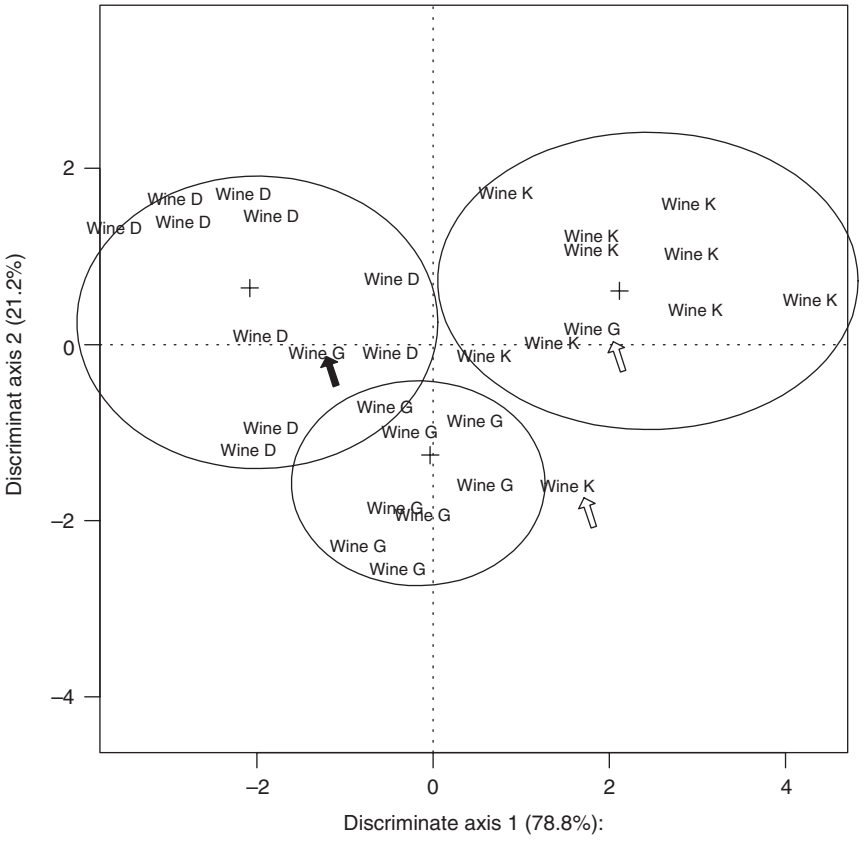

FIGURE 57.5 Discriminate plot for three wines across sensory attributes scored by each of 10 subjects. Arrows show two subjects that differ compared to the other subjects for their evaluation of Products G and K. Filled arrow is Subject #167; open arrow is Subject #542.

TABLE 57.1
Factor Analysis Summary for Consumer Liking and Sensory Attributes

	Factor 1	Factor 2	Factor 3	
Clear Appearance	0.935			
Grape Aroma	0.510			
Coating	−0.804		−0.554	
Body	−0.909			
Grape Flavor		0.732	0.557	
Fruity Aftertaste		0.702		
Consumer Liking		0.533		
Tears		−0.551		
Bitter Flavor		−0.557		
Biting Mouthfeel		−0.888		
Perfumy Aroma			0.950	
Smoky Flavor			0.873	
				Total
% Variance Explained:	41.13	21.92	19.83	82.88

to develop sensory models that best fit each unique preference group as well as one or more models for the aggregate population.

Figure 57.5 is based on a discriminate analysis of individual subject scores for the three wines. This information provides one way to visually identify how well subjects discriminated among the products. Examining Figure 57.5, we see that two subjects differed most among the panel regarding scores for Wines G and K. This information can be used to determine when additional training for subjects is required, or when a subject may be removed from a panel. In either case, these types of visual displays are readily obtainable and provide important insights about products and subjects.

Figure 57.6 is a sensory map that includes consumer acceptance and sensory panel results. The spatial relationships displayed in these types of maps (41) provide useful information to product developers and marketing researchers. In this case, the map identified which sensory attributes were most associated with which products, and that there is a development opportunity to optimize consumer liking for the product category. Sensory maps are typically derived from Factor Analysis (FA) or Principal Component Analysis (PCA) output, similar to that seen in Table 57.1.

X. CONCLUSION

Sensory evaluation is a valuable resource for the food scientist, and has yet to realize its full potential within the food industry. This is partly due to a lack of awareness of what it can do and how to best organize and operate sensory capabilities. The science is dynamic and its applications are almost endless, especially as it relates to its role in consumer research. The sensory sciences outlook is bright as more academic institutions teach and research the topic, and more qualified professionals enter the field. In recent years there has been a significant increase in the use of sensory methods as multinational and domestic companies introduce these procedures on a global basis. This trend will continue, creating new opportunities and demands for the science. Future success will depend in large part on how well sensory professionals and those

that teach and employ them understand that sensory evaluation is about perception; and how best to measure, analyze and communicate sensory information.

CONTENTS

I. INTRODUCTION TO SENSORY EVALUATION

To measure sensory properties and thus determine if the overall objective was achieved is and will continue to be a major accomplishment for sensory evaluation. The development of knowledge and the achievements made possible through this gain regarding the attributes of a product or other pertinent information is another great source layered upon current sensory research and its general knowledge base. The capability of researchers and industry to perform sound sensory science techniques is at all time high. Growth in the area of sensory science has been exceptional during the last decade. Newly applied techniques and development of new modes of observation and data retrieval continue to be implemented and are thrusting sensory science continuously further.

The measurement of human behavior is now directed at a more systematic and professional approach to the testing process. Much of the prior accomplishments were achieved from an indirect method either through marketing services, relations to new product development, or through the dedication of a few select individuals devoted to the sensory profession. Advances in this field were initially slow due to the lack of interest and dedication in sensory science. Today, sensory science is a leading research tool applied to many processes and products.

The importance of the relationship between reliability and validity of results and the credibility of proposed recommendations is often a challenging process in sensory evaluation. Often, evaluations are performed, data is obtained, and results generated which in turn are shuffled into the "meaningless" grouping due to the misunderstandings of and between the separate working group sectors within an organization. Tactics such as these decrease the viability of the sensory group performing the procedures because the achieved information was not properly reported. The success of sensory evaluation, in particular its credibility, begins with an organized effort, and the assurance that the testing process followed accepted procedures and practices in all respected areas of work.

The field of sensory evaluation, being a relatively new discipline, has provoked many divergent opinions and philosophies from both within and outside its parameters. It would be difficult to state the one or two progressive developments that were initially responsible for the emergence of sensory evaluation as a discipline and the limited base of acceptance that ultimately defined the discipline. Agriculture and the international branching of such that began in the 1960's has been seen as one of the major pivotal areas providing growth and interest in sensory evaluation as a necessary function. Also, internationalization of the marketplace as a whole has greatly influenced this growth and interest.

The formal definition of sensory evaluation can be expressed in several different ways. However, the Sensory Evaluation Division of the Institute of Food Technologists (1, 2) has expressed a definition that provides meaningful insight into the subject:

> Sensory evaluation is a scientific discipline used to evoke, measure, analyze and interpret reactions to those characteristics of foods and materials as they are perceived by the senses of sight, smell, taste, touch and hearing.

This definition makes it clear that sensory evaluation utilizes all senses in determinations about products. Often, only taste is of consideration and the industry tends to overlook that sensory evaluation is not just "taste testing." Also, this definition emphasizes the many disciplines that are involved with the complete and correct workings of sensory evaluation. Sensory evaluation is a quantitative science in which numerical data are collected to establish specific relationships between product characteristics and human perceptions (3). Sensory evaluation is a science of measurement. Like other analytical test procedures, sensory evaluation is concerned with precision, accuracy, sensitivity, and avoiding false positive results (4). Analysis of data is a critical part of sensory evaluation. Data generated from subjects are often highly variable. There are many sources of variation in individual responses that are extremely difficult to control in sensory testing. Examples include the participants' individuality in personality traits, habits, attitude, acuity of perception, product familiarity and frequency of consumption.

The interpretation of results is one of the most difficult parts of the formal sensory evaluation process. Once the data are obtained and results generated, it is the tedious job of the sensory analyst to carefully write the report and supply the information to the necessary party of interest. Many persons housed in separate departments within a business or research facility take this information and focus on it in an incorrect manner due to the outcome often times not being as they would have liked.

II. PRINCIPLES OF SENSORY EVALUATION

The sensory technique chosen for a particular test is determined by the objective of the study. When testing for acceptability, trained panels should not be used; consumer groups should also not be used to generate descriptive data. Product samples should be labeled with three-digit random codes to alleviate bias. The sample order should be randomized to assist in reducing biases. Panelist influences should be kept to a minimum during evaluation.

A. Sensory Perception

Sensory adaptation, due to continuous exposure of a particular stimulus, will lead to a significant decrease in responsiveness. Foods can be complex mixtures encompassing all attributes. Due to the complexity of a mixture, suppression within modalities will occur. Thus, the perceived intensity will be affected and could possibly be recorded as a lower value than if the intensity were to be recorded as a single attribute, which would represent a truer representation of the value describing intensity.

Taste and smell can be confusing. Many people cannot distinguish between the two due to olfactory sensations arising from volatiles of the food matrix. If subjects are untrained, these sensations can be recorded incorrectly as either representing taste or smell inappropriately.

B. Sensory Testing

Sensory testing was initially developed from an industry standpoint to perform an economic function. It can determine the worth or acceptability of a product as its final result. The principal uses of sensory evaluation are in research, product development and maintenance, quality assurance and as a marketing tool. Sensory testing encompasses many fields other than food. Its primary function is to conduct valid and reliable tests that will in turn provide necessary data upon which sound business decisions can be made.

If sensory analysis is to be dependable, the skill of the sensory analyst in optimizing the proper techniques in sensory testing is of critical importance. There are several general steps that should be followed in sensory testing. The first step is to define the problem, followed by method choice, decision on panel type, experimental design, data analysis, and report generation. The method selection can be a decisive decision. The three categories of sensory techniques are: discrimination procedures, descriptive analysis, and affective testing. The discrimination procedures are designed for difference detection; descriptive analysis is focused on sensory changes; affective testing gathers consumer, preference, or hedonic data.

The selection of the subjects who will be the measuring instruments of the designated study is a critical step in sensory testing. Humans are excellent relative measuring instruments but poor absolute measuring instruments. The basis of qualification of human subjects can be one of the most time consuming sections of the sensory project. Subject or panel maintenance, performance measurement, participation monitoring, and other concerns are necessary duties that must be continually kept in the forefront of the sensory study.

III. SENSORY EVALUATION OF FROZEN FOODS

Before frozen food can be evaluated properly, quality measurements must be determined and properly defined. The definition of the sensory quality of a food or food product is "the acceptance of the sensory characteristics of a product by consumers who are regular users of the product category, or who comprise the target market for the product" (5).

The effects of prolonged storage of foods in the freezing range are varied. In some instances, such as with butter or fatty foods, the odor may become unpleasant by a process such as rancidity. In other foods, such as peaches, the process of oxidation may alter the appearance or color. In some products, such as fish, off-flavors may develop by

both physical and chemical processes. In other cases, such as asparagus, the texture may become undesirable. And in many cases, the nutritive value of the fruit or vegetable may be affected by processes of hydrolysis and oxidation. All these criteria that go into food quality — odor, appearance, flavor, texture, and nutritive value — are important in the defining of "satisfactory" food storage.

For example, frozen peas will lose their desirable bright green color and acquire a yellow to brown tinge at temperatures above 15°F (6), owing to a slow destruction of chlorophyll, the characteristic pigment of green vegetables and other plants. This change is not evident when the storage temperature is maintained at 0°F or less.

Yet tasting panel tests on frozen and stored halibut (7) and salmon (8) have clearly demonstrated that the temperature of storage is more important in maintaining quality than is the freezing rate. Even the texture of twice-frozen foods cannot be the equal of fresh-frozen quality produce. The following sections are brief overviews of selected foods and food groups. The authors selected the most predominant sensory aspects as the primary focus of discussion and review.

TABLE 58.1
USEPA* National Secondary Drinking Water Contaminant Standards (10)

Contaminant	Effects	SMCL** mg/L
Aluminum	Colored water	0.05–0.2
Chloride	Salty taste	250
Color	Visible tint	15 color units
Copper	Metallic taste, blue-green stain	1.0
Corrosivity	Metallic taste	Noncorrosive
Foaming agents	Bitter taste, odor	0.5
Iron	Metallic taste, orange staining	0.3
Manganese	Bitter metallic taste	0.05
Odors	Musty or chemical smell	3 TON***
pH	Low pH- bitter metallic taste, high pH- soda taste	6.5–8.5
Sulfate	Salty taste	250
Total dissolved solids	Salty taste	500
Zinc	Metallic taste	5

* USEPA — United States Environmental Protection Agency.
** SMCL — secondary maximum contaminant level.
*** TON — threshold odor number.

A. Water

The Safe Drinking Water Act (SDWA) establishes regulations for maximum contaminants (primary and secondary). It is not the aim of this section to review primary contaminants that may affect the health of consumers, but to review the secondary contaminants that can cause flavor problems in water itself and/or products in which water with such defects are used. The International Association of Water Quality (IAWQ) specialist group of taste and odors developed a Drinking Water Flavor Wheel that includes the four basic tastes recognizable by the tongue (sour, sweet, salty, bitter) and eight odor descriptors (chemical, medicinal, fishy, fragrant, swampy, grass/woody, chlorinous). Mouthfeel is a descriptor considered as part of the flavor component (9).

Table 58.1 shows the secondary contaminants in water according to the Environmental Protection Agency (EPA). Major problems encountered are the metallic taste cause by copper, iron, manganese, and zinc. Salty taste is caused by chloride, sulfate, and total solids dissolved. Bitter taste is produced by foaming agents, manganese, and low pH (10). Iodinated trihalomethanes, which are disinfection by-products, are considered to cause medicinal odor with odor threshold concentrations of 0.1 to 8.9 g/L. Using flavor profile analysis (FPA), these odorants are described as sweet, solvent, and medicinal (11).

To control taste in water, it is necessary to control inorganic ions. However, organic compounds such as 2-alkyl-5,5-dimethyl-1,3-dioxanes and 2-alkyl-4methyl-1,3-dioxolanes, malodorous compounds have been identified in groundwater as well as in river water and tap water (12). The use of threshold odor number (TON) for odor detection in water seems to not be the most adequate method; therefore, the use of flavor profile analysis (FPA) has been suggested (13,14). Some of the most common odor reference standards used in raw and finished drinking water for FPA are: geosmin (earthy), 2-methylisoborneol (earthy), trans-2-cis-6-nonadienal (cucumber, green vegetation), m-xylene (sweet solventry), benzofuran (mothballs), cis-3-hexe-1-ol (fresh grass, green apple), and dimethyl sulfide (septic, musty) among others (15).

However, especially for drinking water samples from river sources, there may be 200-300 volatile organic compounds present at concentrations greater than 1 ng/L as measured by capillary gas chromatography (GC). Any of these chemicals alone or in combination can cause water sample odor. The odor-causing compounds are often unknown. The concentrations of individual compounds are usually below their odor threshold concentrations (OTCs). Since the identification of all the GC peaks of a typical drinking water sample by GC/MS is usually not possible and the consideration of all compounds is desirable, statistical correlation methods can be used to mathematically describe the relationships between volatile chemicals and tastes and odors (16).

In the food industry, secondary contaminants have a zero tolerance for turbidity, color, odor and taste. To achieve these criteria several water treatments are available. The traditional water treatment is coagulation/flocculation. An alternative is the multiple barrier treatment that includes the use of Ultrafiltration/Reverse osmosis.

B. Bakery Products

Baked goods are highly perishable, and their attractiveness declines rapidly within a few hours of being taken from the cooking mechanism. Freezing is the most-used preservation method that significantly retards quality changes. This is the main reason for the huge market for frozen bakery goods. The history of the frozen food market began with frozen pizzas and doughnuts. The market has expanded tremendously in the last decade.

Like all foods with a significant level of water activity ($a_w > 0.9$), baked foods are subject to microbial contamination and growth during storage. Freshly baked bread is sterile; contamination with mold spores is deposited on the bread surface during cooling and/or packaging. Staling is another limiting factor in the shelf-life of baked goods. During baking, the starch granules present in the flour gelatinize. Upon cooling and storage at ambient temperatures, this gelatinized starch slowly recrystallizes. This retrogradation contributes to an increase in crumb firmness, and leads to a harsh, dry mouth-feel when the product is eaten (17).

Freezing of freshly baked product that has been properly formulated, frozen, stored and refreshed (regardless of the time it has been in the freezer) has sensory properties comparable with the same unfrozen product less than 1 day after baking (17). Quality defects observed in frozen, thawed fully baked products can be traced, for the most part, to migration of water during freezing, storage and thawing. Defects of migrational sorts are: slimy icing, disappearance of icing, wet surface area. Staling is accelerated at low temperatures, which can often lead to toughness of product. This toughness is mostly due to denatured protein. A high-gluten flour gives a tougher product than a low-gluten flour.

The icings, glazes, and fillings of baked goods depend on a fine balance between water, sugars and hydrocolloids to achieve the desired product characteristics (17). These properties include a dry appearance coupled with flexibility and short body, no free water and good suspension of solid fruit pieces for fillings. Freezing can alter the interaction between water and hydrocolloids so that on thawing, free water is present; this results in melting or disappearance of icings and glazes and leads to wet, leathery, unappetizing fillings. Ice crystals formed from free water are prone to sublime during frozen storage and a rim of ice on the inner surface of the packaging indicates that the water has not been adequately bound and stabilized in the icing or filling (17).

The sensory properties of bread and rolls can be greatly altered by the handling of the products. The importance of complete cooling is utmost and greatly affects the quality. Bagels have a chewy texture, and improper freezing techniques can lead to a leather-like texture. Also, soggy dough is a problem with bagels. Croissants are made with layered dough that is rolled into a thin sheet that is spread with shortening or butter. The detrimental freezing attributes here are decreased flakiness, chewiness, and often wetness. Pizza dough is ideally suited for frozen storage. Having a high surface-to-mass ration, the dough freezes quickly and efficiently in a freeze tunnel. Waffles and pancakes are much like bread and rolls regarding proper handling techniques before freezing. Sogginess and wetness is often a problem with waffles and pancakes.

TABLE 58.2
Sensory Attributes in Frozen Bakery (17)

Product	Attribute
Bread	Crumb firmness
	Harshness
	Dry mouthfeel
Icing, glazes	Wetness
	Leathery
	Unappetizing
Croissants	Flakiness
	Chewiness
	Wetness
Pizza	Sogginess
	Wetness
Cakes	Crumbliness

Cakes and other such sweet products have been successfully frozen without loss of sensory attributes. However, it has been noted that loss of volume by as much as 20% during frozen storage has occurred with certain formulations (17). Moister cakes show better volume retention, whereas dry crumb cakes such as chocolate tend to develop a crumblier texture after being frozen. Pastries that are frozen develop a dryness and hardness. If they are filled with filling, the filling will often be gluey or rubbery.

Biscuits, due to their low moisture content, are successfully frozen for lengthy periods of time. Freezing of biscuits imparts flavor retention and is an excellent method for preserving baked goods of this type. Cookies or cookie dough have similar properties of biscuits when frozen. Products of this type have very good retention of sensory attributes when thawed.

Pies are handled very similar to cakes, but they suffer a greater number of detrimental effects when thawed. Syneresis can be a major problem with pie that has meringue, or certain fillings. The fillings of crème pies can develop a rubbery or gluey texture after extended frozen storage and improper handling techniques. The filling must be formulated to withstand freeze-thaw cycles and still retain stability. Custard-type pies freeze well and typically thaw well with minimal loss of sensory attributes.

C. Dairy Products

The changes that occur during freezing vary among dairy products from minimal to extremely severe. The lower the

temperature at which the product is stored, the slower the deterioration rate of the product, and the better the product quality after defrosting. Since the storage temperatures depend on the type of product (frozen or non-frozen), there is a different relationship between the product in question, the storage temperature, and the product quality. Freezing points of dairy products should not be used as the temperature at which to freeze the product. This is due to the fact that storing products at a temperature above which ice is formed may successfully attain preservation, in some cases. As a result, one needs to understand the impact frozen storage has on product quality before choosing freezing as a preservation method. For a number of dairy products the changes during freezing are minimal while for others the changes are very serious. In liquid dairy products freezing causes destabilization of proteins and fat. The destabilization (dehydration) of the protein is accompanied by an increased concentration of mineral constituents and lactose in the unfrozen part. Ice crystals and fat crystals contribute to the destruction of the fat globule membrane leading to the formation of free fat. The lower the temperature, the slower the speed of the deteriorative reactions and the better the quality after defrosting. For every dairy product there is a different relationship between storage temperature and time it takes to undergo a certain amount of quality change (18,19).

1. Milk

Fresh milk may be frozen if storage is required for consumption at a later date or if shipment of the product is required. When thawed, however, the product should still taste relatively "fresh." The flavor of unfrozen whole milk is pleasantly sweet, possessing neither a foretaste nor an aftertaste other than that imparted by the natural richness (20). In addition, it should have no off-colors or lumps visible to the eye. These attributes are often retained better through freezing than any other method. However, if raw or pasteurized milk is improperly frozen, flavor deterioration may occur. Oxidized flavors may appear as a result of the destruction of the milk-fat globule membrane (21). These flavors may increase in intensity the longer the product is frozen. Tressler et al (22) stated that the occurrence of the traditional oxidized flavor defect can be reduced by adding small amounts of ascorbic acid, pasteurizing at relatively high temperatures, homogenizing and controlling the daily ration of the dairy cow.

Preservation of milk by deep-freezing also causes changes in the physicochemical balance, and separation of milk solids occurs upon thawing. Freezing milk at −10°C results in the destabilization of proteins and fat, whereas storage of milk at −30 to −40°C aids in retaining milk's stability longer (23). This destabilization, in turn, increases the mineral constituents and lactose present. By increasing the concentration of these components, tricalcium phosphate is precipitated and the pH value of the milk is reduced. Fat globule aggregation occurs and milky layers and butterfat lumps are noticed (23). Milk fat and total solids are lower in frozen milk samples. Therefore, milk should be stored at lower storage temperatures to minimize separation of the milk components and increase the quality of the product. Milk fat and total solids have been shown to be lower for frozen samples than for those analyzed fresh. Babcock fat test was also affected by rate of freezing and possibly by an interaction between freezing and thawing rates. Milk fat, protein, and total solids in fresh milk can be accurately predicted from determinations on milk which had been frozen and thawed (24).

Thawing of the frozen milk is also critical in minimizing sensory defects. Thawing the container of frozen milk in warm water or in a refrigerator overnight are considered satisfactory methods with minimal adverse defects (22). However, if the product is thawed improperly and lumps or gels are noticed, warming and stirring the milk may aid in redispersing the protein.

2. Cheese

Quality and acceptability defects from freezing are probably most noticed in cheese. Cheeses vary based on the type of milk they are made from, the method of milk coagulation used, amount of whey retained in the curd, whether the curd is ripened or unripened, method of ripening and the type of milk used to make the cheese (goat, cow, sheep). Structure and quality of the cheese are greatly affected by the fat content. The variances among cheese types affect the overall color, texture, odor, and flavor of the product. Freezing is not usually recommended with ripened cheese as a preservation method due to the physical breakdown in the body and structure of the product. However, it is useful in preserving unripened cheese like cottage curd. Previous studies have indicated no differences in the variables between the control and the frozen cheeses. The increase in pH at the end of ripening was less pronounced in the frozen cheese but not significant.

Processed cheese does not freeze well even with the incorporated emulsifiers typically found in these types of cheese foods. Gordon (25) stated that on no account is processed cheese to be stored below freezing point since freezing has a deleterious effect on the cheese structures as in normal cheese. The appearance of structural defects in processed cheese depends on the temperature, the concentration of water-soluble substances in the cheese and its fat content. The physical change of the structure of frozen cheeses does not affect the subsequent quality of the processed cheese manufactured from them. In a time of surplus Gouda and Cheddar cheese can be stored for 1 year (or even longer) at −10° to −20°C and can then be used for the manufacture of a good quality processed

cheese. This method of preservation does prevent the development of off-flavors or unpleasant sharp flavors found in cheese stored for a long time at normal ripening temperatures. According to Burkhalter (26), Emmental and Gruyere cheese used for making processed cheese may be stored frozen (at −20°C), but otherwise untreated, for approximately 18 months, provided that the outer zone (rind) with its tallowy, soapy flavor is removed. Storage at −10°C for 5 months had no significant effect on the structure and quality of processed cheese while the same type of cheese stored at −30°C became mealy. A cheese spread was even stable at −30°C.

Storage experiments carried out on skim milk cheese and cream cheese at −10°C and −25°C showed that these cheeses could be stored for up to 6 months. Apart from a slight whey separation after thawing, the texture remained smooth and the flavor was good. American Cottage became somewhat softer and had a rancid and sharp flavor. The off-flavor was probably due to the poor quality of the cream used for dressing. The results indicated that cream cheese can successfully be stored at −20° to −30°C for 4 to 12 months depending on the initial quality of the cheese (23).

External characteristics of cheese are the first items noticed by a consumer and qualified judge. The color is less intense in frozen cheese. Luck (23) stated this might be due to the microstructural changes of the paste, which occur due to the formation of ice crystals resulting from freezing the product. The structural changes give rise to a more open structure increasing the refraction and clarity of the cheese. In addition, the number, size and distribution of eyes formed in Swiss cheese are reduced and irregularly distributed.

Consumers observe the internal body and structural characteristics next, which include the texture and flavor of the product. This is where the major defects occur in cheese that is frozen. The physical structure of the cheese is broken down during the freezing and thawing stages. The extent to which the structure and body are affected depends on the degree of ripening, amount of salt used in the formulation, and the moisture content in the cheese variety. This in turn affects the degree to which ice crystals are formed when the cheese is stored between −1° to −16°C and the degree to which the defects are noticed. Hydrogen bonds in the polypeptide chains break down causing water to separate from the protein. A crumbly and mealy body is produced. The grainy texture of the body of cheeses is intensified by slower freezing speeds (27). The main defect of cheeses made from frozen curd is in body and texture. The external appearance of cheese pieces is usually normal whereas internally they were made up of layers, similar to those observed by Schulz in soft cheeses. This layered structure may be from ice crystal formation in the serum phase between the casein micelles although the deep-freezing was rapid (30 minutes at −40°C). The method used in France for deep-freezing curd is only for hard cheese. In this case mechanical stirring of curd or its mixing with freshly made curd before further cheese making, can be used to reduce this texture defect. Deep-freezing of curd is applicable for making Teleme from ewe's milk. The cheese produced is not inferior to the cheese made under normal conditions in constituents or sensory qualities. Deep-freezing of curd is applicable for making Teleme from ewe's milk (28).

The odor intensity, overall taste and acidity are also modified by freezing and storage. An increase of hardness and decrease in creaminess in frozen cheeses after 3 months of storage has been reported by (29). However, the acidity, odor, flavor and intensity decrease during storage (29) producing a very mild cheese. Frozen storage did not result in significant alterations in overall compositional, rheological and sensory properties or the level of lipolysis. The extent of proteolysis was slightly lower in the cheeses frozen prior to ripening. Although, some satisfactory results have been achieved when freezing soft cheeses (30).

The grainy aspect of cheese can be significantly affected by storage time. Quality parameters remained relatively constant up to 180 days storage typically following a sharp increase thereafter. This increase is a clear sign that the texture of the cheese is considered altered and granulous properties therefore determined. The graininess of cheeses frozen at slow speeds and for 9 months have been shown to be significantly different to that of the other storage methods of cheeses. Cheese graininess is therefore more intensely affected at slower freezing speeds and when the frozen storage period exceeded 6 months. In this respect, Luck (23) reported that freezing caused a breakdown in texture, prompted by the formation of ice crystals and the subsequent alteration of proteins.

Although some authors have described changes in the texture of frozen cheeses, it is recognized that intensity is greater with slower freezing processes (27). Neither the storage time nor the freezing process significantly modified the hardness and creaminess of the cheeses during storage. Slower freezing processes should be implored to minimize the flavor, odor, aroma and textural defects when processing cheese. The changes of the texture due to freezing can be prevented by storing the cheese at temperatures just above its freezing point (−2° to −5°C). This is a successful method of preservation. Camembert cheeses frozen immediately after making were acceptable after defrosting under normal conditions for up to 3 weeks. Not only does a slower freezing process minimize quality defects, it is more economical from the industry's viewpoint. When the freezing process is implored in this manner it is a practical and economical method in regulating the quality of cheese products, especially that of ewe cheese (29). Consequently, once the cheeses have been frozen, these attributes would not be modified by excessively long storage times. In this respect, Diefes (31) concluded that freezing lead to local protein dehydration, due to the destruction of the protein matrix, giving rise to

greater hardness of cheese. Differences are typically not seen during more prolonged periods of frozen storage in terms of the attributes characteristic of the appearance of the paste, color, appearance and eyes, due to the specific freezing procedure used. Odor, flavor intensity, acidity, and grainy appearance change as a consequence of frozen storage. With up to 6 months storage, practically no differences can be detected with respect to the nonfrozen cheeses; however, after 9 months storage, the acidity, odor intensity, and flavor decreased and the grainy body increases substantially. Saltiness was not affected by freezing nor by frozen storage. The speed of the freezing process only affects the graininess of the cheese, which is slightly greater in slowly-frozen cheeses. From the sensorial standpoint, freezing is therefore a suitable method for regulating the cheese market.

Cheeses could be stored at −20°C for at least 3–6 months, ensuring their availability for sale throughout the year. Slow freezing speeds are recommended, since the small deficiencies in quality detected in cheese frozen at slow speeds are recovered from an economic standpoint, since the faster process is much more costly. Alterations in texture (28, 27) and the presence of oxidized flavors were the main problems detected in cheeses after thawing. However, some of these studies have not reported any deficiencies in frozen cheeses (32), occasionally obtaining a higher sensorial quality with respect to nonfrozen cheeses (33). Odor intensity, intensity taste, and acid taste were modified by freezing and storage, so that to the 270 days of frozen storage were significantly descended. Significant differences have not been detected between salty taste of nonfrozen cheeses and frozen cheeses and stored in freezing.

Texture is substantially altered by freezing and frozen storage, with noticeable increases in the grainy body at 9 months of frozen storage. In the same way, an increase of hardness had been detected and a decrease in creaminess in frozen cheeses from 3 months of frozen storage. The external characteristics of the cheeses also demonstrate important changes after freezing. Color is less intense in frozen cheese. This could be due to microstructural changes in the paste, produced by the formation of ice crystals, giving rise to a more open structure, increasing refraction and making the cheese seem clearer. The number, size and distribution of the eyes are reduced after 90 days of storage in freezing, probably due to the destruction of the structure or wall forming the eyes. These usually decrease in size and in some cases disappear, giving rise to a more irregular distribution. Even though salty flavor is not modified by either storage time or the freezing process used, the intensity of flavor decreases significantly with longer frozen-storage times. Flavor intensity remains practically stable up to 6 months frozen storage, decreasing rapidly thereafter, and regardless of the freezing process use. Some authors have reported no differences in terms of flavor intensity between cheeses prepared from frozen curds and unfrozen cheeses (33), although others have also described very low scores in slowly frozen cheeses and thawed immediately (34). Similarly, other authors have reported no modification in the flavor of Cheddar cheese undergoing frozen storage (35).

As with regards to the intensity of acidity, frozen-storage time has a significant influence on the acidity of the cheese. Texture alteration is one of the adverse effects of freezing in cheese. This quality defect has customarily been attributed to the formation of ice crystals and the resulting mechanical effects. However, other findings suggest that alterations in cheese texture are a consequence of changes in protein structure, such as breaking of hydrogen bonds in the polypeptide chains and changes in water-binding capacity. Such changes lead to more active proteolysis in cheeses that have previously been frozen. In prefrozen cheeses, unordered structures increase immediately after thawing. The proportion of unordered and turn structures is apparently higher in the cheeses frozen more slowly in a plate freezer than in the cheeses frozen more quickly in liquid nitrogen vapor (27).

Slower freezing processes should be implored to minimize the flavor, odor, aroma and textural defects when processing cheese. The changes of the texture due to freezing can be prevented by storing the cheese at temperatures just above its freezing point (−2° to −5°C). This is a successful method of preservation. Camembert cheeses frozen immediately after making were acceptable after defrosting under normal conditions for up to 3 weeks. Not only does a slower freezing process minimize quality defects, it is more economical from the industry's viewpoint. When the freezing process is implored in this manner it is a practical and economical method in regulating the quality of cheese products, especially that of ewe cheese (29).

3. Ice Cream

Freezing is the standard method for processing and preserving ice cream. The quality, palatability, and yield of the finished product are all dependent upon freezing of the ice cream mix. Since no two individuals will execute the details of the freezing operation exactly the same each time, programmed freezers are becoming widely used in the industry to control quality of the product. An ideal ice cream possesses a fresh, clean, pleasant and delicate flavor with a smooth texture. It has a natural color; melts slowly into a liquid state and any particulates present are evenly distributed (36). Regardless, however, of freezer automation, defects can still occur in the flavor, body and texture of the product.

Texture defects are the most common result of improper freezing of ice cream. The most frequently noticed texture defect is referred to as coarse. It is observed by a grainy or icy feeling and accompanied by unusual coldness. Numerous factors contribute to this widespread defect.

TABLE 58.3
Sensory Attributes of Frozen Dairy Products

Product	Attribute
Fresh milk	Sweetness
	Off-colors
	Oxidized flavors
	Lumping
	Gelation
Cheese	Color- intensity
	Odor- intensity
	Flavor- overall, oxidation
	Off-flavor
	Texture- structure, crumbly mealy, grainy, hardness
Ice Cream	Texture- coarse, greasy sandy, gritty

Higher fat mixes decrease the occurrence of this defect in the product because fat globules obstruct the growth of ice crystals. Dipping cabinets are usually kept around −15°C. At this temperature it is reported that ice crystals can double in size increasing the coarseness of the ice cream (36). Therefore, temperature control in dipping cabinets should be more closely regulated to minimize this particular texture defect. A greasy mouthfeel is often associated with the buttery defect. The cause is over agitation of the ice cream mix in the freezer and can be reduced through automated freezing operations. One of the most objectionable defects in ice cream is known as a sandy texture. A gritty mouthfeel results from crystallization of lactose when temperature fluctuations and extended storage times occur. Again, temperature control is critical in controlling texture defects in ice cream.

Flavor and body defects usually result from the addition or absence of ingredients. However, one body defect resulting from temperature fluctuations during storage is that known as shrunken. The ice cream product does not contact fully the sides of the container according to Marshall and Arbuckle (36). When products are frozen to unusually low temperatures or if the product is allowed to warm and then is refrozen, the pressure on air cells changes and results in a shrunken appearance not desired by consumers.

4. Yoghurt, Cultured Milk and Buttermilk

Normal yoghurt, cultured milk and buttermilk are not successfully frozen to prolong their storage life. After a storage period of 3 months at −10°C the flavor is satisfactory but the texture is completely broken. There is an intense whey separation and the products give a mealy sensation on the tongue. Stirred yoghurt may be successfully frozen (−26°C) provided that the total solids content of the yoghurt is sufficiently high as in the case of plain yoghurt. Storage experiments carried out at −25°C on yoghurt of higher solids content did not confirm these results. The texture of the defrosted products was only slightly improved. The quality of the yoghurt was such that it would hardly have a chance on the market. Because it is possible to make frozen yoghurt dessert, it will probably be possible in the future to preserve yoghurt by freezing after adding a suitable stabilizer. At this stage fermented milks are not suitable for preservation by freezing.

D. Fish and Seafood

Human perception of food is complex and may be influenced by the sensory characteristics of the food material but also by the personal experience of the observer, psychological state, ethnic origin, religious conviction (37). Analytical testing to determine differences or similarities in seafood, to identify quality attributes, or to estimate relative intensity of sensory attributes is usually accomplished in a laboratory setting. Difference tests are designed to identify samples that differ in terms of sensory characteristics. Ranking tests (ordinal scaling) are used to determine the rank order of a set of samples for degree of a specified sensory attribute. Scalar testing methods are used to provide information about quantitative relationships among product samples. Descriptive analysis is the most demanding of any sensory method. Panelists determine the qualitative characteristics of aroma, flavor, texture, aftertaste, etc., and they describe a set of descriptors. The traditional flavor profile method requires intensive training (38).

Changes in appearance and eating quality that occur during frozen storage of fish are of great commercial importance. Freeze burn appears on the surface of frozen fish due to loss of moisture, cooked muscle flavor may possess a characteristic “cold store” note and toughness and dryness increase rendering a less acceptable fish. Tasting and determination of sensory attributes still remains the method of choice to detect changes during frozen storage. Sensory methods used to assess frozen fish can be classified into three categories: a) those in which tasters are asked to assess the fish on a scale of acceptability; b) those in which certain diagnostic features are rated on intensity scales; and c) those in which comparisons between two samples are made in order to distinguish the sample under test. Sensory factors that change during frozen storage include toughness and dryness and flavor. Scoring systems based on odor, texture, and flavor have been developed for fish inspectors. Freezing and frozen storage affect the appearance of fish on thawing (39).

The first quality judgment made by a consumer about a fish product at the point of sale is based on its color/discoloration. The next judgment is about the product’s texture: any gaping or ragged fillets. This is followed by odor judgment. A standard sensory evaluation for fish should include color of the flesh, odor and visual texture, absence/presence of blood clots and of bruising and discoloration,

absence/presence of physiological abnormalities, and workmanship (40). Aroma is one of the most important freshness determinants of fresh fish and fishery products. Sensory assessments are desirable because they provide immediate quality information. Initial changes in the aroma of freshly caught fish involve the shift from the fresh, planty aromas to a neutral, flat-sweet odor. This characteristic sweet aroma appears to be contributed by alcohols and 3,6-nonadien-1-ol, which has a sweet melon-like aroma (41).

Frozen storage is an important preservation method for seafood. Freezing and frozen storage contribute to changes in texture as a result of protein denaturation. Also, the thawing method is important since it is recognized that this can affect the sensory attributes of seafood. Myofibrillar proteins undergo denaturation and aggregation during frozen storage. Different species of fish have different degrees of susceptibility. Ingredients such as triphosphate, lecithin and sucrose ester have been used in order to prevent these changes that will affect the textural properties of muscle (42).

Considering all foods under the category seafood, there is a large range in texture. As long as texture falls within the normal range, it does not influence preference as do flavor and appearance. Texture is a critical factor for shellfish, surimi-based products, and squid (43). The texture of fish muscle changes from soft, moist and succulent to unacceptably firm, hard, fibrous and dry. The unacceptability of fish flesh/muscle as food is caused by its increased tenderness due to myofibrillar fragmentation. At −8 and −20°C, carp shows degradation in its myofribrillar fraction after six months (44). Freeze–thaw cycles affect the loss of protein solubility and the physicochemical and enzymatic properties of cod muscle proteins (45).

Sensory analysis is used to assess the quality of fish products. However, it is considered subjective and prompt to error. During frozen storage there is an alteration of functional properties of muscle proteins, loss of water-holding capacity, juiciness, and changes in texture. Mechanical properties can be measured. Shear resistance can be measured using the Kramer shear-compression cell. Correlation between sensory analysis and shear resistance measured by Kramer has been reported in fish hardened as a result of time in storage and also in fish stored at different temperatures. Shear resistance can also be measured using the Warner-Bratzler shear cell. Shear resistance as analyzed by the W-B cell has been found to increase significantly with time in frozen storage under different forms of pre-processing. The puncture test consists of measuring the force required to push a plunger into a food sample. This method assesses changes in texture during storage in ice as associated with the onset of *rigor mortis*. Tension analysis measures the force required to break a sample when is held by two parallel clamps. This test is sensitive enough to measure the viscoelastic properties of fish muscles and has been used to quantify textural changes in the mantle of squid. In compression analysis, the deformation is measured upon application of compression force. This analysis can be performed in one or two successive compression-relaxation cycles. In minced or cooked fish products a deformation of 50% is customary. However, for some mince products and fillets a deformation of 30 and/or 10% is used. Firmness generally tends to increase with time in frozen storage. Correlations between one-cycle compression measurements and sensory parameters such as elasticity in mackerel (*Scomber scombrus*) and hake (*Urophycis tenuis*) have been reported. When the first compression-relaxation cycle is followed by a second compression cycle, the test is known as texture profile analysis (TPA) (46).

Common descriptor terms for cooked seafood include: flavor intensity, fresh fish, gamey, old fish, sweet, briny, sour, seaweed, bitter, fish oil, buttery, nutty, musty, ammonia, metallic, shellfish, flakiness, firmness, moistness, chewiness, mouth-drying, fibrousness, oily mouth coating, cohesiveness, whiteness, and darkness (47). The Flavor Profile™ method is used to describe the aroma, flavor-by-mouth, and aftertaste attributes of cooked fish muscle. Intensity of aroma and flavor character notes are rated on the traditional 4-point profile scale: 0 = just recognizable or threshold; 1 = slight; 2 = moderate; 3 = strong; a designation of 0.5 was used to show an intermediate level of intensity. To describe 17 species of North Atlantic fish the following aroma descriptors were used: briny, sweet, fresh fish, old fish, stale fish, sour, shellfish, gamey fish, fish oil, earthy, nutty-buttery, musty, and scorched. The flavor descriptors were: salty-briny, sour, sweet, fresh fish, old fish, stale fish, shellfish, gamey fish, fish oil, earthy, nutty-buttery, canned salmon, bitter, metallic, mouth drying, and mouth filling (48).

A new seafood nomenclature system, to be used on the sensory or "edibility" characteristics of fish, has been developed by the National Marine Fisheries Service (NMFS) of the U.S. Department of Commerce. The goal of this system is to enable consumers to make educated choices among novel species by providing the comparative sensory data necessary to select a desired flavor, texture, etc. of fish. Standardized methodology for evaluating the sensory properties of cooked fish has been developed (49).

1. Bluefish

Bluefish has a strong total aroma and flavor impact, with a highly aromatic distinctive gamey, fresh fish, sour, fish oil character. The amplitudes (overall impressions) are moderate, with character notes blending together to give a very full aroma and flavor. The aroma of Bluefish has an early impact of a slight to moderate briny, moderate fresh and gamey fish notes, slight fish oil and sour notes, and a very slight sweet. The flavor has an early impact of slight

sweet, moderate fresh fish, slight to moderate gamey fish and sour (sharp), very slight fish oil and salty-briny, and slightly mouth drying. This fish has a distinctive sour (sharp) at a higher intensity than in most fish. In both aroma and flavor, the gamey and fish oil notes seem to be related. They are found at higher intensities in the dark flesh (especially near the skin), but are also present in the lighter flesh. The aftertaste is strong and persistent. The reported Profile integrates proportionate light and dark flesh. The most common sample variation was in the intensity of flavor of the fish oil and sour notes, and sometimes the flesh and gamey notes (48, 49, 37).

2. Blackback Flounder

Blackback flounder has a low total intensity aroma and flavor with a delicate, fresh fish character. The aroma amplitude is just below moderate and the flavor amplitude is moderate. The aroma is slight sweet and briny, slight to moderate fresh fish and very slight sour. The flavor is slight sweet, slight to moderate fresh fish, below slight salt-briny, sour and mouth drying. The aftertaste is a low level fresh, mouth drying and sweet (48, 49, 37).

3. Catfish

Frozen catfish (*Clarias gariepinus* Burchnell) fillets frozen and stored at −20°C for 11 month using an oxygen-permeable packaging (OPP) material and a vacuum packaging (VP) showed no significant differences between any of the aroma, appearance, texture or flavor attributes for the two packaging materials over time during frozen storage. Texture of the catfish fillets changed after 7 months, becoming more flaky with few ice crystals between the fiber, more so in the fillets packed in the OPP. No color changes were observed during the 11 months of storage. After this period of time the frozen catfish fillets were acceptable (50). In another study, channel catfish (*Ictalurus punctatus*) was evaluated during frozen storage concluding that regardless of size, channel catfish is acceptable after 12 months of frozen storage (51). On the other hand, channel catfish fillets treated with ascorbate and kept frozen at −6°C for up to 6 months showed less rancid flavor (52).

4. Cod

The flavor of cod (*Gadus callarias* L.) has been described as sour and slight cooked potato. Common flavor descriptors are: buttery, green, biscuit-like, roasty, mushroom like, cabbage-like, fatty, and metallic. The malty flavor defect is caused by a strong increase of 3-methylbutanal (53). Cod (market) has a moderately low total intensity aroma and flavor, with a low sweet, fresh fish character. The aroma and flavor amplitudes are moderate, as the overall impression of Cod is of a mild fish with an uncomplex aroma and flavor. The aroma is slight to moderate briny and flesh fish, and below slight sweet, sour and shellfish. The flavor is slight sweet and mouth drying, slight to moderate fresh fish, very slight salty-briny and sour, and below slight shellfish. The aftertaste is fresh fish and sour. Occasionally, samples of Cod have a stale fish character note. Cod (scrod) has a moderately low total intensity aroma and flavor, with a low sweet, fresh fish character. The flavor is below slight sweet, slight to moderate fresh fish, very slight salty-briny, sour, and earthy (slight cooked potato), and slight mouth drying. The aftertaste is fresh fish, mouth drying, and sour. Some cod (scrod) samples have produced a stale fish character note and/or a metallic note.

During processing and storage, fish quality may decline due to oxidation of unsaturated lipids causing off-flavors and odors. In lean fish the production of formaldehyde (FA) is important along with protein denaturation and texture changes. Cod (lean fish) and haddock (non-FA-forming) show hydrolytic activity during frozen storage. Storage at −30°C decreases hydrolytic activity (54). For cod, deterioration in texture of the thawed product is a serious problem. The presence of formaldehyde due to enzymatic degradation of trimethylamide oxide (TMAO) into dimethylamine (DMA) and formaldehyde (FA) is an increasing factor of the denaturation of proteins. The quality index method (QIM) is normally used to evaluate fresh and frozen cod. This method is based on a selected number of independent parameters, which describes the quality of thawed cod. The scores for all single parameters are added to give the total quality index. For fillets the parameters are texture, color, bloodstains and gapping, which vary from 0 to 3, and odor and parasites, which vary from 0 to 2 (55).

Cod fillets are generally frozen after catch. It is recommended that fish filleted prior to *rigor mortis* must be frozen to diminish the risk of shortening and deforming. Cod fillets kept at frozen storage for 17 months and evaluated by a trained panel showed that fillets frozen before rigor keep fresher than those frozen after rigor after two months of frozen storage. The attribute 'dry/succulent' is rated in a scale from 0 to 100. Cod receives a score between 60 and 70 after two months of frozen storage. After 12 months fillets are evaluated 'drier' (score = 40). There is a direct relationship between frozen storage and the attribute 'succulent/dry.' The same relationship has been reported for frozen storage and 'tough/tender' (56).

North sea cod kept for 2, 5, 8, 14, and 17 days in ice, filleted and frozen in an air blast at −34°C and stored at −14°, −22°, and −29°C showed a gradual development of unpleasant odor and flavor called 'cold storage odor.' At the same time the fish becomes firmer and drier until it becomes tough and dry. Freshness flavor is unaffected by the freezing and thawing treatment, while firmness and dryness increase significantly (57). During freezing

at −20°C loss of tenderness and of water-holding capacity and fish flavor changes may occur. Prolonged storage of fish causes deterioration of texture as described in increased toughness, chewiness, rubberines, or stringiness. Toughness increases over time, whereas cohesiveness decreases during storage. Higher storage temperature results in faster rates of textural deterioration of cod muscle (58). Frozen cod fillets change texture over frozen storage (59) as a result of muscle proteins denaturation causing toughness of the muscle. Rapidly-frozen and slowly-frozen cod show no more denaturation after one year of storage than newly frozen fillets (60). Sensory attributes of thawed and refrozen cod include color, flavor (strength, fresh fish, saltiness, sweetness, stale, rancid, bitterness, and other flavors), and texture (firmness, flakiness, resilience, juiciness, cohesiveness, fibrousness, roughness, and fiber size). Thawing/freezing cycles do not affect the structure of the muscle even after 9 months of storage. However, slow thawing followed by refreezing resulted in fish that was grayer in color and staler in flavor. Storage time affected the sensorial attributes (61).

Frozen cod can develop off-flavors during storage. The main component for this off-flavor is hept-cis-4-enal. Samples stored for 18 months at −15°C had some of the following compounds: hept-*trans*-2-enal and hepta-*trans*-2,*cis*-dienal. These two compounds were examined and described as cold storage flavor (cardboard, musty). Threshold study showed that hept-*cis*-4-enal is detectable on very low concentrations (0.00004 ppm). Aldehydes present in cod samples originated from lipid oxidation and tend to increase with temperature of storage. The major aldehyde produced was hepta-*trans*-2,*cis*-dienal (62).

5. Cusk

Cusk has a moderately low total intensity aroma and flavor, with a low sweet, fresh fish character. The aroma and flavor amplitudes are below moderate, as this fish lacks fullness and blending, especially in flavor. The aroma is below slight sweet, slight to moderate fresh fish, slight briny and sour, and below slight shellfish. The flavor is below slight sweet and shellfish, slight to moderate fresh fish, slight salty-briny and mouth drying, and very slight sour. The flavor is flat, washes out quickly, and is affected by the chewy, slightly tough texture. The aftertaste is fresh fish, sour, and mouth drying (48, 49, 37).

6. Haddock

Haddock has a moderate total intensity aroma and a moderately low total intensity flavor, with a sweet, fresh fish, shellfish character. The aroma amplitude is just below moderate and the flavor amplitude is moderate, as this fish has a fullness of flavor and an interesting shellfish characteristic. The aroma is slight to moderate briny, and fresh fish slight sweet, shellfish, and mouth drying, fresh fish at slight to moderate, sour at below slight, and salty-briny at very slight. The sweet, fresh fish, and shellfish flavors seem to be related, and the sour taste is fleeting. Earthy (slight cooked potato) and metallic notes, particularly in the dark flesh portion, have been recorded. The aftertaste is fresh fish, sour and shellfish. There was some variation within a session and between sessions in the Haddock samples, particularly in aroma, and was evidence as stale fish character notes (48, 49, 37).

7. Hake

White Hake has a moderately low total intensity aroma and flavor, with sour (dishrag) aroma, and an earthy note in flavor. The aroma and flavor amplitudes are low to moderate due to the old fish, sour (dishrag), and earthy notes, which indicated a lack of blended characters. The aroma of White Hake is a slight to moderate sour (dishrag) and fresh fish and below slight sweet and briny. Aroma notes mentioned by panelists are old fish, earthy (slight cooked potato), and shellfish (clam). The flavor is slight sweet, sour (sharp), and mouth drying, slight to moderate fresh fish, below slight salty-briny and earthy (slight cooked potato). There was an unblended quality to the flavor, and when both earthy and old fish occurred, they seemed related. The aftertaste is fresh fish, mouth drying, sweet, earthy, and sour. This fish often showed great variation in the fresh fish and old or stale fish characteristics.

Quality of hake species (*Merluccius merluccius*, *M. hubbsi*, and *M. capensin*) varies for many reasons ranging from inappropriate fishing and freezing methods to inefficient distribution. Textural (mechanical) analyses such as puncture test, Warner-Bratzler, and Kramer press have been used in order to account for the variance of frozen fillets. As a result of this, four clusters were identified, ranging from excellent quality (low texture, high viscosity) to very poor (high texture, low viscosity). The parameters required for this classification are viscosity, maximum force from Kramer and maximum force and energy from the puncture test (46). Frozen Patagonian hake fillets (*Merluccius hubbsi*) evaluated by using the cook sensory assessment (CSA) shows that fillets remain acceptable for over 12 months both at −20 and −30°C (63).

8. Halibut

Halibut has a moderate total intensity aroma and flavor, with a sweet, fresh fish character, and a very slight gamey fish flavor note. The aroma and flavor amplitudes are below moderate as some samples lack a blended flavor. The aroma is slight briny, slight to moderate fresh fish, below slight sweet and sharp, sour (pungent). The flavor is very slight sweet, slight to moderate fresh fish, above

slight sour, slight salty-briny and mouth drying, below slight gamey and fish oil. The definite sour flavor note is higher than in most fish. The aftertaste is predominantly sour and mouth drying, with some fresh fish and another hard-to-describe note that seems to be a combination of fish oil and gamey (48, 49, 37).

9. Herring

Whole herring (*Clupea harengus*) wrapped in polyethylene film and block-frozen using plate freezers and frozen for 32 days at −24°C were beheaded and salted. Ten trained panelists conducted a sensory analysis to evaluate taste using the following descriptors: ripened, raw, malty/creamy, stockfish, salty, sweet, spicy, and aftertaste. The attributes for texture were: softness, watery and toughness. Spice-salted herring taste characteristics were typical with a dominant malty/creamy taste and a fairly low intensity of stockfish character. The thawed salted herring achieved higher values of the ripened taste during the first few weeks in comparison with the fresh salted herring. Also, the thawed spice salted herring appeared to become soft quickly during storage, indicating a faster rate of ripening. Hardness increased after salting but decreased steadily. Hardness of fresh spice-salted herring at 21 weeks was comparable with thawed herring kept for 16 weeks (64).

Herring is susceptible to lipid oxidation during processing and storage. Pre-freezing storage in refrigerated seawater followed by minimal tissue disruption, removal of oxygen, fast freezing, and low freezer storage temperatures reduces rancidity and gives the longest shelf life. Fillets of herring kept on ice prior to storage at −18°C for up to 84 days show that samples held for 6 days on ice formed oxidation product at the highest rate during frozen storage. Ice storage had a greater impact than frozen storage (65).

10. Grouper

Grouper has a moderately low total intensity aroma and flavor, with a low level of aromatics. The aroma and flavor amplitudes lack full-bodied characteristics, have a low impact of blended character, and low intensity of fresh fish characteristics. The aroma of Grouper has an early impact of slight sweet, and briny notes, and slight to moderate fresh fish, followed by a very slight sour (pungent), and a shellfish note. The flavor is very slight sweet, salty-briny, slight fresh fish, sour (sharp), and shellfish, and slight to moderate mouth drying (the highest intensity for the fish tested). The aroma and flavor shellfish note has a clam character. There are confusing overtones to the sour and shellfish notes that are difficult to describe. The aftertaste is persistent and consists of a moderate level mouth drying and sour, and a low level of fresh fish. The dry tough texture is difficult to ignore. The samples seemed relatively consistent within a session, and the greatest variations between sessions seemed to be in the sour, shellfish notes, with confusing overtones (48, 49, 37).

11. Mackerel

Mackerel has a strong total aroma and flavor impact, with a highly aromatic distinctive gamey, fresh fish, fish oil character. The amplitudes are moderate, with character notes blending together to give a very full aroma and flavor. The aroma of Mackerel has an early impact of moderate gamey and fresh fish notes, a slight to moderate fish oil, and slight sweet, briny and sour notes. The flavor has an early impact of moderate gamey and fresh fish notes, a slight to moderate fish oil, slight sweet and sour (sharp), and a very slight salty-briny and mouth drying. The mouth drying characteristics seem largely overpowered by the oiliness. In both aroma and flavor, the gamey and fish oil notes seem to be related. They are found at higher intensities in the dark flesh, but are also present in the lighter flesh. The reported profile integrates proportionate light and dark flesh. The gamey fish note of Mackerel is heavy and sometimes associated with a burnt or scorched characteristic. Despite the intensity and heaviness of this fish characteristic, it is typical of fresh Mackerel and not indicative of aged fish. The aftertaste is strong and persistent (48, 49, 37).

12. Monkfish

Monkfish has a moderately low total intensity aroma and flavor. Its distinguishing characteristic is a distinctive shellfish aromatic note similar to lobster and clam. The aroma and flavor amplitudes are moderate as this fish is full, complex and blended with interesting notes. The aroma is slight to moderate briny (fresh, seaweed), fresh fish and shellfish, and slight sweet and sour. The dark flesh and gelatinous areas near the skin have more intense briny-seaweed and shellfish-clam character than with flesh. The flavor is slight sweet and sour, slight to moderate shellfish and fresh fish, threshold salty-briny, and very slight mouth drying. The shellfish note adds interest and complexity to the aroma and flavor. The sweet, shellfish, fresh fish and buttery notes seem closely related and give a full flavor. The aftertaste is sweet, fresh fish, and shellfish (48, 49, 37).

13. Pollock

Pollock has a moderately low total intensity aroma and flavor with sweet, fresh fish, low shellfish character. The aroma and flavor amplitudes are moderate, as they are blended with some interest notes. The aroma is slight sweet, briny and sour (sharp), slight to moderate flesh fish, and below slight shellfish-clam. The flavor is slight sweet, sour (sharp) and mouth drying, slight to moderate

fresh fish, below slight shellfish-clam, and very slight salty-briny. Some of the samples had a small amount of dark flesh which a hard to define character related to gamey and fish oil. The aftertaste is sour, fresh fish, and sweet, with a persistent mouth drying. Metallic and stale fish notes can be found with this fish also (48, 49, 37).

14. Salmon

Flavor profiles of fish aroma and intensity differ among species. For fresh salmon, a fish oil characteristic is common. Also, bitter, metallic, nutty/buttery, and sour characteristics are often observed. Homogenates of salmon stored for 26 weeks at −60°C and −13°C and evaluated using aroma extract dilution analysis (AEDA) and gas chromatography-olfactometry (GC-O) gave some of the odor descriptors such as sweet, buttery, vegetable-like, green, cabbage like, mushroom-like, citrus-like, and cucumber-like. Green (Z-3-hexenal) and fatty green (Z,Z-3,6-nonadienal) are responsible for flavor defect in boiled salmon when stored frozen for a long period. The levels of these two compounds are higher in salmon because of its higher content of n-3 unsaturated fatty acids (53).

Components of low volatility can be the key compounds causing off-flavor. Formation of less volatile oxidation products could also explain why the volatile components identified in the stored salmon did not show significant time-temperature interaction effects nor did they correlate to the sensory attributes.

The most noticeable sensory change during frozen storage of salmon is an increase in intensity of train oil taste, bitterness and metal taste. This change is produced by compounds of low volatility but most of all due to free-fatty acids. Palmitoleic acid and linoleic acid, eicosapentaenoic acid, and docosahexanoic acid have high intensity of train oil, bitter and metallic taste (66). Frozen salmon (*Salmo salar*) become rancid after a few months of frozen storage. Also, fat content of fish diet has a direct relation in some sensory attributes such as color (redness) and the taste of salmon. Fish fed with 17% fat diet has shown differences in color (less red) and taste (less strong). Frozen storage temperature also influences color, hedonic consistency, hardness and juiciness (67).

Rancidity in fatty fish such as salmon is not well characterized and has been described as fish oil taste (67, 68) and as fatty and train-oily odors (53). The rancid off-flavor in salmon is caused by formation of volatile oxidation products such as aldehydes and ketones (53). Some of these volatile compounds have very intense odors and flavors and are, even in small concentrations, able to affect the sensory quality. The rancid off-flavor of salmon is mainly caused by an increase in (E,Z)-2,6-nonadienal with a cucumber odor, (Z)-3-hexanal with a green odor, and (Z,Z)-3,6-nonadienal with a fatty odor (53).

The odor of fresh raw salmon is characterized as cucumber-like with weak sweet, sourish, and fish oil notes. For the fresh and cooked salmon the same descriptors were used, but a boiled potato odor has been described as the most pronounced attribute instead of cucumber.

Panelists normally recognize sensory changes of frozen salmon. For train oil, metal, and bitter taste significant time-temperature relations have been determined. The intensity of these attributes increased during storage at −10° and −20°C. Changes in texture are also noticed at −10° and −20°C. Fresh cooked salmon is described as flaky, form, and juicy. After storage, salmon changed to firmer, less juicy and more fibrous (69, 70).

15. Shrimp

Texture, color and flavor of shrimp are influenced by frozen storage. Quality of frozen-stored shell-on and shell-off prawns at −29°C depends on thawing method and frozen storage time. Muscle proteins of freshwater prawn tails are susceptible to freezing-thawing processes, particularly during the first month of frozen storage. Protein destabilization is independent of the freezing method (blast versus still) and the presence or absence of shell, but is affected by thawing rate (71). Quick frozen prawns (*Machrobrachium rosenbergii*) stored at −18°C for up to 225 days and tasted after 1 day of freezing were rated acceptable. At 133 and 225 days, prawns had acceptable texture but thawing time must be increased from 4 hours, for 133 days old, to 24 hours for the 225 days old. Moreover, prawns should be cooked unthawed or after thawing for no more than 4-8 hours to retain its texture (72).

Shrimp are frozen shortly after catch and kept frozen until they reach the consumer. Shrimp kept in frozen storage can develop white spots in the shell, which definitely influence their appearance. During continued frozen storage the spots increase in size; therefore, the quality decreases. White spots are usually developed after 25 days of frozen storage; however, this is a result of the time a shrimp takes to pass through the production process. More important is the storage temperature. Alternating storage at −25°C and −29°C results in increased white spot formation compared to constant storage at −29°C (73).

Sensory variables for cooked, peeled and individually frozen shrimp (*Pandalus borealis*) include evaluation of natural red color, yellowish discolor, dehydration, shininess, smoothness, natural shape, total odor intensity, fresh odor, stale odor, fishy, ammoniacal odor, urine-like odor, sour odor, old seaweed odor, sulfide odor, rancid odor, cardboard odor, mud-like odor, total flavor intensity, fresh, sweet flavor, stale, fishy, sour, metallic, acrid, cardboard, stockfish-like flavor, rancid, mud-like, salty and aftertaste (74).

16. Squid

Studies indicate that squid has excellent freezing characteristics. Glazing or packing of the frozen blocks is essential in order to prevent desiccation during frozen storage.

Quality tests indicate that frozen squid at −18°C or lower can be kept for one year in storage. The sensory characteristics to be assessed in a sensorial examination are: appearance, texture, and odor of raw product, and texture, odor and flavor of cooked product. Freshness of cooked squid can be expressed in a 10-point flavor score scale that includes: fresh (sweet, meaty), slight loss of freshness (creamy, sweet, meaty, metallic), slightly sweet (slightly meaty, creamy, milky), No sweetness, slightly sour, sour (musty, cabbage), slightly bitter (overripe cheese, oily, slight sulphide), bitter (sulphide), and strongly bitter. Texture can be grouped into three categories: 1) normal (firm and rubbery); 2) borderline (mushy, slightly sticky or very firm and rubbery); 3) unacceptable (extremely mushy and sticky or extremely firm and rubbery) (75).

Squid is one of the most highly potential sources of fish protein. Frozen foods and surimi-based products using squid as raw material have become a trend in recent years. The mantle muscle of squid has a specific toughness that is maintained after a second freezing and thawing process. The mantle toughness (hardness) of fresh Argentinian squid (*Illex argentinus*), neritic squid (*Loligo edulis*) and cuttle fish (*Sepia pharaonis*) increase after frozen storage after 120 days. The protein pattern of Argentinian squid mantle refrozen and thawed does not change. Histological samples show that muscle fibers are injured and aggregated over time being that these changes are the ones responsible for toughening of mantle (76).

17. Striped Bass

Striped bass has a total intensity of aroma above moderate and total intensity of flavor at moderate. It is a moderately strong flavored fish with a fresh, gamey, fish oil character. The aroma and flavor amplitudes are moderate, with character notes blended to give a full aroma and flavor. The aroma has an early impact of fresh and gamey fish at slight to moderate, slight sweet, sour and briny, and below slight fish oil. The flavor also has an early impact of fresh, gamey fish, and sour notes at slight to moderate, sweet, salty-briny, and mouth drying at slight, and fish oil at below slight. The sour flavor note is stronger than in most fish. Particularly in flavor, the gamey and fish oil vary, being more intense in the dark flesh. The aftertaste is sweet, sour, and fresh fish, with some gamey fish character (48, 49, 37).

18. Swordfish

Swordfish has a moderately low total intensity aroma and flavor, with a sweet, fresh fish, shell fish character. The aroma and flavor amplitudes are moderate, complex, tightly blended, and the fish has full flavor, with complex first notes, sour (sharp), and mouth filling characteristics. The aroma is just below moderate fresh fish, slight to moderate shellfish, slight sweet and briny, below slight sour, and very slight nutty-buttery. The flavor is just below moderate fresh fish, slight sweet, shellfish, mouth drying, and mouth filling, slight to moderate sour (sharp, citric), very slight canned salmon, salty-briny, and fish oil. The fish oil appears late in the flavor. In aroma and flavor, the fresh fish, shellfish, and nutty-buttery seem rich, closely related, and to have a salmon or tuna character. The canned salmon flavor note is also related and hard to define. The sour (citric) flavor is almost lemon and is stronger than in most of the fish tested. The aftertaste is sour, fresh fish, sweet, and shellfish (48, 49, 37).

19. Tilefish

Tilefish has a moderately low total intensity aroma and flavor, with a sweet, fresh fish, shellfish character. The aroma and flavor amplitudes are moderate, as this fish is rich and full, complex, and blended. The aroma is slight to moderate fresh fish, below slight sweet and sour (pungent), and slight shellfish and briny. The sweet, fresh fish, and shellfish notes seem closely related and associated with a rich character like butter, lobster or scallop. The aftertaste is fresh fish and sweet (48, 49, 37).

20. Trout

Frozen fillets of rainbow trout (*Oncorhynchus mykiss*) stored at −18°C, wrapped with either polyethylene or polyethylene/polyamide (vacuum), and subjected to a light/dark environment have shown that packaging materials have a strong effect on the development of rancid flavor. Also, the fillets stored in darkness generally received better appearance scores than the ones stored in light (77).

21. Tuna

White tuna (*Thunnus alalunga*) possess white color, firm texture, flavorful flesh, and high nutritional content. To extend production, frozen Albacore tuna is used as raw material in the canning industry. Measurement of sensory, chemical, and physical changes has shown that deterioration of fish quality continues during frozen storage. Quality tests include visual appearance evaluation based on general external appearance, eyes, gills, consistency, and ventral cavity. These parameters are used to classify Albacore tuna in four quality categories (highest quality, good quality, fair quality, and rejectable). Frozen tuna quality is good after 12 months of frozen storage. However, after 6 months some specimens developed a slight rancid odor (78).

22. Weakfish

Weakfish has a moderate total intensity aroma and flavor, with a weak fresh fish, gamey, briny (seaweed) character, and a late, low level fish oil flavor. The aroma and flavor amplitudes are below moderate, as the character notes are

TABLE 58.4
Aroma, Appearance, Texture and Flavor Attributes Measured in Selected Fish

	Sensory Attributes			
Product	**Aroma**	**Appearance**	**Texture**	**Flavor**
Catfish (*Clarias gariepinus*) (50)	Earthy fresh Rancid (oil) Off-aroma	Color Juiciness Flakiness Sponginess Stickiness	Juiciness Mushy/soft Gelatinous Sponginess Stickiness	Earthy fresh Sweet Salty Sour Earthy muddy Bitter Rancid Off-flavor Aftertaste
North Atlantic Fish (48)	Briny Sweet Fresh fish Old fish Stale fish Sour Shellfish Gamey fish Fish oil Earthy Nutty-buttery Musty Scorched			Salt-briny Sour (Sharp) Sweet Fresh fish Old fish Stale fish Shellfish Gamey fish Fish oil Earthy Nutty-buttery Canned salmon Bitter Metallic Mouth drying Mouth filling
Salmon (*Salmo salar*) (69)	Boiled potato Train odor	Color	Firmness Juiciness Fibrousness	Earthy taste Fish oil Train oil Bitter Metallic
Cod (*Gadus morhua*) (61)		Color	Firmness Flakiness Resilience Juiciness Cohesiveness Fibrousness Roughness	Strength Fresh fish Saltiness Sweetness Stale Bitterness

not fully blended. The aroma is slight to moderate briny (stronger than in most fish, with a seaweed character), slight fresh fish, gamey and sour, and very slight sweet. The flavor is slight to moderate fresh fish, slight sweet and sour, below slight gamey, and salty-briny, above slight mouth drying, and very slight fish oil. Gamey and fish oil are more intense in the dark flesh. The aftertaste is mouth drying, fresh, gamey fish, with sweet, and sour notes. Compared to other fish, this aftertaste is stronger and more persistent. The character notes of individual samples varied more than in most fish, especially in the levels of gamey and fish oil notes, which depended largely on the amount of dark flesh present (48, 49, 37).

23. Minced Fish

Turbot (*Atheresthes stomias*), grey cod (*Gadus macrocephalus*), Dogfish (*Squalus acanthias*), shortspine thornyhead (*Sebastolobus alascanus*), pollock (*Theragra chalcogramma*), red-banded rockfish (*Sebaster babcocki*), and ocean perch (*Sebaster alutus*) have been evaluated to produce frozen minced fish flesh. Significant differences were found after one month of storage in odor and taste quality. Pollock, pollock/red-banded blend and ocean perch were given relatively high odor and taste scores. After 3 months, no significant differences in odor quality were found among the different fish species. Differences

were found in taste quality, turbot and ocean perch were given the highest scores. After 5 months, there were no differences in odor quality but significant differences were found for taste quality. After this point Pollock was scored unpalatable. Texture of the flesh of the different species can be grouped into three categories: relatively firm, intermediate in firmness, and relatively soft. Color of the minced flesh for all species changes only in the lightness of hue (79).

Atlantic cod (*Gadus morhua*) frame mince without kidney tissue, responsible for 'chemical' and 'petroleum' type flavors, was stored at −14° or −40°C. Aroma, juiciness, texture and flavor of the cooked samples was evaluated. Instron hardness scores were reduced during storage observing a soft, mushy texture. Color is one of the most important factors for mince quality. Panelist scored fillet mince samples juicy with a soft and moderate texture. No off-odors or off-flavors were detected. Frame mince samples were also juicy but more fibrous and firm than fillet mince (80).

Raw, thawed cod mince texture is commonly evaluated for springiness (0 = completely plastic, 10 = very springy) and stickiness (0 = breaks down, 10 = very cohesive). The frozen deterioration of cod mince is reflected in an increase of cohesiveness (81). Texture scores in cod frame mince stored at −7°, −14°, and −40°C for springiness and cohesiveness are higher for mince stored at −7° and −14°C. Changes during frozen storage change sensorial properties of the mince (82).

Quality changes of fish muscle are normally due to autolytic chemical reactions, microbial proliferation, and physical property alterations. Frozen storage of catfish mince at −20°C can increase storage life to at least 3 months (83). Washed and unwashed catfish mince do not change color during frozen storage at −20°C (84). Washing of catfish mince using sodium citrate, sodium erythorbate, sodium citrate plus sodium erythorbate, sodium citrate plus sodium erythorbate, and polyphosphate reduce lipids and increase Hunter 'L' values (85).

E. Fruit and Vegetables

The most common problems in frozen fruits and vegetables are reactions that cause changes in flavor, color, texture, and nutritional value. A major result of freezing on fruits and vegetables is usually a loss of tissue firmness. Freezing causes disruption of the membranes of cells, and excessive softness (86).

Fast freezing rates produce a large number of small ice crystals that causes less damage. Freezing large-size foods involves problems due to thermal gradients. With the high-pressure-shift method, samples are cooled under pressure (200 MPa) to −20°C without ice formation, and then pressure is released to atmospheric pressure (0.1 MPa). This technique leads to uniform and rapid ice nucleation throughout the volume of the specimen. This method maintains the original tissue structure of the sample (87).

Blanching is often used to inactivate undesirable enzymes that cause unfavorable effects on the quality of frozen vegetables and some fruits. The use of peroxidase as an indicator of the blanching process may result in the loss of color, flavor, texture, and nutrients of vegetables and fruits. Off-flavors from the deteriorated vegetables or fruits can result from the oxidation products created by the action of free fatty acids and/or peroxides degrading enzymes (88).

1. Fruits

Fruits as a class are the most difficult of all products to freeze without causing a radical change in their appearance, texture, flavor, and color. Of all the common fruits, the cranberry is about the only one that can be frozen without special treatment and yet retains its flavor, color, and appearance. All other fruits require packing in sugar or syrup, or some other treatment. Without it, most blackberries turn brown and become sour and flavorless (89). Many of the tropical fruits are even more difficult to freeze. Bananas turn black during thawing. Whole oranges may break open, and upon thawing, become very flabby and bitter and lose their characteristic flavor (89).

Raspberries, frozen without sugar or syrup, become very soft and lose their characteristic flavor. Most plums become so sour that they are almost sharp and also become very flabby. Blueberries get very soft and lose much of their flavor and aroma. Unripe fruit, which is still hard, does not yield a product of desirable texture, flavor, aroma, and color. Immature fruit when frozen and thawed is usually very sour and often very bitter; furthermore, color and aroma are usually lacking. Moreover, browning and discoloration are more pronounced and, as a rule, the texture is not good (89). Frozen fruits allowed to stand after thawing are not as palatable as when served while still slightly frosted. They tend to collapse with resultant poor texture. Unless treated to prevent change, they discolor (90). Thus the nutrients, the desirable juices, the sanitary quality, and the firm texture of fresh frozen foodstuff may disappear with varying rancidity once the produce is left in the thawed condition.

Tree or vine-ripened fruit usually yields a better frozen product as it is generally considered to have better color and flavor than fruit that has been picked while still immature and ripened in storage (89). On the other hand, overripe fruit bruises easily and deteriorates rapidly even when handled carefully and can develop undesirable off-flavors in the frozen product (89).

Most blackberries are altered in color, flavor, and texture by freezing and thawing. Most of the common varieties of blackberries and many of the dewberries turn brown and become rather sour; consequently, most varieties are not

suitable for freezing in small packages for use as desserts (89). The English Morello variety is preferred for certain purposes because of its more pronounced flavor. It is much darker in color than the Montmorency and is considered less desirable for freezing because of this characteristic (89). Some authorities recommend the Early Richmond variety for freezing but, although this cherry has a desirable bright red color, it is likely to be soft and lacking in flavor (89). The Royal Duke and May Duke varieties possess a more pleasing cherry flavor than the standard red sour cherry, the Montmorency. They are more meaty and consequently do not collapse on freezing and thawing to the same extent as does the Montmorency (89). Most varieties of sweet cherries brown (oxidize) badly during freezing, storage, and thawing. A marked change in flavor occurs simultaneously. Sweet cherries are mild in flavor; freezing and thawing cause some loss of flavor, consequently frozen sweet cherries are likely to be lacking in flavor (89).

The Mission variety of figs is considered best for freezing because of pronounced flavor, good texture, and attractive color. The Kadota and Adriatic varieties remain unchanged in appearance but not so in the case of flavor. The Calimyrna variety is inferior because of the development of off-flavors in the skin and therefore unsatisfactory unless peeled before frozen. Brown Turkey discolors badly and has inferior flavor after being frozen (89).

New York state grapes retain flavor and other characteristics during freezing and subsequent storage (89). Muscat of Alexandria retains flavor and appearance best after being frozen. The Thompson Seedless had a flavor loss, but remain pleasantly sweet after frozen storage.

Pears become soft and watery during freezing and thawing. They also lose much of their flavor. Because of these undesirable changes, pears are not recommended for freezing (89).

Black raspberries possess a delectable flavor and are not altered appreciably by freezing. Unfortunately black raspberries have a tendency to be seedy; further, the seeds are much more noticeable and objectionable after freezing and thawing (89).

In order to be desirable for freezing preservation, a strawberry should have a pleasing potent flavor and acidity that should be retained during freezing and thawing; it should be a uniformly deep, bright red and should retain this color during a long period of freezing storage. The berries should be of uniformly good size and of firm texture.

Color is one of the most important attributes of food, both for its aesthetic value and for quality judgment. In strawberries, two anthocyanin pigments mainly determine the red color: pelagornidon (Pgd)-3-glucoside and cyanidin-3-glucoside in a ratio 20:1. These pigments are not very stable chemically and may change easily if not properly protected. (89). Freezing is one of the most important unit operations to retain fruit quality during long-term storage. Raspberry fruits (*Rubus idaeus* L.) frozen at −80°C and stored at −20°C retain sensorial (color and aroma) and nutritional qualities after 12 months (91). Freezing does not change the volatile components that contribute to the aroma of raspberry (α-pinene, citral, β-pinene, phellandrene, linalool, α-ionone, caryophyllene, and β-ionone). However, freezing causes some cellular disruption that increases the release of caryophyllene. The volatile constituents of raspberry aroma remain after one year of frozen storage (92).

Papayas have unusually high amounts of bound water. This bound water has a high affinity for polysaccharides and proteins, and remains unfrozen even at −20°C. Frozen storage develops off-flavors and color modification after prolonged storage as a consequence of enzyme action. When Papaya slices are cryogenically frozen at −80°C and stored at −24°C for 12 months, proteins are denatured and the activity of soluble peroxidases increase as a result of mechanical damage produced by the growth of the ice crystal and leading to color and texture modification (93).

Storage of custard apple (*Annona squamosa* L.) has limitations, since it is perishable, and cold storage is not promising due to the development of brown color. The custard apple pulp is frozen at −25°C and stored at −18°C. The sensory attributes were evaluated using a 10-point hedonic scale, and the conclusion formed that frozen pulp quality is affected by freezing as compared to the fresh pulp (94).

The flavor of most fruit juices can be preserved better by freezing than by any other method of preservation. Despite this fact, the freezing of fruit juice has not developed nearly as extensively as the other food freezing industries. The two principal reasons for this are: (1) Properly prepared flash pasteurized juices are nearly as good, and may be kept at ordinary room temperatures without appreciable change of flavor; (2) thawing of juices requires much time, and, if not carefully carried out, the thawed juice may be inferior in quality to a good grade of pasteurized juice.

If berries are pressed without heating or freezing, the yield of juice is low, the juice obtained is pale in color, very mild in flavor, and oxidizes very quickly due to oxidative enzyme action (89).

Freezing and thawing of berries prior to pressing is desirable as it extracts much color and relatively little tannin (89). When Montmorency or English Morello cherries are pitted much juice leaks from the fruit. This juice is usually saved, and some of it is preserved by freezing. Although this juice is of fine flavor, it is very pale in color and so is not considered to be of high quality (89).

In the case of orange juice, slow frozen juice is likely to have an "oxidized" flavor, whereas properly handled quick frozen juice should not have this off-flavor.

The slush-freezing operation requires only six minutes, consequently, the system is very effective in rapidly reducing the temperature of the juice to the point where changes in flavor take place very slowly.

Concentration of fruit juices involves sublimation, it is possible to dehydrate fruit juice to a dry powder without materially changing its flavor, although some of the more volatile components are lost. The process not only produces less change in flavor than any other method of dehydration but also yields a product that rehydrates almost instantaneously.

If the original flavor of the juice is to be retained unimpaired, it is important not only to thaw the juice quickly, but also to keep the juice below approximately 10°C.

The anthocyanin contents of certain juices, i.e. strawberry, significantly decreases during frozen storage and the addition of sugars significantly improves the pigment retention (89).

2. Vegetables

It is more difficult to produce frozen vegetables with textural quality than to produce quality frozen fish and meat. Textural quality of fruits and vegetables lessen upon freezing and thawing, resulting in excessive softening (95, 86, 96, 98). This is the prime defect of frozen fruit and vegetable products.

There is no single key enzyme that is responsible for all the vegetable quality changes during frozen storage. Quality changes include off-flavor development (lipoxygenase, lipase, protease), textural changes (pectinase, cellulose), and color changes (polyphenol oxidase, chlorophyllase, peroxidase, lipoxygenase) (99). In general, if the blanching treatment is not sufficient to inactivate catalase and peroxidase, frozen vegetables will develop off-flavors. The development of hay like flavors, bitterness, and odors in unblanched frozen vegetable may be due to amino-aldehyde reactions (100).

The effect of low-temperature long-time blanching (60°C for 2 hours or 74° to 79°C for 20 to 3 minutes) on improvement of texture of frozen vegetables was observed in several studies on different foodstuffs preserved by different methods, such as canned vegetables (101, 102) and frozen carrots (103, 100, 104).

Processing conditions like blanching and freezing result in substantial dissolution, depolymerization and apparent destruction of cell wall pectins. As a result, pectins are broken down into smaller sized polymers, lost interpolymer associations, or were released from the primary cell walls and middle-lamella, or remained loosely bound to the walls by relatively sensitive bonds (101, 102, 103, 100, 104).

3. Mushrooms

Since most vegetables and fruits consist of many kinds of enzymes, enzymatic reactions such as oxidation reaction, browning reaction and discoloration present a problem to the frozen vegetable industry. In order to keep better quality, including color, flavor, aroma, taste, texture, and appearance of the frozen vegetables, a lot of chemical additives are occasionally used for this purpose. Because mushrooms are one of the easily browning vegetables caused by enzymatic and chemical oxidations, there are many kinds of enzyme inhibitors or antioxidants recommended to prevent those quality lowering. While numerous factors are involved in quality loss in frozen mushrooms, the most detrimental is the enzymatic browning reaction (105).

Problems may occur during freezing and storage of frozen mushrooms, e.g. loss of weight, decrease in nutritive value, tendency of product to stick together, and sometimes development of undesired color and off-flavor. Shelf life of fresh mushrooms (*Agaricus bisporus*) is limited to 1 to 3 days at room temperature, 5 to 7 days at 0 to 2°C. Washing, freezing, and 1 day storage of mushrooms contributed to the loss of 'L' value. No changes have been reported in whiteness of frozen mushrooms after 90 days of storage. However, washing with water increases browning of frozen mushrooms. Immersion in boiling water increases toughness as the storage time of frozen mushrooms increased more than 14 days. The blanching process itself reduces the initial mushroom whiteness (106), and blanched frozen mushrooms show a remarkable toughness after thawing and cooking. Frozen whole mushrooms, blanched for 5 minutes have a tougher texture than those blanched for 1 or 2 minutes.

Mushrooms immersed in boiling water before freezing are quite acceptable for the consumer for all time storage even though there is typically a loss of whiteness as compared with mushrooms washed in water containing sodium metabisulfite. Dipping mushrooms in 0.1% or 0.5% sodium metabosulfite solution for 5 minutes after blanching has resulted in the best color and other quality characteristics after freezing (107) of mushrooms in boiling water before freezing was harmful to their texture. Appearance and color of unblanched frozen mushrooms were most affected by washing them in sodium metabisulftite solution before freezing. Storage time of frozen mushrooms results in lower discoloration of mushrooms washed in water containing sodium metabisulfite or immersed in boiling water for 20 seconds than mushrooms washed in water only. Their texture (shear-press reading) was higher. Immersion in boiling water containing sodium metabisulfite had a dual effect: a marked loss of whiteness and a significant decrease of SO_2 content. Also, the sodium metabisulfite treated mushrooms tend to show a marked toughness during storage.

Chemical dipping methods were effective in maintaining desirable color of frozen whole and sliced mushrooms stored for 3 months (108). Excellent results in stabilization of the color of frozen mushrooms by inhibiting undesired discoloration have been obtained after washing fresh mushrooms in sodium metabisulfite solutions (109). The better quality of frozen mushrooms treated with sodium

bisulfite solution was obtained before and after blanching. EDTA and $NaPO_3$ do not improve the color and other quality such as dripping loss, texture, and sensory evaluation scores.

Sodium bisulfite and sodium diethyldithio carbanate after blanching has a higher ascorbic acid retention and less dripping loss, but its organoleptic evaluation scores were poor. Since sulfites are essential additives with important effects on the whiteness stability of frozen mushrooms, determination of the minimum amount of SO_2 required to maintain optimum of frozen mushrooms quality seems to be necessary.

Loss of frozen mushroom whiteness after 1d has been compared with fresh ones varying an average of 6% to about 17%. No significant change in whiteness of frozen mushrooms during 90 days of storage was detected when short-time dipping in boiling water was applied. Storage time of frozen mushrooms results in lower discoloration (110). Most mushrooms are frozen commercially by air blast or plate freezing methods. However, after freezing some undesirable color and off-flavor may occur. The frozen mushrooms made by individual quick freezing process were better in quality, firmer in texture, and lower dripping loss than that made by air blast freezing process.

The effects of processing vary with the chemical, physical, and sanitary conditions and sensory quality of the frozen mushrooms. IQF mushrooms show better color and higher sensory scores. After 120 days of frozen storage, color and texture of mushrooms changed (107). Frozen whole mushrooms blanched for 5 minutes had markedly tougher texture than mushrooms blanched for 1 or 2 minutes. As the storage time of frozen mushrooms increased from 3 to 6 months, shear press values increased very significantly. The texture of Freon frozen and plate frozen mushrooms was similar after 3 months storage. Blanching time did not affect texture of frozen sliced mushrooms significantly, but storage time did.

4. Leafy Vegetables

Texture is important in frozen leafy vegetables. After freezing-thawing, firmness and crispness decrease and rupture strain increases. The optimum freezing rate of Chinese cabbage has been established at 5°C/minute because of its high moisture, low sugars and thin cell walls; therefore, freezing effects are more notable. Chinese cabbage frozen at 100 MPa and at 700 MPa shows an increase in rupture strain. However, texture of samples frozen at 200 MPa, 340 MPa, and 400 MPa keep intact (111).

The green color of organically grown spinach (*Spinacia oleracea* L.) evaluated by sensory evaluation and Hunter 'L' value after 6 months of storage at −24°C shows that color and sensory attributes of spinach depend on the cultivar and these differences should be considered during freezing (112). Lipid-acyl hydrolases (LAHases) are responsible in lipid degradation during storage of vegetables. LAHases are found in spinach that naturally contains large amounts of galactolipids and phospholipids, substrates for LAHases. Formation of volatiles is the result of oxidation of lipids in vegetables. The enzymes involved in this process are lipases, phospholipids-degrading enzymes, galactolipid-degrading enzymes, and lipoxygenase. In spinach leaves, unsaturated fatty acids are present in large portions and are oxidized to peroxides. The resulting peroxides are decomposed to aldehydes, ketones, and alcohols, causing off-flavors (88).

5. Asparagus

Studies have shown no significant difference in texture, flavor or general acceptability differences in asparagus existed due to blanching treatment (113). Blanching of green asparagus (*Asparagus officinalis* L.) before freezing is necessary to inactivate enzymes, which cause quality changes during frozen storage. One of the changes is the formation of aldehydes such as hexanal, that is described as a green aroma and is a flavor compound formed during auto-oxidation of linoleic acid. There is no difference in texture of asparagus frozen using cryogenic and blast freezing but there are differences on texture when asparagus are kept at −30 or −70°C. During storage, shear force values slightly increased (114). Blanched asparagus stored at −18°C for 4 weeks and evaluated for appearance, color, texture, natural flavor, off-flavor and general acceptability showed that unblanched asparagus scored the highest in appearance, while microwaved and unblanched asparagus had the highest color scores. Flavor of asparagus changed regardless of the blanching treatment. After frozen storage, unblanched asparagus stems were significant darker than blanched stems. Blanching had no effect on lightness of asparagus stems or tips. Asparagus were greener after blanching and less green after frozen storage, also they were yellower after frozen storage (113).

6. Carrots

Freezing destroys the cytoplasmic structure, producing loss of turgor, weakness of the cell wall and some degree of cell separation. All these changes affect texture of the product. The freezing temperature is the most critical factor that changes the cell structure of carrots; and the rate and type of freezing that is the critical factor in tissue damage. Firmness of frozen sliced carrots decreases by about 50% as compared to raw samples (115). Quick freezing results in better texture than slow freezing in carrots (100). The effect of freezing rate on firmness of raw carrots is greater than that on firmness of blanched carrots. The final temperature of freezing does not affect firmness of thawed carrots. As the freezing rate from 0°C to −10°C was quick, firmness of thawed carrots was maintained. The amount of drip increased as freezing rate decreased.

Effect of freezing rate on firmness of blanched carrots has been shown to be the same as that of raw carrots. Consequently, quick freezing (−5°C/min) is best for acceptable texture of frozen carrots (100). Tamura (116) found that when carrots were preheated for 30 minutes at 60°C, frozen at −30°C, thawed in a refrigerator and then cooked, softening of carrots was greatly diminished but cell damage was observed. Carrots frozen at −30°C, had great amounts of cell separation, thus the optimum rate of freezing for carrots has been determined to be −5°C/min (117). Low-temp-blanched carrots frozen at −5°C/min using a program freezer, should have minimization of softening. Preheating increases firmness and rupture strain of carrots, while freezing-thawing decreases firmness and increases rupture strain. Firmness of carrots decreases when frozen and thawed, except for raw carrots frozen in a program freezer and thawed. Raw and preheated disks frozen quickly (−5°C/min) using a program freezer are typically firmer than those frozen at −35°C using a conventional freezer. Differences in firmness of blanched disks as compared to unblanched, have not been noted. Quick-freezing results in better texture (firmness and rupture strain) than slow-freezing, and also improves the texture of frozen carrots. Texture of frozen carrots differs from that of boiled carrots (100). Blanching, High-Temperature-Short-Time (HTST) and rapid freezing at −4.5°C/min is recommended as optimum thermal processing and conditions for improvement of textural quality in frozen carrots (118).

Also, freezing causes extensive degradation of cell wall pectins in carrot tissue. This is evident by the loss of firmness. Freezing at rates of −4.5°C/min causes less softening than slow rates (−0.19°C/min). Slow rates causes loss of pectin material and structural damage due to growing ice crystals (118).

Before freezing, carrots are blanched to inactivate enzymes that cause flavor deterioration during frozen storage. Unblanched carrots develop an off-flavor due to fatty acids released by estarases. The off-flavor is characterized as ‘stearin’, ‘paraffin’, and ‘soap’. Loss of textural quality during blanching, freezing and thawing includes dehydration, damage, drip loss, tissue fractures and mechanical damage from ice crystals during freezing. Steam-blanched carrots subjected to blast or cryogenic freezing and stored at −24°C for five months showed differences in textural quality between blast and cryogenic freezing. Decreasing the temperature from −30° to −70°C resulted in increased toughness but no changes are observed over time (119).

Studies have shown that carrots immersed in liquid nitrogen (LN_2) cracked and became unacceptable in appearance, but those frozen at −5°C/min or −2°C/min using a programmed freezer (final temp, −30°C) had a better texture than those frozen in a conventional freezer at −80°C, −30°C, or −20°C (117).

7. Broccoli

Broccoli (*Brassica oleracea*) is a highly perishable fresh vegetable that, at ambient temperatures, will yellow and become unmarketable in 1 to 3 days. About 37.8% in florets and 61.1% losses of chlorophylls *a* and *b* in stems occurred during freezing storage at −20°C (120). This loss of green color is a major limiting factor in shelf-life of broccoli. Boiling-water blanched broccoli stored at −18°C for 4 weeks has excellent sensory scores for visual appearance and color (121). Blanching has a significant effect on yellow color intensity (b* value, Hunter). Immediately after blanching, stems and florets are more yellow than unblanched samples. These differences remain after frozen storage for florets but not for stems. All blanching treatments increase chroma (color saturation) of broccoli florets and stems compared to unblanched broccoli (122, 121). To avoid the development of dimethyl sulfide (off-aroma) in frozen broccoli, florets must be blanched for 90 seconds before freezing (123). After frozen storage no significant lightness differences due to blanching treatments have been noted in recent findings.

8. Green Beans

Brewer et al (124) reported no difference in either visual color or appearance scores of frozen green beans due to blanching treatment. Brewer et al (124, 121) found that blanching treatment had significant effects on flavor, off-flavor, tenderness and crispness of green beans and broccoli that had been in frozen storage. Brewer et al (124) reported that blanched green beans were greener (higher hue angle) than unblanched beans; this trend was still evident after frozen storage.

Samples of green beans have been shown to be more yellow (higher Hunter b value) after frozen storage than immediately after blanching. Immediately after blanching, blanched asparagus tips were yellower than fresh and blanched tips. These differences were lost after frozen storage. No differences in yellowness of stems existed either immediately after blanching or after frozen storage. Brewer et al (121) reported similar blanching and freezing effects on yellowness of broccoli florets and stems. Similar color changes have been reported in blanched green beans during frozen storage (125). Sensory characteristics, such as color, texture and flavor, are affected by blanching. For green beans, appearance, beany aroma, sweetness, green flavor, aftertaste (metallic/astringent), tenderness, crispness, and wetness are the principal sensory attributes to evaluate in frozen products. After four weeks of frozen storage, color values drop by 50%. Blanching treatment have no effect on visual color, appearance, aroma, sweetness, raw starchy flavor, green bean flavor, overcooked flavor, aftertaste, tenderness, crispness, and wetness of frozen green beans (124). After 12 weeks of frozen storage, panelists detect no differences in color,

sweetness, aroma, firmness, and presence of off-flavors. Off-flavor is detected in frozen cooked samples that are blanched using microwaves. This off-flavor is describes as grassy, bitter and stored (122).

Bennion (126) stated that two results of chemical changes that may occur during frozen storage of foods are off-odors and off-flavors. Campbell et al (127) noted that one of the principal reasons for off-flavors is rancidity of the fatty material in unblanched frozen vegetables. Noble and Winter (128) reported that in unblanched frozen green beans marked off-flavors developed rapidly by the end of four weeks. Off-flavor descriptions for unblanched frozen green beans reported by Moriarty (129) included earthy, sour and bitter.

Bennion (126) suggested that off-odors in frozen raw or insufficiently blanched vegetables may be attributed to the accumulation of volatile carbonyl compounds during frozen storage. Chow and Watts (130) reported that rancid odors in frozen green beans were related to malonaldehyde values, used as an index of unsaturated fatty acid oxidation. Lipid oxidation as determined by both the thiobarbituric acid test and acetaldehyde formation from anaerobic fermentation contributed to flavor deterioration in frozen green beans.

After frozen storage, steam-blanched and boiling-water blanched beans had the lowest shear values. Visual color was poorest for microwave-blanched. Microwave blanching green beans for 3 minutes in a covered container or bag prior to 4 weeks frozen storage resulted in a product that was not different in retention of color from boiling-water blanched beans; however, these bean samples differ in tenderness and crispness from boiling-water blanched beans.

Katsaboxakis and Papanicolaou (125) found that blanching green beans (30–90 seconds) increased negative a_L values and a_L/b_L ratio during frozen storage. Negative Hunter 'a' values measure sample greenness. Unblanched green beans have higher odor and flavor scores before storage but are considered organoleptically unacceptable for the same attributes after the first months of frozen storage and at all subsequent storage times. Blanched samples for 30-90 seconds are slightly superior in sensory qualities compared to those receiving more drastic heat treatment.

Hue angle ($\tan^{-1}(b/a)$) has been shown to be higher for boiling-water, steam, microwave-blanched fresh beans. The same general trend for hue angle has been shown to still be evident after 4 weeks in frozen storage and cooking. Higher hue angles indicate that the sample color was greener.

After 4 weeks in frozen storage and cooking, chroma was greater for steam and microwave-blanched beans than for unblanched green beans. Total color values drop by nearly 50% after storage and cooking for most blanching treatments; total color of microwave-blanched beans has been shown to drop over 70%. Katsaboxakis and Papanicolaou (125) reported significant color loss (Hunter L value, a/b ratio) due to green bean blanching time and time in frozen storage.

After frozen storage, blanching treatment had no effect on visual color, appearance, aroma, sweetness, raw starchy flavor, green bean flavor, overcooked/canned flavor, aftertaste, tenderness, crispness, wetness or degree of liking of cooked green beans. Microwave-blanched beans had more aftertaste than boiling-water blanched beans (125).

Sensory evaluation after 9 months of frozen storage found no significant difference in green bean off-flavor between short and long blanch times at any storage temperature. Off-color was significantly higher in green beans that were blanched for 63 seconds, however, indicating that in this commodity color may be the limiting factor in frozen storage. In the case of green beans, off-flavor is eliminated by a one min blanch, but off-color prevention may require a longer time (125).

9. Peppers

A major problem of jalapeño peppers (*Capsicum annuum*) is the soft texture after exposure to heat and salt brines with a pH less than 3.5. To overcome this problem, jalapeños can be frozen. The maximum firmness of frozen jalapeño pepper is 4.8 times that of unfrozen samples (131).

10. Tomatoes

Sensory characteristics of tomatoes include appearance, red color intensity, tomato flavor intensity, texture, natural-tomato flavor, off-flavor and general acceptability. After 6 weeks of frozen storage, boiling-water blanched tomatoes have the highest scores for appearance, tomato flavor intensity, and natural tomato flavor. Steam blanched tomatoes have the lowest appearance scores. Unblanched frozen tomatoes are usually mushy and least firm after storage (132). Tomatoes blanched (4 minutes) using conventional boiling water, steam, microwaved in a glass container, and microwaved in boilable bags demonstrated that though visual color and sensory attributes were highest for boiling water blanched tomatoes, microwaved-blanched tomatoes retained more nutritive value in the finished product (132). Pectin methylesterase (PME) can cause texture deterioration in processed tomatoes during storage. Blanching, which reduces the loss of product texture, inhibits PME activity as well as the activities of other deteriorative enzymes (132).

Lycopene, the primary pigment in tomatoes, is affected not only by exposure to oxygen from the air, but also by heat during processing, which may cause isomerization of trans-double bonds in the pigment to cis forms (133). This shift in structure can cause a reduction in color intensity of a variety of food products (134). Preliminary acceptance or rejection of a food is usually influenced by the visual

TABLE 58.5
Color, Appearance, Aroma, Flavor and Texture of Selected Vegetables

	Sensory Attributes				
Commodity	**Color**	**Appearance**	**Aroma**	**Flavor**	**Texture**
Green beans (124)	Green	Plump	Grassy/green Beany	Sweet Green bean Overcook After taste	Tenderness Crispness Wetness
Tomatoes (132)	Intensity	Uniformity of color Wholeness	Aroma	Bitter Natural flavor Sweet Off-flavor	Intact Mushy Firm
Broccoli (121)	Green	Plump	Grassy/green	Sweet Starchy Broccoli Overcooked After taste	Tenderness Crispness Wetness

appearance including color and texture (135). Any changes in blanching technique must take into account the alterations in product color that often occur. This reduced, but still substantial, PME activity may be the reason for poor sensory texture of unblanched frozen tomatoes; as PME breaks down pectic substances, tissues lose structural integrity becoming soft and mushy (132).

Immediately after blanching, microwave-blanched tomatoes have been shown to be lightest (Hunter L value) in color. Boiling water-blanched tomatoes are redder (Hunter a value) with a similar trend for yellowness (Hunter b value). However, after frozen storage, steam-blanched tomatoes are lighter in color followed by microwave-blanched and unblanched tomatoes. Lightness of steam and microwave-blanched tomatoes change little during storage. Although total carotene content does not change as vegetables are heated in water, there is a shift in the visual color: orange carrots may become more yellow, and red tomatoes may become more orange-red (135).

Blanched tomatoes have lower hue angles than do fresh tomatoes indicating that blanched tomatoes are more "true red" than fresh tomatoes. Hue angles decrease after frozen storage.

Chroma increases by two-fold as a result of the blanching process. After frozen storage, total color drops significantly. After 6 weeks of frozen storage, boiling water-blanched tomatoes have the highest scores for appearance, tomato taste intensity, and natural tomato flavor followed by microwave-blanched tomatoes. Brewer et al (121) found a similar trend for broccoli. Steam-blanched tomatoes had the lowest appearance scores. Unblanched tomatoes were most mushy and least firm after storage. No texture differences exist among boiling water and microwave-blanched samples.

Begum and Brewer (113) found only moderate acceptability scores for asparagus (3.27–3.48 on 5-point scale) for all blanching treatments and reported that appearance and color appeared to have greater impact on acceptability than did flavor. Unblanched tomatoes had the lowest scores for general acceptability as compared to blanched by various methods. Stone and Young (122) also reported that, in general, microwave blanched vegetables are less acceptable in terms of texture and flavor than those that are steam or water blanched. Some microwave-heated vegetables exhibit toughening and may have grassy or strong off-flavors and aromas (136, 122). These results may be attributed to the amount of water used during blanching, high microwave power level or extended heating time. However, tomatoes are softer products that are likely to soften even more as pectic substances are solubilized.

Individually quick freezing (IQF) versus blast freezing does not influence texture of sweet corn and green peas. Also, no changes in color are observed in green asparagus, green beans and green peas. Asparagus and green beans blast frozen show softening and sweet corn higher color values (137). For sweet corn on the cob (*Zea mays*), frozen using a blast freezer it is recommended to reduce blanching time from the sensory point of view because longer blanching times results in reduced firmness and freshness and also increase cooked flavors (123).

Freezing method does not affect the color of green vegetables but does affect corn. Blast frozen sweet corn has higher blue (less yellow) color than the IQF sweet corn.

In many vegetables the limiting quality attribute during frozen storage is off-flavor development, which is most often catalyzed by lipoxygenase. Williams et al (138) evaluated the sensory character of blanched vegetable purees to which isolated enzymes had been added and found that lipoxygenase was the enzyme most active in aroma deterioration in English green peas and green beans. Lipoxygenase is widely distributed in vegetables

and evidence is mounting to support its involvement in off-flavor development and color loss.

In the case of corn, green beans, and green peas, there is fairly strong evidence that off-flavor development is the limiting factor in frozen storage and lipoxygenase activity is the primary culprit.

Supersweet corn is popular as a fresh, frozen or dried product, however blanching often results in caramelization of these high sugar varieties and formation of an undesirable gray or brown product. Industrial blanch conditions were established based on the requirement for peroxidase inactivation, however off-flavor catalyzed by lipoxygenase is the greatest limitation to storage life.

Sensory results for stored kernel corn indicated that unblanched kernels were significantly less desirable in appearance, texture, flavor, and overall desirability. It would appear that a one min, or possibly shorter, blanch was adequate to ensure the sensory quality of frozen Supersweet kernel corn.

Corn-on-the-cob sensory results show that, although the appearance of both unblanched and 3 minute blanched samples were preferable to those blanched longer, a longer blanch treatment resulted in better flavor and overall desirability after all storage times.

There have been shown to be no significant differences in off-flavor or off-color between the short and long time blanched corn after 9 months storage at +8°C, 0°F, or −8°F.

F. Spices, herbs, and seasoning blends

A spice is any aromatic vegetable substance in whole, broken, or ground form, except for those substances that have been traditionally regarded as foods, such as onions, garlic, and celery; whose significant function in food is seasoning rather than nutritional; that is true to name, and from which no portion of any volatile oil or other flavoring principle has been removed (139).

The shelf-life of spices is greatly extended while kept in their whole form, but when ground the shelf-life is reduced. The ideal condition for storage of spices is to keep them cool, dry, and protected from light. These storage conditions, in addition to airtight packaging, will reduce oxidation. Freezing is a prime choice of storage condition. The freezing of spices has little to no affect on the sensory properties of spices. Freezing is the means in which the "Gold standard" of a spice is typically preserved. The sensory properties of spices and herbs include aroma, appearance, color, flavor, pungency, and in some cases textural aspects. Sensory profiles can be used to define broad parameters, backed by specific and measurable physical parameters such as moisture, particle size, bulk density, color, and where appropriate, heat units. Several of the physical parameters, such as particle size and solubility, although not primarily responsible for flavor, influence this attribute (140).

The shelf-life of a spice, herb or seasoning blend will depend upon many variables that are typically characteristic of either the raw materials or the packaging, the different characteristics of the spice or herb, or possibly the different types of ingredient(s) used singly or in blended form. Typically, the detrimental properties would be loss of flavor and/or product lumping. Flavor deterioration is a problem when the more volatile ingredients are used, especially spice extracts, oils, and liquid flavors, which have been plated onto a non-absorbent base, such as salt, dextrose, malto-dextrin, or possibly starch. There is virtually a non-existent barrier by which to hold these volatiles in the compounded blend into which they have been incorporated. Thus, even to freeze these types of products would be of little benefit for flavor and aroma retention. From an appearance standpoint, the product could appear slightly faded, but could possibly appear quite normal in color, size, shape, texture and so on. Rancidity is another concern for flavor and aroma deterioration. In particular, spices that have high oil contents often develop rancidity if not properly stored. Freezing most definitely delays this deleterious property (140).

Flowability is a concern for spices and spice-herb seasoning blends because loss of moisture in the product causes lumping, as well as moisture absorption causing stickiness with certain spice oils. Free-flow agents are often added to spice blends to assist with this problem. Freezing does not tend to detrimentally affect these types of spice–herb blends. Most seasoning blends typically have a shelf-life of 3–6 months if properly stored. However, if frozen, this timeline can be extended to 6 months to 1 year. Many spice "houses" and distributors store spices, herbs, and seasoning blends up to 2 years without loss of quality and sensory attributes. However, this shelf-life extension becomes an argument for what the end consumer is willing to accept in terms of perceived freshness of the product. Cryogenic milling of certain spices avoids the volatilization, oxidation and enzymatic damage associated with conventional milling techniques. The higher volatile content of these spices (e.g. nutmeg, mace, and cinnamon) provides improved shelf-life and flavor perception. Thus, using cryogenics these can be extended (140).

G. Meats

Preservation by some means is absolutely essential for prolonging shelf-life, and for storage of all fresh meat and most processed meat products. Regardless of the method used, preservation is accomplished by restricting, or in some instances completely inhibiting, microbial activity, as well as enzymatic, chemical, and physical reactions that would otherwise cause deteriorative changes and spoilage.

The purpose of freezing is the preservation of the original characteristics of the product for an extended period of time. The main requirement is that the product before freezing is in an optimal condition from both microbiological and chemical standpoints. The quality of frozen meat is affected by conditions during freezing and subsequent frozen storage, and the length of the storage period. Quality changes occurring during storage at temperatures less than −10°C (14°F) are unrelated to bacterial growth or metabolism and are of (bio)chemical origin (e.g., drying and oxidation). In lean muscle at −5°C (23°F), approximately 85% of the water is frozen; at −30°C (−22°F) nearly 100% of the water is frozen. Due to the presence of solutes, the freezing point of muscle is approximately −2°C (28°F) (141).

The major physical/chemical changes which occur during storage of frozen foods are typically a result of (1) oxidation of lipids, (2) denaturation of proteins, (3) discoloration of product, (4) sublimation of ice, and (5) recrystallization of ice crystals. Chewiness, juiciness, and rancidity are the sensory attributes to be monitored during the storage. Freezing is one of the most effective methods for meat preservation. Low temperature not only protects the product from microbiological spoilage but also slows down the rates of other degradative biochemical reactions. In spite of the many advantages however, freezing causes certain unfavorable changes in meat quality. Ice occupies a greater volume than water, and the exclusion of solutes from ice crystals causes an increase in the ionic strength in unfrozen water. Together these phenomena cause a loss in tissue structure and a partial denaturation of some muscle proteins, in turn reducing protein solubility and gelation capacities (142).

Freezing and frozen storage produce or enable deleterious changes that can reduce meat quality depending on storage time, temperature, freezing rate, and protective packaging used. Secondary breakdown products of lipid oxidation, especially malonaldehyde, have been shown to precipitate on and crosslink muscle proteins, resulting in reduced ability to hold water under physical or thermal. Low-molecular-weight aldehydes and ketones are known to have strong odors and flavors at low concentrations, some of which are objectionable to sensory panels (143).

Color may be the most important characteristic affecting consumer decision-making on acceptability of meat and meat products (143). Such discrimination may be warranted, as meat color is the quality trait most susceptible to alteration by environmental conditions (144).

Consumers associate color with good quality (145, 146). Freezing or frozen storage generally does not affect the color of cooked meat (147). In frozen meat, color changes as a result of storage time, temperature, freeze-thaw cycles, and exposure to light (148, 149).

If flesh tissue is frozen rapidly, the cellular fluids remain in their location and freeze as tiny crystals uniformly distributed throughout the tissue. The faster the transition from 0° to 5°C, the less the translocation of water during freezing (150). Slow freezing results in more thawing drip and less expressible juice than quick freezing (151). Slow freezing causes fluid in the extracellular spaces to freeze first, thus increasing the concentration of solutes and drawing water osmotically from the still-unfrozen cell through the semi-permeable cellular membrane. There is therefore extensive translocation of the tissue fluid such that the fibers appear shrunken and, in some cases, damaged through rupture of the myofibrillar walls. Drip loss is not only disadvantageous economically but can give rise to an unpleasant appearance. Drip loss is due to denaturation of proteins by the high ionic strength of extracellular fluid.

Drip losses, cooking losses, and shear strength increased with time in frozen storage. Samples with 30% fat had greater drip and cooking losses than did samples with 15% fat. Storage temperatures affected drip and cooking losses but not shear strength. Increased storage time also resulted in loss of color.

Protein damage is a function of time and the quantity of drip will tend to increase as with time in storage (152). Furthermore, the free moisture is a medium for potential bacterial spoilage, and also represents loss of flavor in the meat as nutrients such as vitamins, proteins, and minerals are dissolved in the exudate. Slow freezing rates product greater damage to the mitochondria in the cells than fast freezing, and consequently there is a greater release of enzymes (153).

Freezing is recognized as an excellent method for preservation of meat. It results in fewer undesirable changes in qualitative and sensory properties of meat than other methods of preservation. In addition, most of the nutritive value of meat is retained during freezing and through frozen storage. Some loss in nutritive value occurs when water-soluble nutrients are lost in thawing drip, but the amount of drip and nutrients varies with freezing and thawing conditions. Nutrients found in drip include salts, proteins, peptides, amino acids, and water-soluble vitamins. A study by Anon and Calvelo (154) confirmed that drip loss is reduced by shortening the freezing period, although Bechtel reported that protein in the drip was unaffected by the freezing rate. Meat proteins are less affected by freeze concentration; Jalang et al (155) found that regardless of species, frozen muscle at −19°C provided more expressible (press) fluid than fresh muscle, although pork had more press fluid than beef or lamb. Wagner and Anon (156) explained the effect of freezing rate on denaturing by noting that myofibrillar proteins denature in two stages, with an initial rapid reaction followed by a slower, second stage, with the myosin molecule continuing to denature and leading to a decrease in solubility and viscosity (157). None of the nutrients present in meat is destroyed or rendered indigestible by freezing. Dark color

of fresh frozen meat brightens upon exposure to oxygen or air. Thus, qualitative properties of frozen meat approximate those of fresh meat (158).

In general, sensory characteristics such as rancid, acid, sour and bitter odor and flavors, and rubbery texture increase over time in frozen storage when juiciness decreases. Exclusion of oxygen appears to have the greatest impact on preservation of sensory characteristics. Based on sensory data, apparently, frozen storage of ground pork should be limited to 26 weeks even with vacuum-packaging if "fresh pork" sensory and physical characteristics are to be maintained (158).

Apart from temperature, the nature of the muscle food product is a decisive factor in determining storage time. Ground product with its greater surface area and potential for oxygen penetration is more sensitive to oxidation (rancidity) than whole pieces of meat. As pork contains more unsaturated fatty acids, it is more susceptible to oxidative rancidity than beef. Undesirable oxidation and dehydration occurring during frozen storage may be limited by proper packaging (159).

The length of time meat is held in refrigerated storage prior to freezing affects ultimate frozen meat quality. To preserve optimum quality, meat to be frozen must be handled with the same care as refrigerated meat, especially if products are going to be in freezer storage for several months. Some deterioration continues to occur in meat even at freezer storage temperatures. In addition, quality of frozen meat is influenced by freezing rate, length of freezer storage, and freezer storage conditions i.e., temperature, humidity, and packaging materials used. Included among changes that may occur during frozen storage are development of rancidity and discoloration, with the latter change being due to surface dehydration due to microbial and enzymatic activity. At temperatures below about −10°C, most deterioration due to microbial and enzymatic activity is essentially curtailed. On the other hand, in meat with relatively high microbial loads or in improperly chilled meat, slow freezing rates may allow considerable microbial growth (158). The main effect of freezing upon microorganisms is a cessation of growth. Some microbial destruction will occur during the freeze/thaw process, but freezing should not be regarded as a reliable means of destroying microorganisms other than parasites (160).

Tempering produces the most rapid increase in myoglobin and lipid oxidation. This is probably the result of both the thawing process and temperature fluctuations. Thawing provides an ideal environment for the formation of new, large ice crystals and the temperature fluctuations during tempering further enhance ice crystal growth and formation (161). The formation of large ice crystals enhances muscle fiber shrinkage and distortion and increases the solute concentration, which disrupts the integrity of the muscle cells. Such changes permit catalysts of oxidative reactions to come into contact with myoglobin and lipids (162).

Freezing rates affect physical and chemical properties of meat. They may be influenced by temperature of the freezing medium, type and movement of the freezing medium, packaging materials used, and composition of meat products to be frozen. In the latter case, tissues containing fat have lower thermal capacity than lean tissues, and therefore freeze more rapidly (158). A key property for all the components and membranes of muscle foods is their elasticity. The elasticity determines the consequences of freezing and quality of the resulting thawed material (157).

Undesirable physical and chemical effects occurring in meat during freezing are associated with one or more of the following factors: (1) formation of large ice crystals in extracellular locations, (2) mechanical damage to cellular structures resulting from volume changes, and (3) chemical damage caused by concentration of solutes, such as salts and sugars. Nonvolatile solutes lower the freezing point and therefore, meat freezes at approximately −2°C to −3°C. Extent of damage to meat tissues attributable to these three factors is influenced by freezing rate (158).

During slow freezing, temperature of meat products remains near the initial freezing point for an extended time. As a result, a continuous freezing boundary forms and proceeds slowly from exterior to interior. During the process of slow freezing, long periods of crystallization time exist, producing numerous large extracellular masses of ice crystals that are easily lost as drip during thawing. Mechanical damage due to volume changes is more likely to occur during slow freezing because of expansion associated with formation of large ice masses, as well as concomitant shrinkage of muscle fibers that have lost water to extracellular pools. Such muscle tissue has distorted structure in frozen form that completely obliterates normal striations (158).

Cryogenic freezing is a rapid freezing method utilizing condensed gases such as liquid nitrogen, nitrous oxide (N_2O) and dry ice (CO_2). This rapid freezing is primarily the consequence of very low initial temperature. Costs for cryogenic freezing are greater than for conventional freezing. Justification for this method is better achieved quality (163). During cryogenic fast freezing, meat product temperatures fall rapidly below the initial freezing point. Numerous small ice crystals with filament-like appearance are formed both intra- and extracellularly at approximately the same speed. Because of rapid rates of heat transfer, small ice crystals formed have little opportunity to grow in size.

Thus, fast freezing causes spontaneous formation of many small ice crystals resulting in discontinuous freezing boundaries and very little translocation of water. Since most of the water inside muscle fibers freezes intracellularly, drip losses during thawing are considerably lower than in thawing of slowly frozen meat. In addition, muscle fiber shrinkage and distortion are minimized during fast freezing, resulting in near normal ultrastructure in the

frozen state. Volume changes are less and periods of crystallization are shorter than in slowly frozen muscle and, consequently, mechanical damage is correspondingly less. Filament-like ice crystals entrap solutes and thus minimize the ion concentration effect. In addition, smaller and more numerous ice crystals in rapidly frozen meat reflect more light from meat surfaces, resulting in lighter color than that of slowly frozen meat (158).

Conditions under which frozen meat is stored are even more important for maintaining quality. The length of time frozen meat may be successfully stored varies with species, type of product, freezer temperature, temperature fluctuations, and quality of wrapping and/or packaging materials. In general, lowering storage temperatures may extend storage time of all types of frozen meat. Rates of chemical deterioration are greatly reduced by freezing, but reactions such as oxidative rancidity continue slowly even in the frozen state. Most chemical changes could essentially be eliminated by reducing temperatures to −80°C, but such temperatures are not economically feasible in most storage facilities. Growth of putrefactive and spoilage microorganisms, and most enzymatic reactions, are greatly reduced, if not entirely curtailed, at temperatures below −10°C. In general, storage temperatures of less than −18°C are recommended for both commercial and home freezer units. Most of these units operate at temperatures between −18 and −30°C. Although it is expensive to maintain the lower temperatures of this range, length of meat storage life may be significantly extended (158).

Temperature fluctuations during frozen storage should be avoided as much as possible, to minimize the ice crystal growth, formation of large crystals, and associated drip losses. Almost all water in meat is frozen at about −18°C. However, as temperature increases, unfrozen proportions increases and become especially marked above −10°C. Small ice crystals are thermodynamically less stable than large crystals. Water molecules migrate from small crystals through unfrozen pools of water to recrystallize and form large ice crystals. Migration, recrystallization, and ice crystal growth are enhanced by relatively high storage temperatures and by temperature fluctuations. Fluctuating storage temperatures also may cause excessive frost accumulation inside packages, much of which is lost as drip upon thawing (158).

Acceptable quality may be maintained in frozen meat products for several months, only if certain critical packaging requirements are met. These requirements include use of vapor proof packaging material to keep moisture in and oxygen out of packages. Moisture losses, due to improper packaging materials or techniques, result in dehydration and freezer burn, and oxygen from air in packages causes oxidative changes, including rancidity. Another requirement for quality maintenance for extended periods of time, is to eliminate as much air as possible from packages. Other requirements include use of odorless, grease proof packing materials that are strong when wet and resist scuffing, tearing, and puncturing under normal handling conditions (158).

The amount of time meat may be held in frozen storage, while maintaining acceptable quality, depends on degree of saturation of meat fats. Since fish, poultry and pork fats are more unsaturated than beef and lamb fats, they are more susceptible to oxidative changes. Hence, recommended frozen storage times differ for various species. Gradual decreases in flavor and odor acceptability during frozen storage are primarily due to oxidation of lipids (158). The freezing process causes changes in the structure and color of the muscle. Storage temperature, light intensity, type of display area and packaging all affect the rate of deterioration. The color of frozen meat is known to vary with the rate of freezing. Taylor (164, 165) found that, with lower freezing rates, the appearance of the product changed and at very low rates, there was a marked development of translucence leading to a lighter product. Zaritky et al (166) concluded that small crystals, formed by fast freezing, scattered more light than large crystals formed by slow freezing and hence, fast frozen meat was opaque and pale and slow frozen meat was translucent and dark.

Length of frozen storage is influenced by processing state of meat products i.e., fresh, seasoned, cured, smoked, precooked, comminuted, or chemically preserved. Salt enhances development of rancidity, and processed meat products containing salt have limited frozen storage life. It is generally recommended that cured and smoked products not be stored frozen or stored only for very limited time. Sliced meat products such as bacon and luncheon meat, should not be frozen unless vacuum packaged because air incorporated during slicking, together with contained salt, lead to rancid flavor development in a matter of days or weeks. Precooked frozen meat and poultry products lose their "fresh cooked" flavor during frozen storage and develop "warmed over" flavor due to lipid oxidation. These oxidative changes increase with cooking time, but are minimized to some degree by treatment with polyphosphates, bases or gravies. Oxidation is inhibited by pH increases caused by polyphosphates and by natural antioxidants present in many bases. Frozen storage life of precooked meat products also may be extended by packaging in inert gas, such as nitrogen, in which case elimination of oxygen from packages is responsible for inhibition of oxidation (158).

Sensory quality after freezing in restructured meat products can be similar to that of processed meats. In the manufacture of restructured products, there are additional factors which may also accelerate the rate of discoloration, which is the main sensory quality altered by low temperature storage. Of these factors, (1) grinding and mixing (167), (2) addition of sodium chloride (168, 169),

and (3) tempering of frozen meat logs (161) attribute also to loss of sensory appeal. Several serious problems, namely, color instability and fat oxidation, are encountered in restructured meats. Variable color patterns of restructured meat, especially beef products, continue to trouble processors, and color instability is a prime limitation to acceptance of restructure meat products in the retail trade (170).

Cured meats develop rancidity more rapidly than frozen fresh meats. It is customary to freeze bellies or hams only before curing. In addition to rancidity, changes in flavor and texture occur in frozen cured meats. The relative stability of refrigerated cured meats decreases the need for frozen storage; however, the end user may desire to freeze portions of large products, such as ham. This can be done if the meat is properly wrapped and not held in the freezer for more than a few weeks. Longer storage periods lead to flavor changes (163). Mitchell et al (171) found that while freezing and thawing steaks did not seriously affect the quality of the meat, steaks cooked directly from the frozen state were more juicy and had more flavor than those thawed first. However, they found that steaks thawed before cooking were slightly more tender than unthawed steaks, although there was little difference between steaks thawed in a microwave oven, in a refrigerator, or in air, a result also established by Moody et al (172). The lower juiciness ratings for thawed steaks were attributed to drip loss during thawing (173).

The thawing process probably does greater damage to meat than freezing. Several factors are responsible for damaging effects occurring during thawing. Thawing occurs more slowly than freezing, even when temperature differentials are the same. Further, temperature differentials in thawing are generally much less in practice than those used in freezing. During thawing, temperatures rise rapidly to the freezing point, then remain there throughout the entire course of thawing. This situation increases the duration of thawing compared to freezing and provides greater opportunity for formation of new, large ice crystals (recrystallization), for increased microbial growth, and for chemical changes. Thus, time-temperature patterns of thawing are more detrimental to meat quality than those of freezing (158). Time required for thawing frozen meat depends on a number of factors: (1) temperature of meat, (2) thermal capacity of meat (lean products have higher thermal capacities and therefore thaw more slowly than fat products), (3) size of meat products, (4) nature of thawing medium (water provides faster heat transfer than air), (5) temperature of thawing medium, and (6) movement of thawing medium (158).

Factors affecting quality of frozen meat can be ranked, in order of importance as follows: (1) frozen storage conditions, (2) thawing conditions, (3) freezing rate, and (4) prefreezing treatment and handling. Frozen storage, as conducted under commercial and household conditions, is the most damaging phase in handling and processing of frozen meat. Even though damage due to recrystallization of ice occurs during thawing, it is generally less severe than that occurring during storage because of shorter times involved. Original differences in product quality, caused by fast rather than slow freezing rates, gradually diminish during several months of frozen storage. In addition, cooking further reduces differences in quality caused by different freezing rates (158).

The single factor exerting most damaging effects on meat products during frozen storage is temperature, particularly as it fluctuates. Deleterious effects produced by temperature primarily result from ice crystallization. Damage occurring during frozen storage can be minimized, but not entirely prevented, by maintaining low, constant storage temperatures, and by limiting duration of frozen storage (158). During freezer storage an excessive loss of moisture from meat surfaces will result in localized areas of dehydration and discoloration. This condition is called freezer burn and is characterized by cork-like texture and gray to tan coloration. It can result when wrapping and/or packaging materials have been punctures, or when moisture-proof wrapping and/or packaging is not used. Improper maintenance of temperature, with frequent cycles of partial defrosting followed by refreezing during storage, also contributes to freezer burn. During development of freezer burn, proteins become denatured and rehydration is poor. Meat with severe freezer burn is dry and tasteless or, if oxidative rancidity has developed, bitter in flavor (158). Freezer burn can be prevented by a skin-tight covering (moisture-impermeable film or dip or spray coatings) or an ice glaze (163).

Freezing may cause damage to meat structure, particularly if it is frozen too slowly. Water may collect extracellularly and freeze in large pools, forming spikes of ice crystals that puncture muscle fibers, releasing even more moisture. Physical damage caused by slow freezing results in great loss of fluid from meat when it is thawed. This fluid collects in packages upon thawing, and is called drip. Excessive drip results in unattractive packages, loss of nutrients, and dryness in cooked meat (158). Profound effects on the structural and chemical properties of muscle foods, including changes in the muscle fibers, lipids, and proteins result from slow freezing. All of these have the potential for significantly influencing the quality attributes of meat and meat products.

Alterations in protein have been observed in frozen meat. Sarcoplasmic proteins are less soluble after freezing muscle tissue. The total extractable protein, sarcoplasmic protein and actomyosin extractability decrease with frozen storage. Evidence indicates quality of protein and fat deteriorates, and comminuted products manufactured from frozen meat block components gradually decrease in quality characteristics (163). While Miller et al (174) found no acute emulsion instability during 37 weeks of storage, the

trend indicated an eventual failure on further storage. The first signs of change were evident after only one week of freezing and by 25 weeks all observed characteristics showed significant degradative changes.

During refrigerated storage, meat loses moisture from its surfaces, resulting in weight loss called shrinkage. Other than economic losses associated with shrinkage, loss of moisture during the first few days of refrigerated storage seldom has adverse effects on meat acceptability. However, physical changes accompanying shrinkage during prolonged refrigerated storage include surface dehydration and discoloration (158).

The texture and consistency of meat render it highly susceptible to the absorption of volatile materials. Meat tissues readily absorb aromatic compounds from other foods, such as apples or onions. Consequently, off-flavors may occur when meat is stored in the presence of such products (158). The beneficial effect of low temperature storage is the tenderization of meat. Beef increases consistently in tenderness as freezing temperatures are lowered.

The morphology of ice in the frozen tissue and the size and distribution of ice crystals formed in the intra- or extra-cellular spaces are particularly important. These cause changes in the water-holding capacity of the muscles when thawed, in the texture, and in the surface color. Freezing of meat results in an increase in the amount of drip fluid when the meat is thawed, causing changes in the sensory properties of the meat after it is cooked.

The rate of freezing is of great importance, especially between −1° and −4°C (30–25°F). When frozen slowly, ice crystal formation starts in the aqueous intracellular compartments. Subsequently, water in the connective tissue freezes due to a lower salt content than muscle tissue. The remaining water is more concentrated and the higher osmotic value will result in water diffusing out of the muscle cell and condensate on the outer cell ice. Eventually, the intracellular water will freeze. Under improper freezing conditions, ice crystals may grow to 150 μm (diameter) and damage the muscle cell (141). When the critical temperature (−1 to −4°C; 30 to 25°F) is passed rapidly (within 80–120 minutes), the water in the muscle cell freezes before substantial diffusion can occur. The existence of numerous small ice crystals limits the risk for cellular deformation. Fluctuation in storage temperature may permit the small ice crystals to thaw, leading to recrystallization and the formation of large crystals. This may lead to extensive membrane damage and subsequent problems with increased rancidity and drip or purge (141).

Deteriorative changes occurring during freezing are often due to oxidation. The oxidation of meat during frozen storage is largely due to changes in the triglyceride fraction. Susceptibility to lipid oxidation is influenced by species differences, as well as differences between tissues. For example, beef lipids are more stable than those of chicken white meat. Temperature and length of holding can alter the rate of oxidation of lipids in meat. Even at −30°C (−22°F), lipid oxidation may occur. Oxidation during frozen storage is especially a problem with processed meat products, as salt acts as a catalyst in oxidative reactions. Auto-oxidation proceeds faster during storage at high temperatures. The susceptibility of frozen food systems to oxidation is related to low water activity. Whereas fresh meat has a a_w of 0.99, muscle tissue frozen at −18°C (0°F) has a a_w of 0.60. At water activities of 0.60–0.80, heme pigments appear to initiate lipid oxidation. Porcine myoglobin seems less stable to oxidation than myoblobin from other species. Other substances found in meat products are also known to accelerate oxidation. Lipases and liposydases will, especially at a lower pH, induce lipid oxidation and rancidity (141).

Color deterioration of frozen meat can be a problem. Freezing accelerates metmyoglobin formation, causing an undesirable color change. Rapidly frozen meat is lighter in color than slowly frozen meat. Localized tissue dehydration, or freezer burn, may result in a lightening of dark tissue or a browning of light-colored tissues such as chicken skin. Freezer burn is an irreversible condition. It may be prevented by proper packaging. Even with proper freezing techniques, a concentration of soluble salts within the muscle cell will occur. This will cause denaturation of proteins, and the pH of the product will change (141). MacDougall's (147) contention that major color problem during frozen storage was photo-oxidation of pigments indicating therefore that meat was best preserved by aluminum foil packaging. MacDougall's theory (147) that frozen meat oxidized from the surface inwards (compared to fresh meat, which oxidized from the interior outwards) can be demonstrated by the use of packaging techniques.

Freezing of muscle foods should not start before rigor has set in. The primary textural change occurring in properly frozen red meats and poultry is an increase in porosity. Freezing and frozen storage of seafood can result in an undesirable textural change. The muscle may become tougher, drier, and lose its water-binding capacity. The overall decrease in protein extractability is attributed primarily to alterations in the myofribrillar fraction (myosin-actinomyosin binding). The nature of the reactive groups responsible for the aggregation is not well understood. Formaldehyde, a product of decomposition of trimethylamine oxide, is highly reactive with a variety of functional groups and it has been suggested that it is involved in the covalent cross-linking of proteins in frozen-stored fish. The loss of water-binding capacity is probably due to an increase in the number of cross-linkages between myofibrillar proteins. As fish lipids contain highly unsaturated fatty acids, fish muscle is very susceptible to oxidation (141, 175).

Thawing of meats has been a largely ignored subject. Slow thawing will result in a better product than fast thawing, meaning that thawing at refrigeration temperatures is

preferable to thawing at higher temperatures. Thawing time should be too long, as it may lead to microbial growth. An important consideration in a thawed product is the amount of exudate. The exudate, containing soluble proteins, vitamins, and salts, will be increased when cell damage is extensive. Slow thawing allows for reabsorption of the fluids by the tissue (141).

Bulk frozen meat, typically in block form of up to 25 kg, can be processed immediately at temperature of −20°C to −30°C or below. Heavy duty pre-breakers in the form of guillotines, chisel-type implements or strong cutter blades can rapidly reduce whole blocks into pieces suitable for further comminution (157). Similarly, heavy duty mincers or similar machines can operate at very low temperature and effectively reduce meat into small particles. However, the brittle state of meat and the ice contained within the tissues at these temperatures causes considerable shattering of muscle and fat structures, with the consequences of the meat being in a very finely fragmented state. This can be desirable for very fine comminutes of a homogenous character, but undesirable for products where larger particles and retention of muscle structure are required (157). The temperature at which the pre-breaking of frozen meat blocks takes place can have a major influence on the ultimate particle-size distribution of comminuted products, with meat pre-broken at lower temperatures having smaller particles. The perception of particle size is itself a key determinant of burger texture (176). The breakage of meat and the considerable deformation of internal particle structure, often to the structural level of individual muscle fibers, is characteristic of mincing/grinding and in turn determines the particulate character of many burger, sausage, and other meat products (157).

Beef could be satisfactorily preserved in the frozen state for at least 554 days at temperatures below 0.9°C. A later report (177) indicated that uncured pork cuts were in an excellent state of preservation after being stored for 9 months at −35.5 to −36.7°C and that such cuts were still edible after 16 months under these conditions. A recent report (178) indicated that uncured pork chops and roasts could be stored at −30°C for at least 196 days, regardless of the protective wrap used.

Frozen storage does not affect any of the surface or partial compression properties of meat. However, on the first bite fresh samples are slightly more cohesive and during mastication are chewier, require a greater number of chews, and are more cohesive than frozen and thawed samples. However, stored samples release slightly more moisture during mastication. After swallowing, the mouth coating from fresh samples consist of a higher proportion of particles, and the particles from fresh samples consist of a higher proportion of appropriate residual particles described as being fibrous, grainy, crumbly, and mealy, while the particles from stored samples consisted of a higher proportion of appropriate residual particles described as being fibrous and grainy. As a result of these differences, stored samples received higher texture amplitude ratings than their stored counterparts.

Present findings clearly indicated that freezing, frozen storage, and thawing produced beneficial effects on texture properties that enhanced texture amplitude. Such effects resulted in a slight tenderizing effect, a slight improvement in juiciness, and a breakdown to move appropriate particles, as evidenced by stored samples being less cohesive, easier to chew, and releasing more moisture during mastication. However, it is also clear that freezing, frozen storage and thawing produced detrimental effects that detracted from flavor amplitude. For instance, the higher moisture release during mastication observed substantiates previous findings that the juiciness of pork roasts improved slightly with freezing and frozen storage (178) and is on agreement with the results of Tuma (179) on beef. In addition, present findings that pork loins were less cohesive during the first bite and mastication, and were less chewy and required fewer chews during mastication lends support to, and aids in explaining, previous reports that the tenderness of meat improved during freezing and frozen storage (180, 181, 182, 183, 184, 178). However, the low flavor amplitude ratings received by frozen and thawed samples clearly indicates that freezing, frozen storage, and thawing results in a less appropriate and less well balanced and blended flavor. Present findings also appear to be in agreement with previous conclusions that uncured pork palatability can be maintained for at least 6 months (177, 178).

Furthermore, present findings regarding moisture release, cohesiveness, and chewiness coupled with the fact that frozen and thawed samples appeared to break down to more appropriate particles clearly indicated that freezing and frozen storage is beneficial to the textural properties of pork loins. There is some evidence (185) that rapid freezing affects a greater tenderization because the ice crystals are formed within the muscle fibers, causing a disintegration of the fiber with an accompanying increase in tenderness. In one study comparing the eating quality of rib roasts of beef frozen under ten different conditions, it was concluded (186) that the more rapidly the meat was frozen, the better was its all-round quality. It has been claimed (187) that freezing is important in the maintenance of "bloom," or fresh appearance of poultry. This report refers to a "dark color which results from slow freezing." With a lower freezing temperature and hence a faster rate of cooling tenderness appears to be somewhat improved. As far as the authors are aware, there is no satisfactory data to indicate that freezing, regardless of its rapidity, has an important effect on other palatability criteria in meats. Appearance, odor, and taste seem to be unaffected. Some (188) claim that a short interval between formation of the first ice crystals and the complete freezing of the fruit is essential for the maintenance of texture, palatability, and

satisfactory superficial appearance. There is little question that freezing does "tenderize" or soften vegetable tissues. The final test — and the ultimate one, that of appearance, odor, flavor, texture — was equally negative. The slow-frozen vegetables were as acceptable to the palate as the fast-frozen ones. However, it does seem evident that rapidly frozen fish have a higher taste-panel acceptance than very slowly frozen ones. In appearance, odor, flavor, and nutritive value, the home-frozen product can usually vie with the quick-frozen food in commerce as being a quality item.

H. Poultry and Eggs

1. Poultry

Flavor, texture and juiciness of smoked broilers stored at −18°C for up to 12 months does not change (189). When broilers are fed with a diet containing rosemary and sage, and frozen stored at −20°C no rancidity is detected after 4 months (190). Chicken hot-drumettes containing 2% cayenne pepper are scored 2.5 after cooked (1 = no hotness, 5 = extremely hot) after four days of frozen storage (191). A duo-trio sensory evaluation of the flavor of breast meat from broilers fed with marine algae, vacuum packaged, and frozen stored at −23°C showed no changes among fresh breast samples and frozen stored samples after 3 days of storage. Feeding 5.5% marine algae or 2.1% menhaden oil increase the flavor scores after 82 days of storage (192). Leg meat frozen produces more substantial oxidative decomposition of fats (193). The evidence indicates that juiciness, tenderness, and general palatability of broilers are the same whether the birds are frozen with 2 hours of slaughter or are held until the body temperature has dropped to the temperature of the cooler. Furthermore, as the period between slaughter and freezing is increased, the greater is the tendency for the fat in poultry to turn rancid during zero storage (194).

Frozen turkey breast does not show rancidity after 150 days of frozen storage. Oxidized aromas are normally detected. Color scores increase if the level of vitamin E in their diet is increased. In mechanically deboned chicken and turkey meat stored frozen for 6 months, some color is lost but still acceptable for use in emulsion products (195). Chicken thigh meat patties formulated with 5 to 20% fat, cooked and stored for up to 9 months does not show rancidity (196). Patties made with ground, dark turkey meat frozen and kept for 3 weeks are scored low if only polyphosphates or water are added but those with alkaline tripolyphosphates receive higher sensory scores (197).

2. Eggs

Partial freezing, light freezing or super chilling has been used to preserve freshness of food products. Liquid whole egg, liquid yolk and liquid yolk stored at −0.5 and −3°C temperature for up to 50 days length of storage do not affect the palatability test for scrambled eggs (198). Liquid eggs are used as ingredients in candy, baked good, salad dressing, and ice cream. One-third of all pasteurized liquid egg is frozen prior to distribution to extend shelf-life. It has been reported that pasteurization and frozen storage influence liquid egg rheological properties and functional properties such as emulsifying properties, decrease in foaming and whipping. Pasteurized frozen eggs stored for up to 80 days show changes in the solubility of certain proteins such as lipovitellin and livetin, which are responsible for the emulsifying properties of eggs (199, 200). The lumpy character of the thawed yolk is an undesirable quality that generally must be avoided. Egg yolk subjected to linear electron beam irradiation at ~2.5 kGy dosage and frozen stored at −15°C for 60 days show that hue of irradiated samples is more yellow than the nonprocessed samples after 60 days of frozen storage. The saturation index is lower for the irradiated samples. Storage effect in redness and hue are also observed. Color of egg yolk becomes slightly less reddish yellow during storage or the yolk lost pigment during storage (201).

I. Peanuts

Roasted peanut paste kept at −20 and −10°C does not change its sweetness sensory attribute; however, bitterness (cause by saponins) and tongue burn tends to change over frozen storage. The most important sensory attribute that changes over frozen storage is 'staling' that is used to describe light lipid oxidation and the characteristic flavor that results. This attribute has also been described as 'old, cardboardy, strawberry-like note.' As lipid oxidations progresses, changes are described as 'painty.' The fruity attribute in roasted peanut paste develops from abusive environmental and handling exposure but also increases over frozen storage. There is no change for the 'roasted peanut' attribute during storage at low temperature (202).

J. Soybeans and Soy Products

Food companies and consumers alike use the versatile raw ingredient known as soybeans in various food products for numerous reasons. Soy concentrates have the ability to bind and hold natural flavors and moisture, resulting in products that stay moist and flavorful even after reconstitution in conventional, convection, or microwave ovens (203). Soy flour has a blander flavor and is able to retain meat juices; while many lactose intolerant individuals consume soymilk. As a result, soybeans and their constituents are gaining popularity and usage in the food industry.

Soybean producers claim that consumers seek the sweetness, pleasantness and firm, nut-like texture of the soybean. Young et al (204) has reported that females are likely to purchase frozen soybeans to use in recipes as an alternative to meat as a result. However, if improperly processed, soybeans and soy products develop objectionable

off-flavors and off-aromas. Bitter, astringent, and sour flavors are common flavor defects reported in soybean-based products. A chalky texture may be detected in some products such as soymilk due to improper processing. In other soy protein products, the freeze-thaw cycle will result in a gummy and unacceptable product. These off-flavors and textures are important limiting factors in the use of soybeans and soy constituents in products that are shelf stable and/or frozen. These off-flavors may be the result of the high proportion of unsaturated fatty acids found in raw soybeans. There are two major interrelated causes for development of such flavors. One is the high proportion of unsaturated fatty acids, particularly linolenic acid, in the soybean oil fraction, and the other is the abundant presence of lipoxygenases in soybeans. The enzyme catalyzes the oxidation of polyunsaturated fatty acids of soy lipids, producing hyperoxides. Degradation of hyperoxides leads to formation of various types of volatile compounds, many of which have an objectionable odor or flavor, described as beany or greeny.

Soymilk and soy products tend to have an objectionable aftertaste that has been described as sour, bitter, and astringent. These undesirable characteristics probably result from the presence of some minor compounds in soymilk including phenolic acids, saponins, oxidized phospholipids, and isoflavones. Soymilk, if it is not properly processed, tends to have a chalkiness defect. The freezing of this product tends to worsen this defect (205).

There are many different soy derived products that are incorporated into foods for functional, nutritional, processing, and other properties. These ingredients can actually improve the nutrition, flavor, texture, and consumer acceptance of foods. If properly formulated, these types of soy based or enhanced foods freeze well with little detrimental attributes developed in the freezing process.

Soybean isolate is made from a spun soybean oil and is almost flavorless and the taste of which, therefore — exclusive of texture — depends to a large extent upon the quality and expertise involved in adding the flavors. Freezing has the tendency to make soybean isolates gummy. However, depending on the product in which it is incorporated, this may or may not lend the product unacceptable. Soy protein isolates have been perfected that make possible a hot dog that contains only 3% fat, yet cannot be differentiated in flavor and texture from those one might be accustomed to and are competitive in price. These types of soy products tend to freeze well with virtually no loss of flavor or texture quality.

Extruded soybean extender, which can be in dry form as flour or pellets, often has off-flavors and must be blended with products or must have flavors or spices added that are strong enough to override the flavor of soy itself. Typically, this product freezes well and due to the nature of the flavor system, is not seen as being hindered by freezing. For example, there is a great deal of meatless chili made, both frozen and unfrozen, and the strong chili-powder flavor completely dominates the mixture. In this case, the soy extender is added to give the texture of the meat without the much higher cost of meat. There are even "beef" stews of this sort with no beef at all in them, but the generous quantity of spices present in all such stews drowns out the beany flavor of soy (206).

Formulating with textured soy proteins or such extenders is more complex than a direct substitution of another type of muscle food into a food system. Processors sometimes forget that meat is naturally about 80% water and when an extender is used that absorbs too high a quantity of water it changes the texture and flavor of the beef by increasing the percentage of water to solids. If the product is frozen, this leads to an unacceptable product. Often too, saturation occurs, the cells become ruptured and the product becomes separated and soggy. This is an unacceptable quality attribute for products of this type.

Soy meat extender has also proven valuable in imparting proper texture to mechanically de-boned meat. This product tends to freeze well and no "off" flavors or texture attributes are typically observed. Soy flour has the advantage of holding the juices in meats. Its disadvantage is that of taste and physical feel in the mouth.

Soy proteins are used extensively in breads, doughnuts, rolls and sweet goods. They are not necessarily cheaper than the flour they replace, but they hold the moisture levels at an accepted and desired level thereby producing a better-textured product. Some of those using it don't know whether to attribute the better texture to moisture retention or to some interaction of the soy proteins with the other ingredients that has not been adequately researched as yet (203).

Soy-protein burgers, with taste and mouthfeel of beef, are an excellent source of protein. The grain-based burgers are usually higher in dietary fiber and are marketed to people who want a convenient food that has interesting textures and flavors, not necessarily imitating meat. The only caution is to avoid freeze-thaw cycles, because they make soy protein products gummy. However, most of these products are found in the grocer's freezer case, and are accepted well by consumers.

When used as emulsifiers, binders, moisture retainers, and stabilizers, soy proteins can alter or improve the appearance, taste, and texture of the finished product. Flavor-wise, the white flake (soy flour and soy grits) has a bitter, beany taste. The toasted product is darker in color and the enzyme and anti-trypsin activities are destroyed (207). The flavor is also improved to the point where it takes on a sweet nut-like taste (208). The intermediate or cooked product has properties between the two.

Although the cost of soy protein concentrate is more than double that of soy flour (18½–28 cents per lb.), it is rapidly replacing the soy flour used in emulsion products because of its blander flavor. Soy protein concentrates tend to become over-saturated and are unable to retain

moisture when incorporated into certain food systems and then subjected to freezing. Product shelf-life can be shortened if the temperature of the freeze-thaw cycles is not carefully controlled.

ACKNOWLEDGMENT

I. INTRODUCTION: THE NOTION OF A MEGA STUDY AND CONCEPT RESPONSE DATABASE FOR FOOD AND BEVERAGE

One of today's pressing needs is to better understand the mind of the consumer in order to spot newly emerging trends in the market, and to capitalize on them. Data themselves are no longer the choke point in the market. Researchers and businesses are awash in data. Data that cannot be easily obtained by subscribing to information services can be obtained by commissioning a custom study. In one way or another the marketer, the product developer and the researcher can answer most of the questions about new and current products, advertisements, and consumer attitudes.

Given this abundance of information the question one might naturally ask is why bother with more data? What is missing? Why would the rational businessperson invest in new data when there is so much data from which to choose? The answer is quite simple. There are lots of sources of data, but unfortunately there is no systematically developed database about the "mind of the consumer" that can be interrogated to identify patterns of what communications about products drive acceptance. The situation in the food world today can be likened to an amalgam of differently sourced computer programs that perform the gamut of tasks from spreadsheets to presentations to document control and preparation. Until Microsoft came out with its Office Suite® there were many relatively unconnected alternatives for each task. Going from one task to another, e.g., from document preparation to computation

to presentation, meant learning all sorts of new tasks, finding how to do things, and then doing the task. In the meantime the effort was spent on learning the steps to move from one system to another, rather than on the information to be communicated.

There is no systematic knowledge or database available to understand how consumers respond to different brand names, features of products, emotional aspects of products, or aspects of the buying situation. Most of the knowledge resides in unrelated sources, such as corporate offices, trade and academic journals, and the experience of development and marketing professionals. A lot of information resides in disparate documents available to the public and accessed either by some intelligent search engine such as Google®, or by some "pay-as-you-go" system such as Lexis/Nexis®. A cross-sectional *and* longitudinal database to understand the "algebra of the consumer mind" is a major contribution to academic and business oriented product development, marketing, and consumer sciences.

This article presents the structure of the integrated database for food and drink, showing how consumers respond to messaging about food, and how their responses can be better understood by looking at how the respondents profile themselves in a classification questionnaire. The approach is known as the It!™ system. It!™ uses the power of primary research, with a powerful, state of the art research tool (conjoint measurement), executed in-depth for specific categories, and applied to a related set of 20–40 different related products or services. This approach generates one integrated mega-database. Through this integrated database of 20–40 related studies in a specific area it becomes possible to:

1. Identify the features and messages that drive interest
2. Compare these features and messages across different but related product categories
3. Divide people by their profile of attitudes
4. Segment consumers on the basis of the pattern of features and communications that interest them
5. Prescribe new product concepts based upon the winning elements for each segment
6. Assess trends in the population based upon the patterns across years of utilities from the conjoint measure

The "mega-categories" for the food and beverage industries that have been already developed using the approach below are:

1. Food acceptance (reported here as the Crave It!™ Study), for the US and European respondent, and for teenagers
2. Healthful foods (Healthy You!)
3. Beverages (Drink It™)
4. Fast Foods (It's Convenient)

However, the approach to create these "mega-studies" and their databases has further been used for a number of other categories outside of food such as

5. Insurance (Protect It!™)
6. Consumer Health
7. Charity (Give It!™)
8. The shopping situation (Buy It!™)
9. Personal items (mine™)
10. Financial investments (Finance It!™)

II. THE BASIC TOOL FOR CONCEPT RESEARCH — CONJOINT ANALYSIS

Conjoint measurement refers to a set of research procedures, often called trade-off analyses. The idea behind conjoint measurement is that the respondent cannot easily tell the researcher how concept elements might work in combination, but can respond to concepts as a tonality from which the behavior of the individual concept elements can be deduced. For the researcher to understand the dynamics of concept elements requires an experimental design, or systematic combination of different concepts in such a way that the part-worth contribution of each element can be readily measured. Conjoint analysis uses the experimental design as a structure within which to combine the concept elements systematically, and then requires respondents to rate the concept as a totality (1). From the set of ratings assigned to the concepts the researcher deduces the contribution of the component elements. Conjoint analysis has evolved into a widely used, well respected tool for the practical development of concepts in the business community (2, 3).

Conjoint analysis can take several forms, such as the direct selection of alternatives for the concept elements (so-called trade-off analysis), or response to complete concepts (called full profile). No matter which approach the researcher selects, the goal is always to identify the utility or contribution values of the individual elements. Conjoint analysis was developed in the 1960s as a basic measurement technique by mathematical psychologists (4), but soon found a home in the marketing community (5). More recent adaptations have moved the method to handle hundreds of elements (6), and have seen the migration of the approach to the Internet (7).

A. Setting up the Study

The concept elements appear independently, as prescribed by the experimental design. The experimental design ensures that the elements appear statistically independently of each other, allowing regression to be used. Various

TABLE 59.1
Example of an Experimental Design

Concept	A	B	C	D
1	1	5	0	0
2	6	2	0	1
3	3	2	2	3
4	4	5	6	4
5	6	5	3	5
6	6	0	4	4
7	1	3	2	4
8	2	6	4	1
9	1	4	6	1
10	3	4	1	4
11	0	3	3	3
12	0	2	4	0

methods are used to create the design. Elements cannot be randomly combined, but rather appear in a systematic fashion, dictated by the experimental design. Table 59.1 presents a specific experimental design, comprising four variables (A,B,C,D), and six options for each variable (1–6). In some concepts a specific variable may be absent, denoted by the value "0" for the particular variable, for that particular concept (e.g., in Concept #1 variables C and D do not appear).

B. Modeling Considerations

The independence of the concept elements allows the researcher to create a model using ordinary least squares (OLS), which relates the presence/absence of the concept elements to the rating. The OLS modeling follows the convention of market research, which focuses on the *proportion* of respondents who say that they are interested in the concept, rather than focusing on the intensity of interest. To work within the market research framework we re-code the concept ratings, so that ratings of 1–6 (low end of the scale) are changed to the value "0," whereas ratings of 7–9 (high end of the interest scale; so-called "top 3 box") are changed to 100. The equation is expressed as a simple additive model of the form:

$$\text{Top 3 Box} = k_0 + k_1(\text{Element 1}) + k_2(\text{Element 2}) \ldots k_{36}(\text{Element 36})$$

The foregoing equation is written for 36 elements, the usual case for the mega-study. The additive constant, k_0, is the conditional probability that the respondent would be interested in the concept if the elements were not present. The additive constant is a baseline value, estimated purely from the data, since all of the concepts comprised 2–4 elements by design. The coefficients $k_1 \ldots k_{36}$ are the additive or subtractive conditional probabilities that the respondent would be interested in the concept if the element were added to the concept.

The utility values for the additive constant or for a particular element are aggregated across a relatively large number of respondents to arrive at an average value. Typically the data should come from at least 20 respondents, at which point the results begin to stabilize (7).

C. Segmentation

Segmentation refers to the division of respondents according to specific criteria. The criteria can be developed on the basis of how the respondents classify themselves (e.g., sex, market in which they live, etc.). These segments or subgroups of respondents typically generate highly correlated utility values. That is, what one subgroup likes its complementary subgroup will probably like as well. Quite often the correlations across 36 elements for such complementary subgroups are as high as 0.85 or more, and quite often above 0.60.

Another way to look at subgroups identifies groups of respondents in the population with similar response patterns. These are called concept-response segments. Segmentation using utility values is particularly easy using today's statistical computing power. The method used for the mega-studies is known as k-means clustering (8). The ratings for each respondent are subject to a second analysis by ordinary least-squares, this time without any prior transformation to 0/100, but rather using the "raw" ratings assigned by the respondent as the dependent variable. Each respondent generates a second set of utilities, one utility for each concept element. The method of k-means clustering creates an index of "distance" between each pair of respondents by computing the statistic (1-R), where R = Pearson correlation coefficient. All of the utilities for each pair of respondents are used, with the exception of the additive constant. The statistic (1-R) can vary from a low of 0 when the two respondents show perfectly related patterns (what one person likes the other likes as well), through a middle value of 0 (where they are not related), through a high of 2 (what one person likes the other person dislikes, so the patterns are inverse). The clustering divides the respondents so that individuals in the same cluster are "close" to each other based upon the statistic (1-R); i.e., pairs of individuals located in the same cluster have low values for this statistic (9).

D. Establishing Consistency (and Validity) of Conjoint Method Results

In order for results to be believable one must establish a criterion of validity. This is especially the case for conjoint measurement studies executed over the Internet, where there is no way to ensure that the respondent is paying attention, and where the interview length may be as long as 15–20 minutes. Since the conjoint measurement approach uses ordinary least-squares at the individual

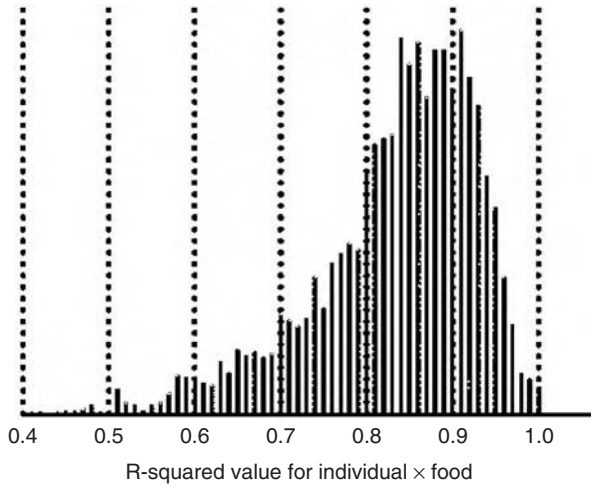

FIGURE 59.1 Distribution of R^2 statistic (consistency and validity measure) from 20 foods, and 4,000+ respondents. An R^2 value exceeding of 0.65 is high significant ($p < 0.05$).

respondent level, it is straightforward to compute a goodness-of-fit measure at the individual level. This measure is the multiple R^2 statistic which shows the proportion of variability accounted for by the equation. The statistic varies from a low of 0 corresponding to random data, up to a high of 1.00 corresponding to a perfect relation between model and data. With 36 elements, the usual number of elements in a mega-study, empirical data suggests that 80% or more of the respondents show consistent results, as shown in Figure 59.1.

III. MEGA-STUDY: A BRIEF OVERVIEW OF THE DATA BASE DESIGN, FIELD EXECUTION, AND ANALYSIS

The approach to create the database uses up to 30–40 linked conjoint studies, following these seven steps:

Step 1 — Identify the general topic area and the specific products for a mega-study. Each mega study comprises 20–40 smaller studies. For example, the aforementioned Crave It! study reported here really comprised 30 different studies. Each study deals with a specific food or beverage (e.g., hamburger, potato chip, coffee). Thus the scope of the mega-study is larger than a typical study that deals with a single product or related set of products. The inspiring metaphor for the mega study is the holistic view afforded by genomics (10).

Step 2 — Develop the experimental design. Conjoint measurement works by main effects experimental design (1). The stimuli or elements are mixed and matched in such a way as to produce different combinations. The statistical objective is to identify the appropriate and efficient experimental design, have a sufficiently large number of independent elements to provide good content (i.e., wide range of concept elements), and enough but not too many concepts to ensure a pleasant interview that does not last too long. The mega-studies use the same type of experimental design, i.e., four independent variables or "categories," and nine alternative concept elements per category. The experimental design dictates the combination of these elements into 60 different combinations. Each combination comprises either one or no element from each of the four categories. The choice of the experimental design is dictated by the desire to minimize the number of combinations that any particular respondent must evaluate, as well as ensure that it is possible to run an ordinary least squares regression on the ratings for the individual. The 60 combinations accomplish both objectives.

Step 3 — Identify the categories and the concept elements. Categories comprise elements that are related to each other. Thus one category might be "primary attributes." The categories are a method for "bookkeeping." The experimental design calls for four "silos" or independent variables, each of 9 elements (E01–E09, E10–E18, E19–E27, E28–E36, respectively). A single category fits into a silo. There may be several categories in a single silo, as Table 59.2 shows. The objective of the bookkeeping approach using silos and categories is to ensure that a concept contains only one message of a certain type, such as emotional reward or product description, so that the concept is logically coherent and does not contain fundamentally conflicting information such as two brand names.

The concept elements in one particular study are comparable to elements in another. The text of the element is appropriate for the particular study, but fundamentally true to the basic overarching design. Furthermore, in quite a number of cases the same text can be used across the studies. This common structure across the studies allowed for meta-analyses, showing patterns transcending a particular study. Emphasis in each study is on the balance of functional and emotional elements (11).

Step 4 — Create a classification questionnaire. The questionnaire deals with different types of issues, such as geo-demographics (age, gender, income, market), what is important in making a decision, state of hunger, time of test, etc. Table 59.3 presents a general set of questions. Where relevant the different answers are given. The classification questionnaire remains virtually the same across individual studies within a mega-study, allowing for comparisons across studies.

Step 5 — Invite respondents to participate. Internet-based research is becoming increasingly easy to execute. More people are obtaining Internet access each week, increasing the number of available respondents. No longer is it a problem to find individuals who have Internet connections, and no longer is the representativeness of respondents on the Internet an issue as it was some years ago. Various service providers have sprung up to deliver either

TABLE 59.2
Example of Categories, Elements, and their Rationales

El	Category	Rationale	Hamburgers	Chocolate Candy
E01	Primary Attributes	Basic physical attributes	Fresh grilled hamburger	A smooth, dense piece of chocolate
E02	Primary Attributes	** (Continuum: basic to complex/detailed physical attributes) in some cases … "healthy"	A chargrilled hamburger with a taste you can't duplicate	Smooth appearance with a light chocolate flavor and a creamy texture
E03	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes)	A grilled aroma that surrounds a thick burger on a toasted bun	Crispy wafers coated in thin layers of milk chocolate
E04	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes) in some cases … "real"	Moist bites of bun, burger, and onion	Real chocolate made with ingredients like chocolate, cocoa butter, vanilla, and sugar
E05	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes)	Juicy burger with the crunch of lettuce and tomato	White chocolate with crunchy cookie pieces throughout
E06	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes)	Gooey grilled burger with rich sauce and fresh lettuce and tomato	Heavy dense chunk of chocolate with complex flavors, velvet appearance ... enticing aroma
E07	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes)	Layers of burger, sauce, pickles, and lettuce on a moist sourdough sesame seed bun	Dense chocolate with swirls of dark chocolate and chocolate sprinkles on the surface
E08	Primary Attributes	** (Continuum: basic to complex/ detailed physical attributes)	Lots of crispy bacon and cheese on a juicy grilled hamburger on a lightly toasted bun	Clusters of chocolate and nuts, with caramel & marshmallow throughout
E09	Primary Attributes	Complex physical attributes; details	Burger smothered in onions and cheese	Golden milk nougat with whole almond pieces on top, caramel drizzled over them and enrobed with semi - sweet chocolate
E10	Secondary Attributes/Mood	Party pleaser/inviting	Burgers are a party pleaser	When it's cold outside, chocolate is cozy and inviting
E11	Secondary Attributes/Mood	Beverages	With a chilled glass of water … or carbonated beverage	With a hot cup of coffee, tea, hot cocoa … or carbonated beverage
E12	Secondary Attributes/Mood	With …	With great tasting french fries … and that special sauce	Bite size pieces; ready for a fast taste … with a chocolate truffle filling
E13	Secondary Attributes/Mood	Premium quality/ classic taste	Premium quality … that great classic taste, like it used to be	Premium quality … that great classic taste, like it used to be
E14	Secondary Attributes/Mood	Savor it …	You can just savor it when you think about it during work and school	You can just savor it when you think about it during work and school
E15	Secondary Attributes/Mood	All natural/ changing flavors	100% natural … a real beef burger!	100% natural … and new choices every month to keep you tantalized
E16	Secondary Attributes/Mood	With all the extras you want …	With all the toppings and sides you want … pickles, relish, jalapenos … lettuce, tomato, chips … whatever	With fruit fillings in any flavor you want
E17	Secondary Attributes/Mood	Imagine the taste …	You can imagine the taste as you walk in the door	You can imagine the taste as you walk in the door
E18	Secondary Attributes/Mood	Lick your lips twice …	So tasty & juicy you practically have to lick your lips twice after each bite	So good … you practically have to lick your lips twice after each bite
E19	Emotional	Quick/ fun/ alone	Quick and fun … eating alone doesn't have to be ordinary	Quick and fun … eating alone doesn't have to be ordinary
E20	Emotional	Have to have it … can't stop	When you think about it, you have to have it … and after you have it, you can't stop eating it	When you think about it, you have to have it … and after you have it, you can't stop eating it
E21	Emotional	Fills that empty spot …	Fills that empty spot in you … just when you want it	Fills that empty spot in you … just when you want it

TABLE 59.2
(*Continued*)

El	Category	Rationale	Hamburgers	Chocolate Candy
E22	Emotional	Cheers you up …	When you're sad, it makes you glad	When you're sad, it makes you glad
E23	Emotional	Escape routine/celebrations	Now you can escape the routine … a way to celebrate special occasions	Now you can escape the routine … a way to celebrate special occasions
E24	Emotional	Multi-dimensional sensory experience	A joy for your senses … seeing, smelling, tasting	A joy for your senses … seeing, smelling, tasting
E25	Emotional	With family and friends	An outrageous experience … shared with family and friends	An outrageous experience … shared with family and friends
E26	Emotional	Ecstasy …	Pure ecstasy	Pure ecstasy
E27	Emotional	Satisfies hunger …	It feeds THE HUNGER	It feeds THE HUNGER
E28	Brand or Benefit	Basic brands/experiences	At White Castle	From Hershey's
E29	Brand or Benefit	** (Continuum: basic to premium brands)	At Jack-in-the-Box	From M&M/Mars
E30	Brand or Benefit	** (Continuum: basic to premium brands)	At McDonald's	From Nestle
E31	Brand or Benefit	** (Continuum: basic to premium brands)	At Wendy's	From Cadbury
E32	Brand or Benefit	** (Continuum: basic to premium brands)	At Burger King	From Lindt
E33	Brand or Benefit	Premium brands/experiences	At Fuddruckers	From Godiva
E34	Brand or Benefit	Fresh … for you … by you	Fresh from the grill, especially for you … by you	Made fresh … especially for you
E35	Brand or Benefit	Best in world …	Simply the best burger in the whole wide world	Simply the best chocolate in the whole wide world
E36	Brand or Benefit	Safety …	With the safety, care and cleanliness that makes you trust it and love it all the more	With the safety, care and cleanliness that makes you trust it and love it all the more

pre-qualified respondents to the study on a pay-per-respondent basis, or are in the business of sending out invitations to e-mail lists of respondents, and charging only by the number of e-mails. The invitation to the respondent appears in Figure 59.2. An interesting invitation letter generates a large number of respondents, so that it is important at the time of invitation to provide an incentive such as a chance to win a cash prize (sweepstakes).

Step 6 — Execute the interview on the Internet. The respondent is first brought to a "wall," where he can select the study of interest (Figure 59.3). The wall is set up so that the least popular study (fewest respondents participating) is at the top left, and the most popular study (most respondents participating) is at the bottom right. The locations of the studies are dynamically changed at frequent intervals according to this rule. This strategy ensures that the studies are not be biased by location. When the base size reaches a specific cut-off, the study option disappears and the button for the particular project disappears from the wall. After selecting the study, the respondent goes to a particular interview. The interview is structured, beginning with an orientation page (Figure 59.4), proceeding to the conjoint analysis portion which presents the test concepts (Figure 59.5), and finishing with the classification page. At the end of the interview the respondent is shown the winning concept synthesized for the total panel and the winning concept synthesized for the respondent himself (informational feedback; Figure 59.6).

The basic structure of the experimental design driving the combination of concepts remains constant, but the particular combinations of elements vary across respondents by a systematized permutation. In this way each respondent's data can be separately analyzed, but there is no need for concern that a particular combination unduly influences the results. That cannot happen, because each respondent evaluates different combinations. For any particular food, there are 200 different experimental designs created, each comprising 60 combinations of the 36 elements, 2–4 elements at a time. A respondent is randomly allocated to a specific experimental design. No more than three respondents are ever allocated to the same design. This strategy ensures minimal bias due to a particular combination.

The respondent rates the concept (systematic combination of elements) on an evaluative measure. For the Crave It! data base the respondent rates degree of craveability on an anchored 1–9 scale. The anchors are appropriate for each scale, located at the low-scale value of 1 and the high-scale value of 9.

The final portion of the interview comprises the self-profiling classification. The objective here is to have the respondent profile himself after the conjoint measurement, in order to better understand his geo-demographics, values, and patterns of behavior pertaining to the specific food. The information provides a snapshot of how the respondent sees himself. Furthermore, the results can be analyzed from the perspective of each particular food.

TABLE 59.3
Types of Classification Questions Asked in the Mega- Studies

Q1: Tell us your gender
Q2: How hungry are you right now? [check one]
Q3: What time is it? [check one]
Q4: Please tell us your age. [check one]
Q5: How often do you eat <FOOD NAME>? [check one]
Q6: Where do you typically purchase <FOOD NAME>? [check two]
- M1. Food store
- M2. Convenience store
- M3. Warehouse or club stores, like BJ's or Sam's Club
- M4. Superstores, like Wal-Mart or Target
- M5. Quick service restaurant, like McDonald's, KFC, or Taco Bell
- M6. Local chain restaurant, like Applebee's or Friday's
- M7. Local eatery, known only in your area
- M8. Specialty shop
- Etc.

Q7: Which 3 product attributes MOST influence your craving for <FOOD NAME>?
- M1. Appearance
- M2. Aroma
- M3. Texture
- M4. Taste
- M5. Memories
- M6. Associations
- M7. Brand
- M8. Advertising
- M9. Packaging
- M10. Portion size
- M11. Social situation
- M12. Mood
- Etc.

Q8: On what 2 occasions do you typically crave <FOOD NAME>MOST? [check two]
- M1. In the morning or at breakfast-time
- M2. Mid-morning
- M3. Around lunch-time
- M4. Mid-afternoon
- M5. Just before dinner or while dinner is being prepared
- M6. After dinner
- M7. When shopping in the food store
- M8. On the way to or from work or school
- M9. After school
- M10. Watching TV
- M11. When I am alone
- M12. When I am with friends or family
- M13. When I want to celebrate
- M14. When I'm bored and restless
- M15. When my hormones are going crazy
- M16. When my kids/siblings are bugging me
- M17. When I just need to escape

From these self profiling data the researcher can create a profile of foods and occasions/situations when they are most desired and/or consumed. It is important to note, however, that these results are strictly from the self-profiling done in the classification questionnaire.

Step 7 — Analyze the data, set up the database. The data from any single study in a mega-study comprises the utility values from respondents, as well as results from the self-classification questionnaire. The utility values are arranged by total panel and by key subgroups. Subgroups include respondents of different ages, respondents who say that they accept a product for specific reasons, as well as segments of respondents based upon their pattern of utility values. Each product in a particular mega study generates its own database. By creating databases with the same subgroups, and by linking together elements with the same rationale across studies, the researcher ensures that database transcends any particular product.

IV. A SAMPLE OF RESULTS FROM A MEGA-STUDY; THE CRAVE IT! STUDY

In a short article is impossible to do justice to the contents of any of the mega-studies. Thus the remaining part of this article provides the reader with a sense of the type of data that one might obtain by running these studies. The data will be taken from the 2001–2002 Crave It! studies, which dealt with rated craveability of a variety of foods.

a. Number of respondents in a study as a measure of latent interest in the product. The respondents can choose any study that they find interesting. Either the rate at which a study fills up or the total number of respondents in the study gives a sense of latent interest. Respondents tend to choose studies that they find interesting. Table 59.4 shows the final number of respondents, and the proportion of men and women respondents in 19 of the Crave It! studies (2001 data). The study was run until every food had at least 150 respondents. Data of this type show that commonly crave foods include chocolate candy, pizza, and ice cream. Furthermore, by looking at the proportion of men versus women the researcher gets a sense of the type of foods that interest the genders. It is clear from these results that although women participate more, there are gender-linked product preferences driving more men to participate frequently in a study dealing with steak than in a study dealing with a sweet baked product such as cheesecake. The foods differ, with men responding relatively more frequently to protein items, and women responding relatively more frequently to fat/sweet products.

b. What aspects of the food or beverage drive craveability? In the self-profiling questionnaire the respondent was instructed to select three answers from a set of 16. Across the full set of 30 foods, and across all 4700+ respondents, the answers most frequently given were "taste,"

Take our survey and win CASH!! The more surveys you take, the more chances to win!!
Are you the kind of person who loves FOOD and DRINK? Whatever you eat or drink, here is a survey for you! Tell us what kinds of foods and beverages you CRAVE ... choose from up to 32 different kinds ... then qualify to receive one of four CASH PRIZES and join one of The Understanding & Insight Group's exclusive consumer panels.
Simply click on the link below (if your email does not support hotlinks, cut and paste the link into your browser) and choose one of the easy-to-answer surveys.
http://12.109.160.54/uics2y4/craveit2002.asp
You will only have until NOON on XXX to complete this survey, so be sure to respond as quickly as possible. Your opinions are important to us!
Depending on your connection speed, each survey should take between 15 and 20 minutes to complete.
Forward this survey to your friends and family so that we know what kinds of food and beverages they CRAVE, too! Everyone's opinion is important!
Please be assured that any information you provide will be held in the strictest confidence. You will not be contacted by any sales or other research organization as a result of your participation in theis survey.
If you have any difficulty accessing the survey, you can contact Tom Farrar at testmaster@theuandigroup.com.
Thanks in advance for your input, and have fun!
The Crave IT! Team

Weather	3
Stress level	3
Packaging	2
None of the above	2

Data from the 2002 Crave It! Study

"thirst," "aroma," and "general feel," as shown in Table 59.5.

c. How the different elements perform for a single product (e.g., chicken). The utilities constitute the heart of the database because they show the reaction of consumer respondents to the different communications. We illustrate the utilities value with data from the 2002 Crave It! database. The study dealt with chicken, comprising 241 respondents and 36 elements. Utilities for the 36 elements for chicken appear in Table 59.6,

TABLE 59.6
Utility Values for the 36 Elements for Chicken from the 2002 Crave It! Database

			Segment 1 of 3	Segment 2 of 3	Segment 3 of 3
		Total Sample	Elaborates	Imaginers	Classics
	Base Size	241	43	101	97
	Constant	47	14	56	53
E01	Classic taste … the way you remember it	−1	−1	1	−2
E02	Fresh grilled chicken	2	9	5	−5
E03	Fresh chicken … slow roasted for added flavor, hot off the rack	6	17	7	0
E04	Everything you want … all in one place … a mixture of tastes and textures	2	6	3	−1
E05	Chicken with a touch of red pepper spice to wake up your mouth	−10	7	−5	−24
E06	Marinated chicken for added flavor and a guaranteed juicy texture	2	11	6	−6
E07	Exactly the way you always imagined it	0	0	2	−3
E08	Char-grilled chicken … cooked over an open fire for a smoky grilled taste	4	16	9	−7
E09	Prepared just to your liking … add whatever your heart desires	4	7	4	1
E10	Premium quality … the best Chicken in the whole world	5	10	2	7
E11	Available at a value price	0	8	−4	1
E12	Cut into strips and served on top of, or mixed into, a bed of crisp salad greens … it's all about crunch	0	16	0	−8
E13	Coated in your favorite batter and spices, then deep fried for a crunchy good taste	7	22	1	6
E14	Cut into strips and served with onions, peppers, cheese, tomatoes, sour cream and guacamole in a soft flour tortilla	−8	32	−15	−18
E15	Baked into a buttery, crispy crust with peas, carrots, and roasted potatoes	−1	30	−17	3
E16	Covered with a delicious wine sauce	−9	11	−3	−24
E17	With great tasting french fries, a baked potato, or creamy mashed potatoes covered in gravy	7	27	2	4
E18	With your favorite beverage	0	0	1	−1
E19	So delicious, just thinking about it makes your mouth water	4	5	4	3
E20	When you think about it, you have to have it … and once you have it, you can't stop eating it	2	4	1	4
E21	You'd drive any distance … at any hour … to get it exactly the way you want it	0	6	−1	−1
E22	Relaxes and refreshes you … inside and out	1	−2	1	3
E23	Reminds you of great home cooking	3	4	3	3
E24	Eating it makes all the stress just melt away	2	−2	1	4
E25	A quick snack for when you're on the run	−1	−3	1	−3
E26	To be enjoyed while surrounded by family and friends	4	3	3	6
E27	A special treat … you will savor every bite	4	3	5	5
E28	At Popeye's	−11	2	−24	−2
E29	At McDonald's	−17	−6	−23	−16
E30	At Wendy's	−10	−1	−17	−6

(*Continued*)

		Total Sample	Segment 1 of 3 Elaborates	Segment 2 of 3 Imaginers	Segment 3 of 3 Classics
E17	With great tasting french fries, a baked potato, or creamy mashed potatoes covered in gravy	7	27	2	4
E03	Fresh chicken … slow roasted for added flavor, hot off the rack	6	17	7	0
	Top 3 Elements — Segment 1 (Elaborates)				
E14	Cut into strips and served with onions, peppers, cheese, tomatoes, sour cream and guacamole in a soft flour tortilla	−8	32	−15	−18
E15	Baked into a buttery, crispy crust with peas, carrots, and roasted potatoes	−1	30	−17	3
E17	With great tasting french fries, a baked potato, or creamy mashed potatoes covered in gravy	7	27	2	4
	Top 3 Elements - Segment 2 (Imaginers)				
E08	Char-grilled chicken … cooked over an open fire for a smoky grilled taste	4	16	9	−7
E03	Fresh chicken … slow roasted for added flavor, hot off the rack	6	17	7	0
E06	Marinated chicken for added flavor and a guaranteed juicy texture	2	11	6	−6
	Top Three Elements — Segment 3 (Classics)				
E10	Premium quality … the best Chicken in the whole world	5	10	2	7
E34	Ready-to-eat, easy to pick up	1	2	−5	7
E26	To be enjoyed while surrounded by family and friends	4	3	3	6

for total panel and for the three concept-response segments. The numbers additive constant shows the predisposition of the respondent to feel that the chicken is craveable. We see at least two simple patterns emerging:

I. The total panel shows only a few elements scoring well. Segmentation reveals more elements that do well, suggesting that in the population there are countervailing forces whose interaction diminishes the utilities of the elements. It is clear from these data and this exercise that for the total panel there are a few winners, but the real information comes from the segmentation. The big opportunities come from identifying the concept-response segments, and building products for them.

II. The additive constants show the predisposition of respondents to find chicken craveable. The Elaborates show the lowest predisposition, with the elements doing the most work. The Imaginers and Classics show much higher predispositions, with the elements doing far less work.

d. How does the same element perform when presented in the context of different foods? By embedding the same element in different studies with various products it becomes possible to determine whether the element performs differently by product. The difference in the performance of a claim, for instance, appears moderate when the claim is "simply the best < FOOD NAME > in the whole wide world."

TABLE 59.7
Utility for the Element "Simply the Best" < FOOD NAME > in the Whole Wide World

	Total	Male	Female
Cinnamon rolls	7	3	8
Ice cream	5	3	6
Hamburger	5	5	5
Tacos	5	7	4
BBQ Ribs	4	6	3
Chocolate Candy	4	5	4
Pizza	4	6	3
Olives	3	6	3
French fries	3	4	3
Cheesecake	3	7	2
Peanut butter	3	0	4
Tortilla chips	3	−4	4
Coffee	2	−1	4
Chicken	2	−1	3
Nuts	2	1	2
Pretzels	1	4	0
Cheese	1	0	1
Potato chips	0	0	0
Cola	0	3	−1
Steak	−1	2	−2

TABLE 59.8
Proportion of Respondents Saying that "Mood" is Key Fact in "Craveability" for 20 of the Foods in the Crave It! Study

	Total Panel	Crave - Mood	Proportion (%)
Chocolate	472	226	48
Ice Cream	316	115	36
Cola	237	86	36
Nuts	149	52	35
Pretzel	148	50	34
Coffee	206	69	33
Olives	147	42	29
Tacos	148	42	28
Tortilla Chips	148	41	28
Potato Chips	151	41	27
Cheesecake	172	45	26
French Fries	148	36	24
Hamburger	150	31	21
Cinnamon Roll	149	29	19
Cheese	149	28	19
Chicken	148	27	18
Peanut Butter	149	27	18
Pizza	318	55	17
Steak	168	22	13
BBQ Ribs	149	17	11

Source: Data from the 2002 Crave It! Database

For cinnamon roles this phrase generates a strong claim (utility = +7), whereas for steak this is a weak claim (utility = −1). Table 59.7 shows these results. Men, in turn, tend to be more swayed by this type of claim than women, but the pattern is somewhat ambiguous. The key here is that the same element can take on different utility values depending upon the context in which it is presented.

e. Foods and mood. Mood is often associated with food, and associated with craveability. The mega study assess the proportion of respondents who feel that a food is associated with mood. Table 59.8 shows these results. The data from the 2002 Crave It! database suggests, without surprise, that chocolate is the food item most frequently associated with mood, whereas pizza, barbecue ribs and steaks are the least associated with mood. It is data like these, cutting across products and respondents that provide the additional insight about how consumers respond to foods.

f. Trends over time. One of the objectives of the mega study was to identify the trends of food acceptance over time, by comparing both the basic level of craveability and the utility values. A sense of changes in craveability over two years comes from Table 59.9. It is clear that some foods, such as pizza, changed more in craveability than did others, such as chips (both tortilla and potato chips). Data of this type developed year after year show changes in how consumers desire food, and may portend trends in the population.

TABLE 59.9
The Additive Constant for Different Foods for 2 Years (2001 and 2002)

	2001	2002	Change
Pizza	30	45	15
French Fries	34	48	14
Pretzels	29	42	13
Hamburger	30	43	13
Tacos	34	47	13
Cheesecake	41	53	12

Chicken	40	47	7
Cheese	36	42	6
BBQ Ribs	44	49	5
Tortilla Chips	27	29	2
Potato Chips	40	36	−4

V. USING THE MEGA STUDIES DATABASE TO DRIVE NEW PRODUCT DEVELOPMENT

The mega-study databases can be viewed as both a knowledge building tool and as a practical guide to product development. Most product developers are accustomed to consumer specifications of products in the form of a product concept. Conjoint analysis in particular and the mega study in general provide a blueprint for product development, albeit a blueprint to be used with judgment. Concepts are statements about a specific concept. The output of conjoint analysis is a set of interlocking variables that can be mixed and matched at the end of the study in the same way that they are mixed and matched during the actual consumer research.

To make the best use of the study data requires the researcher to work with the results in the form of a table that can be sorted. The researcher can sort the elements from winning to losing, and select the combinations that make the greatest sense, and which, from the consumer point of view, look most promising. For example, Table 59.10 shows the chicken data, this time sorted to produce a product idea for each segment. It is important to keep in mind, however, that the mega-study does not prescribe simply one product, but rather provides the product

TABLE 59.10
Suggested Starting Concepts for Chicken from the Crave It! Database

			Seg1	Seg2	Seg3
		Total	Elaborates	Imaginers	Classics
	Additive Constant	47	14	56	53
	A product for Segment 1 (Elaborates)

60 Flavor of Frozen Foods

Edith Ponce-Alquicira
Departamento de Biotecnología, Universidad Autónoma Metropolitana

CONTENTS

I. INTRODUCTION

Flavor is one of the main attributes that, together with color and texture, influences the overall acceptability of foods. Generally, flavor is the result of a complex combination of sensations perceived by the chemical senses taste and smell. Taste is perceived by the taste buds on the tongue and other parts of the mouth, and mainly described as sweet, sour/acid, salt, bitter, astringency, metallic, hot, cooling and umami. The sense of smell detects certain odorous molecules in the air above the food that stimulate the olfactory receptors at the top of the nasal cavity. This volatile substances are detected before we eat, as well as during eating as they pass in the breath from the mouth, through the posterior nares into the nasal cavity. Therefore, compounds contributing to flavor can be divided into aroma and taste or non-volatile compounds [1].

Non-volatile precursors include lipids, peptides, amino acids, reducing sugars, vitamins and nucleotides, among others. Interaction of these compounds and/or their breakdown products generates a large number of intermediates and volatiles that contribute to flavor development during processing and storage [2]. Mechanisms by which flavor compounds are formed are important to improve flavor of the starting materials, during processing to gain optimum flavor, and during storage to maintain the flavor quality. This chapter describes the development of flavor precursors during processing, as well as off-flavors derived during freezing storage.

II. NON-VOLATILE CONSTITUENTS

Non-volatile or taste compounds are water-soluble; these can cause salty, sour or acid, bitter, sweet, umami, and hot or cool sensations. Salty taste is caused by the presence of inorganic salts as sodium or potassium chloride, together with monosodium glutamate and monosodium aspartate. Sweetness is produced by sugars (glucose, fructose, ribose) and some L-amino acids (glycine, alanine, serine, threonine, lysine cysteine, methionine, asparagine, glutamine, proline and hydroxyproline). Bitter tastes are generally caused by hypoxanthine, peptides such as anserine and carnosine, and the L-amino acids histidine, arginine, lysine, methionine, valine, leucine, isoleucine, phenylalanine, tryptophan, tyrosine, asparagine and glutamine. While sour and acid tastes are caused by organic acids (lactic acid, and acetic acid), amino acids (aspartic acid, glutamic acid, histidine and asparagine) and acidic phosphates. Hot and cool sensations or trigeminal responses do not contribute to the flavor of unprocessed foods, but addition of spices like chili and pepper usually contributes to the flavor of processed products. Finally, the umami taste has a characteristic savory quality supplied by glutamic acid, monosodium glutamate

(MSG), 5′-guanosine monophosphate (GMP), 5′-inosine monophosphate (IMP) and some other peptides recognized by their flavor-enhancing properties [1, 2].

It has been suggested that amino acids, peptides, proteins and nucleotides are most important for the taste of red meats, fish, poultry and dairy products [3]. Meat flavor compounds are present in flesh and do not require cooking for their generation; but cooking and further processing may affect their concentration. It has been reported that concentrations of reducing sugars decreased by up to 20% during heating, while concentrations of free amino acids increased according to the cooking temperature from 55 to 95°C [4]. Therefore, changes in sugars, amino acids, and nucleotides that occur during processing and storage will affect not only the taste but also the overall flavor, because many of these compounds are precursors of the aroma components [1].

III. AROMA CONSTITUENTS

Aroma compounds are largely formed during processing by several mechanisms; most raw foods have none of the aroma of their processed foods. For instance, the characteristic aroma of cooked meat is largely generated during processing, when heating gives rise to a several reactions that result in the formation of a complex mixture of chemicals. Aldehydes, ketones and sulfur compounds provide the meaty, toasted, roasted, fatty, fruity and sulfurous desirable meat aroma [2].

In the same way, major flavor compounds of sweet corn include 2-acetyl-1-pyrroline and 2-acetyl-2-thiazoline, dimethylsulphide, 1-hydroxy-2-propanone, 2-hydroxy-3-butanone, 2,3-butanediol, pyridine, pyrazine, alkylpyrazines, and 2-acetylthiazole. However, concentrations of volatiles in canned corn are many times higher than those present in frozen and fresh sweet corn [5]. Moreover, fermented foods as Manchego-type cheeses develop their characteristic flavor during ripening because of lipoliytic and proteolytic enzyme activity [6]. Furthermore, several routes intervene for the characteristic flavor formation of white bread; first enzymes that regulate the metabolism of the grain produce the flavor precursors, that later are transformed by yeast during dough fermentation. Finally, nonenzymically browning reactions that take place during baking are responsible for the roasty, malty, and caramel notes. If the dough is fermented for longer time, 3-methylbutanol and 2-phenylethanol are formed in high concentrations and responsible for the "yeasty" flavor impression [7].

Aroma profiling is also affected by handling and storage. For instance, more than 20 compounds have been reported to be responsible for the yogurt flavor (acetone, lactic and acetic acids, diacetyl, acetaldehyde, and ethanol); during storage the acetaldehyde content increases, while acetic acid and diacetyl decrease, although acetone is unaffected [8].

In the same way, pasteurized guava puree shows a noticeable increase in ethyl alcohol, n-hexanal, decanoic acid, dodecanoic acid and ethyl acetate when stored at 0 and −10°C, but when stored at −20° a slight decrease in alcohols and hydrocarbons were detected [9].

The study or aroma is a complex task, many aroma compounds have relatively high odor thresholds and make little contribution to the overall flavor; others may be present at very low concentrations but due to their very low thresholds have an enormous effect on flavor. In recent years, developments in analytical instrumentation and methodology have allowed the identification of many aroma compounds for several foods. Techniques for aroma collection include either solvent extraction, concentration by means of adsorption through a static or dynamic gas-purging headspace (DHA) [8, 10, 11, 12], selective extraction using supercritical fluid extraction method (SFE) [13], or solid-phase microextraction (SPME) [14]. Separation and identification is usually performed by gas chromatography-mass spectrometry (GC-MS) or gas chromatography-olfatometry (GC-O), using several ionization tools as electron impact (EI), fast atom bombardment (FAB), field desorption (FL), laser desorption (LD), and electrospray (ESI), among others.

IV. CHEMICAL REACTIONS RESPONSIBLE FOR FLAVOR

Interaction of non-volatile precursors and/or their breakdown products generates a large number of intermediates and volatiles that contribute to flavor. Maillard reaction, lipid oxidation, degradation of thiamine and, proteolytic and oxidative enzyme activities are the main mechanism involved in flavor generation.

A. Maillard Reaction

Maillard reaction also known as nonenzymatic-browning is one of the most important routes that provide a large number of compounds that contribute to flavor in cooked foods. This reaction involves several pathways that result in many aromatic products and high-molecular weight melanoidins; high temperature, low water activity and longer storage favor this reaction. The produced flavors can be pleasant or unpleasant, and typically described as caramelized, bready, nutty, roasted, or meaty. Coffee, roasted meats, bakery, and toasted nuts base their flavor on the Maillard reaction [15].

The initial stage involves condensation of a free amine group and a carbonyl group of a reducing sugar to form a glucosylamine. The glucosylamines from aldoses condensation undergo Amadori rearrangement to yield compounds such as 1-amino-1-deoxy-2-ketoses; while condensation of ketoses is usually followed by the Heynes rearrangement to form 2-amino-2-deoxy-aldolases [16].

The intermediate stage comprises dehydratation, fission, cyclization and Strecker degradation; giving rise to a widely spectrum of compounds that modify color, taste, odor and other properties of foods. The final stage involves condensation into high molecular weight melanoidins.

Concentrations of Amadori and Heyns compounds vary according to the reaction conditions; at pH 4–7, they can deamidate to give carbonyls as deoxyosones, which yield many secondary products. Subsequent stages of the Maillard reaction involve interaction of these secondary products with amines, amino acids, aldehydes, hydrogen sulfide and ammonia, among others. An associated reaction is the Strecker degradation that involves transamination between deoxyosones and amino acids. The amino acid is decarboxylated and deaminated to produce an aldehyde, while deosysones produce a-aminoketones or a-aminoalcohol. If the amino acid is cysteine hydrogen sulfide, ammonia and acetaldehyde are produced [17]. Besides, the amino-ketones can yield pyrazine derivatives that together with aldehydes are powerful aroma constituents [7, 15,16]. Therefore, volatile products formed by fission and aldehydes from Strecker degradation are mainly involved in the production of flavors and off-flavors. Aroma compounds come from simple sugars dehydration and fragmentation (furans, pyrones, cyclopentenes, carbonyls, acids), amino acids degradation (aldehydes, sulphur compounds) or derived from further reactions (pyrroles, pyridines, imidazoles, pyrazines, oxazoles, thiazoles) [18].

B. Lipid Oxidation

There are three classes of lipids in foods: triacilglycerols, phospholipids and cholesterol. All of them contribute to the perception and development of flavor. Phospholipids are located in membranes of cells and subcellular organelles, while triacilglycerols predominate in lipid droplets and fat depots. Proportion of saturated, monounsaturated and polyunsaturated fatty acids (PUFAs) varies within foods and process. For instance poultry meat that contains more polyunsaturated fatty acids than red meat is more susceptible to oxidative changes and fed supplements with high n-3 fatty acids appear to be responsible for variations in the aroma profile of meat [19, 20].

Free fatty acids and triglicerides are capable of being oxidized by autoxidation or by enzymes called lipoxygenases, but polyunsaturated fatty acids are especially susceptible to autoxidation. The initial step of autoxidation involves production of free radicals R° from lipids RH by their interaction with oxygen in the presence of heat, light, high-energy radiation, metal ions or metalloproteins. Particularly, the heme iron of myoglobin and haemoglobin accelerates lipid oxidation in meat and meat products, during cooking as myoglobin denatures and iron is liberated. Furthermore, disruption of lipid membrane as in mechanically separated meat facilitates lipid oxidation reactions [19].

The free radical R° reacts to form a lipid peroxy radical ROO° that can react to give a hydroxyperoxide ROOH. The second step or propagation provides further free radicals in a self-propagating-chain process that can be terminated by combination of two free radicals. The enzyme lipoxygenase is widely distributed in plants and animal foods; it is very specific about the substrate and how the substrate is oxidized leading to hydroperoxides. Lipid hydroperoxides are very unstable and break down to alkoxy free radicals, which decompose, leading to undesirable rancid flavors and odors, mainly aldehyde products, including n-alkanals, trans-2-alkenals, 4-hydroxy-trans-2-alkenals and malonaldehyde [21]. The type and source of lipids, the presence of lipoxygenase and inhibitors also affect the rate of lipid oxidation. Major volatile compounds generated from the oxidation of arachidonic and eicosapentaenoic acids by 12-lipoxygenase are 1-octen-3-ol, 2-octenal, 2-nonenal, 2-nonadienal, 1,5-octadien-3-ol, and 2,5-octadien-1-ol. However, addition of lipoxygenase inhibitors, esculetin, and butylated hydroxyanisole (BHA) reduced formation of volatiles [22]. Susceptibility to oxidation also depends on the molecular differences of isozymes present in foods. As an example, the usual corn genotype and three genotypes varying in sweetness were blanched or unblanched, and stored for up to 12 months at −20°C. All genotypes contained an isozyme of 80 kDa/pI 4.5, sweeter genotypes also contained a peroxidase of 13.8 kDa, but after 12 months of frozen storage, an additional isozyme appeared in some extracts giving rise to differences in the flavor profile [23].

Reactive oxygen species and free radicals such as superoxide anion ($°O_2-$), hydrogen peroxide (H_2O_2), hydroxyl radical (°OH), alkoxyl radical (RO°), peroxyl radical (ROO°) and singlet oxygen ($^1O_2$) are unstable and highly reactive; they can be formed in foods by prooxidative enzymes, lipid oxidation, and irradiation or derived from injured cells. These compounds react easily with lipids, polypeptides, proteins and nucleotides increasing off-flavor development during frozen storage [24].

Additionally, saturated and unsaturated aliphatic aldehydes derived from lipid oxidation may participate in the Maillard reaction to yield long chain alkyl-thiazoles and alkyl-pyridines that contribute to the fatty fried aromas [17].

V. OFF FLAVOR DEVELOPMENT DURING FREEZING STORAGE

During frozen storage and distribution, foods are exposed to a wide range of environmental conditions such as temperature variations, reduced water activity, oxygen, and light that trigger several chemical and physical changes. Deterioration in texture, flavor and color are the most serious problem causing shelf-life reduction, particularly when poor freezing practices are used or when the quality of the starting material is low [25]. Fluctuating temperatures

may cause recrystalization leading to undesirable sandy texture in dairy products, and phase changes involving melting and solidifying of fats on lipid containing foods. In addition, to temperature, other environmental factors such as oxygen, water activity and pH induce chemical and enzymic harmful changes. Deterioration of flavor involves rancidity, bitterness or undesirable fishy taste, due to the formation of low molecular weight compounds from lipid oxidation or protein denaturation. Enzymes such as lipoxygenase, if not denatured during blanching process can also influence food quality even at sub-freezing temperatures [25, 26].

A. Changes in Flavor of Frozen Foods Associated to Cell Damage

Freezing has a negative effect on the textural properties on several fruits and vegetables such as mashed potato, broccoli blueberries and strawberries. Freezing and fluctuation in temperature will produce cell damage by ice recrystalization and dehydration. This may be reflected in a more open structure of the frozen product, which permits a greater ingress of oxygen, thus increasing oxidation, vitamin loss and flavor deterioration [25, 27].

The open structure of frozen foods increases migration of fluids containing cell nutrients that can facilitate loss of micronutrients, microbial contamination, and developing of off-flavors during thawing [28]. As observed in frozen and freeze-dried blueberries that loses several flavor compounds, including the typical blueberry aroma (1,8-cineole) [29]. On the other hand, very low temperature can promote the production of off-flavors in frozen-thawed strawberries when stored at −40 and −80°C; as freezing causes disruption of cells and decreases the pH of the cytosol, thus facilitating the subsequent release of sulphide ion as H_2S, and therefore off-flavors formation [30]. Loss flavor as a result of freezing was associated to a peel injury and cell damage in navel oranges stored at various freezing conditions with large emissions of ethanol, ethyl butanoate, methyl hexanoate and ethyl octanoate [31].

B. Changes in Flavor of Frozen Foods Associated to Lipids

Lipids play a multifunctional role in flavor; they influence both the physical (mouthfeel) and chemical flavor perception, as lipids act as a carrier for lipophilic flavor molecules including off-flavors. Reduction in the fat content will result in higher flavor loss during storage due to flavor volatility. On a molecular level, triglycerides lower the vapor pressure of lipidic flavor compounds, thus increasing their thresholds [32, 33]. It has been reported that the use of fat replacers such as maltodextrine can overcome flavor perception and sensory properties in low fat ice cream [33].

Lipids also bring their inherent flavor and are precursors for flavor development by lipolysis and lipid oxidation [34]; there is a high correlation between reactions involving lipids and the development of off-flavors, during storage. Lipid oxidation is influenced by several factors, such as temperature and the presence of oxygen in the immediate vicinity of foods; but water activity also plays an important role, because at very low values lipid oxidation occurs at high rates as it is found in frozen foods [7, 26].

The presence of unsaturated fatty acids in foods is a prime reason for the development of rancidity and off-flavors during frozen storage as long as oxygen is available. The generation of free radicals during rancidity also leads to undesirable reactions such as loss of vitamins, alteration of color and deterioration of proteins and texture, which modify the whole flavor perception. Warmed-over flavor (WOF) is a flavor defect that occurs in reheated foods, and it is of special concern for precooked frozen foods. This occurs in cooked products that are stored under refrigeration or freezing conditions, where lipid oxidation initiates during storage and warm temperature of the reheating process accelerates the oxidation process with the outcome of rancid flavors, resulting in WOF [28]. Furthermore, NH_3 exposition due to refrigerant leakage is related to rancid flavors in foods with a considerable reduction in the frozen storage life; off-flavors in lamb were detected by consumers after 3 to 6 months storage at −20°C [35].

It is well known that lipid oxidation products as hexanal and TBA reactive substances (TBARS) are highly correlated to the development WOF during frozen storage. Attempts have been made to reduce lipid deterioration during frozen storage by addition of vitamins, antioxidants, or phosphate. Incorporation of a commercial oleoresin rosemary (OR)-coated salt (0.5 or 1 g/kg), sodium tripolyphosphate (STPP; 3 g/kg) or TBHQ (0.2 g/kg) in meat batters decreased hexanal production by 95% [36]. Furthermore, dietary vitamin E (DL-alpha-tocopheryl acetate) equivalent to 5x, 10x and 25x the NRC recommendations levels for the diet improved the oxidative stability and functionality of turkey breast meat, and produced the most typical and acceptable meat flavor with the fewest oxidized off-flavor notes in fresh and frozen turkey meat [37]. Besides, frozen meat from birds feed with docosahexaenoic acid (DHA) was more acceptable and stable due to a higher lipid and flavor stability during storage at −23°C for up to 82 days [38].

Although, ascorbic acid is mainly recognized as antioxidant, due to its radical and O_2 scavenging effect. At low concentrations (800 ppm) ascorbic acid may act as a prooxidant, especially in the presence of metal-catalyzed oxidation. Ascorbic acid is able to reduce Fe^{3+} to Fe^{2+}. Nevertheless, the reduced Fe^{2+} catalyzes the breakdown of hydroperoxides ROOH ($ROOH + Fe^{2+} \rightarrow RO^{\circ} + OH + Fe^{3+}$) to free radicals at a higher rate than Fe^{3+} (ROOH +

$Fe^{3+} \rightarrow ROO^{\circ} + Fe^{2+}$) [39]. However, it has been reported that phosphatidic acid and phoshatidylserine can reduce the lipid oxidation catalytic activity of nonheme iron and hemoproteins [40].

Additionally, cholesterol a monounsaturated sterol present in animal foods such as biscuits, snacks, cheese, raw and cooked meat, egg powder, etc. Cholesterol can be oxidized during storage giving rise to a more than 60 oxidation products such as 7-ketocholesterol through a free radical reaction; cholesterol oxides are toxic and may be involved in flavor deterioration during storage [41].

In order to reduce lipid oxidation and off-flavor development during storage, it is commonly the use of antioxidants such as free radical terminators or metal quelating agents. These compounds can react with peroxyl or alkoxyl radicals and terminate the chain reaction by scavenging chain-propagating radicals. BHA and butylated hydroxytoluene (BHT) are effective free radical scavengers in a wide variety of foods including meat and dairy products. Also natural antioxidants such as sesamol, quercetin, tocopherols, carotenoids, and polyphenols, among others have proved their efficiency to prevent lipid oxidation in foods [24, 42, 43, 44]. On the other hand, addition of phosphates [disodium phosphate (Pi), tetrasodium pyrophosphate (PP), sodium tripolyphosphate (TPP), sodium tetrapolyphosphate (TTPP) and sodium hexametaphosphate (HMP)] or sodium ascorbate monophosphate (SAsMP) in 0.3 and 0.5% levels reduce formation of rancid and soapy flavors in frozen vacuum packaged cooked turkey; with the additional decrease in cooking losses and the increase in moisture retention after thawing [45, 46].

Packaging also plays an important role to control off flavors, in particular modified packaging has been used to improve flavor and aroma of cooked beef, where samples stored under vacuum and N2/CO2 atmospheres were meatier, less warmed-over, less cardboardy, and less oxidized and had lower TBA, than those in air-containing packages [47].

C. Changes in Flavor of Frozen Foods Associated to Proteins

Flavor release and perception is caused by interactions of flavor components with protein molecules by physical adsorption via van der Waals interactions, and by chemical reactions via covalent or electrostatic linkages, including salt, amides, ester formation and condensation of aldehydes with NH_2 and SH groups. The specific distribution of hydrophilic and hydrophobic regions in proteins determines their shape, functionality and the binding of volatile compounds; therefore, alterations in the protein moiety can lead to distortion of the sensory profile [48]. Protein denaturation during freezing storage is due to several factors including changes in moisture, interaction with lipids or products derived from lipid oxidation, and by the activity of specific enzymes as lipoxygenases and TMA-oxidase [25].

First, formation of ice crystals induces dehydration and increases salt concentration that promotes protein aggregation. Distribution of hydrophilic and hydrophobic binding depends on the dielectric constant, pH and ionic strength of the media. Thus, high salt concentrations will disrupt the existing equilibrium leading to denaturation. It has been observed that denatured proteins irreversibly bind sulfur-contain flavors by interchanging protein sulfhydryl groups and disulfides, where disulfides containing allyl or furfuryl groups are more reactive than saturated alkyl disulfides [49].

Free fatty acids derived from lipid hydrolysis can attach themselves hydrophobically or hydrophilically to the protein creating a more hydrophobic regions resulting in a decrease of protein solubility [25]. Moreover, free radicals can abstract a hydrogen from SH-side groups forming protein-free radicals that interact with other proteins or lipids forming protein-protein or protein-lipid aggregates.

Additionally, secondary lipid oxidation products as malonaldehyde, propanal and hexanal can react covalently with side-chain groups of histidine, methionine, cysteine and lysine residues; these interactions increase the hydrophobicity of proteins and may decrease the flavor binding ability [25]. In particular, aldehydes are more stable than free radicals and can diffuse into the cellular media inducing protein modifications [25, 50]. In particular, products derived from lipid oxidation denaturate proteins as myoglobin, where the heme iron is exposed increasing its prooxidant activity [51]. However, it has also been reported that α,β-unsaturated aldehydes enhance oxidation of ferrous oxymyoglobin to ferric metmyoglobin than their saturated counterparts [50, 52].

VI. CONCLUSIONS

Flavor perception and stability is related to proteins, lipids, and carbohydrates as well as the conditions of storage. Although, freezing offers an exceptional food safety and extended storage time, many reactions such as moisture migration, lipid oxidation and protein denaturation promote off-flavor formation. Therefore, stability can be achieved with a more integrated understanding of the flavor interactions within the complexity of foods. Also, attention should be focused on the quality of raw materials and the overall product technology to reduce oxidation and flavor loss.

61 Frozen Food Texture

William L. Kerr
Department of Food Science and Technology, University of Georgia

CONTENTS

Freezing is used to preserve and maintain the quality of many foods. These include beef, chicken, pork, fish, and other muscle foods; fruits and vegetables; egg products; dairy foods; doughs and breads; and a wide variety of entrée items (Table 61.1). Relatively low temperatures, the formation of ice as a separate phase, and the freeze concentration of dissolved substances contribute to conditions that limit the growth of microorganisms and preserve quality factors such as flavor and color.

One critical quality factor influenced by freezing is food texture. Texture can be defined as those properties of food determined by the rheological and structural nature of the food and determined by the tactile senses. Many foods are thawed from the frozen state and eaten directly or cooked before consumption. In some cases, the texture of the thawed material is close to that of the fresh and unfrozen food. In other cases, the texture may be changed by the freezing process, yet result in a thawed product that is still acceptable to consumers. For a few foods, freezing results in dramatic changes that are unacceptable to consumers. Yet another class of foods is those consumed frozen, such as ice cream, sherbet, or ice pops. In these foods, the specific composition and freezing process profoundly affect the perceived texture.

TABLE 61.1
Frozen Food Sales in the United States

Type of Frozen Food	Sales ($) 2001
Baked goods	1.4 billion
Breakfast foods	1.05 billion
Fish, Shrimp, Seafood	1.18 billion
Frozen desserts, Fruit, Toppings	786 million
Ice cream, Novelties	6.4 billion
Juices, Drinks	827 million
Meat	333 million
Pizza, Snacks, Prepared foods	12.33 billion
Poultry	890 million
Vegetables	2.9 billion
All Frozen Foods	**28.1 billion**

In this review, we will cover issues regarding the effects of freezing on the texture of major food groups. We will discuss primary texture attributes of specific foods, as well as the fundamental mechanisms that reduce texture quality, and outline basic procedures before and during freezing that are used to ensure the optimal quality of frozen foods.

I. VEGETABLES

Frozen vegetables make up a significant portion of the frozen food market. Vegetables that are commonly frozen include potatoes, corn, peas, green beans, broccoli, cauliflower, brussels sprouts, and pumpkin. Freezing extends the availability of vegetables and preserves quality during transportation and storage. In some cases, it allows for more convenient processing of the food. For example, pre-cut and treated French fries can be stored frozen for extended periods, with required portions available for immediate baking or frying.

A. Texture Attributes

The textural attributes of importance to most vegetables are firmness, tenderness, and crispness. Firmness implies that there is an immediate resistance to biting. Tenderness indicates that the material can be easily separated into increasingly smaller pieces, particularly when sheared. Crispness is a complex attribute related to the sound and discontinuous breakdown of the product.[1] In vegetables, firmness is directly related to structure of the vegetable cells (Figure 61.1).[2] Turgor arises in cells that are fully hydrated, and, as a result, push the plasma membrane against the surrounding cell wall. Firmness also depends on the cell walls that surround the cells. The cell walls provide a semi-rigid scaffolding, holding the cells in a specific formation. Cell walls are composed of bundled strands of cellulose, along with lesser amounts of lipid, pectin, and proteins. A primary cell wall is formed in young plants. As plants age, one or more rigid secondary cell walls form which incorporate lignin into thick cellulose layers.[2] Adjacent cell walls, and thus cells, are held together at the middle lamella by a sticky, pectin-rich substance.

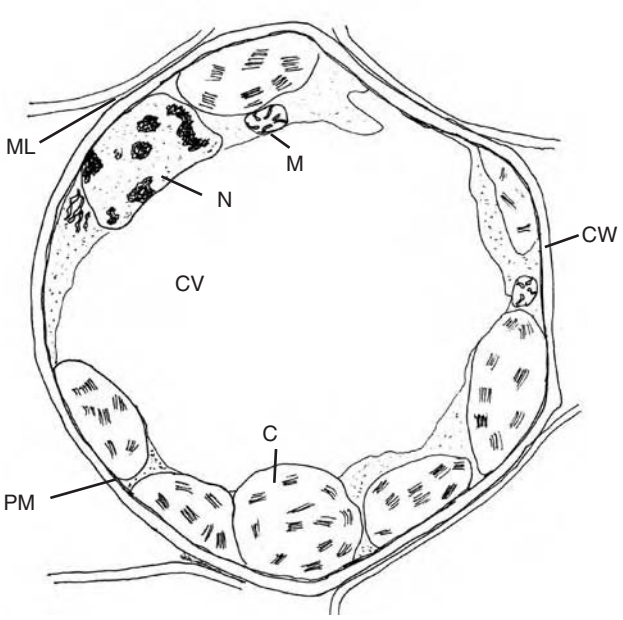

FIGURE 61.1 In the typical plant cell, the intact cell membrane (PM) is pushed back against a rigid cell wall (CW). Internal organelles such as chlorplasts (C), mitochondria (M), and the nucleus (N) are occluded by a large central vacuole (CV).

During freezing, several factors converge to cause degradation of texture related to changes in the cell membrane, cellular contents, cell wall, and middle lamella (Figure 61.2).[3] Particularly during slow freezing, ice forms primarily in extracellular spaces (Figure 61.3). This results in a water activity gradient that causes water to leave the cell. Concurrently, the cell shrinks, the ionic strength of the cytoplasm increases, and the pH changes. These changes may result in protein denaturation, disruption of the plasma membrane, and changes in intracellular organelles. In addition, ice crystals may penetrate the cell wall, and ice formation in the inner lamella may pull cell walls apart.

Several physical tests are available for assessing texture in intact vegetables. Firmness is measured by the force developed as the sample is compressed. Measurements can be made through continuous readings of force and deformation, or through a variety of penetrometers.[4] Tenderness is often measured by the shear force developed when a series of blades is run through the sample. Other specific tests, such as the pea texturometer, may be used.

B. Processing and Storage

The texture of frozen and thawed vegetables will never be better than that of the material before freezing. Vegetables

with good flavor and texture should be used for freezing, and lots should be chosen so as to assure uniform maturity.[5] After initial cleaning, many vegetables may be cut, sliced, or otherwise processed prior to freezing. Such commodities include sliced or diced carrots, French fry cut potatoes, and corn without the cob.

Most vegetables require blanching prior to freezing (Table 61.2). Blanching is the use of hot water or steam to de-activate enzymes in the vegetable.[6] Several enzymes can cause undesirable changes in frozen vegetables. For example, lipases and lipoxygenases lead to the formation of off-flavors.[7] With respect to texture, pectin-hydrolyzing enzymes would cause excessive softening of the tissue during frozen storage. Blanching has the added benefit of reducing microbial load and internal gases.

Unfortunately, the heat of blanching induces significant changes in texture.[8,9] Blanching disrupts the normal cell structure. The cell membrane may be damaged, allowing water to enter the cell. Internal organelles may be distorted and may begin to leak their contents. Heating may also denature proteins, as well as gelatinize starch found in cellular granules. This starch may subsequently retrograde during frozen storage. The major impact of blanching on texture is the reduction of cell turgidity caused by the loss of

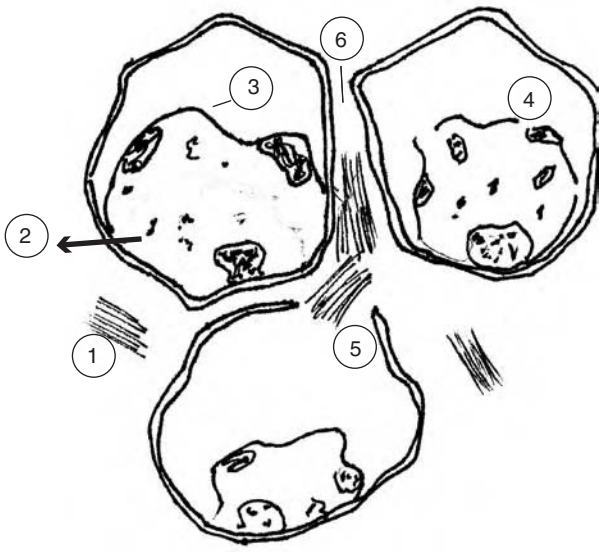

FIGURE 61.2 Formation of extracellular ice (1) causes movement of water from cells (2), resulting in shrinkage of the plasma membrane (3), concentration of internal solutes, and disruption of the membrane (4). Ice may penetrate cell walls (5) or separate adjacent cells at the middle lamella (6).

TABLE 61.2
Advantages to Blanching

1. Deactivate lipases and lipoxygenases which cause off-flavors
2. Deactivate pectinases which soften tissue
3. Reduce microbial load
4. Reduce internal gases

cell membrane function. When cells do not push up against the cell wall, the tissue becomes flaccid and less firm. In addition, during blanching, pectic substances are released from the cell wall. This decreases cohesion between adjacent cells, and enhances breakdown of the structure.

Blanching methods and times depend on the particular vegetable, and, in some cases, on the particular cultivar. In general, it is advantageous to use cultivars that require minimal blanching, thus reducing textural changes caused by heating.

There is some evidence that the particular blanching regimen affects the texture of the thawed product.[10,11] Brussels sprouts preheated to 52°C subsequently required 20% less blanching.[10] Carrots blanched at 76°C were firmer than those blanched at 100°C.[12] Similarly, green beans blanched at lower temperatures were firmer and exhibited less sloughing.[12]

There have been some studies on changes occurring after blanching. The breakdown of pectins is enhanced in high acid conditions,[13,14] and continues at neutral pH. Firmness may be enhanced by the interaction of demethylated pectins and divalent cations. In addition, added calcium may help increase firmness in some vegetables.[14,15] Low temperature blanching may increase calcium availability or pectin methylesterase activity.[16,17,18] Subsequent linking of demethylated pectin by calcium increases firmness.

For most vegetables, rapid freezing results in optimal texture. Rapid freezing allows less time for osmotic dehydration of cells and the associated freeze-concentration of solutes. The particular freezing method depends on the type of vegetable, its size, and its structural features. Air blast and cryogenic freezing methods have been used successfully with most vegetables. In limited cases, freezing in blocks may be warranted.

II. FRUITS

Many fruits are frozen to extend their availability throughout the year as well as to further shelf life through lengthy distribution. In general, fruits have a less fibrous structure than vegetables, and often suffer more textural changes during freezing and storage (Figure 61.4).[19] Thus, direct consumption of frozen/thawed fruits is not as widespread as that of vegetables. Many frozen fruits are destined for further processing, as for use in muffins, ice cream, yogurt, or jams. In addition, large whole fruits do not freeze well. Fruits such as apples, peaches, melons, or pineapples are typically cut into slices, chunks, or segments prior to freezing. Smaller fruits, such as blueberries, strawberries, blackberries, or grapes, may be frozen whole.

A. Textural Attributes

As with vegetables, firm yet tender fruit is desirable for freezing. In general, freezing does not improve fruit texture, so that fruits that are hard, mealy, too soft, or weepy should not be frozen, particularly if they will be consumed directly. Loss of water holding capacity is also a problem for many frozen fruits. Such fruits exhibit excessive drip loss on thawing, and may lack proper juiciness when chewed.

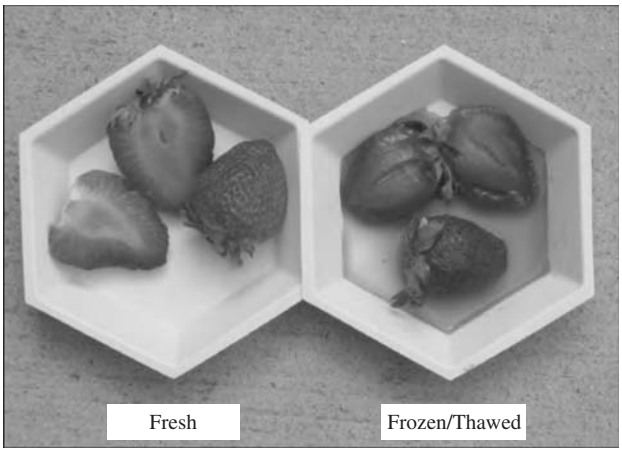

FIGURE 61.4 Fresh strawberries are firm with no juice leakage. Typical of many fruits, frozen/thawed strawberries are flaccid, have poor color, and have drip loss.

B. Processing and Storage

Obviously, the quality of raw ingredients is important to the texture of frozen/thawed fruit. In some cases, the freezing of slightly unripe fruit results in a firmer texture with lower drip loss.[20,21] For example, underripe apricots, cherries, and plums display lower drip loss after freezing and thawing.[21] Similar results have been seen in slightly unripe blackberries.[22]

The fruit variety may also be a factor in freezing performance. Differences in the texture of thawed fruit due to variety differences have been found for strawberries,[23,24] red and black currants,[25,26] and raspberries.[27] However, fruit maturity and grade are probably more important factors than cultivar differences on the texture of thawed fruit.[28,29]

Immediate freezing of fruit after harvest can also improve texture. For example, strawberries frozen within two hours of picking and stored for three months resulted in better texture than those frozen after five hours.[30] In some cases, harvested fruit may be stored for longer times at lower temperatures and in modified atmospheres prior to freezing without affecting textural quality.[20,30]

Fruits are seldom blanched before freezing. Any benefits to be had by blanching are outweighed by the significant cellular damage it causes. Fruits do not have the more extensive fibrous network of vegetables, and therefore become mushy or even disintegrate upon heating. There are some exceptions to the rule, however. For example, polyphenol oxidase can be inactivated in bananas by blanching, without causing unacceptable changes in firmness.[31]

Similarly, blanched breadfruit segments display acceptable texture when thawed and cooked.[32] Some work has also been done on non-thermal blanching of fruits. For example, gas mixtures with sulfur dioxide have been shown to inhibit enzyme activity in sliced and frozen apples.[33]

Many fruits are cut or diced prior to freezing, and have pits or stones removed. As freezing rate is of particular importance to the quality of frozen fruit, pieces with the shortest dimension greater than 2–3 cm are not typically frozen.[34,35,36] Freezing times increase somewhere between linearly with or as the square of the shortest dimension for heat transfer. In addition, much fruit is used for further processing, and fruit cut prior to freezing is often easier to cut and of better quality than fruit cut after freezing and thawing.[37,38] Removal of pits in apricots, plums, and cherries may cause greater drip loss in thawed fruit, but may be necessary for other reasons.[21,30]

Various ingredients may be added to enhance the quality of frozen fruits. Sugar is often used to improve color, texture, and flavor.[39,40] Water is drawn out of the cells by osmosis, leading to a lower freezing point and a decreased fraction of ice at a given frozen storage temperature. An extension of this is osmotic dehydration, in which high concentrations of sugar solutions are used. With this approach, fruit cells may lose up to 40 to 70% of their water. Fruits such as strawberries, apricots, cherries, and pineapples have been subjected to osmotic drying prior to freezing.[41,42] In general, such fruits are sweet, firm, and have lower drip loss.

In some cases, calcium salts may be infused into fruits to enhance firmness. These act by cross-linking the internal pectic substances. Research has indicated that pectinmelthylesterase can be infused into fruit, allowing enhanced action of the calcium.[43]

The formation of extracellular ice concentrates the solutes in the surrounding aqueous phase, which, in turn, drives water from the cells. The higher concentration of intercellular solutes, coupled with the decreased flexibility of the frozen phase, produces cell and cell membrane damage. In addition, cell wall substances, particularly pectins, may be extracted or solubilized from the cell walls, reducing structural rigidity.

Various freezing methods, including air-blast freezing, fluidized-bed freezing, and cryogenic freezing have been used successfully with fruits. Individual quick frozen (IQF) methods are preferred. Contact plate freezing of fruit in blocks is infrequently used in current practice. A significant body of work exists to show that rapid freezing results in the best retention of quality in thawed foods.[36,37,44,45] This is especially important in frozen fruits, which are subject to greater textural changes in the freezing process. Rapid freezing results in smaller ice crystal size, less cell dehydration, and less cell damage.[38,44] Comparative studies on mangoes,[46] strawberries,[47] apples and peaches,[48] and blueberries[49] have shown that rapid freezing rates result in thawed products with the best texture and least drip loss. Cryogenic freezing with liquid nitrogen often results in the best texture. However, prolonged immersion in cryogens may cause "freeze fracturing" at the surface.[50,51] Sprays of liquid nitrogen generally cause less freeze-fracture damage than immersion.[52]

III. MEAT

Many muscle foods are frozen to preserve quality, including red meats (primarily beef and pork), fish and other seafood, and poultry. Properly frozen and stored meat will maintain good texture and flavor for many months. All muscle foods are high protein foods composed of cells containing an orderly sarcomere structure, and with tissues held together by membranes and collagenous material (Figure 61.5). Each requires the proper mix of firmness and tenderness for optimum texture, as well as the retention of moisture for optimum juiciness. Unlike fruits and vegetables, virtually all meats are cooked before consumption with the goal of affecting muscle texture. This occurs as sarcomeric proteins are denatured and solubilized to form soft gel networks, and as collageneous materials melt and reduce muscle toughness.[53] Differences in muscle type, metabolic processes, and production practices exist, dictating variations in freezing practices. In this section we will discuss texture changes during freezing of red meat, with fish, seafood and poultry meats covered in subsequent sections.

A. Texture Attributes

In general, meats have a more challenging texture for consumers than vegetables and fruits. Intact meats should be relatively firm and cohesive, offering a certain amount of bite resistance; however, cooked meat should be tender enough that excessive chewing is not required. Meat toughness is largely dependent upon the properties of the connective tissue proteins.[54] For example, as an animal ages, irreversible cross-links develop in the collagen, causing the meat to become tough.

Muscle tenderness is usually measured by the amount of force required to shear through the meat. In the Warner-Bratzler shear method, cylinders of cooked meat are cut into cylinders and placed in a holder. A knife blade with a triangular opening is passed through the sample, and the maximum force attained before the sample is cut through is used as the measure of tenderness.[4] Irregular shaped pieces, or restructured products, may be tested with a multi-blade apparatus such as the Kramer shear device.

Quality meat should also be juicy and have maximum water holding capacity (WHC). Meats lacking WHC are dry, tough, and yield unsightly losses of liquids during thawing and cooking. Thaw and cook loss can be quantified by weighing before and after thawing or cooking and

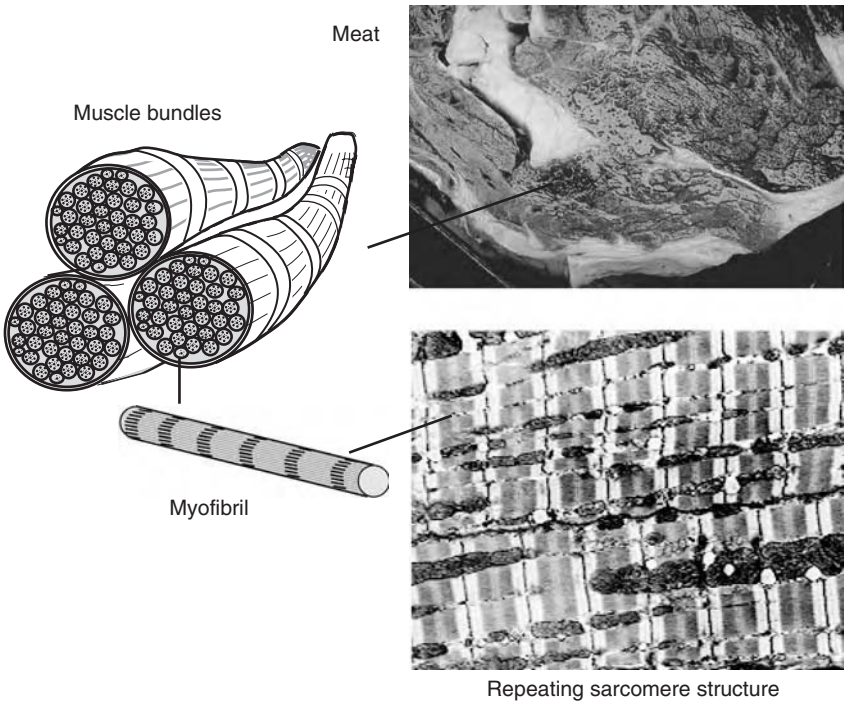

FIGURE 61.5 Muscle foods have a complex hierarchy of structure. In addition to bone and fat, meat is composed of muscle bundles surrounded by a tough connective tissue. Muscle bundles contain many long, parallel myofibrils. Each myofibril, a multinucleated cell, contains a repeating mesh of overlapping proteins, organized into sarcomeres.

calculating the drip loss by the difference in these weights. WHC can also be measured by compressing cooked samples, such as 1 cm cubes, by a given force or deformation, and weighing the amount of liquid expressed onto a filter paper.

B. Processing and Storage

The biochemical state of meat is one of the prime factors determining quality after freezing. After slaughter, most meat must undergo aging and conditioning before being frozen. Much of the meat quality is related to the pH in the muscle. As muscle ages, glycogen in the muscle is converted to lactic acid, which, in turn, reduces muscle pH. The meat is aged in a cold room, so that an ultimate pH will be attained.[55,56,57] An ultimate pH of about 5.6 is attained within a few days, which results in the best meat texture. Typically, the process is speeded up by electrical stimulation of the carcass.[58]

Animals with low glycogen levels may result in meat with higher ultimate pH, which, in turn, causes a dark, firm, and dry (DFD) meat.[59,60,61] In addition, if muscle pH remains high during cold storage, "cold shortening" of the muscle may occur.[62] Such meat is very tough and often unacceptable.[63] Shortening is particularly a problem in meat that has been removed from the bone,[63] but can be minimized with proper cooling.[64] Conversely, if muscle glycolysis occurs too quickly, a pale, soft, exudative (PSE) meat will result,[65] particularly in pork. PSE meat has high drip loss before and after freezing, resulting in colorless, dry meat that lacks juiciness.

As found with most foods, rapid freezing results in optimal texture of the thawed, cooked meat. In some cases, freezing may even increase the tenderness and juiciness of the final product.[66] Slow freezing results in larger ice crystals, greater cell dehydration, more extensive cell damage, and greater protein denaturation.[67,68,69] The movement of cell water to extracellular spaces during slow freezing results in decreased water holding capacity. Such meat is more likely to incur thaw and cook loss, and, consequently, to be less tender and juicy. Freezing times of less than 20 minutes were found to produce the least amount of exudates in frozen or thawed meat.[70] The amount of time that the product spends at temperatures near −3°C may be particularly important, as the freeze-concentration of ions at this temperature produces the greatest protein denaturation.[69]

Air-blast, cryogenic, and contact plate freezing have all been successfully used for meat freezing. Fast freezing rates attained with cryogenic freezing may be advantageous, but such methods are limited to meat pieces of modest volume that can be individually exposed to the cryogenic fluid.

Frozen meat may also incur a drying of the meat surface known as "freezer burn." Although a slight amount of surface drying is useful for limiting microbial growth, excessive drying results in a pale, dry-looking surface with

greater toughness and reduced juiciness. Freezer burn may occur during freezing, and is a particular problem during extended frozen storage. It is enhanced by low humidity and fast moving air, and meat with less surface fat tends to suffer more surface dehydration.[71] Appropriate wrapping can help limit the occurrence of freezer burn.[72,73]

Other textural changes can occur during frozen storage, and storage temperatures below −18°C are recommended to limit these changes. Ice recrystallization is a problem in that it encourages protein denaturation, and subsequent toughening and loss of water holding capacity are all possible. Higher temperatures, and, in particular, repeated temperature fluctuations, are detrimental to texture quality.

Thawing methods can also affect the final texture of the meat. Unfortunately, not many thawing alternatives exist. Rapid thawing, particularly through temperatures near −5° to 0°C, prevents further toughening and loss of WHC.[70] In some cases, thawing and holding the meat may help improve tenderness. By this logic, thawing in a cooler or refrigerator would seem not to be recommended. However, thawing at higher temperatures may result in parts of the product reaching elevated temperatures before all of it has thawed. This would subject the meat to greater microbial spoilage. Thawing by direct immersion in water can be beneficial. In a few instances, meat may be cooked directly from the frozen state, but the possibility for uneven cooking or uncooked centers limits this approach. Research on vacuum, dielectric, infrared, and microwave thawing is ongoing.

IV. FISH AND SEAFOOD

Although fish and seafood are muscle foods, they do have unique characteristics that distinguish the way they are processed for freezing. First, harvesting of particular fish has more seasonal variability, so that freezing becomes necessary to ensure availability throughout the year. In addition, fish are harvested at locations remote from where they are frozen and stored. Fish also have shorter muscle fibers and less connective tissue than land animals, and are expected to be more tender than red meat and poultry. Different metabolic processes also lead to more substantial flavor changes in frozen fish.

A. Texture Attributes

Changes in flavor are perhaps the greatest concern in frozen fish. Fish have different types of muscle fibers, and do not have the large skeletal system and great amounts of connective tissue associated with land animals. Fish meat is generally expected to be firm but tender, and remain juicy and succulent. Some changes in texture do occur in the freezing process, and are often associated with protein denaturation and drying out of the meat.

B. Processing and Storage

Fresh fish are often chilled, placed in ice, or frozen while on board ship. Ice glazes using salts, phosphates, antioxidants, or sodium alginate help prevent surface drying and lipid oxidation during transport.[74] Moisture-proof packaging is important to prevent dehydration, and vacuum-packaging is useful for limiting lipid oxidation.[75] In some on-board operations, fish are individually placed in plastic bags and vacuum-sealed, then frozen in brine freezers.[76]

Like red meats, fish and seafood should be frozen as rapidly as possible. Slow freezing results in cell dessication and damage, resulting in toughness and lack of moisture retention. Fish is especially subject to protein denaturation during freezing and frozen storage.[77,78,79] Freeze concentration of solutes enhances the denaturation of myofibrillar proteins. Some fish, particular cod and deep water fish, contain trimethylamine oxide (TMAO). TMAO breaks down to dimethylamine and formaldehyde in frozen storage, creating protein crosslinks that produce a spongy texture.[74] Such fish release moisture quickly, leaving behind a dry, tough texture.

V. POULTRY

Poultry is another excellent source of protein, and the poultry market has enjoyed substantial growth in the last few decades. Much of the chicken and turkey sold these days has been further processed. Most chicken is sold in cut pieces rather than as whole birds, and often incorporates phosphate or other marinades. Turkey may be sold as whole birds or pieces, and is usually injected with salt and phosphate solution. According to USDA regulations, poultry that is held at temperatures below 0°F must be labeled as “frozen,” while “fresh” poultry is that held at temperatures above 26°F.

A. Texture Attributes

As with other muscle foods, poultry meat is expected to be tender and juicy. Loss of juices during thawing can be a particular problem. Meat from different parts of the bird typically have different textural characteristics. Red meat has more fat, is generally less dry, and has more lubrication when chewed. White meat has more of a tendency to be dry and tough if improperly processed. Simple tests, similar to those used for red meats, are used to assess chicken texture, including Warner-Bratzler shear tests, water holding capacity tests, and analysis of yield, drip loss, and cook loss characteristics.

B. Processing and Storage

As with all products, the quality of the commodity before freezing is perhaps the most important factor in determining

final texture. The USDA provides grades (A, B, C) which may or may not be indicators of good texture in the cooked meat. The age of the bird at slaughter is one determinant of texture.[80] Young "broilers" tend to have more tender meat than older hens. Similarly, young turkey fryer-roasters have more tender meat than older hens and toms.

Rough handling during processing may result in carcass damage, but the effects on texture are not known. In general, poultry must be chilled to 4°C within 4–8 hours to meet USDA specifications. Although used primarily to limit microbial growth, rapid chilling also ensures optimum tenderness. During ice-water chilling, moisture may be absorbed, but must be limited to less than 8% for chicken and 4.3% for turkey. This water, in turn, may increase freezing times and influence final juiciness. In general, freezing immediately following slaughter is not recommended. As with other meats, poultry should be aged to allow development of the ultimate pH, which results in the most tender meat.[80,83] For chicken, the hold period is 6–8 hours, while for turkey it is 12–24 hours.[81] The aging time for poultry is much shorter than that for red meat, and some studies suggest that the pre-freeze hold time is not a major factor affecting quality after frozen storage.[82] Generally, poultry should be frozen to less than −18°C within 72 hours.[80] Although, not strictly freezing, there has been a move towards deep-chilling of poultry to −2 to −3°C, particularly for younger broilers.

A wide variety of further processing operations are performed on poultry, including deboning, chopping, forming, and breading. Poultry must be raw or fully cooked prior to freezing. Operations that slice, cut, or expose more surface area allow for greater drip loss. However, drip loss may be controlled in such products. In particular, marination combined with tumbling or injection has a profound affect on the yield, tenderness, and juiciness of poultry meat.[53] The solubilization of muscle proteins and breakdown of sarcomeric structure result in lower shear values, enhanced swelling of myofibrils, and greater water holding capacity.

Appropriate packaging is critical to maintaining quality during freezing.[83] In addition to preventing oxidation and flavor changes, moisture barriers help prevent dry meat by limiting surface dehydration and "freezer burn". In general, vacuum packaging or gas flushing is used to limit flavor changes, while also preventing overly slow freezing.

As with other muscle foods, rapid freezing provides the best product quality. Excess time spent at sub-freezing temperatures is detrimental, and leads to protein denaturation, resulting in toughening and drip loss. Rapid freezing also helps ensure a light, chalky surface.[84]

Poultry is frozen by a variety of methods, including air-blast, cryogenic, and immersion freezing. As long as the freezing rate is sufficiently rapid, there does not seem to be much effect on meat texture for different freezing processes. Some research has shown that tenderness in chicken breast is not dependent on freezing rate,[85,86] but rapid freezing may decrease the amount of drip loss.[87,88,89] Fried broiler pieces frozen with liquid nitrogen have shown greater tenderness than those frozen in air[90]. It has been recommended that the freezing front progress at rates greater than 2–5 cm per hour.[81] Combination freezing, which is initial freezing with liquid nitrogen or by immersion followed by air-blast freezing at less than −30°C, may be advantageous.

If properly stored, some poultry meat may be kept in frozen storage for up to two years without significant deterioration in quality.[91] Storage temperatures should be below −18°C for optimum quality. Some studies suggest that drip loss may increase during extended frozen storage.[92] As with other frozen foods, large temperature fluctuations are particularly detrimental. The resulting recrystallization and formation of large crystals leads to toughening and drying of the meat.

Pre-processing and freezing seem to be greater factors than thawing method on drip loss and tenderness. Thawing of whole turkeys is especially of interest. However, studies have shown that different thawing procedures have little effect on texture and moisture retention.[93,94]

VI. EGGS

Egg products are used extensively in restaurant and fast-food establishments, and as an ingredient in baked goods and entrees. Much of the eggs are prepared at an egg-breaking facility, then dried, cooked, or pasteurized and frozen. The resulting products are frozen liquid eggs or frozen cooked eggs. Eggs lack the fibrous structure of vegetables and muscle foods, so are not subject to the same deterioration of structure. Although the physical process of freezing is the same, eggs have unique characteristics that determine how they are processed and frozen. The freezing of eggs is governed by USDA regulations.

A. Texture Attributes

In products in which eggs are a minor ingredient, the texture of eggs is not a major issue. However, the functionality of egg proteins in such products is important, as it may determine foam or gel structure and emulsification properties. As a liquid product, the viscosity of thawed, uncooked eggs is characterized by its viscosity, and viscosity is usually a good indicator of the suitability of liquid eggs for further processing. The texture of eggs cooked from frozen liquid eggs should be similar to that of unfrozen eggs. In general, cooked eggs should be firm but tender as well as have adequate cohesion and little run-off. The association of egg white proteins produces a gel network. However, excessive cross-linking may produce an undesirable rubbery texture.

Eggs have clearly distinct phases, the egg yolk and egg albumen, and these have unique chemical compositions.

The albumen is approximately 89% moisture, 10% protein, 0.5% carbohydrate, 0.5% ash, and 0.03% lipid.[95] The yolk contains 48% moisture, 16% protein, 0.8% carbohydrate, 1.1% ash, and 33% lipid. In addition, the functionality of protein and lipid differs in each region. Compositional factors produce differing rheological properties for egg yolk and albumen, while functional properties also dictate the textural characteristics of products made from eggs or egg components.

B. Processing and Storage

Most pre-processing of eggs includes washing, breaking of the shell, and relatively low temperature pasteurization. In addition, yolks may be separated from the whites, then later remixed or sold as separate products. Due to compositional differences in egg yolk and albumen, the effects of freezing are different for each.

Liquid egg white has a relatively high level of solutes, including protein, glucose, and salts. Freeze concentration during freezing produces high solute concentrations and ionic strength. This, in turn, may cause denaturation of the egg white proteins.[96] The concurrent aggregation of denatured protein reduces functionality. However, egg whites are not greatly changed by the freezing process. Cakes and other baked goods made from frozen/thawed egg white have volumes similar to that made from unfrozen egg white.[97] However, gels made directly from frozen/thawed egg white are firmer than those from unfrozen egg white.[98] Viscosity and denaturation depends somewhat on the freezing rate. Rapidly frozen egg white has a viscosity, foam stability, and native protein content closest to that of unfrozen eggs.[99] Lower freezing rates result in greater denaturation, lower viscosity, and less foam stability. In some cases, adjuncts may be added to modify the rheological properties of egg albumen. The addition of 5–10% sucrose helps to prevent loss of protein functionality caused by freezing. Gels made from egg white with added sugar have higher gel strength and elasticity.[100] The addition of 5–10% NaCl, however, reduces gel strength, elasticity and viscosity.

Egg yolk undergoes greater changes in texture during freezing than does egg albumen. The yolk contains granules and lipoprotein micelles that can become unstable and aggregate. Freezing causes thickening and partial gelation of the yolk[101,102] at freezing temperatures below −6°C, with maximum gelation occurring at temperatures below −18°C. The degree of gelation increases during frozen storage. Textural changes occur as freeze concentration of salts and changing pH produces protein denaturation.[103,104,105] Gelation has also been attributed to interactions between granules and low density lipoproteins.[106]

While deterioration of egg yolk is ameliorated by rapid freezing, storage at low temperatures increases the amount of yolk gelation.[106] Gelation is also reduced by the addition of low molecular weight solutes such as sucrose, NaCl, or glycerin.[107,108]

Liquid egg products are generally frozen in cans or pouches in air-blast freezers. Cryogenic freezing with liquid nitrogen or carbon dioxide provides more rapid freezing, but is used mostly for cooked egg products. These are generally flat, thin sandwich eggs or omelets. In addition, there has been some promising research on drum freezing of liquid eggs to form flakes.[96]

VII. DAIRY PRODUCTS

Unlike fruits, vegetables, and muscle food products, most frozen dairy products are eaten while still frozen. Such products include ice cream, sherbet, and frozen yogurt. Products such as milk, cheese or butter are typically refrigerated and consumed within relatively short periods. However, in some cases, dairy products are frozen in order to extend shelf life.

A. Texture Attributes

Desirable texture attributes vary with the type of dairy product. The chemical composition of milk, cheese, yogurt, butter, and frozen desserts are narrowly defined. Processing methods are also usually standardized, so that uniform texture is expected for most dairy products. Liquid milk is typically expected to have a certain viscosity and mouthfeel, be free of aggregated material, and have some cling in the mouth. As protein and carbohydrate content are similar in most milk, the serum viscosity does not vary much. Fat content plays a more important role in viscosity. Milk with more fat has greater viscosity and mouthfeel. The degree of homogenization has some affect on viscosity; however, most homogenization schemes produce particle sizes between 0.25 to 3 μm. Milk with much larger particle sizes would tend to separate. Milk with higher average fat particle size will have higher viscosity. Changes in particle size which occur through aggregation or coalescence will have a profound effect on the fluid rheology.

Cheeses have perhaps the most textural variety. The firmness, cohesiveness, adhesiveness, and chewiness vary with the moisture and fat content, the type of milk used, and the preparation procedure. For example, cream cheese is expected to be soft, smooth, cohesive, and spreadable. Hard cheddar cheese should be firm, less cohesive, and more springy.

Ice cream may also have some textural variety. An ideal ice cream should be cold but not icy, firm but not too hard, have a smooth body and meltdown, and be free of any grittiness. Some textural differences are expected, for example, in soft-serve ice creams or frozen shakes. Some differences in texture may be attributed to price and composition. Premium ice cream has higher fat (14–18%) and

contains lower levels of stabilizers. Shorter shelf life and more stringent distribution channels may be needed to ensure product stability. Other ice creams have at least 10% fat, and may incorporate a variety of stabilizers, sugars, and dextrins. These help prevent changes in ice crystal structure during frozen storage, but may contribute to stickiness or unexpected meltdown characteristics.

B. Processing and Storage

Very little fluid milk is frozen for storage. Concentration of milk prior to freezing increases the efficiency and improves the quality of frozen milk.[109] However, significant textural changes can occur in frozen milk.[109,114] Due to freeze concentration, casein micelles tend to precipitate or coagulate, resulting in increased serum viscosity. In addition, fat separation can be significant, and fat must be redispersed after thawing. The texture of milk has been found to deteriorate in frozen storage.[110] When stored at −10°C, the texture has been found to deteriorate significantly after two months of frozen storage.

There is a greater potential for freezing of high fat cream for use in other products. Cream with more than 25% fat can be frozen with minimal separation. The addition of up to 10% sucrose increases stability. The use of drum freezing to produce flaked cream has been researched.[111] The texture of butter is little affected by freezing, although lipid oxidation may occur at storage temperatures above −20°C.[109] Cheese can also be frozen to good effect, particularly for cheese to be used on pizzas or entrees that are cooked or baked. However, frozen and thawed cheese has a tendency to be more "crumbly" than unfrozen cheese.[112]

Ice cream and dairy desserts comprise the major portion of frozen dairy products. Ice cream is a complex food in which air is incorporated in a composite of ice, unfrozen aqueous solution, and oil in water emulsion. The formulation and processing of ice cream has a profound effect on the final texture. Higher fat content produces a rich, smooth texture and body, with excellent melting properties.[113] During freezing, the protein-stabilized fat membrane can disrupt, producing coalescence with other fat particles. A modest amount of coalescence can increase smoothness and richness. Excessive coalescence is produced when there is too much shear. The resulting ice cream has a "churned" quality reminiscent of butter.

The nonfat solids present in ice cream products include milk proteins, lactose, minerals, and other components. The surface active milk proteins help stabilize the relatively small (0.5–2 μm) fat globules produced during homogenization.[114] The proteins also contribute to serum viscosity, and help stabilize the foam structure produced during initial freezing.[115]

To produce ice cream, homogenized and pasteurized ice cream mix is placed in a swept-surface heat exchanger. Air is incorporated into the product, either by whipping or direct injection of compressed air.[116] as the heat of fusion is removed by the freezer. The amount of air, or overrun, in the product, as well as the air bubble size have an important effect on ice cream texture. Up to half the volume of the frozen ice cream may be air. Increased air provides a lighter, less dense texture. Generally, smaller, more uniform air bubbles produce better texture.[116]

After approximately 50% of the water in the product is frozen, the soft-frozen ice cream is placed in packages, and then stored in hardening freezers. Once the ice cream reaches the consumer, perhaps the most important determinant of texture is temperature. At progressively lower temperatures, more and more water exists as ice, and the ice cream becomes progressively harder. As the temperature is increased towards the freezing point, the ice cream becomes softer.

Several defects in texture may occur during frozen storage. Crystallization of lactose causes a gritty texture known as "sandiness." Lactose often exists as a supersaturated solute in the unfrozen phase. Crystallization is limited by control of diffusion by high viscosity.[117] In this sense, the incorporation of whey protein and hydrocolloid stabilizers may help limit sandiness. Current stabilizers include carrageenan, locust bean gum, gelatin, guar gum, and sodium alginate.[118,119,120]

Iciness is another defect in texture that is manifest during frozen storage. Small ice crystals produce smooth body in ice cream, but, unfortunately, are inherently unstable. Larger crystals produce a texture that lacks smoothness and is overly cold (Figure 61.6). At constant temperature, "Ostwald ripening" causes migration of water from small crystals to form larger ones. Temperature fluctuations are even more detrimental to texture. As the temperature rises, ice melts. As the temperature is lowered, this water refreezes slowly to form relatively large ice crystals. Stabilizers provide some protection against recrystallization and subsequent iciness.[121,122] Presumably, stabilizers limit diffusion of water, preventing continued growth of large crystals in neighboring regions.

VIII. BAKED GOODS

A variety of doughs and baked products are made from cereal-based flours. In the United States, bread is a major staple of the diet. However, the flavor and texture of bread deteriorates quickly, and it would be advantageous to develop processing systems to extend shelf life. Freezing is one technique that has had some success in preserving the quality of dough and bread. Currently, it is more advantageous to freeze dough than to freeze bread. With the advent of in-store baking in supermarkets and fast food restaurants, the accessibility of frozen dough allows for the continuous production of fresh bread.

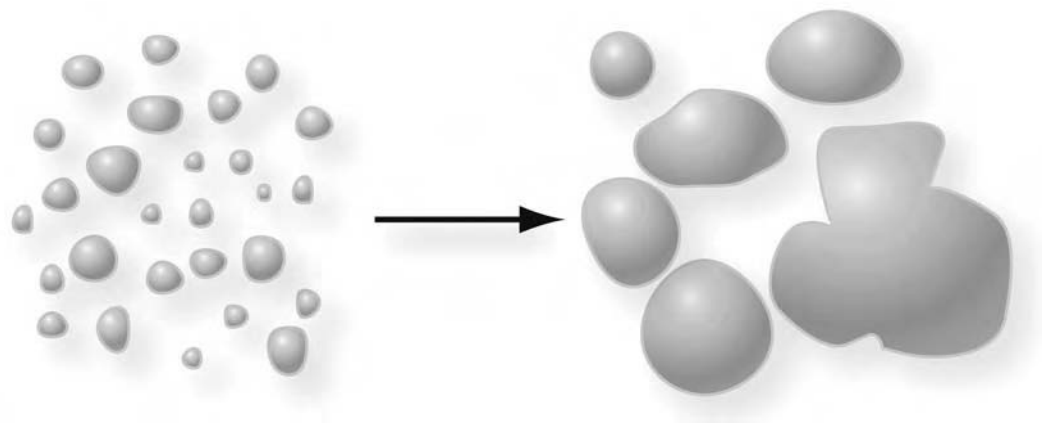

FIGURE 61.6 Over time, and particularly with temperature fluctuations, ice crystals become fewer and larger, and may fuse together.

A. Textural Attributes

Bread has a semi-solid foam structure, which incorporates different levels of air depending on the bread type. Dense, heavy breads have less air cell structure while light, fluffy breads have more air cells. Bread is expected to be relatively soft and easy to shear, but firm enough to resist the forces of spreading. Bread is particularly susceptible to changes in texture due to staling. Linked primarily to the recrystallization of starch, staling causes a firm, tough, dry texture. Firmness is normally measured by the maximum resistance developed when a cylindrical probe compresses a bread sample.

B. Processing and Storage

When freezing dough, the most important consideration is retention of yeast activity. After thawing, the dough should expand as carbon dioxide is formed from yeast fermentation. This provides the finished bread with a lighter, softer, less dense texture. Curiously, slow freezing is the least harmful to yeast activity.[123,124,125] Although slow freezing produces more yeast cell dehydration, it has been proposed that this helps protect the cells from freeze damage.[124] It has also been found that freezing should be done as soon as possible after dough formation.[126,127] Dough systems in which fermentation has commenced prior to freezing display lower yeast activity after thawing. Yeast strains with greater freeze-thaw tolerance have been developed for use with frozen dough.[128] Rapid rise yeast does not withstand freezing as well as slower rising varieties. Adding higher levels of yeast initially may help make up for loss of activity during freezing and frozen storage.[129] Loss of yeast activity increases with time in frozen storage.

Weakening of the gluten network is also a problem during freezing and frozen storage of dough. Weakened dough is less able to retain the gases produced during fermentation. One way to mitigate the effects of dough weakening is to add more protein to the initial mix. French bread made from 12.8% protein, as opposed to 11.1% protein, yielded better dough properties and texture in the finished bread.[130] Protein content may be increased by using a harder wheat or by adding vital wheat gluten. A weaker dough has also been associated with high amylase flour[131] as well as excessive dead yeast cells.[132,126] Using 3–5% less water in the dough mix can also help improve dough quality.

Non-flour ingredients also affect the dough properties. Oxidants can help strengthen the dough.[133,131] Adding higher levels of shortening can help improve the quality of frozen dough.[134] Surface active agents can also improve dough properties and, subsequently, the loaf volume of the baked bread.[135,136]

Doughs meant for freezing are usually prepared at lower temperatures to limit pre-freezing fermentation,[137] with best results achieved with mixing temperatures around 20°C.[138] A compromise freezing rate is needed to freeze the dough, slow enough to maximize yeast activity but fast enough to limit dough weakening. Freezing rates of 0.3 to 1.2°C/min have been recommended.[125] Air-blast and contact freezers have been used successfully for freezing dough.

Baked bread can also be frozen, and studies have shown that freezing can retard staling.[139,140] However, as retrogradation proceeds faster at temperatures between −3°C to 5°C, it is important to cool and freeze the bread rapidly.[141] Cryogenic freezing is an excellent means for freezing bread, but air-blast freezing can also be effective.[142] Avoiding dead spaces in the wrapping helps enhance the rate of freezing.

Moisture loss during frozen storage can result in a dry, firm texture.[143,144] The useful storage life of frozen bread is often limited by the pickup of undesirable flavors. Storage temperatures should be less than −18°C to prevent retrogradation during storage.[144] As with other frozen foods, temperature fluctuations in frozen storage are particularly detrimental to textural quality. Proper thawing of bread is also important to limit staling, firming, and loss

of moisture.[145] Breads rapidly thawed at 40–60% relative humidity display the minimal changes in texture.[146]

IX. CONCLUSIONS

Due to the chemical and structural differences in different food groups, each has unique issues associated with changes in textural quality. With the exception of bread dough, most food groups suffer the least changes in textural quality when frozen at a rapid rate. In addition, storage at low temperatures is preferential, and particular care should be taken to limit temperature fluctuations during frozen storage. Methods of thawing can also affect the texture of foods. However, the variety of thawing regimes is limited, particularly as much thawing is accomplished by consumers.

This chapter has reviewed the effects and processes of freezing major food groups. In addition to these, there are a number of further-processed entrees and heterogeneous foods that are frozen and prepared as convenience meals. Although the issues associated with these foods are too numerous to cover here, it is hoped that this chapter can also be used as a starting guide for understanding such foods.

CONTENTS

I. INTRODUCTION

In the mind of the consumer, one of the most important quality attributes of many foods is colour (1). Colour is correlated with aspects of quality and disagreement may occur between buyer and seller. It is therefore not surprising that the measurement of colour has become an area of much interest and practical importance in recent years (2).

In general, colour properties and their measurement are critical quality control parameters. The quality of food products as perceived by humans is very difficult to describe and quantify as it is usually a function of several food properties (3) including colour, which is affected by most of the technological processes involved in the manufacture of foodstuffs (4). Freezing is one such process and many problems are associated with the maintenance of the colour of frozen foods (1). However, in general, little attention has been given to the effects of freezing and frozen storage on the final colour of muscle-based food (meat, fish, shellfish and their products).

Frozen storage is an important preservation method for muscle-based foods. Freezing, in general, offers advantages in terms of a long storage life and allows better control of production levels. However, freezing and frozen storage can have marked effects on the structural and chemical properties of muscle foods, including changes in the muscle fibres, lipids and proteins, all of which have the potential for significantly influencing final quality attributes (3), especially colour (5). Quality deteriorates during freezing and frozen storage due to the osmotic removal of water, protein denaturation and mechanical damage (6).

The colour of muscle-based foods at the retail level exerts a strong influence on consumer purchasing decisions, and appearance probably is the most important factor in determining retail selection. This is particularly true in the case of meat (7). Food stores assign a relatively large display space to meat in order to attract consumers, frequently using bright lights (8). Most of the frozen muscle-based foods are sold in cool or warm fluorescent illumination (9) on a gondola, where different types of processing, e.g. glazing, and packaging are evident. However, to avoid colour damage especially in beef, the type of light used should be warm fluorescent light, which shows an excellent colour spectrum and has no adverse effect on meat pigments (10).

Some types of product, especially fish and shellfish, are not sufficiently protected from the action of light and oxygen, and may show surface discoloration during frozen storage, for which reason they are frequently packed in vacuum, in gas permeable packages or in modified atmospheres (11).

II. COLOUR MEASUREMENT

The colour of foods can be defined as the interaction of a light, an object, an observer and the surroundings of the food.

Objective colour measurements may refer to include several properties or various ratios or colour difference indices (12). By summarising all the reflected colours (wavelengths) and expressing them as one colour (13). The colour a consumer sees can generally be described in one or two words, which indicate the main colour and its shade. However, colour measurements whether descriptive or specific, must be made as carefully as other measurements (12).

The colour of foods can be studied in two main ways: chemically by analysing the pigments present or physically by measuring the interaction of light. Colour necessarily requires a light source that illuminates an object, which, in turn, modifies the light and reflects (or transmits) it to an observer. The observer senses the reflected light, and the combined factors provide the stimulus that the brain converts into our perception of colour, a property which has three quantitatively definable dimensions: hue, chroma and lightness (12).

Several methods are available for objectively measuring the colour of foods, some of which depend on the extraction of pigments from food products followed by spectrophotometric determination of pigment concentration (14, 15). However, since such pigment extraction methods are time-consuming and tedious, some researchers have sought simpler methods of colour measurement. For example, several methods measure the light reflected from the surface of foods. There are also tabulated coefficients of various objective values which are correlated with panel scores (16). These objective values consist of numerous combinations of percentage reflectance values and tristimulus values such as Hunter Lab, CIE XYZ, Munsell hue, chroma and value or CIELAB. Others researchers have measured reflectance values, which consist of indices and/or differences of reflectance at different wavelengths (17).

A. Fundamentals of the CIE 1976 Lab (CIELAB) Colour Space

Nowadays, colour can be measured by objective methods, with the CIELAB space being the most widely used method because of its degree of international (industrial and research) acceptance (18). It is often used to facilitate the quality control of coloured products, including foods, by measuring colour differences and characterising colour, so that colour quality decisions can be made**.** This colour space has been adopted throughout the world, and many official quality standards for a variety of different products use it, CIELAB replacing other colour spaces such as those of Munsell, Hunter Lab (HLab) or CIE 1931 (12).

CIELAB has the advantage of being more perceptually uniform, and is based on the accepted colour description theory that colours cannot be red and green, or yellow and blue at the same time. Colours are considered as combinations of red and yellow, red and blue, green and yellow, and green and blue. CIELAB is a reasonable descriptor of colour (2) and is also used for measuring and ordering an object's colour.

The CIELAB space is a mathematical transformation of the colorimetric system first published by the CIE (International Commission on Illumination) in 1931 (19). Although the 1931 system proved useful, its practical application was limited as it did not express differences between colours in a uniform perceptual manner. In CIELAB space, however, the numeric differences between colours agree consistently well with visual perceptions (20). CIELAB colour difference equations contain valuable information about the characteristics of human colour vision and provide quantitative metrics corresponding to psychological colour descriptors (21). Their performance in describing visual colour differences is much improved compared with the tristimulus colour space of CIE (19, 22).

CIELAB space was recommended by the CIE in 1976 for use as a colour difference metric (2). CIELAB space was specifically recommended for meat colour evaluation in 1995 (23), before which time the most used colour space was Hunter Lab (HLab), which is still mentioned in some guidelines (12).

Although the studies of this colour space were developed for flat two dimensional objects (21), the CIELAB colour space can be visualised as a three dimensional space, where every colour can be uniquely located. The location of any colour in the space is determined by its colour co-ordinates: L* (lightness), a* (the red/green co-ordinate, with +a* indicating red, and −a* indicating green.), and b* (the yellow/blue co-ordinate, with +b* indicating yellow, and −b* indicating blue). These colour co-ordinates are adimensional (20). The L*, a*, and b* co-ordinate axis define the three dimensional CIELAB colour space. Thus, if the L*, a*, and b* co-ordinates are known, then the colour is not only described, but also located in the space.

Colours in CIELAB can also be described and located using an alternative method, that of specifying their L*, C*, and h values (18). The resulting L*C*h* colour space is also three dimensional, where L* is the same parameter as in CIELAB, while the C* (chroma) and h (hue) are computed from the a* and b* co-ordinates, L*C*h* notation is preferred, since the concept of hue, and chroma agrees well with visual experience (19). Colour can also be located

using the CIEa*b* chromaticity diagram or C* and h. In both cases, L* is usually displayed separately, as a number.

One of the most important things that the CIELAB colour space describes is the colour difference, defined as the distance between the colour locations of any two colours in CIE space. This distance can be expressed as DE* or DE* where $DE^* = (DL^{*2} + Da^{*2} + Db^{*2})^{1/2}$, where DL* is the lightness difference, Da* is the red/green difference and Db* is the yellow/blue difference. It is possible to express DE* as differences in chroma and hue terminology, instead of Da* and Db*, using $DE^* = (DL^{*2} + DC^{*2} + DH^{*2})^{1/2}$, where DC* is the chroma difference, and DH* the metric hue difference (18).

Experimental knowledge of colour-difference perception is incomplete because the CIELAB colour space lacks distance uniformity. Colour difference perception does not depend only on the measured colour tristimulus values of each member of a colour difference pair but also depends on experimental conditions related to the visual environment, sample characteristics, and the way in which the samples are presented. These are called parametric effects and include the influence of such factors as illumination, illuminance, surroundings, viewing mode, sample size, sample separation, sample structure, and size of visual colour difference (18). These effects are very important for colour measurements in muscle foods, and must be considered or standardised when preparing the samples for colour evaluation (12).

B. Colour Measurement in Muscle-Based Foods

Measuring the colour of muscle-based foods involves two basic methods: human visual appreciation (sensory analysis) and instrumental analysis (absorbance and reflectance methods) (12). Objective determination of colour by means of reflectance spectrophotometry is one of the most commonly used methods due to its close correlation with the visual perception of the human eye. In contrast to absorption spectrophotometry, reflectance is measured over the surface of the object, thus making destruction of the object unnecessary and allowing the changes in colour over a period of time to be evaluated (12).

According to how light interacts with muscle-based foods, they can be classified as translucent or opaque, although such foods rarely fall into one category alone. The colour of fresh meat is known to be largely determined by the relative proportions of deoxymyoglobin (DMb), oxymyoglobin (OMb), metmyoglobin (MMb) for fresh meat, and nitrousmyoglobin (NOMb) are specific for cured meat products (24).

Guidelines for colour measurements in muscle-based foods are not complete and only for meat are they well documented. Fish and shellfish do not have specific guidelines for colour measurements, although the guidelines that do exist could be adapted to their specific characteristics. The same basic principles can be used for these types of food when colour is measured.

In the standardisation of colour measurements of fresh meat the CIELAB colour space has been recommended using D_{65} as light source and 10° as standard observer, with the illumination/viewing system as 45/0 or diffuse 8 (d/8) and specular reflectance excluded if within the capabilities of the instrument used (23). In fresh meat, the sampling should be a cross-section taken perpendicular to the long axis of the muscle, and the sample should have a minimum thickness of 1.5 cm (the sample should be opaque or an opaque backing must be used) (12). In measuring the colour of muscle-based food with low myoglobin concentrations the relationship between samples thickness and light transmittance can be checked with white and black backgrounds. The American Meat Science Association (AMSA) recommended that, in the case of frozen meats, the sample surfaces should be as flat as possible, and that a black rubber gasket slightly larger than the aperture should be used to help level uneven frozen surfaces and block stray light. The history of frozen meat (time, temperature, package, etc) when colour is being measured should also be stated, because temperature fluctuations during transportation or storage can affect the colour of muscle-based foods.

III. OPTICAL PROPERTIES OF MUSCLE-BASED FOODS

From a physical point of view, the colour of muscle-based foods, is considered as a surface phenomenon of an opaque solid, where light falling upon it may undergo processes of absorption, reflection or scattering but, where, generally, there is little transmission (12). MacDougall (25) described meat colour as partly determined by light scattering, presumably due to the gaps existing between myofibrils (26).

Light is unable to penetrate a significant distance into the meat without being scattered (27), such penetration and reflection being pH-dependent. Thus, a low pH causes greater scattering and a high pH less (28). In frozen muscle foods (meat and fish) it is generally accepted that pH decreases during storage (29, 30), although some authors found that the pH of some foods can also increase during frozen storage (31).

Swatland (32) describes the optical properties of meat as several levels of organisation. This author describes four levels; 1: sliding filaments and myofibrilar birefringence, 2: myoglobin and protein precipitation in the sarcoplasm, 3: postmortem fiber shrinkage and 4: the release of fluid and the macroscopic surface reflectance properties of cut meat. All of these phenomena can affect the colour of muscle-based foods in different ways.

Muscle proteins in frozen meat may be affected by factors such as ice crystal formation, dehydration, increased

solute concentration, fat hydrolysis and/or oxidation, the presence of atmospheric gases (particularly oxygen), protein oxidation and proteolysis and rigor temperature. During frozen storage total/myofibrillar protein solubility increases, while the solubility of sarcoplasmic proteins is reduced (33). Sarcoplasmic proteins (in which myoglobin is included) are more susceptible to low temperature and frozen storage denaturation than myofibrillar proteins. Pigment also decreased as a result of ice storage (34). Modifications in sarcoplasmic protein fractions during frozen storage occur because endogenous enzymes are released and are not inhibited.

The colour of frozen meats is governed by the freezing rate, which affects light scattering properties. Fast freezing results in small crystal sizes, which scatter more light than the large, slow growing crystals produced during slow freezing. Fast frozen meat is opaque and pale (reflectance of the small ice crystals), and slow frozen meat is traslucent and dark (35, 36). Frozen meats in any circumstances can appear darker than fresh meat due to the concentration of meat pigments during the freezing process (27).

IV. COLOUR PROPERTIES OF MUSCLE-BASED FOODS DURING FREEZING AND FROZEN STORAGE

In general, the quality of frozen muscle-based foods decreases as the storage period increases. Colour, especially, is affected although other important sensorial characteristics including odour and flavour are also affected (37).

The consumer's acceptability of frozen meat products on display are related to the colour of the product, the redder the meat the higher the degree of consumer acceptability. However, the consumer will reject fish and shellfish when they appear dark. Some authors have used objective parameters to evaluate acceptability as the % of reflectance difference between 630 and 580 nm; the a*/b* ratio, Lovibond tintometer red colour units, chroma or metmyoglobin content (%) etc. (38, 39).

Different factors affect colour and its stability in frozen muscle-based foods. Such factors include the particular freezing technique used (individually quick frozen or IQF, plates, glazing, etc.), temperature (-5 to -60°C), time and storage temperature, storage methods, freezing-thawing cycles, type of packaging and type and product characteristics (pigment concentration, polyunsaturated fatty acid concentration, etc.) (4, 33, 40, 41, 42).

During freezing, enzymes and other components are released. The ice crystals formed may injure the cell and release pro-oxidants (iron) (41). For any unprotected muscle-based food during frozen storage, surface dehydration may, in extreme cases, produce an important defect known as "freeze burn" (caused by ice sublimation) which becomes apparent after thawing and affects the appearance and functional properties of the products. This problem is very important for frozen mussels that are sold in "bulk" without any packaging. "Freezer scorch" is another defect that can appear during frozen storage. This shows as small grey and white areas, and is also caused by dehydration (27).

The freezing-thawing process is also very important for the physical and physicochemical properties of muscle-based foods. The denaturation of muscle, structural changes and lipid oxidation induced by the freeze-thaw process affect colour. Lipid oxidation is one of the major problems with frozen muscle-based foods (fish, shellfish and meats). However, the relation between lipid oxidation and pigment oxidation is not fully understood (43).

The primary catalysts of lipid oxidation in skeletal muscles are hemoprotein and iron (44). In general, iron is distributed among five main components: the insoluble fraction, ferritin, haemoglobin, myoglobin and the low molecular weight fraction (45). The two pools of iron in muscle foods, heme and non heme, are altered during frozen storage. Non heme in cod and mackerel muscle increase during frozen storage (46). Since myoglobin and haemoglobin are the pigments, responsible for colour, this property is affected by the freezing process. The iron released from ferritin may act as a lipid oxidation catalyst in muscle (47). During the freezeing-thawing cycle, the distribution of pro-oxidants and oxidation stability affect colour (41). The freezing-thawing process potentially disrupts muscle cells and leads to the deterioration of subcellular organelles, such as mitochondria. Enzymes are released from the mitochondria into the sarcoplasm, while cytochrome c (48, 49) and other heme pigments present in muscle food may also be released and contribute to colour loss. These proteins are soluble and so drip loss in muscle may also can lead to a less acceptable colour.

A. Meat and Meat Products

The frozen storage time of muscle-based foods is related to the characteristics of the product. Meat origin (pork, beef, turkey, etc), type of muscle, pigment concentration, type of pigment, fatty acid profile, antioxidant type and concentration, etc. are related to colour retention and discoloration (50, 51, 52). Also important to colour is the frozen storage time and type of freezing process used.

The effect of packaging on the colour of frozen meat is very important especially if one takes into account the relation of meat colour and oxygen or other gases such as carbon dioxide. If packaging highly permeable to gas is used, oxygen can come into contact with frozen meat and different myoglobin states (OMb, MMb) may be formed. As occurs in fresh meat, MMb is formed from OMb (53). Metmyoglobin plays a pro-oxidant role in fresh and cooked muscle foods, although, in fish, the oxidation

mechanism is still not fully understood. MMb formation increases with the freezing-thawing cycles (41).

Colour parameters (CIELAB) and reflectance ratios vary with the different states of myoglobin, while redness decreases as MMb concentration increases (54). Brownness can be observed in packed frozen stored meats (55). In the case of cured meat products, Sakata and co-workers (56) confirmed that in a model system, nitrousmyoglobin, the main pigment responsible for the colour of this type of product, is stable under frozen storage conditions.

During frozen storage MMb% values gradually increase (4, 55), changing the appearance of muscle-based foods. Farouk & Swan (33) explained this increase by the fact that metmyoglobin-reducing activity decreases during frozen storage and consequently MMB is accumulated. When meat or fish is treated with carbon monoxide during frozen storage MMb% values remain constant (4), while meat stored under carbon dioxide atmosphere is less red than meats stored in other types of packaging.

In general, the colour of salted fresh meat (57) and cured products deteriorates (sodium chloride promotes lipid oxidation), more rapidly in oxygen-permeable packaging than in vacuum packaging (58). Bhoyar and co-workers (31) reported that vacuum-packaged restructured meat products scored higher in colour and other sensorial attributes (flavour, juiciness, texture) and showed greater overall acceptability during frozen storage. Vacuum packaging also reduce the amount of MMb in meat (39).

To prevent colour deterioration, natural antioxidants (alpha-tocopherol, rosemary extract, ascorbic acid, carnosine, etc.) are frequently added to muscle-based foods (30). The use of antioxidants during frozen storage is particularly useful for low fat meat products (59). Industrially, other solutions are sometimes used to avoid this problem, one of them being to dip the product in gelatine solutions to create a coating that improves colour stability during frozen storage (58). Another method is to dip the product in a 3% brine solution before freezing at −45°C, especially in the case of Ascidians (60). In some cases, colour changes during frozen storage are related with lipid oxidation, both of which occur as the same time. This is the case of meats with a low myoglobin concentration, but when the myoglobin concentration is high (e.g. beef), discoloration occurs much earlier than lipid oxidation (50).

When meat is stored in carcass form or as primals, before being cut and packed the exposure of the meat surface to harmful environmental, effects is minimised (61, 62). When large blocks of meat are frozen, colour loss is more pronounced on the exterior than in the interior (55).

Thawed pork chops showed better colour stability after storage when vitamin E had been added to the feed (63)

From a sensorial point of view, the colour shelf life of frozen muscle-based foods depends on species and muscle type (43). The quality characteristics of ovine, for example, begin to deteriorate after 180 days of storage. Other attributes also diminish its acceptability to consumers.

A general rule governing the effect of frozen storage on the colour of muscle-based foods cannot be provided, because the effect changes according to the product in question and storage conditions. For example, the colour of the same sample can vary with the length of storage. For short and long-term frozen storage, different parameters may act as colour indicators. For example, hue may be a better indicator of colour in short-term frozen storage (33), while redness is the best indicator during long-term frozen storage.

Objective colour parameters may behave differently during frozen storage. Farouk & Price (51) reported that lightness decreased in ovine muscles. Heat & Owens, (64) described a similar behaviour for chicken meat, while rabbit and bull meat were seen to be darker after frozen storage (40). In the case of lamb chops brightness increased, and lightness increased in rainbow trout, as a result of the colour oxidation pattern of carotenoids. Decreased redness in meat and meat products is caused by a reduction in OMb and DMb concentrations (55), a phenomenon which has been observed in ground pork (51), low fat ground beef patties (45), rainbow trout and Atlantic salmon (1, 4). Less information is available, concerning yellowness although it is known to depend on the type of product, for example in low fat ground beef patties it decreased, while in rainbow trout and chicken it increased during frozen storage (4, 64, 65).

B. Fish and Fish Products

In the case of fish and shellfish, most are caught at sea and are processed immediately, mainly in frozen form, on board ship, to ensures a high degree of freshness.

Fish and fish products are very prone to discoloration. As mentioned above, lipid oxidation takes places, and changes in meat structure or pigment degradation are common. Minces produced from "white" fish have an unacceptable colour after six months of frozen storage (66), while "blue" fish products need antioxidants to prevent colour changes (30).

To prevent discoloration in tuna fish (the pigments of which are very prone to colour changes) a combined treatment is made. First the meat is frozen in a $CaCl_2$ solution at −30 to −45°C and then the $CaCl_2$ treatment is repeated. The freezing process is intensified by using liquid nitrogen during the first 2–3 h of freezing. Flesh colour changes and general spoilage can be limited by freezing and storing at −35 to −40°C, while lowering the temperature to −50 to −60°C ensures a high degree of freshness retention over several months' storage.

In some types of fish, it is important to preserve skin colour during frozen storage. This can be done by using natural or artificial antioxidants such as tocopherols, ascorbic acid (the most effective skin colour preserver) alone or

with butylated hydroxytoluene (BHT) and sodium erythorbate. These antioxidant, alone or mixed, significantly improved colour retention during the frozen storage of Thornyhead rockfish (*Sebastolobus alascanus*) (67).

Fish and shellfish both contain significant levels of polyunsaturated fatty acids. Benjakul and Bauer (41) postulated that the decrease in heme iron due to heme breakdown in fish muscle was affected by freeze-thaw cycles.

Metmyoglobin plays a pro-oxidant role in fresh and cooked muscle foods. In the case of fish muscle the oxidation mechanism is still not fully understood, although MMb formation tends to increase with the number of freezing-thawing cycles (41).

It is known that MMb reductase is a component of red blood cells and is found in fish muscles (68). Since some blood is retained in the fillets, the residual activity of this enzyme could result in the retardation of colour deterioration (41).

1. Salmonids

It is very important to maintain the colour of farmed Salmonids. This can be largely done by dietary means because colour is affected by dietary carotenoid pigment. The shelf life or frozen storage stability of these farmed fish are affected by the fatty acid (saturated and unsaturated) profiles and natural antioxidant levels present in the flesh (69). Colour studies carried out to date have mainly concerned farmed Salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*).

The effects of frozen storage are also related with the structural changes that take place during the freezing process, as was mentioned above. However, the changes which take place during frozen storage depend on carotenoid content and stability, characteristics which are mainly related with astaxanthin and canthaxanthin (from natural or synthetic sources) (70).

Salmonid colour and its stability depend on storage time and the packaging system. Sheehan and co-workers (1) reported that canthaxanthin-fed Atlantic Salmon were more sensitive to frozen storage than astaxanthin-fed fish. For the same storage time (3 months) canthaxanthin levels decreased by 59%, visual colour scores and redness values decreasing at the same time, while lightness increased. The same authors reported that no differences in visual colour score or carotenoid content were observed in astaxanthin-fed fish.

Salmonoid flesh is mainly dedicated to producing smoked specialities, while freezing affects colour. When frozen astaxanthin-fed fish is smoked, the astaxanthin content decreases, while the canthaxanthin content of canthaxanthin-fed fish remains unaffected after 3 months. Canthaxanthin-fed fish are better for smoking (if stored for less than 6 weeks) although, when frozen, they lose colour more rapidly than astaxanthin-fed fish. Nevertheless, Sheehan and co-workers, (1) reported that the astaxanthin content depends on the frozen storage time of the raw material, falling from 9.39 (fresh) to 7.99 after 6 weeks and 7.26 mg/kg after 12 weeks.

Packaging plays an important role in preventing the discoloration of Salmonoid flesh and its processed products. Different packaging materials (69) and techniques are used (vacuum packed, modified atmospheres, etc.), and it is uncommon to find Salmonid flesh in light display cabinets without any protection to avoid discolouration. When flesh (fillets) of rainbow trout is vacuum-packed, astaxanthin or canthaxanthin remains stable (maximum 5% loss) for 6 months at −20 or −80°C (52, 70). When this meat was analysed by colour objective methods, no change was observed in redness (a*), even if a thawing/refreezing cycle had taken place. In general, prolonged frozen storage increases lightness (L*), redness (a*) and yellowness (b*), but decreases the hue (h) values.

Light exposure (mainly fluorescent light) has a catalytic effect on lipid deterioration in frozen Salmonoids flesh. Oxygen-impermeable packaging materials inhibit rancidity and increases the length of time the frozen can be exposed to light.

Bjerkeng & Johnsen (69) pointed to the antioxidative effects of astaxanthin. during the frozen storage of rainbow trout fillets (70), while the concentration of dietary vitamin E are also important. The synergistic activity of alpha-tocopherol and rosemary oleoresin during refrigerated/frozen storage increased the retention of carotenoids and reduced lipid oxidation.

C. Shellfish

The frozen storage of shellfish decreases overall quality, particularly in the case of shell-on ascidians and mussels. This phenomenon is caused by the development of ice crystals in the muscle, which discolours after thawing. Choon (71) reported that, the muscle of shrimps (*Penaeus japonicus*) after 60 days of frozen storage began to blacken, while colour sensory scores fell after 7 months of storage (72). The colour of the giant Pacific oyster (*Crassostrea gigas*) becomes unacceptable during frozen storage, a problem caused by freezing temperatures rather than glazing in storage.

Shell-on cold-water shrimps (*Pandalus borealis*) packaged in atmospheric air and exposed to light, during frozen storage, lose colour. In this case the exclusion of O_2 from the pack would improve overall storage stability and extend the shelf life to at least 9 months. Light influences lipid oxidation and colour stability and its exclusion can extend the shelf life by up to 3 months. One of the main problems with shell-on shellfish are shrimp horns because they can break the packaging materials, and so it is not possible to maintain anoxic conditions (11).

Fermentation Principles

63 Fermentation

Nejib Guizani and Ann Mothershaw
Department of Food Science and Nutrition,
Sultan Qaboos University

CONTENTS

I. INTRODUCTION

In this chapter the term fermentation is used to describe the process of intended chemical change in foods catalyzed by microbial enzymes. Prescott and Dunn (1) defined fermentation, in its broad sense, as "a process in which chemical changes are brought about in organic substrates through the action of enzymes elaborated by microorganisms." Steinkraus (2) defined more specifically fermented foods as "food substrates that are invaded or overgrown by edible microorganisms whose enzymes, particularly amylases, proteases and lipases hydrolyze the polysaccharides, proteins and lipids to non-toxic products with flavours, aromas and textures pleasant and attractive to the human consumer."

A. History

Fermentation is an ancient tradition. In all parts of the world indigenous fermented foods have been prepared and consumed for many centuries. These foods have influenced the settlement sites and cultures of many communities. The first fermented foods eaten were probably fermented fruits, as scarcity of adequate food supplies would require the maximum amount of a crop to be consumed. There is evidence that fermented drinks were prepared many thousands of years ago (3,4). Compromises between starvation and disease from over-ripe/spoilt foods needed to be continually made before the advent of preservation technology. Solutions to the problems of food wastage and food-borne diseases were of major concern even before man had any concept of microbiology. Along with cooking, smoking and sun-drying fermentation is one of the oldest methods for food preservation. The methods established were obtained by trial and error and experiences obtained by many generations with information being passed between generations.

For many centuries cereals and breads have been a basic, major component of the diet of many individuals. Several loaves of bread were found in tombs estimated to be over 3,500 years old in Egypt (5). These are some of the first indications that man had begun to use the process of fermentation to develop new foods and not just to eat naturally fermented fruits, vegetables and grains (6).

B. Classification

A number of methods can be used to classify fermentation processes. They can be segregated on the basis of the microorganisms involved, the biochemical changes that occur or on the commodity type (7). In this chapter the fermentations are grouped in terms of the substrates used e.g. cereal products, fruit and vegetable products, dairy products and meat products (8). Campell-Platt (8) classified foods in 7 classes: (1) beverages; (2) cereal products; (3) dairy products; (4) fish products; (5) fruit and vegetable products; (6) legumes; and (7) meat products. Whereas, Steinkraus (9) classified fermentations according to the type of fermentation, e.g., alcoholic — wines and beers, alkaline — Nigerian dawadawa.

TABLE 63.1
Examples of Common Fermented and Microbial Foods

Food	Principal Ingredient	Key Microorganisms
Wine	Grapes	Yeasts
Beer	Barley	Yeasts
Cider	Apples	Yeasts
Sake	Rice	Moulds
Bread	Wheat	Yeasts
Yoghurt	Milk	LAB
Cheese	Milk	LAB
Buttermilk	Milk	LAB
Kefir	Milk	LAB + yeasts
Vinegar	Grapes	Yeasts followed by *Acetobacter* + *Gluconobacter*
Tempeh	Soyabeans	Moulds
Soy sauce	Soyabeans	Moulds + LAB + yeasts
Pickled cucumbers	Cucumbers	LAB + yeasts
Sauerkraut	Cabbage	LAB
Pickled olives	Olives	LAB + yeasts
Fish pastes	Fish	LAB
Fermented sausages	Meat	LAB + moulds
Microbial biomass/Products	Many including ethanol, molasses, whey, petroleum hydrocarbons	Bacteria, yeasts, moulds
Quorn	Mycoprotein	Mould *Fusarium venenatum*

LAB represents lactic acid bacteria.

C. Benefits of Fermented Foods

In many parts of the world, particularly in developing countries, fermented food products form an essential part of the human diet. Today a large variety of foods are produced either from microorganisms or as a consequence of their biochemical activity. Many of the foods listed in Table 63.1 are amongst the most common and have wide geographical distributions.

TABLE 63.2
Potential Benefits of Fermented Foods

Increased	Decreased
Safety	Toxicity
Revenue from the sale of the transformed food	Cooking time
Nutritional value	Processing costs
Digestibility	
Suitability of food commodities for subsequent processing	
Acceptability	
Sensory properties	
Ease of storage and transportation	
Shelf-life	
Health benefits	

Specific foods were developed simultaneously by many cultures using their available resources for two main reasons:

1. to preserve harvested or slaughtered products, which were abundant at certain times and scarce at others.
2. to improve the sensory properties, e.g., taste and aroma of an abundant produce.

The importance of fermentation processes for food preservation are less important now as new preservation techniques have been developed. However, fermentation is a low energy-requiring process that is relatively efficient at extending the shelf-life of foods, and it remains a very appropriate method for use in developing countries and rural communities that have no access to alternative preservation methods. The simple techniques mean that the procedures can often be carried out in the home (10). Also, a number of studies have shown that consumers regard fermented food products as healthy and natural (11). A range of potential benefits can be gained from fermented foods (Table 63.2).

II. MICROORGANISMS ASSOCIATED WITH FERMENTED FOODS

A. Starter Technology

Fermented foods may be produced with the use of starter microorganisms or by the action of natural fermentative microorganisms present in the raw materials or production environment. The activities of the fermenting organisms are dependent on the intrinsic and extrinsic growth factors. Food fermentations frequently involve a complex succession of microorganisms induced by dynamic environmental conditions. A range of properties constitutes an ideal fermentative microorganism (Table 63.3). Of paramount importance is that the organism must be safe for the consumer to ingest even when in large numbers. A variety of groups of microorganisms are frequently used in fermented foods (Table 63.4).

TABLE 63.3
Factors that Contribute to the Suitability of an Organism for Fermentation

Factors
Safe to consume in high numbers
Produces considerable amounts of the required end-product
Does not breakdown the required metabolised end-product
Not too fastidious
Genetically stable
Competitive

TABLE 63.4
Principal Groups of Fermentative Microorganisms

Microbial Group	Product
Lactic Acid Bacteria (LAB)	Lactic acid
Acetic acid bacteria	Acetic acid
Yeasts	Alcohol and carbon dioxide
Moulds	Enzymes
Micrococcus spp.	Proteases
Bacillus spp.	Amylases

Most substrates used for food fermentations are not sterile, therefore, a knowledge of the composition of the natural, heterogeneous microflora of the food substrate is required. In the past starter cultures were not used, the closest procedure was to use one batch of food to inoculate subsequent batches. However, in many traditional approaches, the advantages of some form of inoculation of new batches is recognized and generally practiced by simple techniques like back-slopping or the repeated use of the same container (12).

Problems may arise from natural fermentations as the composition and selectivity of the natural microflora determine which microorganisms dominate the fermentation and this determines the acceptability of the final product. Consequently, natural fermentations have a degree of unpredictability, which may be unsatisfactory when a process is industrialized. Starter cultures are increasingly used to provide a degree of assurance of quality fermentation and to improve the rate at which fermentation is initiated. Failed, poor quality or unsafe products lead to loss of customers and revenue and are to be avoided at all costs.

Modern biotechnology has moved a long way since ancient times when only empirical food fermentations occurred. Starter cultures are now developed mainly by design rather than by screening (13, 14). The composition of starter cultures is based on knowledge of food-grade microbial genetics (15, 16), metabolism and physiology as well as their interactions with foods (16). The overall aim is to produce reproducible, acceptable, good quality, wholesome, easily digestible, low toxicity, safe products by exploiting the properties of the starter cultures (17).

Innovations in starter technology are being made in many areas including probiotics, increased yields and quality of high revenue products and also for development of new fermentation products.

B. Yeasts

Yeasts are widely distributed in nature, with their natural habitats usually being nutritionally rich and high in carbohydrates. They are regularly associated with plant nectars and fruits (18). Consequently, in fermentations they are frequently used for beverages and foods based on fruit or vegetable substrates. Yeasts are ideal agents for fermentation of food products as they are generally acceptable to consumers and are rarely toxic or pathogenic (19). As a consequence of their value they have been extensively studied, and are well classified (20). Separate classification of yeasts and moulds is well accepted and has proved useful. The oldest and still widely used approach to grouping of yeasts is based on morphological, biochemical and physiological characteristics (21).

More recently, progress in molecular biology has enabled yeasts to be characterised at the genomic level using methods based on polymerase chain reaction (PCR) technology (22, 23). Determination of individual genes coding for 18S and 26S ribosomal RNA has resulted in many changes in the identification and classification of yeasts (24). Also rapid techniques such as API kits are being evaluated for their identification (25).

Although there are about 500 species of yeasts, (20), only a few are commonly used in the production of fermented foods. These are all either ascomycetous yeasts or members of the imperfect genus *Candida* (18). The sexual process of ascomycetous yeasts involves the production of haploid ascospores contained within an ascus (ascocarp).

Sacchaharomyces cerevisiae is the most important and frequently used and there are more than 80 different variants of this species available. All strains ferment glucose and many ferment other plant-associated carbohydrates such as sucrose, maltose and raffinose, although none ferment lactose (18). In general, yeasts do not ferment starch in nature.

Yeasts are used to produce ethanol, CO_2, flavour and aroma. The important reaction of yeasts can be represented by the following equations:

- $C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2$
- glucose $\rightarrow$ ethyl alcohol and carbon dioxide

In addition to alcohol and carbon dioxide various metabolic products including ethyl acetate, fusel alcohols (pentanol, isopentanol and isobutanol) sulphur compounds and leakage of amino acids and nucleotides can all contribute to the fermentation changes induced by yeasts (19). They contain good concentrations of amino acids such as lysine, tryptophan and threonine and are also rich in B-group vitamins.

The technology for the propagation and storage of starter yeasts has developed. Traditionally yeasts were collected from the sediments of beer making. Compressed yeasts were the most common form of starter cultures, this is a compressed mass of dormant cells that must be stored refrigerated. Other more convenient forms are now available such as instant dried yeast which is small beads of freeze dried yeasts. This is sold vacuum packed and can be stored at room temperature for up to two years. Rehydration in water between 30–40°C is required before use, or gas production may be impaired. Protected active dried yeast is the most convenient, it is similar to instant dried yeast, but can be used without any prior rehydration.

TABLE 63.5
Characteristics Common to Lactic Acid Bacteria

Characteristics
Gram positive
Catalase negative
Oxidase negative
Non-sporeforming
Fermentative anaerobes that are aerotolerant
Produce most of their cellular energy from the fermentation of sugars
Produce lactic acid from hexoses

C. Lactic Acid Bacteria

Lactic acid bacteria are a group of bacteria that predominate in many fermented foods. These bacteria are grouped together based on a set of common properties (Table 63.5) (26).

Lactic acid bacteria are subdivided based on their end products from glucose metabolism. Two distinct groups known as homofermenters and heterofermenters are identified. The homofermenters produce lactic acid as virtually the sole product of glucose fermentation. The heterofermenters produce equimolar amounts of lactate, carbon dioxide, and ethanol/acetate from hexoses. Unlike the homofermenters, the heterofermenters are responsible for the production of other compounds involved with flavour, such as acetaldehyde and diacetyl, and other characteristics. The principal genera of lactic acid bacteria are shown in Table 63.6.

Lactic acid bacteria are generally fastidious on artificial media but they grow readily in most food substrates and lower the pH rapidly to a point where other competing organisms are no longer able to grow. Leuconostocs and lactic streptococci generally lower the pH to about 4.0–4.5 and some of the lactobacilli and pediococci to about 3.5 before inhibiting their own growth (27).

In addition to producing lactic acid, the lactobacilli also have the ability to produce hydrogen peroxide through oxidation of reduced nicotinamide adenine dinucleotide

TABLE 63.6
The Predominant Genera of Lactic Acid Bacteria Used in Food Fermentations

Genus	Cell Shape/Grouping	Homofermenter	Heterofermenter
Lactobacillus	Rods — single or chains	+	+
Lactococcus	Oval cocci — pairs or chains	+	−
Leuconostoc	Oval cocci — pairs or chains	−	+
Pediococcus	Cocci — pairs and tetrads	+	−
Streptococcus	Cocci — pairs and chains	+	−
Weissella	Coccoid/short rods — single, pairs or short chains	−−	+
Enterococcus	Cocci — single, pairs or short chains	+	−

Modified from (18, 26).

(NADH) by flavin nucleotides, which react rapidly with gaseous oxygen (28). Flavoproteins such as glucose oxidase also generate hydrogen peroxide and produce an antibiotic effect against other organisms that might cause food spoilage (27). The lactobacilli themselves are relatively resistant to hydrogen peroxide (29). Accumulation of hydrogen peroxide in some fermented foods has been demonstrated, but its effects are likely to be small.

Lactococcus lactis produces the polypeptide antibiotic nisin that is active against Gram-positive organisms including *L. cremoris* which, in turn, produces an antibiotic "diplococcin" active against Gram-positive organisms including *L. lactis.* Thus, these two organisms compete in the fermentation of milk products while inhibiting growth of other Gram-positive bacteria (30). Carbon dioxide produced by heterofermentative lactobacilli also has a preservative effect in foods resulting partially from its flushing action leading to anaerobiosis if the substrate is properly protected (27).

Lactic acid bacteria perform an essential role in the preservation and production of wholesome foods. Examples of lactic acid fermentations include: a) fermented vegetables such as: sauerkraut, pickled cucumbers, radishes, carrots, olives, b) fermented milks such as: yogurt, kefir, cheeses, c) fermented/leavened breads such as sourdough breads and d) fermented sausages (Table 63.1).

In recent years there has been extensive research into the use of lactic acid bacteria to control pathogenic and spoilage microorganisms and to promote health. Consumers are taking a greater interest in the quality of foods and are creating a demand for chemical free, 'natural health' foods. Lactic acid bacteria can inhibit other microorganisms by many methods (Table 63.7) and several applications are already in common use in the food industry, whilst others are the subject of research to establish their efficacy and safety.

Bacteriocins are bactericidal peptides or proteins that are usually active against species closely related to the producing organism (18). There is interest in the use of LAB bacteriocins as food additives to inhibit food-borne pathogens and to act as preservative as they are produced by food-grade organisms and could therefore be classed as "natural" and hence more acceptable. Nisin is a Class I bacteriocin, a lantibiotic that contains the unusual amino acid lanthionine. Nisin is active against most Gram-positive bacteria including *Listeria* and spore-formers such as *Clostridium botulinum.* It is especially useful for inhibiting the outgrowth of spores from heat-resistant spoilage organisms such as *Bacillus* and *Clostridum* spp. in heat-processed foods. It does not inhibit Gram-negative bacteria, yeasts, or filamentous fungi.

TABLE 63.7
Antimicrobial Factors Used by Lactic Acid Bacteria to Inhibit Competing Organisms

Factors
Competitive exclusion
Bacteriocins (184)-nisin, natamycin, lactococcin, pediococcin
Hydrogen peroxide
Carbon dioxide
Ethanol
Diacetyl
Organic acids
Low pH, by production of lactic acid and minor amounts of acetic and formic acid
Low redox potential
Reduced levels of available nutrients (32)

Nisin is the only bacteriocin being used in the food industry (18). It offers processors a "natural" label as well as extending refrigerated shelf life by 14 to 30 days depending on the product. While most bacteriocins are produced only during exponential growth, nisin is produced in large amounts after cells reach their stationary phase, making it appropriate for foods in which lactic acid bacteria are not expected to grow after processing.

Nisin creates pores in the plasma membrane of vegetative cells allowing leakage of intracellular, cytoplasmic components and causes disruption of the transmembrane potential required to drive active transport. In Gram negative bacteria the outer membrane provides protection (18).

TABLE 63.8
Potential Health Benefits of Lactic Acid Bacteria

Benefits
From foods
Improved nutritional value e.g. production of vitamins or essential amino acids
Reduced toxicity e.g. by degradation of noxious compounds
Increased digestibility and assimilability of nutrients (31)
From colonisation
Control of intestinal infections
Improved digestion of lactose
Inhibition of tumor growth
Lowering of serum cholesterol levels
Immune stimulation (185)

Drouault and Corthier (186).

Some Gram negatives become sensitive when their outer membrane has been damaged. Bacterial spores are particularly sensitive, the most important use of nisin has been to inhibit the outgrowth of spores in heat processed foods, particularly processed cheese, canned foods, but also sometimes clotted cream, dairy desserts and pasteurized soups.

There are several potential health or nutritional benefits possible from some species of lactic acid bacteria, although at present many are controversial (31) and are the subject of research to identify specific roles (31, 32, 33). The benefits may arise from the growth and activity of the lactic acid bacteria during food fermentation or during colonisation of the gastrointestinal tract (Table 63.8).

Selection of species with the properties to perform the required functions e.g. preservation, good fermentation properties or health promotion can be made from wild-type species or by genetic manipulation where strains are engineered to produce the required activities.

D. Bacteriophage

Bacteriophage are viruses that are host specific and multiply inside bacterial cells. Although bacteriophage have no direct role in fermentation as they exist as inert particles on food and only replicate inside susceptible host cells, they cannot be ignored when discussing fermentations. Bacteriophage infection can lead to inadequate fermentation and possible safety risks. They have caused major problems in milk fermentations. Several steps can be taken to reduce the risk of phage infection. These include:

1. Using mixed culture starters (34)
2. Rotation of starter culture species with different phage susceptibility (35)
3. Following rigorous hygiene strategies.
4. Propagating starter cultures in phage inhibitory media (18)
5. Inserting a plasmid which confers phage resistance.
6. Using phage-insensitive bacterial strains.

III. FERMENTED PRODUCTS

A. Fermented Fruits and Vegetables

1. Sauerkraut

Sauerkraut is the product resulting from the natural lactic acid fermentation of shredded fresh cabbage to which salt is added at a concentration of 2.25–2.5%. Figure 63.1 shows the main steps in the manufacture of sauerkraut (36). The fermentation yields lactic acid as the major product. The salt extracts liquid from the vegetable which serves as a substrate for growth of lactic acid bacteria. Anaerobic conditions should be maintained to prevent growth of microorganisms that might spoil the sauerkraut (27). Many researches have shown a sequential involvement for different species of lactic acid bacteria (3, 37, 38, 39). It is now well established that *Leuconostoc mesenteroides* grows first producing lactic acid, acetic acid and CO_2. The pH of the product is lowered quickly, thus limiting the activity of undesirable microorganisms and enzymes that might soften the cabbage shreds. The carbon dioxide flushes out residual oxygen making the fermentation anaerobic which stimulates the growth of many lactic acid bacteria. Then *Lactobacillus brevis* grows continuing the acid production. Finally *Lactobacillus plantarum* grows producing more acid and lowering the pH to below 4.0, allowing the cabbage to be preserved for long periods of time under anaerobic conditions.

The end products formed during the fermentation of the cabbage contain significant amounts of lactic acid and a small amount of acetic acid and propionic acid, and a mixture of gases, CO_2 being the most important. Minor end products also appear. Diacetyl and acetaldehyde were reported by Hrdlicka *et al.* (40) as the primary carbonyls produced during kraut fermentation. According to Lee *et al.* (41), the major amount of the volatiles in sauerkraut is accounted for by acetal, isoamyl alcohol, n-hexanol, ethyl lactate, cis-hex-3-ene-1-ol, and allyl isothiocyanate. The predominant volatiles are cis-hex-3-ene-1-ol, and allyl isothiocyanate define the character of sauerkraut, they do not contribute significantly to its quality. Instead, they believe that the fresh, fruity aroma of compounds such as ethyl butyrate, isoamyl acetate, n-hexyl acetate and mesityl oxide probably are more important in determining the acceptability of sauerkraut (41).

Microbial spoilage of sauerkraut can induce changes in texture, color and flavour. Sauerkraut softening occurs when fermentation takes place at too high a temperature, when the cabbage is exposed to air, too little salt is added; or by faulty fermentation when the lactic acid content

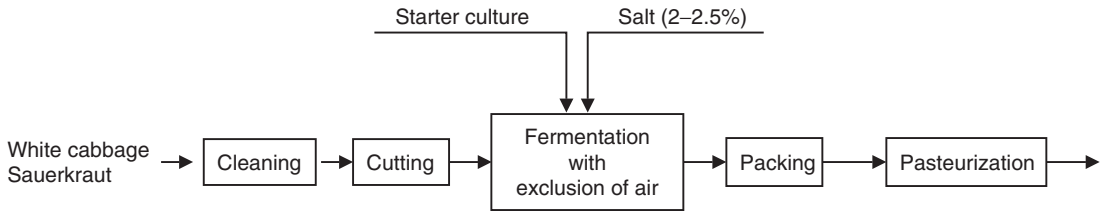

FIGURE 63.1 Flow chart for production of sauerkraut.

remains too low (36). Pink kraut is caused by the surface growth of yeasts mainly of *Torula* spp., especially *T. glutinus* (42). Rotted sauerkraut may be caused by bacteria, molds and/or yeasts.

2. Pickled Cucumbers

Pickled cucumbers are acid fermented in the presence of salt. Cucumbers for pickling are harvested while still immature. The fermentation of cucumbers varies according to the salt concentration used, and two quite different products can be produced, namely high-saltstock (8–10% increasing to 15%) and low-salt dill pickles (3–5% salt containing dill and spices) (43). Usually, the salt solution is poured onto the cucumbers in tanks and then fermentation is allowed to proceed, if necessary, glucose is added to stimulate activity. Fermentation takes place at 18–20°C and yields lactic acid, CO_2, some volatile acids, ethanol and small amounts of various aroma substances (36).

Once the cucumbers have been brined and the tank closed, there is a rapid development of microorganisms in the brine. The normal mixed flora of the cucumbers form the initiating culture. The rapidity of the fermentation is correlated with the concentration of salt in the brine and its temperature. In general, the lower the salt concentration, the more kinds of bacteria will grow at the start, the faster the acid production, and the greater the acidity produced. The lactic acid bacteria chiefly responsible for production of high-salt pickles are initially *Pediococcus cerevisae* followed by the more acid-tolerant *Lactobacillus plantarum* and *Lactobacillus brevis. Leuconostoc mesenteroides* makes little contribution in the high-salt pickles but is active in the low-salt pickles (43). The lactic acid initially formed is later metabolized partly by film yeast or oxidative yeasts that grow on the surface of the brine, thus increasing slightly the original pH value of the fermenting medium (36).

In controlled fermentations the cucumbers are washed and soaked in a chlorinated brine of 25° salinometer. The brine is acidified with acetic acid, buffered with sodium acetate or sodium hydroxide, and inoculated with *L. plantarum* alone or in association with *P. cerevisae* (42, 44). The controlled fermentation reduces economic losses and leads to a more uniform product over a shorter period of time (1).

The two main defects of pickles are bloaters and softening. Pickled cucumbers are often softened due to endogenous or microbial pectolytic enzymes (36). Softening is caused by microorganisms growing inside or on the cucumbers (18). Pectolytic organisms causing pickle softening belong to the genera *Bacillus*, *Fusarium*, *Pencillium*, *Phoma*, *Cladosporium*, *Alternaria*, *Mucor*, *Aspergillus* and others (42). Bloaters are those pickles that float on the brine and are hollow or have large air spaces in the interior. This condition is caused by gas-forming microorganisms, i.e. gaseous fermentation. *Enterobacter* spp., lactobacilli, and pediococci have been implicated as causes of bloaters (42).

3. Olives

Green olives are brined and fermented in a manner similar to cucumbers. Spanish, Greek and Sicilian are the most important types of fermented olives. Before brining, green olives are treated with a 1.25 to 2% lye solution (sodium hydroxide), depending on the type of olives usually at 21 to 25°C for 4 to 7 hours. This treatment is necessary to remove some of the oleuropein, a bitter principal in the olives. Some microorganisms may be destroyed during lye treatment. After treatment, the lye is removed by soaking and washing the olives in fresh water. Excessive washing may induce a loss in some nutrients and a low acidity development due to a high loss of carbohydrates. To overcome these problems inoculation with *Lactobacillus plantarum* may be necessary to neutralize any residual lye. Adding sugar to the brined olives for acid production has also been suggested. Washed olives are then placed in a brine solution, the concentration of which varies from 5 to 15% salt, depending upon the variety and size of olives (3). Ten to 15% is recommended for Manzanillo olives, whereas a 5 to 6.25% is recommended for Sevillano olives. Additional salt is added during fermentation of olives in order to maintain a constant salt concentration, usually at 28° to 30° Salinometer level. The microbiology of the olive lactic acid fermentation is complex with a number of microbial strains being involved. Vaughn *et al.* (45) have divided the normal olive fermentation into three stages. The initial stage is the most important from the standpoint of potential spoilage if the brines are not acidified. Acidification eliminates the original contaminating population of

dangerous Gram-negative and Gram-positive spoilage bacteria and, at the same time provides an optimum pH for activity of the lactic acid bacteria (46). The natural flora of green olives, consisting of a variety of bacteria, yeasts, and molds carries out the fermentation with the lactic acid bacteria becoming prominent during the intermediate stage. *Leuconostoc mesenteroides* and *Pediococcus cerevisiae* are the first lactics to prominate, followed by lactobacilli, mainly *Lactobacillus plantarum* and *Lactobacillus brevis* (47). The fermentation takes as long as 6 to 18 months, and the acidity of the final product varies from 0.18 to 1.27% (48). A level of at least 0.6 to 0.7% acid is needed for proper preservation and flavour of the product.

For the fermentation of black lactic-fermented olives, the ripe, violet to black fruit is washed and directly allowed to undergo spontaneous lactic fermentation in an 8–10% salt solution. No alkali treatment is performed on black olives. Lactobacilli and yeasts are involved, but the yeasts normally dominate. The final product has a pH value of 4.5–4.8 and contains 0.1–0.6% lactic acid (49).

Olives may undergo spoilage owing to the growth of undesirable microorganisms. Zapateria spoilage is characterized by a malodorous fermentation, due apparently to the production of propionic acid by *Propionibacterium* (50). Sloughing spoilage is a defect that includes severe softening, skin rupture and flesh sloughing. It is caused by Gram negative pectinolytic bacteria, especially *Cellulomonas flavigena* (51). Softening of olives is caused by the pink yeasts, *Rhodotorula*, and fermenting pectinolytic yeasts, *Saccharomyces* and *Hansenula* (52, 53).

4. Cocoa Fermentation

Cacao beans grow on the *Theobroma cacao* tree. They can be processed to make cocoa and chocolate. The popularity of cocoa is not its nutritional value but rather its unique flavour, colour and aroma. To obtain these sensory characteristics the beans must be fermented, as roasting unfermented dried cacao does not result in the desired flavour, aroma or colour (54, 55, 56). To induce fermentation the pods are opened following harvesting to reveal the seeds, called beans, covered with pulp. The beans are heaped into piles or placed into boxes on the farm. Fermentation methods vary between different countries and even between different processors (57). The fermentation is natural; therefore, the microbial species present also differ between batches and different geographical locations. Occasionally a more controlled situation is required and starter cultures are used, however, these generally do not compare favorably with the natural fermentations (57).

The pulp is predominantly water with 10–15% sugars and has a low pH, between pH 3.6–4.0 (58). The sterile pulp is inoculated with a variety of microorganisms during handling and storage which perform the fermentation. The beans are fermented for 2–12 days (42, 54). During this time the sticky pulp becomes a turbid broth from which the beans absorb flavours (57, 59). Yeasts and acetic acid bacteria are the most important fermenters of cacao beans.

Fermentation takes place in two stages; firstly the sugars in the acidic pulp are converted to alcohol, which is subsequently oxidised to acetic acid. Yeasts ferment the sugars to ethyl alcohol in the anaerobic piles. *Candida krusei*, *Saccharomyces* spp., *Geotrichium candidum*, *Hansenula anomala* and *Schizosaccharomyces pombe* are amongst the most frequently isolated species (42, 54, 60, 61). In addition the yeasts hydrolyze the pectin that covers the beans (57). Without pectin, the bitter alkaloids may leach out of the bean or be altered by alcohol that can now enter the beans (54). Although yeasts have an important role in producing alcohol, in this fermentation their presence appears even more essential to the development of the final desirable chocolate flavour (42). It has been observed that the endoenzymes released by autolysing yeasts and the levels of reducing sugars and free amino acids have some role in the development of chocolate precursor compounds (42, 62).

As the microorganisms ferment the sugars they produce heat and high temperatures, up to 45–50°C develop (54). As the temperature rises and alcohol accumulates the proportion of yeasts falls rapidly. Lactic acid bacteria such as species of *Lactobacillus*, in particular *L. plantarum*, and *Streptococcus* spp. start to grow, although their numbers and activity is thought be subordinate to that of the acetic acid bacteria (59, 61, 63). In some countries the levels of lactic acid bacteria are higher and their activity is thought to account for the acidity of cocoa from these areas (63).

The pulp is stirred and drained which increases the level of aeration (57). The presence of oxygen and the low pH favor the growth of acetic acid bacteria, including *Acetobacter* spp. (42, 62, 64). The acetic acid makes the bean tegument permeable to the yeast enzymes.

If the fermentation is prolonged microbial growth may start on the beans instead of just the pulp. Off-tastes result when *Bacillus* and filamentous fungi, including *Aspergillus*, *Penicillium*, and *Mucor*, hydrolyze lipids in the beans to produce short-chain fatty acids which cause rancid tastes (54). As the pH approaches pH 7, *Pseudomonas*, *Enterobacter*, or *Escherichia* spp. may grow and produce off-tastes and odors.

When fermentation is complete the beans are sun- or air-dried to reduce the water content to below 7.5%. As they dry moulds including *Geotrichium* grow and may oxidize lactic acid to acetic and succinic acid. The beans are then roasted at 121°C to obtain the characteristic smell and flavour of chocolate. Roasting kills most of these microbes although some species of *Bacillus* may survive (54).

Microorganisms are also used in the production of finished chocolate products. Alpha amylase from *Aspergillus* is used to hydrolyze starch for chocolate syrup and invertase from *Saccharomyces* to hydrolyze sucrose in filling mixtures to make soft-centered chocolates.

Additionally, chocolate is tested for the following specific bacteria: *Staphylococcus aureus*, coliforms, and *Salmonella.* Several outbreaks of salmonellosis have been traced to chocolate that was contaminated after roasting (62, 65).

B. Dairy Products

1. Yogurt

Yogurt is a fermented milk product produced with a yogurt starter culture consisting of *Streptococcus thermophilus* and *L. dulbrueckii* subsp *bulgariecus* in a 1:1 ratio. The symbiotic growth of the two organisms results in lactic acid production at a rate greater than that produced by either when growing alone, as well as the production of various metabolites. Carbonyl compounds have been the subject of intensive research in recent years, because of their possible role in flavour balance or in flavour defects in dairy products (66). Yogurt is prepared using either whole or skim milk, to which approximately 5% by weight of milk solids or condensed milk is usually added. The concentrated milk is heated to 82–93°C for 30–60 min and cooled to around 45°C. The yogurt starter is then added at a level of around 2% by volume and incubated at 45°C for 3–5 h, followed by cooling to 5°C (23). For optimum shelf life at refrigeration temperature the product should have a titratable acidity around 0.85–0.90%. The symbiotic association of the *streptococci* and the *lactobacilli* have been reported by many workers. *Streptococcus thermophilus* produces lactic acid, formic acid, and carbon dioxide. Formic acid stimulates the growth of the *lactobacilli*. The latter exhibit proteolytic activity and liberates some amino acids used by the *streptococci* for their growth. The streptococci tend to be inhibited at pH values of 4.2–4.4, whereas the lactobacilli can tolerate pHs in the 3.5–3.8 range. The lactic acid of yogurt is produced more from the glucose moiety of lactose than the galactose moiety (67).

Substances that contribute to flavour are particularly significant in the preparation of natural yogurt. Various researchers have shown that strains of *Streptococcus thermophilus* and *L. delbrueckii* subsp *bulgaricus* produce different amounts of carbonyl compounds, in particular acetaldehyde, when grown in skimmed cow's milk (68, 69, 70). More acetaldehyde is produced by *L. bulgaricus* when growing in association with *S. thermophilus* (71). Acetaldehyde is the compound that contributes mostly to the typical flavour of yogurt, while acetoin, diacetyl and ehanol are produced in lower concentrations (66). Yogurt flavour continuously changes during manufacture and storage. Flavor changes may vary depending on the cultures, mix formulation, and incubation and storage conditions (72, 73).

The selection of the appropriate starter culture is of great importance in yogurt manufacture. The type of yogurt starter used can change the physical characteristics of the final yogurt product, thus altering both its texture and appearance. For example, "ropy" and the "non ropy" starters are used for the manufacture of "stirred" and "set" types of yogurt respectively. Ropy cultures comprise *Streptococcus salivarius* ssp *thermophilus* and *Lactobacillus* strains capable of producing extracellular polysaccharides during fermentation (74). These starter cultures are used to enhance the viscosity of stirred yogurt.

2. Kefir

Kefir is produced by the fermentation of milk with a mixture of lactic acid bacteria, yeasts and other bacteria. The final product is acidic, slightly alcoholic, liquid to semiliquid and effervescent, and is consumed as a beverage (75, 76).

Kefir is prepared by the use of kefir grains, which contain Lactic acid bacteria and lactose-fermenting yeasts held together by layers of coagulated protein. The yeast flora of kefir varies with its source of production, but mixtures of lactose and non-lactose fermenting species, identified as *Klyveromyces marscianus*, *Candida kefir*, *C. pseudotropicalis*, *Saccharomyces. cerevisae*, *S. exiguus* and *Torulopsis holmii* have been reported (76, 77, 78). The essential bacterial component in the grain is *L. brevis* (79, 80). Kefir fermentation requires a moderate room temperature (17 to 23°C). Acid production is controlled by the bacteria, and the yeast produces alcohol. The final concentration of lactic acid and alcohol may be as high as 1%.

3. Koumiss

Koumiss is similar to kefir except that mare's milk is used, and the alcohol content may reach 2%. The primary fermenting microorganisms are *L. bulgaricus* and Torula yeasts (81). Fermentation produces mainly lactic acid, ethanol, and carbon dioxide. These products give koumiss its effervescence and sour, alcoholic flavour.

4. Acidophilus Milk

Acidophilus milk is produced by the inoculation of a strain of *Lactobacillus acidophilus* into sterile milk. The inoculum of 1–2% is added, followed by holding of the product at 37°C until a smooth curd develops. Acidophilus milk contains from 1.5 to 2.0% acid (as lactic) and no alcohol (81).

5. Cheese

Cheese is commonly made from cow, ewe, goat, or buffalo milk. Less commonly used is milk from mare, reindeer, camel, and yak. The majority of cheeses are made from heat-treated or pasteurized milk. Research groups in many countries have extensively investigated the subject of cheese making, and in-depth information has been

reported, for example, by Kosikowski (82), Scott (83), and Fox *et al*. (84).

Cheese making is initiated by a process of destabilization of casein micelles followed by the formation of a protein network and sequential expression of whey caused by a spontaneous process termed syneresis, which is often complemented by application of external pressure. All modern cheeses, with the exception of whey cheeses, are made using variations of the same basic process: acidification; coagulation into curds and whey; curd drainage/syneresis; shaping of the coagulum; and salting. In case of ripened cheeses, the curd is allowed to ripen under conditions appropriate to the cheese in question. Slight variations of these and the use of different milks combine to generate the huge range of cheeses available today. There are over 400 varieties of cheeses representing fewer than 20 distinct types, and these are grouped or classified according to texture or moisture content, whether ripened or unripened, and if ripened, whether by bacteria or molds (85). Table 63.9 shows the classification of cheeses based on moisture content, with subdivision depending on the milk type and the role of microorganisms in cheese ripening.

In general, the process of manufacture starts with the preparation of milk. Although it is not compulsory, a heat treatment equivalent to pasteurization is usually applied at the start of the processing. The milk is then cooled to the fermentation temperature, which depends on the type of cheese to be manufactured, 29–31°C for Cheddar, Stilton, Gouda, Camembert and Leicester; higher temperatures are employed in the manufacture of high scalded cheeses such as Emmental, Gruyere and Italian cheeses. Milk is inoculated with an appropriate lactic starter. The starter culture produces lactic acid, which, with added rennin, gives rise to curd formation. The starter organisms most used for cheese production are mesophilic starters, strains of *Lactococcus lactis* and its subspecies. Thermophilic starters such as *Lactobacillus helveticus*, *Lb*. Casei, *Lb. Lactis*, *Lb. Delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus* are used in the production of cheeses where a higher incubation temperature is employed. Propionic bacteria, molds, such as *Penicillium camemberti, P. candidum*, *P. roqueforti*; red- or yellow-smearing cultures, such as *Bacterium linens* are also added, depending on the type of cheese to be manufactured. The time of renneting and the amount added differ with cheese type. Rennet is a preparation from the fourth stomach or abomasom of suckling calves, lambs or goats. Recently, due to world shortage of calf rennet, recombinant or genetically engineered pure chymosin derived from different microorganisms is available on the market, and is currently used by many cheesemakers in different countries. Microbial rennets are produced from fungi such as *Mucor miehei*, *Mucor pusillus*, and *Endothia parasitica*. Genes from chymosin have been cloned into a number of organisms such as the bacterium *E. coli* and yeasts to produce nature-identical chymosin.

TABLE 63.9
Cheese Varieties and Their Classification

Moisture Content	
50–80%	SOFT CHEESES
	Unripened
	Cottage, Quark, Cream, Neufchatel
	Ripened by surface molds, mainly
	Camembert, Brie
	Salt-cured or pickled
	Feta, Domiati
45–50%	SEMI SOFT/SEMI HARD CHEESES
	Ripened principally by internal mould growth
	Roquefort, Stilton, Gorgonzola, Danish blue
	Ripened by bacteria and surface microorganisms
	Limburger, Brick, Trappist, Port du Salut
	Ripened primarily by bacteria
	Bel Paesa, Pasta Filata, Provolone, Brick, Gouda, Edam
<39%	HARD CHEESES
	Without eyes, ripened by bacteria
	Cheddar, Caciocavallo, parmesan, Romano
	With eyes, ripened by bacteria
	Emmental, Gruyère
<34%	VERY HARD CHEESES
	Asiago old, Parmesan, Romano, Grana

After coagulation of the milk, the curd is cut into small cubes for whey expulsion. The curd is further shrunk by heating it and then pressed to expel more whey, followed by salting. Finally the cheese is ripened under conditions appropriate to the cheese in question.

Cheese ripening involves a complex series of chemical and biochemical reactions. Proteolysis and lipolysis are two primary processes in cheese ripening with a variety of chemical, physical, and microbiological changes occurring under controlled environmental conditions (86, 87). Several workers have indicated the importance of free fatty acid levels on the flavours of different types of cheeses (88, 89, 90). Free fatty acids form during ripening and are precursors for methyl ketones, alkanes, lactones, and aliphatic and aromatic esters, all of which are characteristic aroma components in cheese (91). Moreover, short chain fatty acids contribute directly to aroma in many aged cheeses (92, 93, 94). During ripening, a part of the casein is converted by proteolysis into water-soluble nitrogenous compounds, such as peptides and amino acids, which contribute to the flavour and texture (86). Specifically, flavour development has been associated with an increase in total amino acids (95, 96). Particular amino acids, glutamine, methionine, and leucine have been found to influence cheese flavour (96, 97).

According to Fox *et al.* (98) probably five agents are involved in the ripening of cheese: (1) rennet or rennet

substitute (i.e. chymosin, pepsin or microbial proteinases); (2) indigenous milk enzymes, which are particularly important in raw milk cheeses; (3) starter bacteria and their enzymes, which are released after the cells have died and lysed; (4) enzymes from secondary starters (e.g. Propionic acid bacteria, *Brevibacterium linens*, yeasts and molds, such as *Penicillium roqueforti* and *P. candidum*) are of major importance in some varieties; (5) non-starter bacteria, i.e. organisms that either survive pasteurization of the cheese milk or gain access to the pasteurized milk or curd during manufacture; after death these cells lyse and release enzymes.

Although most ripened cheeses are the products of metabolic activities of the lactic acid bacteria, several known cheeses owe their particular character to other related organisms. In the case of Swiss cheese, *Propionibacterium shermanii* is added to the lactic bacteria organisms *Lb. bulgaricus* and *S. thermophilus*. Propionibacteria contribute to the typical flavour and texture of Swiss-type cheese (99). The lipolytic and proteolytic activities of molds play an important role in the maturation of some cheeses. In blue cheese such as Roquefort and Stilton *Penicillium roqueforti* grows throughout the cheese and impart the blue-veined appearance characteristic of this type of cheese. *P. camemberti* is associated with surface-ripened soft cheeses such as Camembert and Brie.

C. Fermented Soybean Products

The use of various bacteria, yeasts, and fungi to make fermented foods from soybeans or a mixture from soybeans and cereals, such as rice or wheat, has been known in the orient for centuries. A variety of fermented soybean foods, including tempeh, sufu, miso, shoyu are produced in the Orient. It is worth noting that fungi are the organisms most frequently used to process soybeans.

1. Soy Sauce

Soy sauce is a dark brown liquid food condiment that is used to add flavour and color to the normally bland Oriental diet including rice, raw fish, beancurd, fermented beans, and boiled vegetables. Figure 63.2 illustrates the different steps for soy sauce manufacture. Soy sauce fermentation is a two stage process; the first is aerobic and the second anaerobic. The first stage, the koji, consists in growing *Aspergillus oryzae* or *A. soyae* on either soybeans or a mixture of soybeans and wheat. The mixture is allowed to stand for 3 days. The mold grows and produces enzymes mainly amylases and proteases that break down, respectively, the carbohydrates and the proteins present in the substrate. This results in the production of large amounts of fermentable sugars, peptides, and amino acids. The second stage, the moromi, consists of adding the fungal-covered material to a 17–19% sodium chloride solution and incubating it for at least 1 year at ambient temperature to give the product a good quality. The high salt concentration ensures the development of flavour enhancing yeasts (100). During the first stage of the fermentation, salt-tolerant homofermentative lactic acid bacteria principally *Pediococcus cerevisae* and *Lactobacillus delbrueckii*, lower the pH to 4.9 (101). One of the most important characteristics of the lactic acid bacteria *P. cerevisae* is the ability to form aroma and flavours essential for soy sauce. In the later stages, salt tolerant yeasts primarily *Saccharomyces rouxii* ferment parts of the sugar to produce ethanol and various aroma compounds (102). Other yeasts such as *Hansenula* and *Torulopsis* may also be involved. Yeasts are also responsible for the production of furfual, an important flavour compound (103). In the final stage of the fermentation, the pH is lowered to about 4.5-4.8. At this stage the fermented mash is filtered and the liquid obtained is soy sauce. The liquid soy sauce is pasteurized at 70–80°C to help remove heat-coagulable material as well as preserve the product.

2. Tempeh

Tempeh is a protein-rich meat substitute produced in Indonesia and Africa by overgrowing soaked, dehulled, partially cooked beans with *Rhizopus oligosporus* or related species such as *R. oryzae* or *R. arrhizus* (27). The general principle of tempeh manufacture starts with the cleaning and overnight soaking of beans for hydratation and to remove the hulls. During this initial soaking acid fermentation lowers the pH to 5.0 or below, which is inhibitory to many organisms but not to the mold. Dehulled beans are cooked in boiling water and spread on a bamboo tray to cool and surface dry. Surface drying inhibits growth of bacteria that might spoil the product (7). They are then inoculated with tempeh from a previous fermentation and wrapped in banana leaves or perforated plastic. The wrapped packages are kept at room temperature for 1 to 2 days during which mold growth occurs and knit the cotyledons into a compact cake — the tempeh. During the fermentation, proteins are partially hydrolyzed, the lipids are hydrolyzed to their constituent fatty acids, stachyose is reduced (decreasing flatulence in the consumer), riboflavin nearly doubles, niacin increases sevenfold and vitamin B-12 is synthesized (7, 27, 104).

D. Fermented Grain/Cereals

1. Beer

Beer is a product of fermentation of barley malt and other grain starch by yeasts. Beer making involves several steps. The first step is to make malt (105). Barley is first allowed to germinate by soaking in water for 5 to 7 days. During this time germinated grains produce amylases and

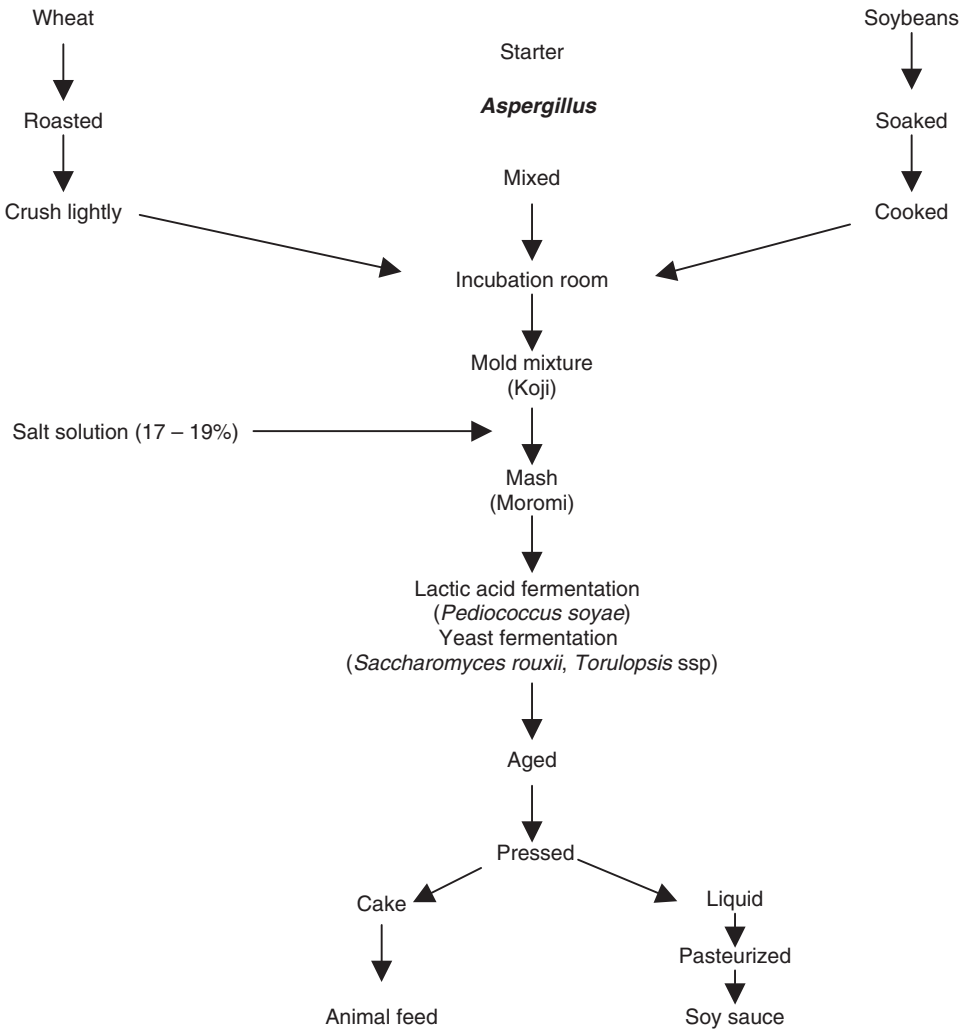

FIGURE 63.2 Flow sheet for the manufacture of soy sauce.

proteases. These two enzymes are essential to the brewing process. Amylases degrade starch to glucose, a sugar needed for the yeast fermentation, and proteases solubilize compounds in the grain and hops important for the quality of beer. After germination, heat is applied to stop the sprouting process and to dry the grain. The dried and crushed malt is suspended in water and mixed with boiled malt adjuncts, such as ground rice and corn. Adjuncts are low in enzyme activity, hence their use may necessitate the addition of microbial preparations with α-amylase and proteinase activities. The addition of amylase is important in order to assure complete hydrolysis of starch.

The mash is then incubated at 65–70°C for a short time to allow the amylase to degrade the starch to glucose. The temperature is raised to 75°C to inactivate the enzymes and then allowed to settle. Insoluble matter sinks to the bottom and serves as a filter as the liquid, called wort, is taken from the container.

Here, hops or hop extracts are then added to the wort. Hops are a very important ingredient in beer production. Their function is to (i) act as a clarifier, since they precipitate the proteins in wort, (ii) change the wort character to give a specific aroma and bitter taste and, (iii) to contribute to the stability of beer because of their antibiotic properties, which act together with ethanol and carbon dioxide. In addition, the protein content of hops enhances the foam-building ability of beer (36). The mixture is then boiled for 1.5–2.5 h to obtain the correct delicate hop flavour (106, 107). Boiling with hops serves several purposes: concentration, sterilization by killing many spoilage microorganisms, further inactivation of enzymes in the mash and solubilization of important compounds in the hops and mash. The color and roasted aroma of the malt are formed during kilning by Maillard reactions. The roasting temperature is important in the development of the color of the beer. The malt is heated to the roasting temperature for 4–5 hours at 80°C for light malt or at 105°C for dark malt (36). Some of these add to the flavour of the beer while others, especially from the hops, have antiseptic qualities and help preserve the beer. The wort is then

separated, cooled and fermented. Water is a key ingredient of beer and its quality has a significant effect upon the final product. The calcium content is important as it can precipitate as calcium phosphate lowering the pH of the wort to around 5.4 which is close to the optimum for some of the malt enzymes (18).

There are two major types of beer separated by their fermentation characteristics; lagers and ales, both of which can be either light or dark in appearance. Lagers are produced using pure cultures of *Saccharomyces carlsbergensis* which is a yeast that flocculates to the bottom. Lager fermentation temperature is generally low, in the range 8–12°C and consequently takes longer than that of ale (18). Most beer produced is of the lager variety. Ale is produced mainly in Great Britain and Continental Europe using *Saccharomyces cerevisiae* which flocculates to the top and is recovered by skimming and reused after each batch. Fermentation temperature is generally warm, 18–25°C. A huge variety of beers exist. Changes in any of the process conditions can result in vastly different beer styles. Beers can be classified by region and original gravity (OG). OG refers to the amount of sugar present prior to pitching (yeast inoculation) and determines the final beer alcohol content.

Fermentation begins by adding the yeast *Sacchromyces cerevisae* to the wort. Ale results from the activities of top-fermenting yeasts, which depress the pH to around 3.8 whereas bottom-fermenting yeasts, *S. carlsbergensis* strains, give rise to lager with pH values of 4.1–4.2. A top fermentation is completed in 5–7 days; a bottom fermentation is completed in 7–12 days (1, 42). Fermentation results in the conversion of glucose to ethanol and CO_2. Other compounds in the wort are also fermented to add to the characteristic flavour of beer.

The fermented wort, called green beer, is aged at 0°C for a period of weeks or months depending on the brewer. At this time the yeast settle to the bottom of the vessel, bitter flavours are mellowed and other compounds are formed that enhance flavour.

The beer is then filtered to remove yeast cells. The beer is finished by addition of CO_2 to a final content of 0.45 to 0.52% CO_2. The pasteurization of beer at 60°C or higher, may be carried out for the purpose of destroying spoilage microorganisms (42).

There are a number of factors that protect beer from the growth of contaminating microorganisms. These include low pH and redox potential, the isohumulones of hops that inhibit Gram-positive bacteria and the alcohol produced by the yeast (44). The usual spoilage agents are acetic acid bacteria, lactic acid bacteria and wild yeasts. The industrial spoilage of beers is commonly referred to as beer infections (42). Four types of spoilage defects have been identified: ropiness, sarsinae sickness, sourness, and turbidity. Ropiness is caused by *Acetobacter*, *Lactobacillus*, *Pediococcus cerevisiae*, and *Gluconobacter oxydans* (108, 109, 110). Ropiness is characterized by an increase in the viscosity of the beer, which pours as an "oily stream" (42). Sarcinae sickness produces a honey like odor as a result of diacetyl production by the spoilage organism *P. cerevisiae* in combination with the normal of odor of beer (42). Sourness in beer is caused by increased levels of acetic acid, as a result of oxidation of ethanol by the action of the acetic acid bacteria *Acetobacter* and *Gluconobacter* (44). *Zymomonas anaerobia* and several other yeasts such as Saccharomyces spp. can cause turbidity and off-odors in beer.

2. Bread

Bread is one of the most common, convenient and inexpensive foods, with leavened forms now the most popular in many countries although flat breads remain very common in India and the Middle East (111). Bread has made a major contribution to the diets of many countries for centuries (111). Bread is basically made from flour or meal by moistening, kneading and baking. Bread has always been made from flour or meal from a number of grains and seeds. However, only flours from wheat and to a certain extent rye are able to produce dough that is able to hold sufficient leavening gases to produce loaves with good volume and a fine, soft cellular structure (5, 112). The characteristics of bread made from wheat flour are directly related to the presence and properties of gluten which is the hydrated protein of wheat. Gluten can form elastic, extensible films within dough which enable it to stretch and retain gas (111, 113, 114). The gas content comes from air incorporated during mixing and CO_2 from yeast fermentation of sugars. Most breadmaking processes involve modifications of the natural properties of the gluten which leads to improved gas retention and a thinner dough.

Although, many microorganisms ferment sugars with the release of CO_2, *Saccharomyces cerevisiae*, or baker's yeast is the best adapted for leavening bakery products (5). A number of advantages are gained by using yeast fermentation for bread making:

- Yeasts produce a delicious flavour and an appealing aroma
- Gas evolution can take place over long periods of time
- Yeast activity helps to ripen and mellow the gluten in the dough enabling it to expand and retain accumulating gases
- The product is viewed as more natural by the consumer
- Yeasts often are easier and more economical to use

Although some yeasts can hydrolyse starch present in flour, *S. cerevisiae* cannot. Amylases naturally present in the flour, or added hydrolyze the starch to maltose making

it available to the action of *S. cerevisiae* enzymes. Sucrose is sometimes added to give the bread a sweat taste. Yeast invertase enzymes convert added sucrose to the monosaccharides glucose and fructose. Glucose is then metabolised by the yeast cells to CO_2 and ethanol. It takes approximately 4 hours for the yeasts to replicate in dough so little reproduction occurs during production of bakery products. Also, the level of ethanol produced is quite low and this evaporates during baking.

Protease enzymes from the yeasts are also active in the dough, they change the soluble flour proteins into simpler forms which can pass through the semipermeable membrane of the yeast for use in replication. There is very little oxygen within the dough so most of the processes take place anaerobically.

Bread is a perishable product with a relatively short shelf-life. Moulds, particularly *Rhizopus stolonifer* and *Nerospora sitophila* are the main spoilage agents due to the low water activity (115, 116) Yeasts have been shown to be responsible for the defect known as "chalky bread" (21). Calcium propionate, up to a level of about 3000 ppm, is permitted as a preservation agent in bread (117). Ascorbic acid is also frequently used for the same purpose. Although, they have been associated with a number of *Bacillus subtilis* outbreaks, baked goods such as bread have an excellent reputation for safety (7), *B. subtilis* is responsible for a defect known as ropey bread where spores, naturally contaminating the flour survive the baking (118, 119), germinate and grow degrading the loaf's internal structure and producing a sticky slime (120). This defect is not always dramatic enough to prevent people eating the bread.

a. Sourdough

Sourdough starters and bread have existed for thousands of years (121); however, the term sourdough originally referred to specific bread making starter cultures that were carried by settlers in the San Francisco area. Prized cultures were handed down from generation to generation. The term is now used for any sour bread.

Sourdough bakery products have remained popular due to their superior sensory qualities and extended shelf life (122, 123). These properties are achieved by combining the metabolic activity of both LAB and yeasts during the sourdough fermentation. In general, the yeasts are responsible for leavening the bread and the bacteria for the souring. However, the bacteria do produce some carbon dioxide from sugars in the flour which helps the bread rise. The sourness of the product depends on many factors including temperature, fermentation time, type of grains, (wheat or rye are most frequently used), amount of water and primarily the strains of yeast and *Lactobacillus* in the starter culture (124). Lactic and acetic acids produced by LAB contribute to the rich complexity of bread flavours. Flavor compounds are formed by the activity of endogenous cereal enzymes, microbial metabolism, and the baking process. LAB and yeasts also form a range of desirable aroma volatiles (125, 126, 127).

Traditionally sourdough fermentations use a natural starter culture of wild yeast and bacteria. The culture is continuously propagated and is frequently maintained by constant back-slopping from one fermentation to the next (128). Several varieties of yeast and *Lactobacillus* have been identified in sourdoughs from around the world. The ratio of yeast to bacteria in San Francisco sourdough cultures is about 1:100. The dominant yeast strain was classified as *Saccharomyces exiguous* called *Torulopsis holmii*s, (129) later reclassified as *Candida milleri*, (postulated to be reclassified as *Candida humilis*). The most common LAB in sourdough fermentations are *Lactobacillus* spp. including *L. sanfranciscensis* (also referred to as *L. sanfrancisco*) (130) *L. reuteri*, *L. brevis* and *L. pontis.*

Fermentation conditions must encourage high levels of metabolic activity by both yeasts and LAB for a stable symbiotic relationship to occur that can exclude other microorganisms. The two organisms do not compete for the same carbon source, degradation of starch by amylases in the dough provides maltose which is utilized by the lactobacilli (131). *Candida milleri* cannot metabolise maltose but catabolises the other sugars present. During the assimilation of maltose by the lactobacilli the activity of maltose phosphorylase releases glucose which stimulates the yeast (132). In turn, the nutritional requirements of the lactobacilli are complex, they require a number of amino acids and fatty acids which may be derived from dead yeast cells (133, 134). *Candida milleri* has a tolerance to the acid environment produced by the lactobacilli (135). The pH of sourdoughs ranges from pH 3.8–4.5 (23).

Mould growth is the most frequent cause of bread spoilage. The LAB produce antimould compounds. *L. sanfranciscensis* has a broad spectrum of inhibitory activity against a range of moulds related to bread spoilage such as *Fusarium*, *Penicillium* and *Aspergillus*. A combination of organic acids including acetic, caproic, formic, propionic, butyric and n-valeric cause the antimould activity with caproic acid playing a major role (136). The lactobacilli also secrete an antimicrobial cycloheximide which kills many organisms in the dough. *Candida milleri* is resistant to cycloheximide.

E. Fermented Grains or Fruits

1. Wine

Wine is a beverage obtained by full or partial alcoholic fermentation of fresh, crushed grapes or grape juice (must), with an aging process. However, it is also produced from the fermentation of berries, fruit, honey, palm juice, rhubarb, and dandelion. The major grape cultivars used to produce wine belong to *Vitis vinifera*, *L.* ssp. *vinifera* (36).

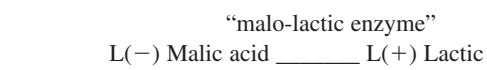
Grapes are either wine-type grapes, for white or red wine making, or table grapes. The cultivars are different in sugar content and aroma. The quality of the grape is influenced by some factors such as climate, soil conditions, and variety of grape (137).

Grape clusters cut from vine stocks are cleaned of rotten and dried berries and then separated from the stems using a roller crusher. The crushed grapes are then subjected to pressing to release juice, the must. The remaining grape skins and seeds (pomace) are loosened or shaken-up and pressed again to provide the second or post extract. The pomace is then removed. In red wine making the must is fermented together with skin in order to extract the red pigments, which are released only during fermentation. The extraction of the red pigments is sometimes facilitated by raising the temperature to 50°C prior to fermentation of the mash, or to 30°C after the main fermentation, followed by a short additional fermentation.

The fresh sweet must is treated with sulfur dioxide to suppress the growth of undesirable microorganisms and to stabilize wine color. Due to health problems caused by the consumption of sulfites, there is a desire to eliminate this additive. Some strains of *S. cerevisiae* can stabilize wine color, apparently by producing sulfite. One strain produced 30 to 80 mg/L (ppm) (138).

The must is then inoculated with a suitable wine yeast strain of *Saccharomyces cerevisiae var. ellipsoides* or *pastorianus*. The must is then fermented for up to 21 days at temperatures 12–14°C for white wines and 20–40°C for red wines (36). Ethanol production could reach 14–18%. For red wine, the must is allowed to ferment until the correct amount of color is extracted from the skin. Following this initial fermentation, the wine is racked to get rid of the sediment. The wine is pumped into barrels, vats, or tanks for aging. The clearing and the development of flavours occur during this stage. Various compounds, such as esters, are formed and contribute to the bouquet and aroma of the wine. In general the wine is removed from vats after 3–9 months and poured into bottles in which aging continues. The duration of aging and stability differ and depend on wine quality (36).

A fermentation called malolactic fermentation can be achieved to reduce the acidity and mellows the wine. Malic and tartaric acids are two of the predominant organic acids in grape must and wine. They account for about 90% of the acidity in grapes (44). The malolactic fermentation can be carried out by many lactic acid bacteria, mainly of the genera, *Lactobacillus*, *Leuconostoc* (*L. oenos*), and *Pediococcus* (*P. cerevisiae*). This fermentation usually follows the alcoholic fermentation and degrades malic acid to lactic acid and CO_2:



The monocarboxylic lactic acid is not as acidic as the dicarboxylic malic acid. Hence, the acidity of the wine is reduced (36).

Not all lactic acid bacteria can tolerate the alcohol and low pH required to convert malic acid to lactic acid. The bacterium *Oenococcus* is an acidophile that can grow in grape must and wine at pH 3.5–3.8, and actually prefers an initial growth pH of 4.8 (139).

Wine can be subjected to some defects. Spoilage is evident by appearance, odor, and flavour changes. Spoilage may be due to molds (140), lactic acid bacteria (141), acetic acid bacteria (142, 143) and chemical reactions (144). Browning of wine is a chemical defect caused by oxidative reactions of phenolic compounds, which in red wines, may result in complete flocculation of the color pigments. Yeast spoilage is induced by species of the genera *Candida*, *Pischia* and *Hansenula*. Other microorganisms are involved in the formation of viscous, moldy and ropy wine flavour defects. Bacterial spoilage may involve acetic acid and lactic acid bacteria. In this case vinegar or lactic acid souring is detectable. The most serious and the most common disease of table wines is referred to as "tourne disease" (42). Tourne disease is caused by a facultative anaerobe or an anaerobe that utilizes sugars and seems to prefer conditions of low alcoholic content. This type of spoilage is characterized by an increased volatile acidity, a silky type of cloudiness, and later in the course of spoilage, a "mousey" odor or taste.

2. Distilled Spirits

Distilled spirits are alcoholic products that result from the distillation of yeast fermentations of grain, grain products, molasses, or fruit and fruit products. Whiskeys, gin, vodka, rum, and liqueurs are examples of distilled spirits. Although the process for producing most products of these types is quite similar to that for beers, the content of alcohol in the final products is considerably higher than for beers.

a. Whiskey

Whiskey is an alcoholic distillate made from fermented mash of grain. Rye whiskey may be made from rye and barley malt. At least 51% of the mash must be rye. For bourbon (corn), the mash must contain more than 51% corn. For example, a typical mash could contain 70% corn, 15% rye and 15% malt. The cereals are first ground, mixed with acidified water, and made into an uniform mash by starch gelatinization. A sour wort is maintained to keep down undesirable organisms, the souring occurring naturally or by the addition of acid. The mash is generally soured by inoculating with a homolactic such as *L. delbrueckii*, which is capable of lowering the pH to around 3.8 in 6–10 h (3). Saccaharification is then accomplished by incorporating 15% kiln-dried malt in a pre-mashing vat and stirring constantly at 56°C. Saccharification proceeds rapidly

through the action of malt diastase enzymes. The enzymes are inactivated by heating the mash to 62°C, followed by cooling to 19–23°C. The cooled mash is then pitched with a suitable strain of *Saccharomyces cerevisiae* for the production of ethanol. When fermentation is completed, the liquid is distilled to obtain higher alcohol levels. Whiskey is aged in white oak barrels. This process increases the solids, esters, acids, fusel oil, aldehydes, furfural and color (1).

b. Rum

Rum is an alcoholic distillate made from the fermented juice of sugar cane, sugar cane syrup, sugar cane molasses or other sugar cane by-products. The alcoholic content is less than 80%. Strains of *Saccharomyces cerevisiae* or *Schizosaccharomyces pombe* are used in the fermentation. Phosphorous and a nitrogen source are added to black-strap molasses (12–14% sugar) or a similar carbohydrate material. The pH is adjusted to 4.0–4.7 with H_2SO_4. This is done to speed up the fermentation and produce a light-flavoured rum. The fermentation is usually run at 21°–35°C for 3 to 7 days. The mash is then distilled to increase the alcohol content of the beverage. Rum is normally aged in charred white oak barrels. The flavour, color, and aroma develop during aging due to an increase in esters, organic acids, and solids (1).

3. Vinegar

Vinegar is a clear, sour tasting liquid that may be colourless, may take the colour of the raw substrate or be coloured by the addition of caramel (144). Vinegars are classified according to the raw material from which they are made e.g. grapes are the substrate for wine vinegar (7). Basically, vinegar can be produced from any food that can be fermented by yeasts to ethyl alcohol. Frequently used substrates include fruits, honey, coconut, malt and cereal grains (44). Distilled grain or spirit vinegar is made from an alcoholic solution that has been distilled.

The common types of vinegar in a region often reflect the local alcoholic beverage, e.g., rice vinegar is popular in Japan, wine vinegar in France and malt vinegar in the UK (18, 145). This suggests that vinegar was discovered as a consequence of defects occurring during alcoholic beverage production. In fact the term vinegar comes from the French for "sour wine", vin aigre (18). The extensive history of vinegar is confirmed by reference to it in ancient texts (146).

Vinegar is frequently used as a condiment, but is also an important preservative and flavouring agent in products such as pickled vegetables, sauces and dressings. Higher strength vinegars are frequently used for pickling (7). Some types of vinegar, e.g., komesu, which is made from polished rice, are used as health drinks (145). Increasing consumer interest in health has made any health benefits of traditional vinegar a matter of interest (7, 145, 146).

Vinegar is the product of a two-stage fermentation:

1. Yeasts convert sugars to ethanol anerobically, an alcoholic fermentation**.** The alcoholic vinegar stock is produced using essentially the same processes to those used to make alcoholic beverages. Alcoholic fermentation should be complete before vinegar production occurs since acetic acid and the environmental conditions inhibit further alcohol production.
2. Ethanol is oxidised to acetic (ethanoic acid) aerobically by bacteria of the genera *Acetobacter* and *Gluconobacter*. In a reaction known as acetification, this is a common reaction in the spoilage of alcoholic drinks. Acetification can be represented by the reaction

$$C_2H_5OH + O_2 = CH_3COOH + H_2O$$

The minimum acceptable acetic acid content of vinegar is between 4–6% w/v (40 and 60 g/l) and the pH value should fall between pH 2.0 and pH 3.5 (18, 144).

There are various systems for converting the alcoholic vinegar stock to vinegar. All the methods provide a means of effectively combining alcohol, air, and acetic acid bacteria. Acetic acid bacteria gain energy during the oxidation of ethanol. As members of the genera *Acetobacter* and *Gluconobacter* are strict aerobes techniques for acetification have been developed to maximize the available oxygen supply to the bacteria. Increasing the available oxygen is not only desirable in that it increases the metabolic rate of the bacteria and hence the rate of vinegar production, it is also essential. An interruption in the oxygen supply, even for a short period of time will result in death of the bacteria and failure of the process (18).

Acetobacter are better acid producers and are more commonly used in commercial vinegar production. However, they can oxidise acetic acid to CO_2 and H_2O (over-oxidation) which is not a problem with *Gluconobacter* (146). Ethanol represses over-oxidation. Consequently, to reduce the risk of over oxidation during acidification a residual level of ethanol is always maintained. This is easier to achieve using semi-continuous methods where samples of fresh alcoholic vinegar stock are added into residual amounts of finished vinegar (18, 144, 147).

Three main techniques are used in vinegar production, namely surface culture, the trickling method (quick vinegar process) and submerged fermentation (18, 146, 147). Static, surface fermentation is the oldest method and is still employed in making traditional vinegars. The Orleans method is one of the oldest, static, surface fermentation methods. In the Orleans process a large wooden barrel is laid on its side and partially filled with vinegar stock. Air holes situated just above the level of the stock increase the level of available oxygen Figure 63.3. The inlets to the

barrels are covered with muslin or similar material to prevent insects entering, but to allow free flow of air.

A surface culture of acetic acid bacteria forms at the interface between the acetifying medium and the air, forming a bacterial 'mat' (Figure 63.3). The barrel is left undisturbed until the acidity reaches the required level, then point about two-thirds of the volume of the vinegar is removed through a port near the bottom of the barrel (Figure 63.3). New stock is added through a tube to the bottom of the mix so that the film of bacteria remains undisturbed. The residual volume charges the next batch and the process restarts. It usually takes about 14 days for one acidification cycle (18) but the same barrel may be used continuously for extended time periods. The surface film of acetic acid bacteria has oxygen readily available and consequently is active. Whilst succeeding batches of vinegar will proceed if this mat is broken, they will start and proceed more rapidly if the layer remains intact. The optimum temperature for this conversion is about 29°C.

The advantages of this technique are that it is simple and does not require expensive plant investment, also the quality of the product in terms of both aroma and flavour is excellent. The rather long time required to complete the fermentation makes the Orleans technique less attractive for mass production and only a small proportion of vinegar is now produced by this method.

The "quick vinegar process" or "trickling method" gets its names from the faster rate of vinegar production or from the fact that the alcoholic stock trickles down over the bacteria. This process employs a larger area of bacterial film in conjunction with improved oxygen transfer to the acetifying stock. The acetifying stock is sprayed onto the surface of packing material and slowly trickles down against a counter current of air (Figure 63.4). The packing material is loosely packed and lignocellulosic in nature, e.g., birch, vine, rattan, corn cobs, beachwood shavings. Films of active bacteria develop throughout the packaging material greatly increasing the surface area of bacteria that the stock comes into contact with. Making the acetator larger also increases the distance that the stock travels through the packaging and the time of contact between the bacteria and the vinegar stock. The process is operated semi-continuously; samples are collected at the bottom of the equipment and recirculated until the required acidity is achieved (Figure 63.4). When the vinegar is harvested most of the bacteria are retained in biofilms in the packaging material. The process time is about 4–5 days in a well-controlled system (18, 147).

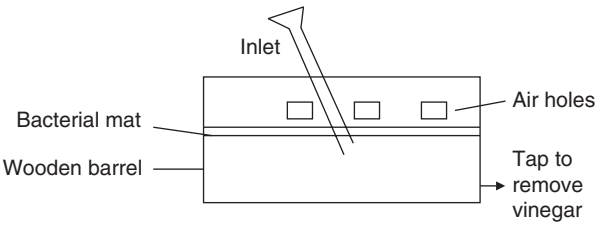


FIGURE 63.3 Schematic diagram of the Orleans process for acetification.

The latest advance in vinegar technology is the use of submerged fermentation, which began around 1952. In this system the entire volume of vinegar stock is oxygenated by tiny bubbles of air that continually sparge through the culture (Figure 63.5). This enables the acetic acid bacteria to grow and metabolise suspended within the volume of the stock. The culture is mixed to ensure homogeneity. Semi-continuous runs are used. The most commercially successful system is the Frings Acetator (18, 144, 146).

Due to the sensitivity of the bacteria, submerged cultures require continuous monitoring. Bacteriophage infection can also result in fermentation failures. The enhanced efficiency of these systems can reduce the time for conversion of alcoholic vinegar stock to vinegar to 24–48 h (18, 144, 146).

Many of the acetobacter species are difficult to culture on conventional media, however they have been extensively studied. Genes have been characterized which encode indispensable components of the acetic acid fermentation, such as alcohol dehydrogenase and aldehyde dehydrogenase. In addition, spheroplast fusion of the *Acetobacter* strains has been applied to improve their properties for use in vinegar production (148, 149).

F. Fermented Proteins

Initially, the main purpose for fermenting meat and fish was to extend the shelf-life of these highly valued, perishable

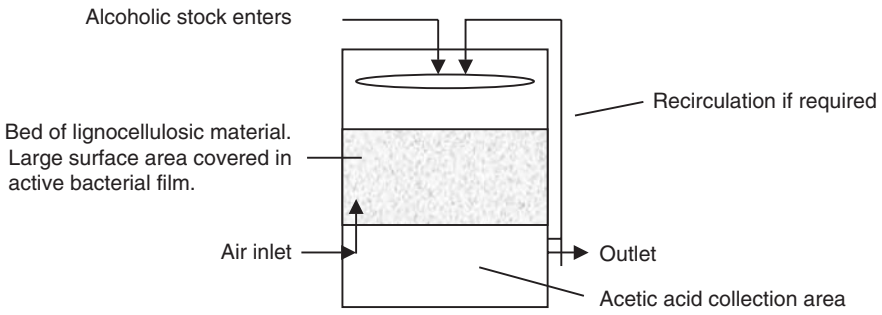

FIGURE 63.4 Schematic diagram of the quick method for acetification.

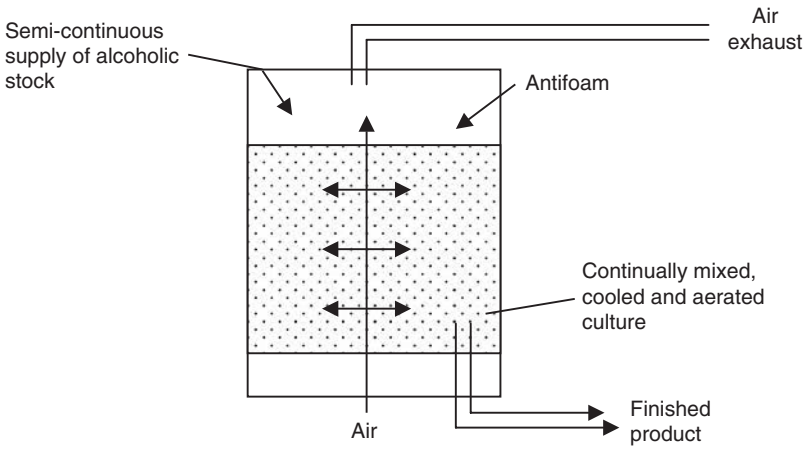

FIGURE 63.5 Schematic diagram of the submerged process for acetification in vinegar production.

foods. Sausages became the most popular method of preserving meat with a host of different recipes and techniques developing around the world. Although many other preservation methods are now available the production of fermented sausages and fermented fish continues, as they are highly valued for their enhanced flavours.

1. Fermented Sausages

The characteristic properties of fermented sausages are partially or completely dependent on the fermentative activity of bacteria. Sausage processing may also include curing, smoking, drying and ageing. The two principle groups of fermented sausages are semi-dry and dry (Table 63.10). The meat used in semi-dry sausages is often finely chopped resulting in spreadable products.

Fermented sausages are prepared by mixing ground meat with various combinations of spices, flavourings, salt, sugar, additives and frequently bacterial cultures. The levels and types of spices and flavouring agents influence the flavour and odour of the final product (150). It is not possible to cover all the types and potential variants of fermented sausages, but the typical ingredients of European sausages are:

Lean meat	55–70%
Fat	25–40%
Curing salts	3%
Fermentable carbohydrates	0.4–2.0%

Additional ingredients include, spices, flavourings, acidulant, colouring etc. (18).

The quality of the meat is critical to both the safety and sensory properties of the sausage. Most production methods do not heat the meat before processing as this leads to defects in the texture of the sausage (18). Also, fermented sausages are frequently eaten without cooking. The hygienic properties of the raw meat influence the production of biogenic amines (tyramine, cadaverine, putrescine; aromatic amines such as histamine, phenylethylamine, or tryptamine; polyamines, e.g. spermine and spermidine) (151) By using appropriate conditions to favor starter development and the use of the raw materials with good hygienic quality it is possible to produce fermented sausages nearly free of biogenic amines (152). Spices can be heavily contaminated with microorganisms, which makes contamination control of spices critical. Sometimes spices are sterilized by radiation.

TABLE 63.10
Properties of Semi-Dry and Dry Sausages

Property	Semi-Dry Sausages	Dry Sausages
Starter culture	Frequently used	Less successful than with semi-dried
Flavour	Tangy, predominantly from fermentation	From fermentation, and biochemical and physical changes during drying and aging
Processing time	Usually <several days	May be up to 90 days
Approx. water content	35–50%	<35%
Examples	Lebanon bologna	Pepperoni, Lola sausages, Genoa
	Mortadella	Salami

The physical characteristics of the meat and fat particles affect drying. The size of the meat particles must encourage efficient release of moisture and the cut edges must not be smeared with fat.

Sausages were traditionally produced in sections of gastrointestinal tract and then regenerated animal hides as they provided the required range of properties (Table 63.11) (18). When the casings are filled air should be excluded as this will lead to discolouration of the meat and reduce the shelf life of the sausage.

The mixed ingredients are allowed to ferment at different temperatures for varying periods of time. Natural fermentations are still used, but more often starter cultures

TABLE 63.11
Properties Required from Sausage Casing Material

Permeable to moisture and smoke
Acceptable to the consumer
Shrink as the meat is dried
Retain the sausage mixture
Form the required sausage shape

are added. The principal components of starter cultures are lactic acid bacteria and nitrate reducing bacteria and the high salt tolerant yeast *Debaryomyces hansenii* (18, 153). *Lactobacillus* spp. and *Pediococcus acidilactici* are primarily responsible for converting sugars into lactic acid thereby lowering the pH of the meat product. Whilst species such as *Micrococcus varians* and *Staphylococcus carnosus* are important for conversion of nitrates to nitrates (18, 154). A major role for nitrates is to control *C. Botulinum*. Lactobacilli with or without micrococci are components of starter cultures used to slow fermentations whereas pediococci with or without micrococci are used for rapid fermentation. *Pediococci* spp. do not occur in fresh meat at high enough levels to be significant in traditional slow fermentations and therefore are only important in meat product fermentation when added in starter cultures.

Following fermentation, the product may be smoked and/or dried under controlled conditions of temperature and relative humidity, further developing the flavour and odour of the final product. Several chemical changes occur during the ripening of dry-fermented sausages including 1) acidification of the sugars by lactic acid bacteria 2) reduction of nitrates and nitrites to nitric oxide by micrococci 3) degradation of the proteins and lipid.

Superficial mold growth can occur on unsmoked sausages which has been shown to significantly improve the sensory properties, including the flavour, of sausages at the end of ripening by altering the levels of amino and free fatty acids, and volatile compounds (155). The fungi should be atoxigenic and have proteolytic, lipolytic and antioxidative activity (155).

Microbial growth and the activity of endogenous meat enzymes are only partially responsible for the development of flavour and odour compounds (90). Lipid autooxidation reactions also have an important fuction in sausage ripening. Research has focused on the breakdown of triglycerides into free fatty acids, diglycerides, and monoglycerides during ripening. Carbonyl compounds probably play a significant role in determining flavour (90). Protein breakdown to peptides and amino acids is involved in microbial and chemical reactions that generate many flavour compounds (90). Also smoking sausages provides distinctive flavours e.g. in salami and hot dogs by accumulation of phenolic componds from the wood smoke (18).

A number of parameters contribute to the final microbial safety of sausages (Table 63.12). The extent of drying

TABLE 63.12
Parameters Contributing to the Microbial Safety of Sausages

Parameter	Comments
Phenolic componds	From smoking, have important antioxidant and antimicrobial properties
Acidity	Approximately 2.5% w/w as lactic acid
Salt	Approximately 3% NaCl and curing salts
pH	4.9–6.0
Various antimicrobial compounds	E.g. hydrogen peroxide
Drying	Reduces the water activity
Spices	Stimulate LAB and inhibit normal spoilage microflora
Low availability of oxygen	Oxygen reduced by growth of LAB

Adams and Moss (18); Adams and Nout (153).

varies; the weight loss in less shelf-stable varieties like Bologna is about 20–30%, and reaches 50% in the more stable salamis (156). The lowered water activity inhibits the proteolytic spoilage Gram negatives and allows the proportion of LAB to increase. LAB growth results in a decrease in pH and available oxygen, these inhibitory factors help control both Gram negative and Gram positive pathogens that are commonly present on the raw meats. When the growth of aerobic spoilage bacteria is inhibited, lactic acid bacteria may become the dominant component of the microbial flora (157). The safety and stability of fermented sausages depends upon fermentation caused by lactic acid bacteria (157).

A combination of antimicrobial hurdles (Table 63.7) in fermented sausages usually provides a shelf-stable, safe product. However, outbreaks of disease following ingestion of fermented sausages caused by *Staphylococcus aureus*, *Salmonella*, and verotoxigenic *E. coli*, and more dramatically, *C. Botulinum*. Salmonellae have been shown to survive during the production of pepperoni. Their persistence was lowest in sausages fermented with a lactic acid starter (158). Although the counts of *Salmonella* and other Enterobacteriaceae have been shown to decline during fermentation and drying we can not rely on this being sufficient to eliminate these organisms, again emphasising the need for high-quality meat and the fermentation process to be controlled (18, 159).

To minimize the risk from outgrowth of *C. botulinum* spores and toxin development in the shelf-stable cured product nitrite/nitrate salts should be added. However, the level should not interfere with the process of fermentation.

2. Fermented Fish

Fermented fish products fall into two major groups, sauces and pastes; they are most popular in Asia. In this region of the world, fish provides a major contribution to the human diet. They are often used as condiments much like salt in

Western cooking and soy sauce in Chinese cooking. They are often the most important flavouring ingredient of the diet. They can be added to soups, curries, salads, rice etc.

Sauces and pastes are primarily made from whole or eviscerated small schooling fish that are found in abundance and that would otherwise have little value for consumption, many of which are anchovies or related species. Larger varieties of fish, such as mackerel and sardines, also make good fish sauce, but because they are relatively more expensive due to their value as a food fish, they are seldom used in the commercial production of fish sauce. Fresh water fish, fish roe and shrimps are also used to a lesser extent.

Fish sauce and paste are considerably different products, but are produced by similar processes. The fish variety, fermentation conditions, cure duration and technique all affect the texture, amino acid content and volatile flavour profile of the finished product. Good-quality fish sauce imparts a distinct aroma and flavour. Products where less extensive autolysis of the fish occurs are classified as fish pastes (18). Some example of fermented fish sauces and pastes are shown in Table 63.13.

To obtain products with a pleasant, fragrant aroma and taste, the fish must be very fresh. Fresh whole fish are rinsed and drained, then mixed with salt usually in an approximate ratio of three parts fish to one part salt. The salted fish are packed into concrete tanks or earthenware jars, and are frequently weighted down to prevent them from floating as liquid accumulates inside the tank as a consequence of autolysis. The tanks are sealed and left undisturbed for at least six months and possibly up to eighteen months. To maintain a relatively high temperature the tanks are either placed in sunshine or buried in the ground.

The amount of salt added is sufficient to produce a water activity value below 0.75 (18) inhibiting most microbiological activity and spoilage, with the possible exception of growth of anaerobic extreme halophiles. The higher the concentration of salt, the slower the production rate of fermented fish products, but the longer the shelf life of the product (153, 160).

During "fermentation" the fish protein undergoes hydrolysis by autolytic enzymes (e.g. gastric juices), which are naturally present, and becomes liquefied. This process releases free amino acids and creates volatile flavour components. At the end of the liquefaction process the liquid is harvested and filtered to remove any sediment. The filtrate is transferred to clean jars and ripened in the sun for a couple of months; this allows the strong fish odors to dissipate. The fish sauce is then ready for use. Good fish sauce is clear without any sediment, brown in color, has a pleasant aroma of the sea, not an overpowering fishy smell, and should not be overly salty. Fish sauce is high in protein (up to 10%), and contains all the essential amino acids. It also provides a rich supply of B vitamins, especially B 12, pantothenic acid, riboflavin and niacin. Other beneficial nutrients include calcium, phosphorous, iodine and iron. Low numbers of streptococci, micrococci, staphylococci and *Bacillus* spp. have been isolated from fish sauces and associated with the development of flavour and aroma (161).

Fermented fish paste is prepared from salted fish with or without flavouring ingredients which is allowed to ferment or ripen. It has a smoother consistency and lower moisture content than sauces. Fat is often added to the final product so that it is spreadable and can be used for example as a sandwich spread.

The carbohydrate content of fish is low, usually less than 1%; therefore, for lactic fermentation of fish to occur an additional source of carbohydrate is required. A range of fish/carbohydrate/salt products are available, although they tend to be less popular than the traditionally made and time-tested fish sauces and pastes. Garlic and rice are often used as carbohydrate sources, and inulin is the fermentable carbohydrate in garlic (162, 163).

The higher the level of supplemented carbohydrate the faster the fermentation. Using this technique the product is often ready after only a few weeks, enabling the production of large quantities of product in a shorter time period. Fermentation of the carbohydrate leads to a product with an acidic flavour. Natural fish sauce production is a lengthy process and substantial investment is necessary for large-scale production. This has resulted in the search for more rapid, cost-effective techniques. These have included adding enzymes or acid to accelerate the fermentation.

The high salt content and consequent reduced water activity of fish sauces and pastes usually guarantees microbial safety of the products however fermented fish products have been implicated in outbreaks of botulism (164, 165). Other potential risks of fermented fish products are disease from products contaminated with *L. monocytogenes* (166) and cancer (167, 168).

IV. OTHER MICROBIAL PROCESSES

A. Treatment of Industrial Wastewaters

The treatment of industrial wastewater should be considered as part of the total effort towards conservation of the quality of the natural environment.

The wastewater to be treated varies depending on the type of the industry. It can include floating matter; sand

and grit; oil and grease; toxic elements; biological pollution; chemical pollution; and thermal pollution.

The treatment process required will depend on the composition of the wastewater and the required effluent quality. The main constituents in the wastewater from food processing are animal or vegetable fat, protein and carbohydrates. These can normally be removed by traditional biological wastewater treatment, but it can sometimes be advantageous or even necessary to take special precautions, such as adjusting the nutrient balance, pH etc. (169).

The choice of method to tackle a specific industrial wastewater problem will be based on experience with similar wastewater, analysis of the actual situation and, if it is unusual process, on testing. Testing can determine whether the wastewater will settle or whether it is biologically degradable (170). In principle four types of treatment can be distinguished:

- Mechanical treatment system
- Biological treatment system
- Physico-chemical treatment system
- Combinations of the above three systems

As this chapter deals with microbiology, we will look only at the biological treatment system. For more detail on all the systems the reader is referred to Droste (171).

1. Biological Wastewater Treatment

This is primarily used to remove dissolved and colloidal organic matter in a wastewater. Some suspended organics will also be metabolized and because of the natural flocculation and settling characteristics of the biomass formed in biological treatment, the biomass along with other suspended matter can be removed in a sedimentation.

2. Aerobic Biological Treatment

In aerobic treatment, microorganisms which need oxygen are used to convert the wastewater compound. In this process, air (oxygen) is supplied to microorganisms that are in contact with the wastewater. The microorganisms metabolize the organic material into carbon dioxide and other end products and new biomass. Several types of aerobic systems are possible for the aerobic biological removal of dissolved and suspended organics. These are the activated sludge, the trickling filters, the lagoons, and the tower technology.

The common activated sludge process is a suspended growth process where the microorganisms are mixed with the wastewater. Air is pumped into a basin to supply oxygen and mixing. Pure oxygen may be supplied as an alternative to air but supplemental mixing is required.

Some processes such as trickling filters use a solid support media to provide surfaces on which bacteria grow and accumulate. In this system wastewater is sprayed over a rock or synthetic media bed. Wastewater is applied on a continuous or an intermittent basis. Bacteria attach and grow on the media. Natural air currents supply oxygen.

A recent development is the use of tower reactors. The microorganisms can be dosed in flocculated form (comparable to activated sludge systems) or attached to grains. The main advantages of theses processes are: saving of space, more efficient use of oxygen, and cheaper off-gas treatment.

Processes may also be designed to oxidize nitrogen or remove nitrogen from the wastewater.

3. Anaerobic Biological Treatment

Anaerobic treatment or anaerobic digestion processes are biological degradation processes in the absence of oxygen. Instead of oxygen other electron-acceptors are used. High-strength wastewaters are amenable to treatment by anaerobic process. Industrial and agricultural wastewaters are often highly concentrated. Anaerobic treatment occurs in enclosed reactors to prevent access of oxygen. Biodegradable substances in wastewater are converted by anaerobic bacteria that are in contact with the wastewater into biomass and methane. Thus, anaerobic treatment is a process which not only removes pollution from wastewater but also generates a by-product, methane gas, which is rich in energy and therefore valuable. As in aerobic biological treatment operations, some processes incorporate solid support media to the microorganisms (fixed film process), whereas others keep the microorganisms in suspension. The biological solids produced in an anaerobic process must be settled in a clarifier that may follow the process or be incorporated into the anaerobic reactor.

B. Microbes as Foods

1. Single Cell Protein

In most fermentation production of biomass is incidental; however, there has been considerable interest in the use of microbial biomass as a food or feed supplement to meet the expanding demands for foods. Algae, bacteria, yeasts and fungi have been considered as protein sources. The food value of the cells is dependent upon their protein and amino acid composition and their lipid, vitamin and nucleic acid content (172). Many attempts have been made to manufacture foods that are protein rich as cheaper alternatives to meat. Microorganisms can grow on waste materials that contain appropriate nutrients (e.g. paper, whey, wood, sugar-refining waste, ethanol and paraffins) (173). The protein-rich cellular microbial mass is commonly known as “single cell protein.” It is often odorless and tasteless and can therefore be used in a wide variety of foods.

2. "Quorn" Mycoprotein

The production of mycoprotein represents an economical means of converting any surplus carbohydrate into foods of much higher nutritional and commercial value. From the many studies into single cell proteins one that has obtained commercial success is Quorn which is mycoprotein, the consumption of which is widespread and increasing (174). Cleverly anticipated consumer demand for healthy, vegetarian, convenience foods led to the development of Quorn. Quorn is the processed cellular mass obtained by continuous, aerobic cultivation of the filamentous fungi *Fusarium venenatum* under steady-state conditions. The taxonomic status of this organism has recently been reevaluated. This organism was previously classified as *Fusarium graminearum* (174, 175, 176).

Before Quorn could be marketed, an evaluation of its safety was required (177). Growth conditions that were not conducive to mycotoxin production were determined. *F. venenatum* is grown at a high rate without any nutritional limitations. The culture is supplied with a nutritionally balanced chemically defined fermentation medium containing easily metabolizable nutrients, including glucose as a carbon source, growth factors and ammonium salts (18, 177). Studies have shown the product to be free from mycotoxins that could have posed a major risk to human health (174).

The biomass removed from the fermenter is rapidly heated by injection of steam to kill the cells. The cellular mass is subsequently harvested by centrifugation. The combination of rapid heating and centrifugation reduces the content of RNA in the cellular mass.

To be acceptable for human consumption the RNA content must be reduced. RNA constitutes about 10% of the mycoprotein (18, 177) which is high when compared to traditional sources of protein, such as meat, fish, or soybeans (178, 179). Ingested RNA is ultimately broken down to purines and pyrimidines, and purines are subsequently converted to uric acid. Elevated levels of uric acid can increase the risk of developing gout and kidney stones in susceptible individuals. The RNA content is reduced to below 2% of the dry weight of the mycoprotein (177). The processed cellular mass is subjected to numerous tests to demonstrate compliance with specifications.

Quorn can be prepared following a variety of recipes. Its texture and "mouth feel" are much like chicken, the mycelium is bound together with egg which does not come unglued in cooking (as do some soy products) and flavoring ingredients are added. The filamentous nature of the cells gives the cellular mass a meat-like texture that makes it suitable for a variety of applications in food including use as a muscle fiber replacer in meat-alternative products, a fat replacer in certain dairy products and as a cereal substitute in products such as breakfast cereals or puffed snacks (177). A range of commercially available products are available based on Quorn, these include meat-free burgers and fillets and prepared meals (e.g., stir-fries, curries, and pasta dishes in which mycoprotein is the central component).

Quorn is low in fat, cholesterol-free, and a good source of protein (about 44%, (18)) and dietary fiber (177). The high fiber content of Quorn derives from the cell wall constituents e.g. chitin and beta-glucans. There are indications that the fiber content may also act as a prebiotic in the lower gut (177).The fat content of mycoprotein typically ranges from 12 to 14% dry weight and is more like vegetable fat than animal fat having a low proportion of saturated fatty acids and a high proportion of mono- and polyunsaturated fatty acids (177).

There was concern that inhalation or ingestion of mycoproteins could lead to adverse reactions in allergenic individuals (180). So far studies have given reassuring, largely negative results although this area is still a matter for concern and study (180, 181). The trouble-free history of Quorn in Europe suggests that the levels of adverse reactions are no higher that for other foods.

C. Microbial Products

1. Microbial Metabolites Used in the Food Industry

Biocatalysis is an important part of fermentation. Research and development of microbial products is becoming increasingly important. Enzymes enable reactions to occur under milder conditions, making them particularly beneficial to the food industry. Some microorganisms do not participate in fermentations, but are used to produce metabolites. Vitamins and amino acids increase the nutrient content, whilst gums and dextrins improve the physical characteristics, and enzymes provide a range of functions including improved flavours (182, 183). E.g., the amino acid, glutamic acid is used in the production of monosodium glutamate, which is a flavour enhancer in many foods (44). Microbial gums are used in the food industry for thickening, emulsion stabilization and rheological modifications. One gum that has wide commercial use is xanthan gum, which is produced by *Xanthomonas* spp. as an extracellular polysaccharide coat surrounding the cell wall (44). Yeasts and bacteria are an excellent source of group B vitamins. Autolysed yeast extract can also be used as a flavouring agent in many foods such as soups, sauces, gravies, snack foods, canned meats (173).

In some cases enzymes can be used more effectively than live microbial cells. When a series of reactions or several types of reactions are desired, such as in wine production, the intact microorganism is the system of choice, but if only one reaction is needed, separated enzymes may be beneficial.

Since microorganisms can be grown in large amounts in controlled conditions they offer an unlimited source of many

TABLE 63.14
Examples of Microbial Enzymes/Metabolites Used in the Food Industry

Enzymes/Metabolites	Commercial Source	Use in the Food Industry
Amylases	*Aspergillus* *Rhizopus* *Bacillus*	• Help prevent the staling of bread. • Important in the colour and texture of bread • Manufacture of syrup for use in confections, • Clarification of fruit juices.
Catalase	*Aspergillus niger Micrococcus lysodeikticus*	• Added to milk for cold sterilisation, • Removes excess hydrogen peroxide.
Cellulase	*Aspergillus, Micrococcus*	• Removes cellulose cloud, clarifies citrus juices • Improves the body of beer • Extraction of flavour compounds (such as essential oils) • Increases the digestibility and nutritive value of plant products.
β galactosidase	Many microbial sources including *Aspergillus niger Aspergillus oryzae.*	• Removal of lactose from milk. • Improves the solubility of dried milk and the consistency of concentrated milk, ice cream bases, and frozen milk. • Lower calorie products. • Sweet whey production for yeast cultivation.
Acidulants	*Aspergillus niger*	• Acidify the environment
Colours — β-Carotene	*Dunaliella salina*	• Food coloring
Thickeners — Glycan	*Saccharomyces cerevisiae*	• Viscosity changes
Vitamins — ascorbic acid	*Acetobactersuboxydans*	• Improve nutritional value
Lipases	Many organisms *Aspergillus niger, Aspergillus oryzae Mucor, Rhizopus, Pseudomonas*	• Develops flavour in cheese. • Treatment of milk fat in the production of ice-cream, butter or margarine.
Pectic enzymes	*Aspergillus niger* *Rhizopus oryzae*	• Clarifying agents. • Improve pressability, color extraction, filtration speed and yield of free run juice. • Removal of the gelatinous coating from coffee beans for fermentations.
Proteases	*Aspergillus oryzae, Bacillus subtillis Streptomyces griseus*	• Chillproofing of beer. • Meat tenderization. • Mellowing of dough in bakery products. • Production of fish protein solubles.
Rennets	*Mucor*	• Cheese making.

Adapted from (44).

enzyme systems and metabolites, only a limited number have wide commercial use. Some examples are shown in Table 63.14.

Microorganisms synthesize enzymes internally, although some may be secreted into the surrounding substrate. Extracellular enzymes are easier to obtain (98). To obtain intracellular enzymes it is necessary to break the cell wall and membrane.

64 Fermented Products: Role of Starter Cultures in Quality and Flavour Generation

Gerrit Smit, Jan T. M. Wouters, and Wilco C. Meijer
Department of Food Chemistry, Wageningen University and Research Centre

CONTENTS

I. INTRODUCTION

Various fermented products have an origin of spontaneous fermentation of a raw material, such as milk, meat or vegetables. Initially, the main focus was on preservation of the raw material. Raw milk, for example, will be susceptible to microbial spoilage at room temperature; the milk will rapidly acidify, due to the activity of lactic acid bacteria. Apart from preservation, fermented products also develop distinctive tastes and smells, which are widely appreciated. During the years, many variations developed, partly on purpose and partly spontaneous and in relation to the technology used. Their nature depends very much on the type of raw material used, on the pre-treatment of it, on the temperature (climate) and the conditions of fermentation. This practice is still common in various parts of the world: a part of a spontaneous fermented product is transferred deliberately into a new batch of raw material in order to maintain or even strengthen it. This principle is the basis for controlled preservation, sustainable and safe, with many times an attractive flavour, although the process is not controlled.

Many fermented products contain lactic acid bacteria, but other bacteria, yeasts and moulds may be involved as well. In order to be able to produce products with a more consistent quality, starter cultures for the preparation of fermented food have been developed. These cultures are composed of selected micro-organisms, propagated as defined mixtures of pure cultures or as undefined mixtures of different types of bacteria. The use of starters, on the one hand, has been tremendously positive with respect to the quality of the product, but, on the other hand, it has decreased the diversity of fermented products. Since the food industry is keen to explore new possibilities for enhancing the diversity of its product range, there is a new interest nowadays in searching for potential starter organisms from the pool, which existed at the time of spontaneous fermentations. This chapter gives an overview of various fermented products and the main organisms used with their functionalities. It focuses in particular on dairy fermentations, since these fermentations belong to the best-studied cases and information obtained from these studies can also be applied to other fermentations.

II. VARIOUS FERMENTED FOOD PRODUCTS AND STARTER ORGANISMS USED

The preparation of fermented foods is a practice with a very long history. Already thousands of years ago, for instance as reported in scriptures like the Bible, the making of wine and cheese have been reported. In those times, hardly anything was known about the underlying mechanisms, however, many interesting products evolved. All of them were the result of spontaneous fermentations, essentially resulting in products with an extended shelf life and (often) tasteful characteristics. The extension of the shelf life was obviously a major reason for fermentation practices. Later on, after the discovery of micro-organisms as the causal agents for the fermentation processes, these micro-organisms were isolated and used in order to be able to produce products with a consistent quality. This led to the practice of using industrial starter cultures and gave the manufacturer more control about the technological, safety and consistent quality aspects of their food products.

Many fermented products exist and for each of them cultures with specific characteristics are involved. For instance, in the fermentation of meat, combinations of various bacterial species are used. In almost all cases, lactic acid bacteria are present in these starter cultures, with *Lactobacillus sakei, L. curvatus, L. plantarum, Pediococcus pentasaceus* and *P. acidilactici* as most important species. Also *Micrococcus varians*, *Staphylococcus carnosus* and *S. xylosus* species are used. These micro-organisms are able to grow under low pH (4.5–5.0), low water activities (A_w 0.9–0.95), anaerobic conditions, and in the presence of salt (2–3%). Not only do these organisms cause a decline in pH, but they also contribute in the typical flavour of fermented meat products.

A number of fermented meat products also exhibit a fermentation on the surface, resulting from the growth of yeasts (*Debaromyces hansenii, Candida famata* and *C. utilis*) and moulds (*Penicillium chrysogenum* and *P. nalgiovense*). The surface flora usually adds to the flavour formation through specific lipolytic and proteolytic activities.

For the production of bread and sourdoughs, yeast (*Saccharomyces cerevisiae*) and lactic acid bacteria, e.g., *Lactobacillus sanfransiscensis*, *L. amylovorum*, are employed. The required gas formation in these products is by enlarge due to the sugar fermentation of the yeast cells, although also some heterofermentative lactobacilli can add to this. The fermentation of sourdough is more complex, since it requires the interaction of various micro-organisms. The various flavour components formed in these products, like aldehydes, alcohols, pyrols, etc. are partly the result of biochemical conversions by the starter cultures, but also result from the baking process itself [54, 27].

The fermentation of vegetables, such as olives, cabbage and pickles, belong to the least developed practices. The production methods are still rather simple. Basically lactic acid bacteria like *L. plantarum, Leuconostoc spp, Pediococcus* and *Lactococcus* are used in these productions. The acid formation results in the extended shelf life, and also flavour formation by the micro-organisms adds to the overall quality of these products. For the fermentation of soy, which is a very common and traditional process in the East Asia, various mould species are used like *Rhizopus oligosporus* and *R. oryzae*. These fermentations are often solid state fermentations, for which the raw material is inoculated with micro-organisms which grow at the surface of the raw material, making it essentially an aerobic fermentation process. For some of the products there is an extensive proteolysis, leading to products like soy sauce, whereas in other fermentations (e.g., tempeh) only limited proteolysis occurs [10].

Wine and beer are fermented with various yeast strains (*S. cerevisiae*). In some wines, also *Leuconostoc oenos* is used. In these cases, the main pathway related to preservation is the formation of alcohol from sugar of the grain or the grapes, respectively. Again, like in other fermentation processes, many other reactions occur, which contribute to the final sensory quality of the products and which are in fact even more important for the final quality. In the preparation of the malt, for beer brewing, micro-organisms are also employed in order to lower the pH and to reduce the outgrowth of spoilage organisms, e.g., certain moulds [88, 72].

III. CULTURES USED FOR THE MANUFACTURE OF DAIRY PRODUCTS

All types of lactic acid bacteria as well as other micro-organisms are used for the manufacture of various dairy products. Since dairy fermentations are among the best-studied fermentations, with several new developments, we focus on starter cultures in these fermentations and their characteristics. This section will give examples of the main species used, various characteristics required for the quality of the final products and flavour formation in particular. Many of the described characteristics are also of importance in other fermented products.

A. Lactic Acid Bacteria

When raw milk is left at room temperature for some time, a microflora will develop in which lactic acid bacteria generally dominate. These bacteria acidify the milk and, as a consequence, inhibit the growth of other bacteria. Concomitantly, they give the milk a pleasant flavour. This spontaneous fermentation has been the basis of several fermented dairy products in the history. The discovery of the role of lactic acid bacteria in milk fermentation paved the way for their isolation, characterisation and exploitation. This started more than a century ago and has resulted in the development of starter cultures for the manufacture of fermented dairy products. Both industrial and small-scale manufacture now almost always relies on industrially prepared starters [100].

The lactic acid bacteria used in the dairy fermentations can roughly be divided into two groups on the basis of their growth optimum. Mesophilic lactic acid bacteria have an optimum growth temperature between 20 and 30°C and thermophilic strains with an optimum between 30 and 45°C. Traditional fermented products from sub-tropical countries harbour mainly thermophilic lactic acid bacteria, whereas the products with mesophilic bacteria originate mainly from Western and Northern European countries. Currently, most dairy industries use starter cultures for rapid acidification, because a spontaneous fermentation acidifies the milk too slowly. This method of working has reduced the number of strains present, and is responsible for certain uniformity in dairy products. On the other hand, it has made the production very reliable and efficient. The micro-organisms present in natural niches still form a very interesting potential for product diversification, due to their large biodiversity (see below).

Industrial (dairy) starter cultures can be divided into two groups: undefined and defined starters. The undefined starters are a mixture of an unknown number of lactic acid bacteria types, which are originally derived from an artisanal production practice and further selected for the production of good-quality dairy products. Mesophilic undefined starter cultures are commonly used for the manufacture of Cheddar, Gouda and other cheese types. Their use is based on their consistent performance, especially their well-recognised phage resistance [110, 71].

Defined-strain starters are blends of two of more strains; in the case of Cheddar cheese they are frequently used nowadays in stead of the former undefined mixed-strain starters. Since the risk of phage attacks is greater here than with the use of undefined mixed-strain cultures, cultures with different phage sensitivity profiles are used in rotation [55, 71, 56]. Another well-known example of a defined-strain starter is mixture of thermophilic lactic acid bacteria in the manufacture of yoghurt.

B. Lactococci

It is interesting to consider that the industrial starters for the majority of cheeses are based on a single mesophilic species, namely *Lactococcus lactis*. Strains of this species are employed for the manufacture of various cheese types and, although they exhibit different characteristics, they have several biochemical attributes in common [25, 31]. The most important properties are their ability to produce acid in milk, and to form flavour components.

For the manufacture of Gouda cheese, the undefined mixed-strain starters are composed of acid-forming lactococci, *Lactococcus lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris*, possibly in combination with the citrate-utilising strains *L. lactis* subsp. *lactis* biovar *diacetylactis* and *Leuconostoc* spp (Fig. 64.1). These starters are thus composed of complex mixtures of strains, forming a bacterial population, which is equipped with the properties suitable for the production of the desired cheese. Since their composition would change depending on the conditions of cultivation [58], their subculturing is minimised and the cultures are preserved by freezing or lyophilisation.

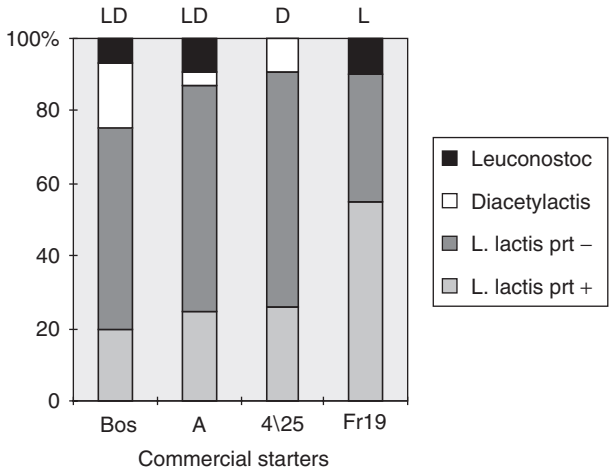

FIGURE 64.1 Composition of some commercial mixed-strain undefined starter cultures used for cheese making.

Also, the manufacture of Cheddar cheese and several other cheese types is entirely dependent on the fermentative activity of lactococci, sometimes in the form of defined-strain starters, consisting of *L. lactis* subsp. *lactis* varieties in case of Cheddar cheese, but frequently still in the form of undefined mixed-strain starters.

Mesophilic lactococci are generally considered to be associated with the milk environment [99], but they can also be isolated from other sources [65]. Lactococci isolated from artisanal manufacture of fermented dairy products without the application of industrially prepared starter cultures and from non-dairy environments are generally referred to as 'wild' lactococci. In an international project funded by the European Community many wild strains of lactic acid bacteria were isolated and partially characterised [21]. Initial studies showed that this pool of lactic acid bacteria contained many *L. lactis* strains, which differ in a number of phenotypic properties from the strains commonly present in industrial starters. Among those characteristics is the ability to form flavour components [122, 4, 5, 6]. This aspect, interesting for diversification in the manufacture of fermented dairy products, will be discussed below.

C. Mesophilic Lactobacilli

Although mesophilic lactobacilli are undoubtedly inhabitants of raw milk and the dairy environment, upon acidification of raw milk they are frequently overgrown by strong acidifiers of the genus *Lactococcus*. However, they do gain access to the cheesemaking process, because they are often found as secondary flora during the ripening of different cheese varieties. This is especially true for raw-milk cheese, but mesophilic lactobacilli are also common in cheese manufactured with modern technologies, using pasteurisation of the milk, defined-strain starters and hygienic processing. The starter is responsible for the acidification during the first stages of cheese manufacture and may reach up to 10^9 colony-forming units (cfu) per gram of cheese. During ripening, however, the number of starter cfu generally decreases rather quickly to lower than $10^7\,g^{-1}$, whereas subsequently the non-starter adventitious lactobacilli grow out and may reach numbers higher than those of the starter culture [103].

The secondary flora in Cheddar cheese have been examined most extensively; they consists mostly of mesophilic lactobacilli and sometimes include pediococci. These bacteria are collectively referred to as non-starter lactic acid bacteria (NSLAB). Isolates from this group belong to the species *Lactobacillus paracasei*, *Lb. plantarum*, *Lb. rhamnosus* and *Lb. curvatus*. The composition of the NSLAB in the cheese varies with the day of manufacture and with the age of the cheese [123, 21]. Adventitious NSLAB have also been reported for Emmental, Comté and other type of cheeses [29, 51, 13].

The NSLAB have the unique ability to grow under the highly selective conditions prevailing in a ripening cheese. Lactose is largely depleted in the first hours of cheese manufacture by the fermentation of the starter bacteria. The pH is between 4.9 and 5.3, the temperature below 13ºC, the moisture content less than 50%, the salt concentration in moisture is 4–6% and oxygen is barely available. All in all, the ripening cheese seems a hostile environment for micro-organisms. Yet, the adventitious lactobacilli manage to grow, obviously with a low rate, but the generally long ripening period allows them enough time to reach considerably high levels of cfu per g of cheese. They apparently consume compounds other than lactose such as lactate, citrate, glycerol, amino sugars, amino acids and perhaps even on material released from lysed starter bacteria. Although the NSLAB, like other lactobacilli, exhibit fastidious nutritional requirements, they clearly find ample opportunities for growth in a ripening cheese. They possess a wide range of hydrolytic enzymes and are able to effect proteolysis and lipolysis [62, 123].

Since NSLAB dominate the microflora of many long-ripened cheeses, they are believed to contribute to the maturation of cheese. The numbers of NSLAB are reported to be higher in Cheddar cheeses made from raw milk than in those from pasteurised milk [78]. Differences in flavour between these cheeses, with a more intense flavour in raw milk cheeses, suggest that the indigenous NSLAB play an important role in flavour development. Indeed, they have been shown to contribute to the formation of small peptides and amino acids, which are the precursors for the flavour components [45].

The observation that the presence of NSLAB in cheese on the one hand leads to a desirable flavour, and on the other hand may induce possible defects or spoilage [115, 114, 60] makes it a delicate choice for the cheese maker to use a certain lactobacillus as adjunct starter. This strain should be selected with care, because only a limited number of the NSLAB present in cheese combine all the required properties with the concomitant lack of imperfections. McSweeney et al [79] were successful in improving the flavour of Cheddar cheese by using strains isolated from raw milk cheese. This improvement was believed to be due to increased formation of amino acids. Cheese made from milk inoculated with strains of *Lb. plantarum* or *Lb. casei* subsp. *pseudoplantarum* received the best gradings [75].

D. Thermophilic Lactic Acid Bacteria

The thermophilic lactic acid bacteria are best known as starters for fermented milks. Several varieties of fermented milks originate from countries in Asia Minor and the Balkans, e.g. Bulgarian yoghurts. These yoghurt products have emerged from spontaneous acidification of raw milk by indigenous organisms, and have now been developed into microbiologically well-controlled industrial processes.

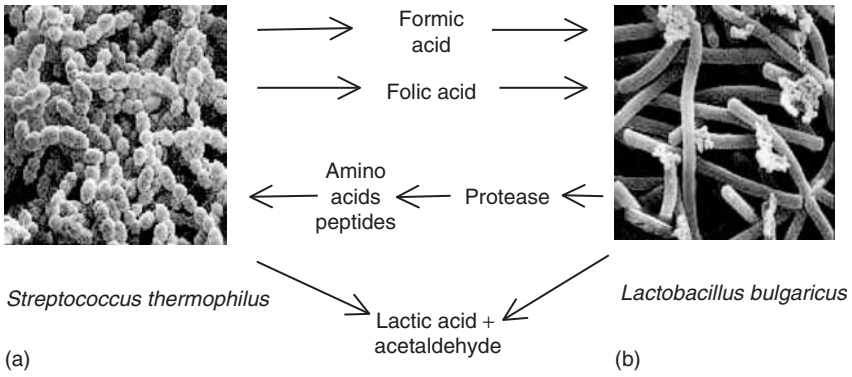

FIGURE 64.2 Proto-co-operation between *Streptrococcus thermophilus* and *Lactobacillus bulgaricus* in a yoghurt culture. This symbiosis results in an increased lactic acid and acetaldehyde (yoghurt flavour) production.

The two most frequently used starter bacteria are classified as *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus salivarius* subsp. *thermophilus*, generally shortened as *Lb. bulgaricus* and *S. thermophilus*, respectively.

Yoghurt is usually made by inoculating an equal mixture of *S. thermophilus* and *Lb. bulgaricus* in milk and incubating it at 37–45°C. *S. thermophilus* grows optimally at these temperatures and hydrolyses lactose via a β-galactosidase. *S. thermophilus* is nutritionally fastidious and requires a complex mixture of amino acids for growth. Since it is proteolytic negative, the coupling with the more proteolytic *Lb. bulgaricus* stimulates its growth in milk. The production of formic acid and carbon dioxide from lactose by *S. thermophilus* on the other hand stimulates the growth of *Lb. bulgaricus* (Fig. 64.2; [35]).

Thermophilic lactic acid bacteria also play an essential role in the manufacture of some cheese types. The starters of Swiss-type and Italian cheeses consist mainly of *S. thermophilus, Lb. helveticus* and *Lb. bulgaricus* [111, 9]. Also in the ripening of Greek hard cheese types made from ewes' and goats' milk, the thermophilic lactic acid bacteria play a dominant role [61]. The specific high cooking temperature used in the manufacture creates their niche in these cheese types. They convert lactose to lactic acid as in all dairy fermentations. This acid plays its usual role as preservative and, for the Swiss-type cheese, is the substrate for the subsequent propionic acid fermentation, leading to large eye formation in the cheeses.

Since thermophilic lactic acid bacteria were found to be very active, they are employed as adjunct cultures in the manufacture of various cheeses. In some cases they are specifically selected to address certain flavour aspects of cheese, e.g. bitterness. Smit et al. [104, 105, 106] reported on thermophilic lactic acid bacteria with high debittering activities, which were found to be very useful in debittering of cheeses made with a mesophilic starter culture which causes bitterness (Fig. 64.3). Various thermophilic adjunct cultures are also employed to enhance the formation of desired flavour notes in a given cheese.

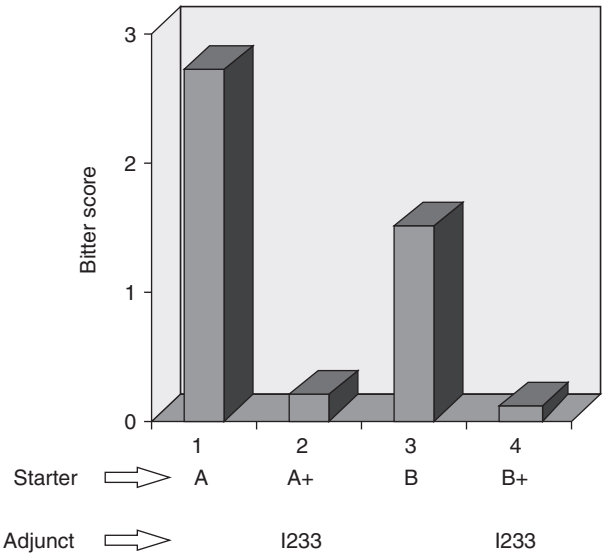

FIGURE 64.3 Effect of addition of the thermophilic adjunct culture I233 on the flavour development of a Gouda cheese after 3 months of ripening. The application of this adjunct culture results in a strong decrease in the bitter score during sensory evaluations. Starters A and B are known for the production of bitter-tasting peptides during cheese ripening.

E. Yeasts

Although yeasts play a minor role in dairy fermentations, several fermented milk products with a natural yeast-containing microflora exist. A distinctive feature of these products is that, in addition to the lactic acid fermentation induced by lactic acid bacteria, a slight alcoholic fermentation due to yeasts takes place [68, 93]. The best known examples of fermentation of milk by a combination of yeasts and lactic acid bacteria are kefir and koumiss, both originating from countries of Eastern Europe and Asia. The predominant species of yeast in kefir and koumiss are *Kluyveromyces marxianus, Candida kefir*, *Saccharomyces cerevisiae* and *Saccharomyces delbrueckii*. The heterogeneity of the

species found can be explained by the different techniques of kefir grain cultivation. Yeasts play an important role in promoting symbiosis among the micro-organisms present, CO_2 formation and development of the characteristic taste and aroma [67].

Yeasts are also involved in the ripening of surface-ripened cheeses. Their primary role is to lower the acidity of the cheese surface, which allows the development of a secondary microbial flora [95, 17]. Positive interactions between yeasts and starter organisms are well documented for semi-soft cheeses, like Limburger and Tilsit [43]. The yeasts metabolise lactate, which causes an increase of the pH, and may secrete factors that promote the growth of *Brevibacterium linens*, which is essential for the ripening of these cheeses [17]. Yeasts are also believed to promote the development of *Penicillium roquefortii* in blue cheeses. They may contribute to the open structure of these cheeses by formation of gas [22]. On the surface of Camembert, the dominating yeast flora inhibits the growth of the spoilage moulds. The most prominent yeasts in cheese are *Debaromyces hansenii, Kluyveromyces marxianus, Kluyveromyces lactis, Yarrowia lipolytica, Saccharomyces cerevisiae* and *Zygosaccharomyces rouxii* [8; 14].

F. Moulds

Moulds are mainly used in the manufacture of semi-soft cheese varieties together with the lactic acidifiers. Their major role is to enhance the flavour and aroma and to modify the body and the structure of cheese. On the basis of their colour and growth characteristics, they can be divided into white and blue moulds. The former type grows on the outside of the cheese, e.g. Camembert and Brie, and is known as *Penicillium camembertii.* The blue mould is named *Penicillium roquefortii* and grows inside the cheese. Examples of 'blue' cheeses are Roquefort, Blue Stilton, Danish Blue and Gorgonzola [113]. Several varieties of these two *Penicillium* species have been described in the past, but they should all be considered as biotypes. The characteristic feature of mould-ripened cheese is the extensive proteolysis and lipolysis. These biochemical activities ultimately result in the formation of precursors for the typical volatile flavour components of the cheeses. Methyl ketones have a key role in the typical flavour. There is a positive correlation between the free fatty acid level and the amount of methyl ketones formed, and cheeses with limited lipolysis score lower in flavour [52, 53]. Other typical compounds besides methyl ketones are secondary alcohols, esters, aldehydes and lactones. Various compounds arising from the proteolysis and amino acid conversion of course complete the aroma of these cheeses. Clearly, the flavour of mould-ripened cheese is a delicate balance of several compounds, produced by a succession of micro-organisms, which each performs their particular activity. Not only the choice of the *Penicillium* strain is important for the successful production of the soft surface mould cheeses; the selection the concomitant starters is also crucial.

Geotrichum candidum is used as one of the starters for the manufacture of the Finnish fermented milk viili and Camembert cheese. The starter of viili consists of mesophilic lactococci and *Leuconostoc* strains with *G. candidum*. Viili is made from non-homogenised milk and the fungus forms a mouldy layer on the cream. Its growth is generally limited due to the restricted amount of oxygen present in the container with the fermenting mixture [77]. *G. candidum* is one of the contributors to the flora that plays a key role in the ripening of Camembert cheese. It starts to grow on the surface of the rind of Camembert, Pont l'Evêque and Livarot cheeses at the beginning of the ripening process and contributes to typical cheese flavours [57, 81]. Most notably, *G. candidum* is known for its potential to form sulphur-containing flavour components, which contribute to the typical flavour characteristics of Camembert cheeses [30, 11, 108].

G. Other Bacteria

Finally, some other groups of bacteria, which have not been covered above, are nevertheless worth mentioning. The propionic acid bacteria constitute the essential secondary flora in Swiss-type cheese. After the homofermentative lactic acid fermentation, they convert lactate into propionate, acetate and carbon dioxide. The latter is responsible for the characteristic eye formation in these cheeses. Interest in the role of propionic acid bacteria in flavour formation has recently been renewed [48]. Also for this group of bacteria, the raw milk environment appears to be a versatile and interesting source of strain variation [42].

A second group of bacteria, which play a major role in the maturation of surface-ripened cheese, comprises the brevibacteria and other coryneform bacteria. They are obviously present in the smear of these cheeses and are strongly proteolytic, which results in high levels of sulphur-containing volatiles [16, 17]. They also show some lipolytic and esterolytic activity, and produce distinct red-orange pigments [92]. The variation in proteolytic activity, antimicrobial activity and pigment biosynthesis in these bacteria may offer opportunities for the selection of appropriate variants for specific applications in the manufacture of smear-ripened cheeses or even other types of cheeses [15].

IV. STARTER FUNCTIONALITIES

As listed above, various micro-organisms are used as a starter culture for the production of fermented products, e.g., dairy products. Apart from acidification and thus preservation, it is found that these organisms often possess certain characteristics, which offer specific benefits to the consumer. These benefits are now leading in the development of new and improved starter cultures. A number of

specific characteristics will be discussed below. Special attention is paid to the flavour-forming abilities of starter cultures, since flavour perception is the most prominent motivator for the consumer to choose a food product.

A. Bacteriocins

Different lactic acid bacteria are able to produce bacteriocins, proteinaceous substances with bactericidal activity against micro-organisms closely related to the producer strain [63, 64, 26; 89]. Lactic acid bacteria are generally regarded as safe micro-organisms and so are their bacteriocins. Thus these bacteriocins can potentially be used to control the growth of spoilage and pathogenic organisms in food [32]. Bacteriocin-producing lactococcal strains have been used successfully in starter cultures for cheese-making in order to improve the safety and quality of the cheese [73, 76, 28]. For instance, the use of nisin-producing starter cultures was found to effectively reduce the spoilage by *Clostridium tyrobutyricum* strains (Fig 64.4).

Recently it was found that the production of bacteriocins and bacteriocin-like compounds is a property which is very common among strains isolated from natural sources [65, 21, 39, 7]. This phenomenon can possibly be explained by the fact that the ability to produce antimicrobial compounds offers these wild strains the power to withstand the competition of other micro-organisms and thus to survive in their hostile natural environment. The bacteriocin-producing wild lactococcal strains may be useful as starters in cheese making, not only because of their antimicrobial activity but also because of their potential to synthesise interesting flavour compounds (see below). These strains should then be combined with other strains, which are bacteriocin-resistant.

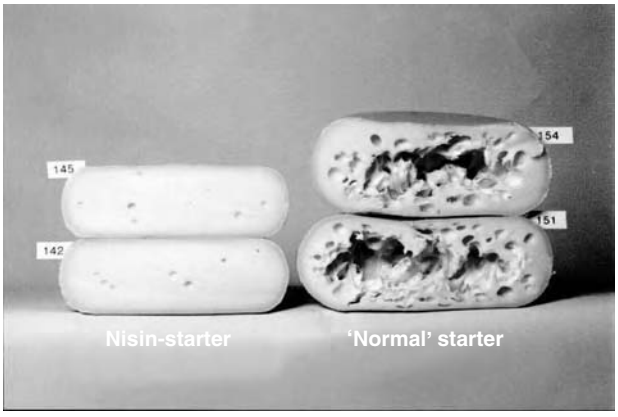

FIGURE 64.4 Effect of a nisin-producing starter culture on the reduction of growth of *Clostridium tyrobutyricum* after 12 weeks of ripening. In the absence of nisin ('normal' starter), this bacterium causes excessive gas formation leading to large holes in the cheese and a strong off-flavour.

B. Vitamin Production

Lactic acid bacteria are able to produce certain vitamins, for in yoghurt a higher concentration of folic acid is found than in milk [44]. *S. thermophilus* is known to produce folic acid during growth in milk [90, 91]. The amount of folic acid found in cow's milk ranges from 20 to 60 µg L^{-1}, whereas its concentration in yoghurt may be increased depending on the strains used for the fermentation and on the storage conditions to values above 200 µg L^{-1}. This level appears also to be dependent on the strain of *Lb. bulgaricus* used, because the latter organism has been shown to use and to degrade folic acid during its growth [124]. It is therefore of utmost importance to select the optimal combination of *S. thermophilus* and *Lb. bulgaricus* strains leading to organoleptically acceptable yoghurt with concomitantly an increased folic acid concentration. The pools of available strains will undoubtedly harbour such strains.

C. Exopolysaccharides

By producing exopolysaccharides, both *S. thermophilus* and *Lb. bulgaricus* contribute to the viscosity and the smooth texture of fermented products like yoghurt. They stabilise the gel and decrease its tendency to synerise [102]. These bacteria produce rather low amounts of exopolysaccharides with a wide variety of chemical structures. Glucose, galactose and rhamnose are its main monomers and the composition might be affected by the fermentation conditions [74, 120]. The chemical structure of the polymer apparently has an effect on the rheological properties, because the use of different starters results in differences in its microscopic structure and viscosity [119]. The underlying mechanism of this effect, however, is not well understood. The emerging knowledge on the genetics of exopolysaccharide biosynthesis *by L. lactis* and *S. thermophilus* strains (Fig. 64.5;

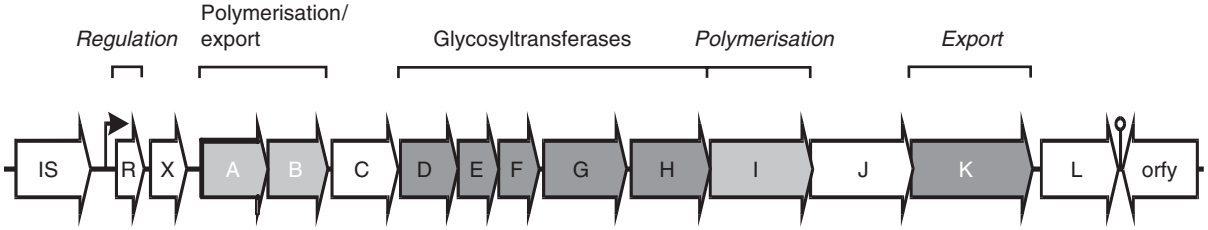

FIGURE 64.5 Genetic map of the genes involved in EPS production in *L. lactis*. (adapted from Van Kranenburg et al. 2000 [117]).

[112, 117]) will offer opportunities to modify the structure of the polymer and to regulate the amount synthesised.

D. Eye Formation

Lactic acid bacteria are able to ferment citrate, which is present in many raw materials used for food fermentations such as fruit, vegetables and milk. Citrate can be fermented by a limited amount of mesophilic lactic acid bacteria [59, 83] for a review). Its degradation results in acetate, diacetyl, acetoin, 2,3-butanediol, and CO_2. Besides the formation of the flavour component diacetyl, which is a crucial flavour attribute in buttermilk, ripened cream butter, sour cream, and quark, the formation of CO_2 is responsible for eye formation in cheese.

In the production of Swiss-type of cheeses, such as Gruyere, Emmental and Maasdammer, propionibacteria are used to achieve the characteristic sweet and nutty flavour notes as well as the large eyes. Various metabolic pathways have been described for the utilisation of lactate as energy source and aspartate as electron acceptor [24]. The eye-formation in Swiss-type of cheese can be controlled by a combination of aspartate-weak propionibacteria in combination with facultative heterofermentative lactobacilli [46].

E. Probiotic Features of Starter Cultures

Probiotics are live microbial food supplements, which benefit the health of consumers by maintaining, or improving their intestinal microbial balance [47]. Species of *Lactobacillus* and *Streptococcus* have traditionally been used in fluid fermented dairy products to promote the human health [98]. These probiotic starters may influence the microbial ecology of the host, lactose intolerance, incidence of diarrhoea, mucosal immune response, levels of cholesterol and cancer. Besides the traditional carrier of probiotics, which is yoghurt, the market share of probiotic drinks is expanding rapidly. The most common probiotic strains are lactobacilli. A number of them are now being successfully commercialised, such as *Lactobacillus rhamnosus* GG [101], *L. casei* Shirota [3] and *L. acidophilus* LA-1 [12]. The scientific basis of these strains in relation to their proposed positive effects on the human health is quite extensive, however most of the evidence is obtained with diseased human populations. Evidence for probiotic claims in healthy populations has still a weak basis.

V. FORMATION OF FLAVOUR COMPOUNDS DURING FERMENTATIONS

Flavour development in fermented products results from a series of (bio)chemical processes in which the starter cultures provide many of the enzymatic activities. Particularly the enzymatic degradation of proteins leads to the formation of key-flavour components, which contribute to the sensory perception of the products [36, 37, 107]. In the following section, the flavour forming enzymes of lactic acid bacteria will be discussed, with dairy products as the main example. On the other hand, it is important to note that very similar activities can be found in other fermented products, such as meat and sourdoughs.

The formation of flavours in fermented dairy products is a complex and, in the case of cheese ripening, rather slow process involving various chemical and biochemical conversions of milk components. Three main pathways can be identified: the conversions of lactose (glycolysis), fat (lipolysis), and caseins (proteolysis) (Fig. 64.6). The enzymes involved in these pathways are predominantly derived from the starter cultures used in these fermentations.

In the case of the lactose fermentation, the main conversion obviously leads to the formation of lactate by LAB, but a fraction of the intermediate pyruvate can alternatively be converted to various flavour compounds such as diacetyl, acetoin, acetaldehyde, or acetic acid, some of which contribute to typical yoghurt flavours.

Lipolysis results in the formation of free fatty acids, which can be precursors of flavour compounds such as methylketones, alcohols, and lactones. Lactic acid bacteria contribute relatively little to lipolysis, but additional cultures, e.g. moulds in the case of surface-ripened cheeses [82] often have high activities in fat conversion. Flavours derived from the conversion of fat are particularly important in soft cheeses like Camembert and Roquefort.

The conversion of caseins is undoubtedly the most important biochemical pathway for flavour formation in hard-type and semi-hard-type cheeses [118]. Degradation of caseins by the activities of rennet enzymes, and the cell-envelope proteinase and peptidases from lactic acid bacteria yields small peptides and free amino acids. A good balance between proteolysis and peptidolysis prevents the formation of bitterness in cheese [104, 105]. Although it is known that peptides can taste bitter and that amino acids can taste sweet, bitter, or broth-like [84], the direct contribution of peptides and amino acids to flavour is probably limited to a basic taste [36]. For specific flavour development,

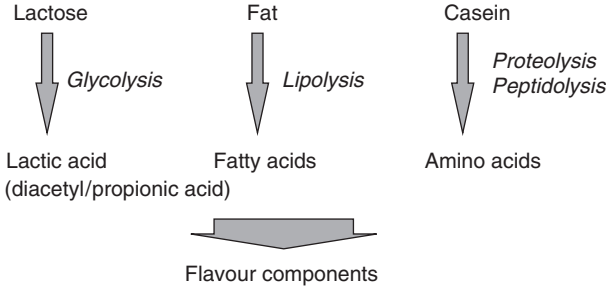

FIGURE 64.6 General conversions of the milk constituents during the ripening of cheese. Three main pathways can be distinguished. The pathway from casein is the most important one, leading to typical cheese flavours.

further conversion of amino acids is required to various alcohols, aldehydes, acids, esters and sulphur compounds. The current knowledge on these pathways is shown in Figure 64.7.

A. Proteolysis Leads to Peptides and Free Amino Acids

Since the concentrations of free amino acids and peptides are very low in milk, the starter cultures depend for growth in milk heavenly on their proteolytic systems. The degradation of milk proteins (caseins) leads to peptides and free amino acids, which can subsequently be taken up by the cells [69, 23]. Proteolysis is initiated by a single cell-wall-bound extracellular proteinase (Prt), which can be either chromosomally or plasmid-encoded. While most dairy LAB strains contain such an extracellular proteinase, several do not and these are mainly dependent on other strains in the starter culture for the production of peptides and amino acids. Such dependency of strains is rather common in starter cultures, and indicates the relevance of knowledge on the population dynamics between strains in order to be able to develop stable starter cultures.

Peptide and amino acid transport systems have been studied extensively in lactococci, but far less is known for other lactic acid bacteria such as mesophilic and thermophilic lactobacilli (see for a review Kunji et al. [69]). Peptide and amino acid uptake occurs via oligopeptide transport systems, di-/tri-peptide transporters, and various amino acid transport systems [66]. Following uptake, the peptides are degraded intracellularly by a variety of peptidases [69, 23]. These peptidases of lactic acid bacteria can be divided into endopeptidases, aminopeptidases, di-/tripeptidases, and proline-specific peptidases. The specialised peptidases in LAB for hydrolysis of Pro-containing peptides have been postulated to be important for the degradation of casein-derived peptides, since these are known to have a high proline content.

The balance between the formation of peptides and their subsequent degradation into free amino acids is very important, since accumulation of peptides might lead to a bitter off-flavour in cheese [109, 121, 104, 105]. Various bitter-tasting peptides have been identified and especially these peptides should be degraded rapidly in order to prevent [109, 121, 70]. Specific cultures have been selected with high bitter-tasting-peptide degrading abilities [104, 105] and such cultures are nowadays frequently used in the preparation of various types of cheese (Fig. 64.3).

The ability of cultures to degrade bitter-tasting peptides was not only found to be dependent on the strain used, but also on the growth conditions. For example, it was found that pH-controlled growth conditions resulted in a higher debittering activity [106]. The mechanism behind these differences was found to be strongly correlated with the sensitivity of the cells to lyse. Meijer et al. [80] showed that the introduction of a transposon in *L. lactis* SK110 not only increased the stability of the cells, but also the bitterness in cheese made with this culture. These results

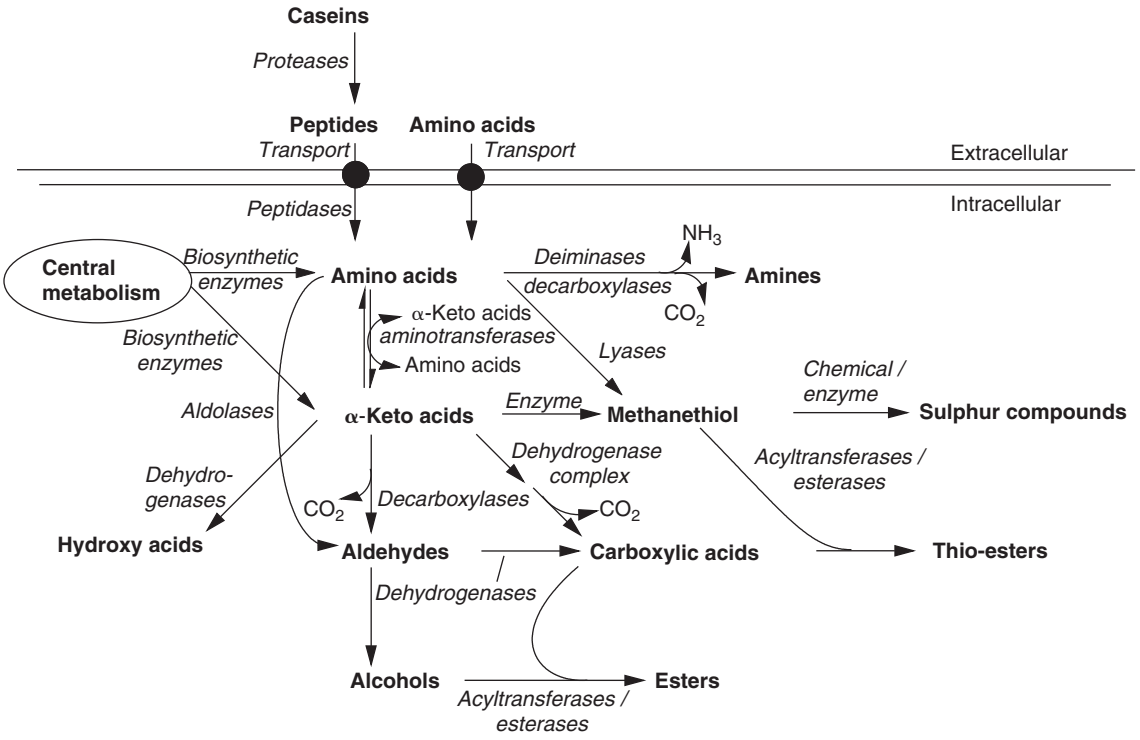

FIGURE 64.7 Pathways from amino acids to flavour compounds (adapted from Van Kranenburg et al. 2002 [118]).

indicate that the cell membrane can be a barrier between the enzymes, located intracellularly, and the peptide substrates, present in the cheese matrix. Apparently, there is not enough active transport anymore with the starter cultures once they are present in the cheese matrix for a certain ripening time.

B. Amino Acid Converting Enzymes (AACEs)

Amino acids are the precursors of various volatile cheese flavour compounds, which have been identified in cheese Engels and Visser, 1996; Engels, 1997]. They can be converted in many different ways by enzymes such as deaminases, decarboxylases, transaminases (aminotransferases), and lyases (Figure 64.7). Transamination of amino acids results in the formation of α-keto acids that can be converted into aldehydes by decarboxylation and, subsequently, into alcohols or carboxylic acids by dehydrogenation. Many of these components are odour-active and contribute to the overall flavour of the dairy product. Moreover, other reactions may occur, e.g. by hydrogenase activity towards α-keto acids resulting in the formation of hydroxyacids, which contribute little to the flavour.

Using biochemical and genetic tools, various flavour-forming routes from amino acids and enzymes involved have recently been identified, mostly in *L. lactis* (see [128, 107 and 118] for a review).

Aromatic amino acids, branched-chain amino acids, and methionine are the most relevant substrates for cheese flavour development. Conversion of aromatic amino acids can result in formation of undesirable flavours, so-called *off-flavours*, such as *p*-cresol, phenylethanol, phenylacetaldehyde, indole, and skatole, which contribute to putrid, faecal or unclean flavours in cheese [23]. Many of these reactions can also occur under cheese conditions and are highly dependent on the strain used [49]. This implies that by target selection of starter bacteria the formation of undesirable flavours can be avoided. A similar strain dependency is also found for enzyme activities, which result in the formation of desired flavour compounds, indicating that a strong potential for starter improvement exists (see below).

Conversion of tryptophan or phenylalanine can also lead to benzaldehyde formation. This compound is found in various hard-type and soft-type cheeses and contributes positively to the overall flavour [37, 82]). In *Lb. plantarum* as well as in other LAB, the formation of benzaldehyde out of phenylalanine is initiated by an aminotransferase reaction followed by a chemical conversion of the intermediate phenylpyruvic acid into benzaldehyde [86, 85]. The latter reaction requires the presence of manganese, for which an efficient uptake system was found [87]. Since this chemical conversion occurs at a high pH and in the presence of oxygen, it is not very likely a main conversion pathway in cheese.

Branched-chain amino acids are precursors of various aroma compounds such as isobutyrate, isovalerate, 3-methylbutanal, 2-methylbutanal and 2-methylpropanal. These compounds are found in various cheese types. Several enzymes that are able to convert these amino acids have been detected in *L. lactis* (see [128, 107 and 118] for a review). The aromatic aminotransferases can convert aromatic amino acids, but also leucine and methionine, while the branched-chain aminotransferases can convert the branched-chain amino acids leucine, isoleucine and valine, but also methionine, cysteine, and phenylalanine.

Volatile sulphur compounds derived from methionine, such as methanethiol, dimethylsulphide, and dimethyltrisulphide, are regarded as essential components in many cheese varieties [116]. In fact, a Gouda cheese-like flavour can be generated by incubation of methionine with cell extracts of *L. lactis* [36]. Conversion of methionine can occur via a aminotransferase-initiated pathway by branched-chain or aromatic aminotransferases, or via an α,γ-elimination of methionine by the lyase activities of cystathionine β-lyase (CBL), cystathionine γ-lyase (CGL), or methionine γ-lyase (MGL) (Figure 64.2) [1, 18, 33, 34, 38, 49, 50, 96, 125, 40, 41, 118].

It was found that the amount of α-keto acids determines the rate of the first step in the conversion of amino acids. Overproduction of the transaminases alone did not lead to a strong increase in amino acid conversion without a simultaneous addition of keto acids as co-substrate [126]. The introduction of a glutamate dehydrogenase gene from *Peptostreptococcus* in *L. lactis* resulted in a similar effect [97]. However, whether this activity also results in a strong increase in the desired flavour components remains to be determined. Ayad et al. [6] found that also the presence of enzymes required for subsequent conversions might be of crucial importance (Fig. 64.8).

Although cystathionine lyases are active under cheese-ripening conditions [1], their activity towards methionine

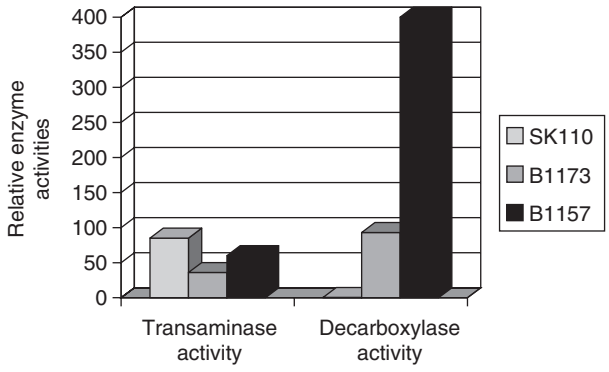

FIGURE 64.8 Variation in enzyme activities between industrial (SK110) and wild *L. lactis* (B1173 and B1157) strains in the two-step conversion of leucine towards 3-methyl aldehyde. The largest difference was found in step 2; the decarboxylation of the ketoacid towards the aldehyde.

could not be detected using ^{13}C nuclear magnetic resonance [49]. With this technique, only the aminotransferase-initiated pathway was observed suggesting that this pathway is most prominent in methionine catabolism to produce methanethiol. On the other hand, strains that overproduce cystathionine β-lyase, where found to be able to degrade methionine, indicating the potential of this enzyme in the production of sulphury flavours [40, 41]. The specificity of CBL [1] is a particular advantage in this respect, since one might expect that only sulphury flavour components would increase in strains with high activity. In case of overproduction of other less-specific enzymes such as transaminases more pathways will be influenced at the same time.

Biosynthesis and degradation of some amino acids are intricately coupled pathways. For instance, the above mentioned cystathionine β-lyase can convert methionine to various volatile flavour compounds, but in bacteria its physiological function is the conversion of cystathionine to homocysteine, which is the penultimate step of methionine biosynthesis [118]. This means that many of the AACEs are in fact involved in the biosynthesis of amino acids. It is well known that biosynthesis of amino acids is highly regulated, and therefore the growth conditions of the starter cultures might affect their flavour forming capacities. For instance, in *L. lactis* the expression of the gene coding for cystathionine β- lyase is strongly influenced by the amounts of methionine and cysteine in the culture medium [40, 41]. High concentrations of these amino acids completely abolish transcription and result in *L. lactis* cells almost deficient of cystathionine β-lyase activity.

Similarly, it is found that the branched-chain aminotransferase is also regulated at the transcriptional level in *L. lactis* [127]. The physiological role of branched-chain aminotransferases in bacterial metabolism is to catalyse the last step in the biosynthesis of branched-chain or aromatic amino acids. Several enzymes can thus been considered as being involved in both biosynthesis and degradation of amino acids, and α-keto acids are intermediates in both directions. These examples illustrate that the choice of culture conditions can strongly influence the flavour-forming capacities of starter cultures like *L. lactis*.

C. Natural Biodiversity

It is already mentioned that various lactic acid bacterial strains differ in amino acid converting abilities and that these activities are in fact linked to the ability to synthesise amino acids. [4, 5] focused on the flavour-forming and the amino acid forming abilities of *Lactococcus* strains isolated from various natural sources, the so-called 'wild lactococci' (Fig. 64.8). These strains originated from dairy and non-dairy environments and they were found to have unique properties, when compared to commercially available starter strains. For instance, many of these strains do not degrade caseins, produce antimicrobial compounds and/or have low acidifying activity. When the amino acids forming capacities of these strains were determined using the single omission technique [20], it was found that these strains had a much larger potential to synthesise amino acids as compared to industrial strains. Lactococci used in dairy fermentations are known for their limited capacity for biosynthesis of amino acids, which explains their complex nutritional requirements; they require several amino acids for growth [2, 94, 19, 4]. For instance, most dairy *Lactococcus* strains need glutamate, valine, methionine, histidine, serine, leucine and isoleucine. Industrial *L. lactis* subsp. *cremoris* strains require even more different amino acids for growth [4]. Wild *L. lactis* subsp. *cremoris* strains generally require two to three amino acids while some *L. lactis* subsp. *lactis* strains only need one amino acid. The absence of some amino acid biosynthetic pathways in dairy lactococci might be a consequence of their adaptation to dairy products, since in milk, the amino acids are readily available from the proteolytic degradation of caseins. Wild strains are not naturally associated with a rich environment such as milk, which makes them more dependent on their own biosynthesis of amino acids compared to industrial strains. The large natural biodiversity, which is found within LAB species, offers good possibilities for flavour diversification. It can obviously also be applied in various other fermented food products.

VI. CONCLUSIONS AND FUTURE PERSPECTIVES

Fermented products bring the consumer a sense of appreciation, which is by enlarge due to the interaction of the right starters cultures, technology and care in manufacturing. The starter cultures play a specific role in this respect and for that reason deserve specific attention. Not only are the starter cultures responsible for the preservation, due to lowering of the pH or increase of ethanol, but they also form various important compounds, most notably flavour components, which contribute directly to the perception of the consumers.

This knowledge makes it necessary to put special emphasis on the research in the area of starter cultures and their functionalities. Especially in view of the natural biodiversity, which still exists in food-grade micro-organisms, it is important to preserve this pool of microbial strains for future applications. The product innovator is challenged to use strains from them in his trials to create the flavour or other attributes the consumer demands.

The variation in microbes and their intrinsic biochemical potential is huge in size. This will make it necessary to have a better understanding of the enzymatic pathways in these starter cultures, in order to be able to select strains with specific desired characteristics. For instance, the rapidly growing knowledge of pathways prevailing in these bacteria which are active in the flavour formation offers

new insights in the required properties of a given starter culture. This should lead to the design of probes to screen collection of microbes (pools of genes) very effectively for the presence of certain desired traits. Moreover, apart from the best-studied examples of starter cultures, e.g. the lactococci, also other micro-organisms receive more attention recently. This will even enlarge the potential possibilities in this field. An interesting time is ahead of us, not only from a scientific point of view, but also from the perspective of manufacturers of fermented products.

ACKNOWLEDGMENT

The information in this chapter has been modified from "Quality and flavor of fermented products," by G. Smit, J. T. M. Wouters and W. C. Meijer. In *Handbook of Food and Beverage Fermentation Technology.* Editors: Y. H. Hui et al. Marcel Dekker, New York, 2004.

65 Meat Fermentation: Principles and Applications

Daniel Demeyer
Department of Animal Production, Ghent University

CONTENTS

I. INTRODUCTION

Fermented foods can be defined as products whose specific properties are mainly due to the effects of bacterial metabolism during their manufacture. Although meat products are not the most representative examples of fermented foods, it is clear that microbes contribute to both the conserving and flavouring effects of salt added to meat, a practice dating back to the Neolithicum, e.g. anywhere between 5,000 and 10,000 years ago (1). Such contributions are evident when the meat surface flora is evenly distributed by chopping, grinding or comminution of the meat together with the salt. The stuffing of such mixture into a casing produces a « sausage », a product first referred to in writing by Homerus in 900 BC. Centuries BC, a similar product (« lup-cheong ») was already produced in China, adding more sugar however than salt as a preservative. Since these beginnings, variable degrees of mixing and comminution of different « meats » with salt, together with spices, herbs and other plant material have been applied, resulting in a range of products, the stability of which is mainly determined by a combinations, varying in relative importance, of

- acidulation, brought about by lactic acid production and
- lowering of water activity (a_w), brought about by the addition of salt (« curing ») and drying.

Campbell-Platt (2) discusses 36 whole and 56 comminuted fermented meat products, including e.g. an East-African sausage made from fat and bones, a ham like product made by the Greenland Inuits from the eider duck, as well as 33 species of country or raw ham. The contribution of microbial activity in the production of large whole meat products is limited: as the meat interior

is practically free of microbes, the specific characteristics of such products are largely determined by remaining muscle proteolytic and lipolytic activity (3), with a limited contribution of bacterial activity to nitrate reduction, color formation and acceleration of salt introduction by some lactic acid production (4). This introductory discussion will therefore be limited to comminuted products or sausages, subjected to a variable combination of fermentation and drying. The first production of such "fermented sausages" started in Italy in 1730 and spread from there to Germany, Hungary and other countries, including the U.S. and Australia. The basic concept of processing involves comminution of muscle and fat tissue with salt, nitrate and/or nitrite and spices including eventually sugar, starter cultures and other additives such as non meat proteins. After stuffing the mixture into a casing, the resulting sausage is left to ferment and dry. This "ripening" often occurs in two consecutive and separate stages, referred to as fermentation and drying respectively. The lowering of a_w resulting from the presence of salt and drying and the exclusion of O_2 selects for salt tolerant lactic acid bacteria, producing lactic acid from carbohydrates added or present. This lowers pH to final values between 4.5 and 5.5, inducing denaturation of salt solubilised protein to a gel structure that can be sliced. The adequate (fast) reduction of pH and the lowered a_w ensure both product stability and safety. Once these basic requirements are met, the production technology allows for many but imprecise variations, yielding a variety of very different products. A broad distinction can be made between:

- Northern type products (NP): they contain beef and pork and are characterised by relatively short ripening periods, up to about 3 weeks, involving clearly separated fermentation (about 3 days) and drying periods. Rapid acidulation to final pH values just below 5 followed by product dependent weight losses during drying ensure safety and shelf life. Smoking is applied to add specific flavour (taste and aroma).
- Mediterranean or Southern type products (MP) are predominantly pure pork products and production involves longer ripening periods, up to several months. Fermentation occurs at lower temperatures (ca. 20°C vs. ≥25°C), and acidulation to final pH values above 5 is therefore slower and often not clearly separated from drying. Superficial mold growth is often involved, smoke is not applied (with the exception of Hungarian type salami) and shelf life is mainly determined by drying and lowered water activity.

More detailed or official classification of fermented sausages is done in various ways, based on e.g. moisture content, moisture/protein ratio, weight loss, water activity a_w, surface treatment, texture and fat particle size. It has become increasingly clear that the major characteristics of these products are determined by numerous interactions within the trialogue (meat + fat) − (micro-organisms) − (processing technology), whose control presents a considerable challenge to standardization and management of quality. Such lack of control — and thus standardization — is apparent from the between and in batch variability observed in the levels of end products of biochemical changes as well as of volatile flavour compounds, showing variation coefficients between 15 and 35% and exceeding 50% respectively for both NP and MP in a collaborative European project (5, 6). Several aspects of each actor in the trialogue determining variability have been discussed in several recent papers on e.g. meat enzymes (7), the role of bacteria in flavour development (8), the control of bacteriological safety (9), starter cultures (10), overall sausage metabolism (11) and process engineering (12). This paper does not want to add to existing excellent comprehensive literature reviews (4, 11) but to briefly summarize some aspects of the subject, emphasizing the importance of interactions for product quality. The text is inspired mainly by the long term interest of the author's laboratory in an integrated approach to sausage fermentation (13, 14, 15) and the role of muscle enzymes (16).

II. SAUSAGE MANUFACTURE

Table 65.1 lists representative conditions for industrial production of both NP and MP, as studied in a recent collaborative research project (6).

A. Ingredients

1. Meat and Fat

The meat/fat ratio is 2/1 in most industrial sausage mixes, containing 50–70% of frozen and "tempered" (≈−4°C) lean meat, consisting of pork and beef in equal amounts for NP and exclusively pork for the more valued MP. For pork, ham trimmings, shoulders and bellies are used, as well as jowls and throats, in proportions determined by the sausage quality level as reflected in more than twofold price differences (F. Vandendriessche, personal communication, 2002). Pork necks are avoided as well as beef head meat, because of risks of antibiotic and BSE contamination respectively. Only frozen (≤−18°C) pork back and belly fat (excluding less firm sites from the groin and teat line) after removal of rind (lard) and classified according to a visual estimation of fat content (50% vs. 30% respectively) are used as fat source. Pork rind may be added after cooking. Lard and "sausage meat" account for about 10% and 20% of the pig carcass respectively (17) and classic selection criteria for these raw materials are mainly based on bacteriological

TABLE 65.1
Main Production Characteristics for Northern and Mediterranean Types of Fermented Sausages Produced in Belgium (6)

Characteristic	Northern Type	Mediterranean Type
Diameter (mm)	90	60
Weight	1 kg	0.8 kg
Meat species	pork/beef, 1/1	pork only
Lean meat cuts	pork shoulder + beef	shoulder
Fat tissue	Pork back fat	Pork back fat
Meat/fat ratio	2/1	2/1
Starter bacteria (CFU)	$+10^7$/g[b]	$+10^7$/g[c]
Additives (g/kg)[e]		
NaCl	30	30
Nanitrite[f]	180	180
Knitrate[f]	0	0
Saccharose	0	0
Dextrose	7	7
Na-ascorbate	0.9	0.9
Ascorbic acid	0	0
Skimmed milk	0	0
Caseinate	11.5	11.5
Spices[f]	7000[h]	7000[h]
Fungial starters	−	+
Particle size	1–2 mm	1–2 mm
Smoking	+	−
Ripening conditions		
Fermentation		
°C/hrs	20–26/62	5–24/113
pH after 24hrs	5.70	5.80
3 days	4.68	5.20
%rH/hrs	50–90/62	10–90/89
Drying		
°C/% rH	14/78	14/78
Total ripening time	2 weeks	4 weeks

[a] Unspecified *Lactobacillus* [b] 2.10^6 each of *Pediococcus pentosaceous* and *Lactobacillus Sake* as lactic acid bacteria and *Staphylococcus xylosus, Kocuria varians* and *Staphylococcus carnosus* as flavor enhancers. [c] 7.10^5 each of *Pediococcus pentosaceous* and *Lactobacillus Sake* as lactic acid bacteria with 4.10^6 and 2.10^6 of *Staphylococcus xylosus* and *Micrococcus varians* (now properly called *Kocuria varians*) respectively as flavor enhancers. [d] A commercial powder containing a mixture of *Lactobacillus curvatus* and *Kocuria varians* (2.10^{10}/g) was used (50 g/100 kg). [e] per kg meat and fat mince [f] mg/kg [g] oleoresins containing mainly black pepper, with coriander, paptika and cognac (140 mg/kg) and garlic (400 mg/kg) [h] pure black pepper only [i] cracked whole black pepper (700), white pepper (300) and garlic (100).

quality and pH (<5.8) and on oxidation status and unsaturation of fat (<12% of polyunsaturated fatty acids, minimal peroxide vlue) (18,19). Recent developments however report the use of differently specified alternative sources of "meat" and fat as well as the need for more specification for actual meat and fat to improve flavour in the more valued products. Technology for producing fermented sausage from poultry, including ostrich (20), from carp (21) and using olive oil (22) has been proposed. Lyophilized meat can be incorporated to shorten drying time (23), but this may require the lowering of salt addition, unless used after rehydration (24). For the more valued MP, muscle protease and muscle and fat lipase activities are probably important for (spieces dependent) sausage flavour development (25) as described for raw ham (3). Relationships of pig muscle enzyme activities with both carcass and meat quality have been demonstrated (26, 27). Analogous to suggestions made for raw ham production, enzymes and corresponding genes might be considered for specification of raw materials (3) and selection of animals (28) in the production of fermented sausages.

2. Additives

Generally used additives and their ranges of incorporation level include salt (2–4%) containing $NaNO_2$ (80–240 mg/kg aded as curing salt containing 0.4–0.6% $NaNO_2$), glucose (0.5–1%), sodium ascorbate or ascorbic acid (0.5–1%) and spices. The use of nitrite is considered essential because of its antibacterial, color forming, anti-oxidant and flavouring properties. The use of lower nitrite levels, imposed because of health considerations, requires adaptation of technology including e.g. minimal fermentation temperatures and oxygen free chopping (29). For MP part or all of the nitrite is substituted for by KNO_3, although there is little technological and microbiological necessity for the use of nitrate and its reported positive effects on colour and flavour development may in fact be more related the accompanying lower nitrite levels (30, 4). Both the amounts and the nature of carbohydrates have been related to the rate and extent of acidulation (31) but only the use of lactose clearly results in lowering both rate and extent of acidulation (32) whereas its residual presence may improve sensory quality (33). Optimal levels of glucose (dextrose) are reported to be 0.3 and 0.7% for MP and NP respectively (34). Both ascorbate and ascorbic acid are used to improve stability of the red nitrosylated pigment, an effect closely associated with the prevention of lipid oxidation. Both effects may also associated with the presence of anti-oxidants such as BHT and vitamin E in the raw materials, due to their use in animal feeding. However, although protective effects on lipid oxidation and colour stability of supranutritional dosing of animal feeds with γ-tocopherol are clear for beef, and less so, for fresh and cured pork (35), it would seem that it cannot prevent sausage colour deterioration due to incorporation of polyunsaturated fat (36). Ground pepper (0.2–0.3%) is usually present in all types of sausages and especially MP may contain higher levels (1–3%) of other spices such as paprika and garlic that were shown to be effective anti-oxidants, comparable to ascorbate (37). Besides yielding flavor compounds, spices may stimulate lactic acid bacterial activity, e.g., by supplying manganese, and decontamination should be considered (38). Apart

from these "classic" additives, additional additives are sometimes used for NP: phosphates (0.5%) to improve stability vs. oxidation (39), glucono-δ-lactone (GdL, 0.5%) to ascertain fast but chemical acidulation with generally negative effects on flavor development and vegetable proteins (mainly soya isolate) that may also accelerate fermentation (40).

3. Starter Cultures

Starter bacteria were first introduced in the US to ensure rapid fermentation. In Europe, lower fermentation temperatures were and are more common and, certainly in MP, rapid fermentation results in color and flavor defects. In order to avoid the latter, *Micrococci* were introduced as starters by Niïvaara (41). Although excellent fermented sausages can be produced without the addition of starter cultures or re-inoculation with finished sausages, the majority of fermented sausage produced in Europe nowadays makes use of "combined" starter inoculation ($1–2.10^6$/g) as frozen cultures of both *Lactobacilli* and *Micrococcaceae* to ensure rapid acidulation and optimal flavor development respectively (4). Their desired properties have been discussed at length (e.g., 42) and obviously include lag time and rate of lactic acid production for *Lactobacilli* and the resistance of *Micrococcaceae* to an acid environment. Inhibition of the latter by rapid acidulation was indeed found to impair the typical flavor of MP (43). For flavor development lipolytic and proteolytic activities have long been emphasized. It is now realized however that muscle and fat tissue enzymes are by far the more important actors in this respect and more important selection criteria for flavor producing starters such as *S. carnosus* may be their potential for leucine degradation to 3-methyl butanal and for protection of poly-unsaturated fatty acids against oxidation (5, 8). Attention has also been directed recently to biogenic amine (44) and bacteriocin (45) production by starter bacteria. These aspects are considered of less importance, as raw material quality and processing appear to be the main factor controlling amine production (46), and bacteriocin effects are bound to be limited (10). Bacterocin production by *L. sakei* strains, isolated from fermented sausages, may however contribute to safety, without inhibition of *Micrococcaceae* and, thus, of flavor development (46, 47). Besides bacteria, yeasts and fungi are used to a limited extent in the production of MP. *Dabaryomyces hansenii* and *Penicillum nalgiovense* are the major species sold as starters for MP production (19). They are both aerobic organisms and thus situated at the periphery or surface of the sausage, where they oxidize lactic acid and produce ammonia. Their contribution to flavor development is less clear, may involve fatty acid oxidation to methyl-ketones and the strongest argument for the use of fungal starters may be the prevention of growth of mycotoxin-producing fungi (19).

B. Processing

1. Comminution or Chopping

Industrial processing generally uses the cutter, involving a rapidly rotating set of knives ($1–3.10^3$ rpm) producing a batter in a slowly rotating bowl (10–20 rpm) within less than 5 minutes. The relative speeds of rotation of bowl and knives as well the sequence of addition of raw materials and additives determine fat particle size ($1–25\ mm^2$) and are optimized to minimize both, damage to the fat tissue added and increase of the batter temperature ($\leqslant -2°C$). Because air bubbles in the batter and oxygen may interfere with drying and color development respectively, chopping is best carried out under vacuum. The use of blunt rather than sharp knives is to be preferred for good texture (48). For traditional preparation of MP, often characterized by larger particle sizes, a meat grinder rather than a cutter may be used.

2. Stuffing

Traditional methods using nitrate, may still incorporate a "pan curing" phase (49), leaving the batter 24 hrs at low temperatures before stuffing to allow for optimal colour development. In most industrial processes however, vacuum filling devices are used, to immediately stuff the batter into natural or man made collagen or cellulose based casings, permeable to water and air. The size of sausage diameter (e.g., 2–15 cm) is related positively to the relative importance of fermentation (pH) vs. drying (a_w) for stability and a small diameter of collagen casing is required to ensure sufficient oxygen supply for full development of the mould aroma in MP (4, 50).

3. Fermentation and Drying

For industrial production of NP, fermentation and drying are usually carried out in separate rooms. Representative temperature/time/rh combinations for NP and MP respectively are shown in Table 65.1. It is recommended to have air rh values not more than 0.10 points below the associated a_w values of the sausage, to prevent case hardening. When $pH < 5.3$ a steeper rh gradient may be applied. Recommended air speeds are approximately 0.1 m/sec and a back and forth shifting of rh between 80% and 88% during drying is recommended (34). Controlled fermentation and ripening in air conditioned surroundings consumes considerable amounts of energy and alternative methods, involving the use of fresh air, have been proposed, inspired by the traditional methods for MP, adapted to local climatic conditions (51).

4. Smoking

At the end of the fermentation period, NP are subjected to smoke, generated by controlled combustion of wood

(300–600°C) to minimize the production of polycyclic hydrocarbons. Smoke contributes to anti-microbial and anti-oxidant effects, besides generating specific flavor and color components. Smoking is not used in the production of MP, except for Hungarian and Roemanian products, where a light smoking period precedes fermentation (34).

III. THE NATURE AND DYNAMICS OF RIPENING

It has been repeatedly confirmed that safety, stability and sensory quality of fermented sausages are the result of a complex and interacting set of microbiological, physical and chemical changes (4, 11, 13, 14). Within this complexity, most attention has been directed to the role of bacteria in relation to both safety and flavor: a "Web of Science" search for "fermented sausage" in April 2002 shows 194 papers published since 1977 (0.00075% of all documents!), 100 of which were published since 1997, containing 62 dealing exclusively with the behaviour of desirable or undesirable micro-organisms. Safety has been the subject of excellent reviews, describing the "hurdle concept" (34) as well as focussing on the potential of bacterocinogenic lactic acid bacteria (52) and will not be further discussed here. Besides an adequate redox-potential and the presence of nitrite and competitive desirable bacteria, major hurdles ensuring bacteriological safety are considered to be either the rate and extent of acidulation (10) or the extent of drying (lowered a_w) (9) for NP and MP respectively.

A. The Dynamics of Acidulation and Drying

Both the rates and extents of acidulation and drying can be quantified using simple exponential models (13) allowing demonstration of effects of processing factors such as the use of back slopping and starter cultures, sausage diameter, as well as the use of additives such as spices and soy protein (13, 53, 54, 55). The same models allow for the quantitative evaluation of the relations between rates of acidulation and those of drying and texture development (19). Predicted changes of DM content are assumed to be determined by water loss (drying) only, can thus be used to predict weight losses (55), for the calculation of empirical or "effective" diffusion rates (13,56) and, together with data for salt content, for the prediction of a_w values with acceptable precision (57, 58).

B. The Nature and Dynamics of Sausage Metabolism

The carbohydrate, protein and lipid fractions of the sausage are subject to changes, brought about by chemical as well as biochemical changes and the latter are mediated by microbial as wells by muscle and fat tissue enzymes. Multifactorial effects involving raw materials, additives, starter cultures as well as processing determine the relative intensities of these changes, mainly reflected in the rate and extent of acidulation and the development of sensory quality characteristics.

1. Sausage Metabolism and Acidulation

It is now clear that acidulation of the sausage matrix is induced by the interaction of salt solubilized muscle proteins with both lactic acid and ammonia formed during fermentation (33, 59). Molar amounts of lactate and ammonia present (59) as well as produced (54) during sausage ripening have indeed been related to pH and pH changes respectively. Lactate is mainly produced from (added) carbohydrates but may also be formed during microbial fermentation of glycerol, liberated in lipolysis, and, together with ammonia, from fermentation of amino acids. Besides lactic acid, variable amounts of acetic acid are produced, determined by the nature of the bacteria and their metabolism, both affected by the processing conditions. Finally, considerable amounts of oxygen are consumed during "fermentation", therefore better referred to as "metabolism"(60). This overall "sausage metabolism" affects the relationship between the amounts of carbohydrate "fermented" and lactate produced and has been described in a simplified "stoichiometric model" (61, 14), represented in Fig. 65.1.

Such model ignores the complexity of bacterial amino acid metabolism (11), representing it by either deamination to ammonia or decarboxylation to amines. Nevertheless, it has been supported by experimental data, within experimental error (60). Together with simple exponential analytical models, stoichiometry can be used to characterize the respective rates and relative importance of carbohydrate and protein oxidation (respiration) and fermentation, as well as the nature of fermentation (lactate/acetate) (14). In contrast to the kinetic and analytical models, referred to under III.A, models for metabolism are mechanistic, require more analytical data and are therefore better suited for comprehensive rather than predicting purposes (62). They have e.g. been used to illustrate effects of the processing factors mentioned earlier (IIIA) as wells as chopping intensity (63) on the relative importance of respiration and protein fermentation. Table 65.2 shows that in a series of experiments characterizing ripening metabolism of NP, carbohydrate disappearance accounted for between 82 and 94% of pyruvate equivalents metabolized.

An increase of diameter was shown to increase the relative contribution of protein fermentation as well as the accumulation of free amino acids, buffering the increased rate of lactate production. The relative importance of protein (amino acid) fermentation with ammonia production was lowered by addition of active lactic acid bacteria.

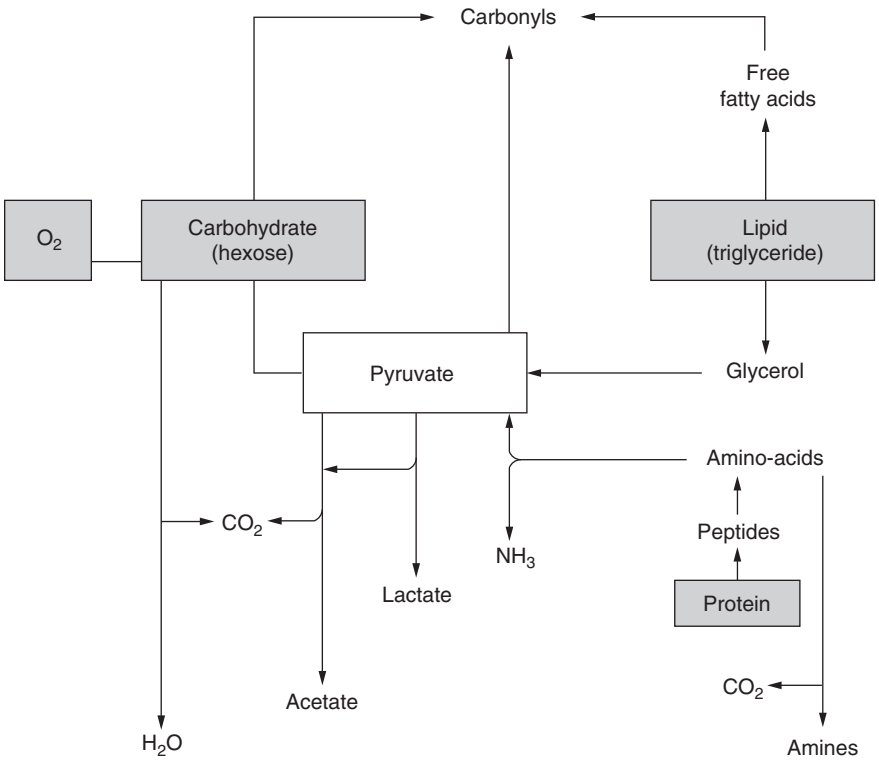

FIGURE 65.1 Reaction scheme underlying the stoichiometric model of sausage metabolism.

TABLE 65.2
Effect of Processing Contitions on the Pattern of Sausage Metabolism During Ripening of NP (21 days): % of Pyruvate Equivalents Derived of Carbohydrate and Protein and Utilised in Fermentation to Lactate and Acetate and in Respiration

						Chopping Time[c] (min)			
Effect of	Added Starters[a]			Sausage Diameter[b]		4.5		7	
Metabolism (%)	None	S1	S2	47 mm	90 mm	(1)	(2)	(1)	(2)
of:									
carbohydrate	82	86	91	93	92	87	89	89	88
protein	18	14	9	7	8	13	11	11	12
to:									
lactate	54	57	86	60	78	73	83	69	77
acetate	16	7	7	7	6	6	10	6	10
respiration	30	35	7	33	16	21	7	25	13

[a] Data from (52): starters used were fermented sausage, e.g. back slopping (S1) or a lyophylized culture of bacteria (S2) [b] Data from (13) [c] Data from (62): results of two experiments are shown involving longer chopping with salt (1) or pork back fat (2) respectively.

When the latter were added during backslopping however or as isolates from fermented sausages, proteolytic activity is apparent, an important effect for flavour, as recently confirmed (47). Inhibitory effects on deamination activities of both rates and extent of acidulation, more outspoken with larger diameters, associated with lower rates of drying have been confirmed in recent work (Demeyer http://fltbwww.rug.ac.be/animalproduction). Protein fermentation seems to be associated with the importance of acetate in the recovery of pyruvate equivalents. The most striking finding however is the large variability in respired substrate: between 7 and 43% of pyruvate equivalents metabolized. These calculated values obviously reflect an enormous variability in oxygen consumption, one that may involve chemical oxidations besides respiration. Factors determining variation are probably related to processing characteristics such as sausage diameter and chopping (Table 65.2), but variability in factors such as

vacuum stuffing, gaseous exchanges during ripening and respiratory activity of bacteria and molds may be more important.

2. Sausage Metabolism and Sensory Quality

Estimates of the nature of sausage metabolism as discussed above, allow better comprehension of the mechanisms determining both rate and extent of acidulation. It is however clear that the generalized pathways used in such estimates cover and/or accompany a set of detailed (bio) chemical reactions and end products affecting the development of sensory quality. Flavor is considered to be the more important sensory characteristic, determining renewed purchase by the consumer, whereas texture and color determine initial purchase and rejection respectively (64).

a. Texture

Texture, measured e.g. as the force necessary to penetrate the sausage surface or interior (sausage slice) under standardised conditions, e.g., "hardness", is determined by two processes, occurring consecutively in NP and simultaneously in MP:

- Gel formation because of acidulation. During chopping, myofibrillar structures are degraded (65) and myofibrillar proteins are solubilized into a sol, e.g. a network of filamentous aggregations of myosine molecules, whose dimensions and formation depend on factors such as pH and NaCl concentration that determine the relative rates of filament formation and aggregation (66). Acidulation induces coagulation, e.g. the conversion of a sol into a gel by intensification of aggregations, associated with the release of water and the formation of a matrix surrounding fat and connective tissue particles. The pH necessary for coagulation increases with increasing salt concentration and is 5.3 for salt concentrations between 2 and 3% (67)
- Drying: after gel formation, hardness is further increased because of loss of water, determined by diffusion limited water transport.

  The rate and extent of pH decline in the sausage, itself a reflection of overall sausage metabolism, determines both processes. During fermentation, muscle cathepsin D is activated by the decrease in pH and degrades sausage myosin (68, 69). It is known that such damage lowers the strength of heat coagulated myosin gels (16) and negative effects on texture of sausage proteolytic activity (70) and of increased myosin degradation because of added proteases (71) have indeed been reported. It is therefore clear that acidulation during fermentation induces two opposing effects on texture development: coagulation of the myosin sol into a gel as well as accelerating proteolytic cleaving of myosin molecules, lowering their contribution to gel strength, and, possibly, to water retention within the gel. Differences in gel structure and its water retention because of different relative rates of acid induced coagulation and proteolysis may explain the positive relationship found between initial rates of acidulation and texture development during drying. The use of PSE pork (72), spices (54), starter organisms (13) and soy protein (40) increase rates of acidulation and drying and thus, of texture development. For obvious reasons, an increase of sausage diameter decreases rate of drying and thus, rate of hardness development (73). Also however the rate of pH decline is lowered because of an increasing contribution of proteolytic processes to metabolism (14, 74).

b. Colour

The stable red colour of fermented sausage is due to nitrosylation and subsequent acid induced denaturation of myoglobin. In MP, formation of the nitrosylating NO occurs after bacterial reduction of added nitrate to nitrite, a process generally attributed to *Micrococceae*. Its inhibition by pH values below 5.2 hampers the use of lactic acid bacterial starters to ensure rapid acidulation. In NP, characterised by rapid acidulation, nitrite is the additive ensuring colour development. However, upon addition it acts as a very reactive oxidant for myoglobin: it is reduced to NO during chopping with an immediate grey discoloration of the batter, due to (nitrosylated) metmyoglobin formation. The rates of both this initial oxidation and the subsequent reduction and denaturation to the red nitrosylated myochromogen during ripening, as well as the stability to subsequent oxidation of the colour formed are determined by a complex set of factors, including e.g. the amounts of nitrite used, the rate of pH drop during fermentation, the use of anti-oxidant additives and the anti-oxidant activities of the meat and starter bacteria used. It would seem that for the Northern ripening process the use of sodium ascorbate (e.g. 600 ppm) with minimal amounts of sodium nitrite (e.g. 150 ppm) is sufficient to obtain an acceptable colour stability also reflected in a low redox potential (30) and minimal lipid oxidation (75). These conditions are promoted by the use of starter organisms with antioxidant activities (catalase, superoxide dismutase and/or nitrate reductase activities in *Micrococcaceae*) also contributing to flavour development (76) and/or low hydrogen peroxide producing activity (lactic acid bacteria). Net peroxide production is low at lower rates of acidulation (4) and minimal oxidation during sausage metabolism because of a low redox

potential may be reflected in its high potential of oxygen removal/ consumption (Torfs & Demeyer, in preparation).

c. Flavor

The simultaneous confrontation of the consumer with texture, taste and smell of the product during chewing creates his impression of flavour. Aroma (smell, odour) determined by volatile compounds, is considered to be the most important component because of the very high sensitivity of the nasal receptors. It is often considered separately from taste, determined by non-volatiles sensed by the receptors predominatly situated on the tongue. One should however be conscious of a "taste-olfaction integration" of senses (77) also apparent from the aroma enhancement due to the glutamate-umami taste. Peptides in fermented sausages may have a similar effect. In this respect it may be significant that fermented sausages were found to be better distinguished by taste than by odour for the descriptor "dry-sausage" (78).

i. Volatile aroma compounds More than 200 chemical compounds have been identified by gas chromatography — mass spectrometry or gas chromatography-olfactometry in volatiles present in the sausage "head space" or isolated by steam distillation (5, 19). Not all compounds in such "spectra" are of sensory relevance and the majority is derived from spices and smoking (NP). A limited group of compounds, thought to be responsible for the specific "fermented sausage" flavour however, consists of:

- Compounds considered to be derived from carbohydrate metabolism represented by acetic, propionic and butyric acids, acetaldehyde, diacetyl and acetoin.
- Compounds considered to be derived from protein metabolism, mainly represented by branched aldehydes and the corresponding acids and alcohols.
- Compounds derived from lipid degradation, mainly represented by methyl ketones, produced by microbial β-oxidation. Chemical autooxidation of unsaturated fatty acids produces a whole range of volatile carbonyl compounds, such as hexanal, contributing to the rancid notes and as such important for the overall flavour.

These compounds have been clearly associated with sensory descriptors such as maturity and salami and their relative importance, as well as that of esters, is increased by the Mediterranean low temperature and long time ripening process with use of *Staphylococci* as starter organisms (79). Higher temperatures and the use of *Pediococci* as lactic acid producing starters promote the production of dairy related volatiles such as diacetyl and accelerate the rate of pH drop, inhibiting *Staphylococci* (5).

ii. Non volatile taste compounds In contrast to MP, an "acid" taste is often sought for in NP and is positively correlated with the contents of D-lactate and acetate (61, 80). The extent of proteolysis, as reflected in the levels of low molecular weight peptides and free amino acids is clearly correlated with sensory analysis (14), specifically in relation to mould growth (10) and it is known that peptides affect taste rather than aroma, as shown for raw ham (81). Preliminar data (15) have associated small peptide (<500 D) and amino acid containing fractions isolated by gel permeation chromatography with sensory descriptors such as salami and bouillon, in analogy with the known importance of such fractions for raw ham flavour (82). Also, the non-protein nitrogen fraction will affect sausage pH (59) and may thus affect liberation of aroma determining acid compounds during chewing (83). ATP metabolites such as IMP and hypoxanthine contribute to taste, whereas free higher fatty acids are generally considered of less importance (64).

The relative importance of the different flavour compounds is determined by interactions between muscle and microbial metabolism as well as chemical reactions. The use of antibiotics and paucibacterial meat incubations has clearly established that initial proteolytic changes mainly involve myosin and actin degradation through the action of cathepsin D like enzymes. The contribution of bacteria in further endo- and, mainly, exoproteolytic changes increases down to ammonia production, the end of the proteolytic chain. Mediterranean, low temperature ripening, lowers rate of pH drop and thus, cathepsin D activity and initial protein degradation, but further proteolysis is not affected. Paucibacterial meat incubations demonstrate free amino acid production by meat enzymes.

In similar experiments, it was clearly demonstrated that endogenous lipases are by far the main responsible enzymes for the liberation of free fatty acids during ripening, with preferential release of poly-unsaturated fatty acids, both because of the more important phopholipase activity on muscle membrane phospholipids and the specificity of fat cell lipases. The importance of lipolysis for lipid oxidation and thus, flavour, remains unclear but a promoting effect is often assumed (15). Our laboratory has participated in studies on the impact of processing and of bacteria on the production of volatiles important for flavor in meat and meat products (6, 15, 84), using standardized methodology and our results suggest that the major contribution of bacteria to dry sausage ripening may be more related to lowering of lipid oxidation than to amino acid fermentation. Anyway, both amino acid fermentation and anti-oxidant characteristics are probably more important selection criteria for flavor enhancing starter bacteria than their lipolytic and proteolytic properties. It is indeed now generally accepted that initial proteolytic and lipolytic changes during dry sausage ripening are brought about by enzymatic activity of the raw materials, rather than from

micro-organisms (10). It is known that such activity in muscle shows considerable variation, related to anatomical location, gender, animal age and post-mortal rate of pH drop (26, 27, 85) The effects of such metabolic variability on flavour development in relation to bacterial activity should be further investigated.

ACKNOWLEDGMENT

66 Fermented Liquid Milk Products

Vikram V. Mistry
Dairy Science Department, South Dakota State University

CONTENTS

I. INTRODUCTION

Fermented milk products have been an important part of the diet for thousands of years. These products are believed to have originated in the Middle East region as a means of extending the shelf life of milk and over time they have spread around the world. They now form an important industry in most countries of the world (1) and consumption in many countries is considerable (2), especially in Europe (Table 66.1). Scandinavian countries and Russia are among the world's largest consumers of fermented milks (1).

In the early years the objective in fermented milks manufacture was primarily that of production of acid (usually lactic) to enable extended storage of milk in the absence of refrigeration. Now, consistency in fermentation and production of selected specific flavors along with a clean acid flavor are the norm. With the proper selection and propagation of cultures it is possible to produce numerous types of cultured products with a wide range of flavor and texture characteristics. In addition, these products offer various functional and nutritional characteristics for ingredient applications and therapeutic value for the maintenance of proper intestinal microbial ecology. The therapeutic properties of fermented milks have been recognized for many years (3). Many of these properties are generally not available in the original milk from which they are produced. Fermented milk products have thus added much to the diversity of the diet. While the commercial technology for the production of these products has advanced significantly

TABLE 66.1
Consumption of Fermented Milks around the World, 1998 (Ref 2)

Country	Per Capita (kg)	Country	Per Capita (kg)
Netherlands	45.0	Czech Republic	10.0
Finland	38.8	Portugal	9.8 (1997)
Sweden	30.0	Hungary	9.4
Denmark	27.3	Poland	7.4
France	26.9	Slovakia	7.4
Iceland	25.3	USA	7.1 (1997)
Germany	25.0	Australia	6.4
Israel	24.8	Argentina	6.0
Norway	19.3	Canada	3.6
Bulgaria	15.6	Ukraine	3.4
Austria	14.7	South Africa	3.1
Spain	14.5	China	0.2

TABLE 66.2
Examples of Fermented Milks (Refs 1, 4)

Name	Characteristics
Acidophilus milk	Medium acid
Bulgarian buttermilk	High acid
Cultured buttermilk	Low acid
Kefir	Acid and alcohol
Koumiss (Kumys)	Acid and alcohol
Lassi	Medium acid (with added salt or sugar)
Langfil	Medium acid, ropy
Mala	Medium acid with added fruits
Viili	Medium acid, mold, ropy

in the realms of cultures, production techniques and packaging, many types of cultured products are routinely prepared on a small scale in the home because of the relative ease of manufacture.

A selection of fermented milks from around the world is listed in Table 66.2. A comprehensive list can be found in the *Encyclopedia of Fermented Fresh Milk Products* (4) and some are described elsewhere (5, 6). The primary focus of this chapter is on the discussion of Acidophilus milk, Kefir, and Koumiss.

II. ACIDOPHILUS MILK

Acidophilus milk is produced mainly by the fermentation of milk with *Lactobacillus acidophilus* and it can have up to 2% lactic acid (1). The manufacture of acidophilus milk is outlined in Figure 66.1. With DNA-DNA homology studies, the acidophilus group of bacteria has been classified in to six major species: *Lactobacillus acidophilus* (A1), *Lactobacillus crispatus* (A2), *Lactobacillus amylovarus* (A3), *Lactobacillus gallinarum* (A4), *Lactobacillus gasseri* (B1), and *Lactobacillus johnsonii* (B2) (7). It is possible therefore, that acidophilus milks manufactured prior to this classification may have actually contained one or more of the above species. Currently, *Lactobacillus acidophilus* and *Lactobacillus johnsonii* are used in the manufacture of fermented milks commercially.

Therapeutic properties of *Lactobacillus acidophilus* have been recognized for long (8) and it is believed that this organism is able to implant in the large intestine and survive (9, 10). Consequently, acidophilus milk is found in health food stores and is used as a therapeutic product. A major characteristic that limits its consumption is poor palatability owing to its extremely high acid content. Furthermore, the sterilization treatment applied to the milk also imparts a strong cooked flavor to the product. Most strains of *Lactobacillus acidophilus* are not able to survive the high acid conditions created by their growth in milk so maintenance of high numbers in products is difficult. Various alternative products have therefore been developed that have better flavor qualities but supposedly have

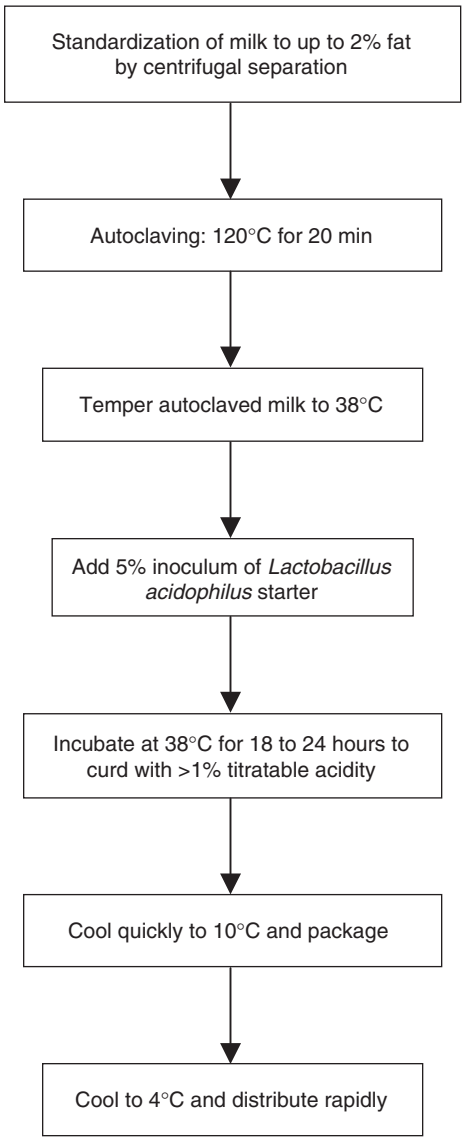

FIGURE 66.1 The manufacture of acidophilus milk.

therapeutic properties similar to acidophilus milk because of the presence of large population of *Lactobacillus acidophilus*. Among these are sweet acidophilus milk (11), also marketed as AB milk in the USA, BRA in Sweden (1), Actimel (Dannon company), which contains *Lactobacillus casei*, and LC1 of the Nestle company in Switzerland. This product contains *Lactobacillus johnsonii*.

As implied by the name, some of these alternative liquid products are not fermented, hence the term "sweet". Early versions of sweet acidophilus milk contained only *Lactobacillus acidophilus* but now also include one or more strains of bifidobacteria. The strain used for such milk generally is *Lactobacillus acidophilus* NCFM, which is a member of the *Lactobacillus acidophilus* A1 group (12). The BRA milk of Sweden has viable bifidobacteria, *Lactobacillus acidophilus* and *Lactobacillus reuteri.*

The latter produces an antibiotic (reuterin) that inhibits the growth of undesirable bacteria in the intestinal tract. In the manufacture of these acidophilus beverages, concentrated cell masses of the above selected bacterial strains are added to pasteurized, cooled, low fat milk, packaged and stored at 4°C until consumed. The cell count of the added bacteria is approximately 5 million per milliliter of milk. There is no fermentation, hence no acid is produced but the consumer ingests large amounts of live lactobacilli and/or bifidobacteria cells that are subsequently implanted in the intestinal tract. The shelf life of such milks is limited to 2 weeks under refrigeration because of the presence of live lactic acid producing bacteria. Extended storage under refrigeration or exposure to higher temperatures during storage will initiate the growth of the added cultures and rapid production of acid, followed by curdling of milk, which would be regarded by consumers as spoilage even though the curdling is caused by lactic acid bacteria.

In Finland a liquid product is manufactured by fermenting demineralized, lactose-hydrolyzed whey concentrates or concentrated whey with *Lactobacillus* strain GG (1). This strain, named after Goldin and Gorbach, the scientists who discovered the organism, is isolated from the human intestinal tract and is believed to possess therapeutic properties especially those pertaining to gastrointestinal disorders. This product is produced with or without any added fruit flavors and has a pleasant acid flavor.

III. KEFIR

Kefir has a long history in Russia, where it originated, but is now manufactured and consumed in several other parts of the world as well (1, 13), though the per capita consumption remains high in Russia at 4 to 5 kilograms. The name kefir is derived from the Turkish term kef or from kefy in the Caucasus region implying pleasant taste (4). Kefir is a viscous pourable liquid, with a smooth, slightly foamy body and whitish color. It is yeasty, acidic, mildly alcoholic, refreshing and slightly effervescent. Kefir is generally made from cows' milk but in the early years it was also made from goats' and sheeps' milk in leather sacks. It perhaps still is in some rural areas. Industrial manufacture of kefir began in Russia in 1930 (14).

Like many other milk products, Kefir ranges in fat content from nonfat to 3.5% but it is in many ways a unique product in that it entails acid and alcohol fermentation. Alcohol fermentation is the result of the addition of yeasts in the form of kefir grains. Because of the multiple fermentation process, the resulting product possesses flavor that is characterized by a balance of lactic acid (0.8%), diacetyl, acetaldehyde, and ethanol (1%). Diacetyl and acetaldehyde in a 3:1 ratio provide optimum flavor. The complex flavor is rounded out by fizz from carbon dioxide that is also produced during fermentation.

Kefir is manufactured using one of two main procedures. In the traditional process, kefir grains are employed for fermentation. Another method involves the use of lyophilized concentrates of cultures. In the latter method, kefir grains are not used.

A. Manufacture of Kefir with Grains

Kefir may be manufactured with grains in one of two ways (1). In the traditional system, Kefir grains are added to cows' milk that has been heated to 85°C for 30 min and cooled to 22°C. Incubation is for 24 hours at 22°C with occasional stirring. The grains are sieved when they rise to the surface due to carbon dioxide production and ripening for alcohol production continues at 10 to 15°C for 24 hours.

In another process a kefir starter is first obtained from the grains for fermentation. Here, freeze dried kefir grains are rehydrated in a sterilized 0.9% sodium chloride solution at 20°C for 5 hours. The grains are then washed with sterile water and added in a 1:30 ratio to skim milk that has been heated to 95°C for 30 min and cooled to 25°C. After incubation for a day the grains are sieved and the process of fermentation in skim milk is repeated two more times. After the final fermentation, the grains are sieved and the skim milk without the grains is then added as the kefir culture at the rate of 5% to milk that has been heated to 85°C for 30 min and adjusted to 22°C. Fermentation ensues for 12 hours (pH 4.5 to 4.6) followed by ripening for 1 to 3 days at 8 to 10°C. During ripening yeast fermentation occurs.

The ratio of kefir grains to milk affects the microflora of the starter. If a relatively large proportion of grains are added to milk (e.g., ratio of 1:10), the proportion of lactococci and yeasts is lower than when the proportion is smaller (1:30 to 1:50) because of the rapid accumulation of lactic acid. The optimum development of all groups of organisms in the grains takes place at a ratio of 1:50 (14).

B. Manufacture of Kefir from Concentrated Culture

Kefir may also be produced with a concentrated culture that is prepared from isolates obtained from kefir grains (1, 15). In the actual manufacturing process, no grains are used, as the organisms have already been isolated as a concentrated culture. This culture consists of 75% homofermentative lactococci, 24% citric acid fermenting lactococci, 0.5% lactobacilli, and 0.1% *Candida kefir* yeasts. A bulk starter made from this concentrated culture is added to heated milk (94°C, 5 min, cooled to 22°C) at the rate of 1%. Incubation is for 18 to 22 hours until pH is 4.5 to 4.6.

C. Kefir Grains

Kefir grains are the most important components of kefir manufacture (Figure 66.2). The concept of kefir grains is

believed to have originated in the accidental discovery of kefir many hundreds of years ago in the Caucasus region. These grains vary in size from a wheat grain to the size of a walnut. They are of whitish to yellowish color and gelatinous and irregular in shape and with a rough surface. The dominant microflora of kefir grains are listed in Table 66.3 and consist of mesophilic, homofermentative and heterofermentative lactococci, heterofermentative lactobacilli, lactose fermenting and lactose non-fermenting yeasts, and acetic acid bacteria. The microbial ecology within the grains depends on the origin and method of cultivation of the grains (4, 16, 17, 18). In one study 120 strains of lactobacilli were isolated from kefir grains. The most predominant was *Lactobacillus kefirogranum* (19). These groups of bacteria when purified do not grow at all or grow very slowly in milk. In fact it has been demonstrated that manufacture of good quality kefir by using isolated bacteria is difficult (20). Thus, the symbiosis within kefir grains is critical in optimal growth for kefir production. Koroleva has described such symbiosis (14), i.e., proteolysis and vitamin production by yeasts and acetic acid bacteria stimulates lactic acid bacteria, which in turn utilize lactose to promote growth of lactose non-fermenting yeasts. The metabolites of growth of lactic acid bacteria also check the growth and alcohol production by yeasts.

FIGURE 66.2 Kefir grains. Courtesy F. V. Kosikowski LLC.

TABLE 66.3
The Microflora of Kefir Grains

	Species
Yeasts	*Candida kefir*
	Candida pseudotropicalis
	Kluyveromyces marxianus subsp. *marxianus*
	Saccharomyces kefir
	Saccharomyces turicensis
	Torula spp.
	Other Yeasts
Bacteria	*Acetobacter aceti*
	Lactobacillus casei
	Lactobacillus helveticus
	Lactobacillus kefir
	Lactobacillus kefirogranum
	Lactobacillus kefironafaciens
	Lactococcus lactis subsp. *lactis*
	Leuconostoc mesenteroides subsp. *dextranicum*
	Leuconostoc mesenteroides subsp. *cremoris*

Newer strains from kefir grains such as *Lactobacillus kefiranofaciens* (21) and *Saccharomyces turicensis* (22) have been isolated. It is conceivable that as new microbiological techniques become available, newer strains will be identified and the microbial ecology of kefir grains will be better understood.

Kefir grains may be contaminated with coliforms, bacilli, micrococci, and mold, which will rapidly spoil the product manufactured with such grains. According to Koroleva, a good quality kefir culture prepared in skim milk should contain 10^8 to 10^9 lactococci, 10^7 to 10^8 leuconostocs, 10^5 thermophilic lactobacilli, 10^2 to 10^3 mesophilic lactobacilli, 10^5 to 10^6 yeasts and 10^5 to 10^6 acetic acid bacteria per milliliter (23).

Kefir grains consist of approximately 24% polysaccharide called kefiran, which consists of glucose and galactose in equal proportion and is not easily attacked by enzymes. Various lactobacilli such as *Lactobacillus kefiranofaciens* (24) and others (25, 26) that are present in the grains produce these polysaccharides. The polysaccharide content of kefir is approximately 0.2 to 0.7% and provides a slightly ropy texture to the final product.

Kefir grains are an excellent example of the coexistence of yeasts and bacteria. When kefir grains are soaked in milk, they swell and turn white and fermentation proceeds. During this process the grains also increase in number, possibly by splitting into smaller ones. Viable microbes from the grains are also shed into the milk during this process. The grains can be propagated and recovered in this manner and used in subsequent kefir production but it has not been possible to synthesize kefir grains.

Newly purchased kefir grains become fully active after two or three propagations (1). Kefir grains when left wet have a limited shelf life. When stored at 4°C they lose activity within 8 to 10 days if not used. Dried grains are active for 12 to 18 months of storage. Kefir grains if properly used and maintained can be reused many times. Grains that are recovered in a strainer should be washed with sterile water and can be stored wet in cold sterile water for reuse within a few days. Excessive washing can alter the microflora of the grains and hence the quality of the final product. They can be dried at room temperature for 36 to 48 hours and stored in a cool and dry place until reused (1) or be maintained in frozen state (−20°C) for extended storage (27).

In place of kefir grains freeze-dried kefir microflora have been suggested for kefir manufacture for uniformity

in quality (15). This was accomplished by cultivating kefir bacteria and yeast isolated from grains under controlled pH and incubation conditions. Bacterial concentrates obtained by centrifugation were freeze-dried with protective agents with survival rates of up to 70%. Including 20% sucrose and starch solutions enhanced survival rates of yeasts during freeze-drying.

D. Application of New Technologies

Kefir has gained popularity in many parts of the world outside its location of origin because of its refreshing taste and potential therapeutic value. The product has therefore continued to evolve and manufacturing procedures have been modified to produce products that meet consumer preferences and also improve the efficiency of manufacture.

Acid and alcohol fermentation can continue in finished kefir during storage because of the relatively high residual lactose content and the presence of yeasts. The result of this is extremely strong and undesirable products. Methods have been developed to control such post-production fermentation. In one such method (28), kefir is manufactured with selected lactic acid bacteria and yeasts. The selected lactic acid bacteria, which include *Streptococcus fecalis, Lactobacillus casei, Lactobacillus lactis, Lactobacillus fermenti,* and *Lactobacillus yogurtii*, are able to hydrolyze galactose and prevent the build up of galactose. Yeasts strains that do not hydrolyze lactose and galactose are used, e.g., *Saccharomyces bisporus, Saccharomyces mellis*, etc. Calculated amounts of sugars fermented by these yeasts such as glucose and fructose are added such that all sugar is utilized by the time the required amount of alcohol has been produced. During storage therefore, there is no more alcohol production.

Kefir with enhanced nutritional value may be produced by the application of ultrafiltration (29). In this process, milk is ultrafiltered to raise the solids content by 0.5 to 4%. This increases the protein content and reduces the lactose content of the milk and hence kefir. After high heat treatment, this milk is fermented to a pH of 4.5 to 4.7 and packaged. This product is especially designed for patients who rely heavily on kefir for therapeutic purposes but do not have other significant sources of protein. It has been recommended that for manufacturing kefir, skim milk should be ultrafiltered to no more than 1.8 fold in order to retain optimum texture quality (30). The application of ultrafiltration to increase the protein content by 0.2 to 0.3% is also useful for improving the consistency of low fat kefir (31).

Kefir products with added value have also been developed such as kefir fortified with a patented colostrum product for enhancing the immune system (32). Kefir products with prebiotics such as fructooligosaccharides (33) and probiotics such as bifidobacteria (34) have also been developed.

IV. KOUMISS (KUMYS)

Koumiss is a frothy beverage with greyish-white color, a refreshing taste and characteristic aroma (1). The name Koumiss is derived from the Kumanes tribe of the central Asian steppes, where it is believed to have originated many hundreds of years ago and was a common drink of the Tartar and Mongol tribes. Traditionally, this product was obtained by fermentation in a vessel made of horse-skin (35) but now it is made on a large scale in some parts of the world from mares' milk. It is an important product of Russia and Mongolia, where horses have been maintained especially for the production of this product. A distinctive feature of koumiss is that it, like kefir, is also produced by acid-alcohol fermentation. Koumiss is regarded as a product of high therapeutic value and a thirst-quenching beverage of high nutritional value in Russia.

Vladimir, Soviet and Russian heavy draft horse breeds are used for koumiss production in Russia and they yield 10 to 20 liters of milk per day (36). Milking occurs every 2 to 3 hours because of a low milk-holding capacity of the udder (37). Mares' milk resembles human milk more than it does cow-milk. On average, it has 1.9% fat, 1.3% casein, 1.2% whey proteins, 6.2% lactose and 0.5% ash (38), which gives it a lower viscosity than cows' milk. There is no visible curd when the milk is set and there is no wheying off. Protein characterization studies of mares' milk have shown that the isoelectric point of casein is 4.2 compared to 4.6 for cows' milk (39).

While Koumiss is traditionally made from mares' milk, limited availability of such milk has led to the development of procedures for its manufacture from cows' milk as well. There is however, a concerted effort in Russia to increase the production of mares' milk for koumiss production via improvements in horse breeding and management techniques (40, 41, 42).

There are several types of Koumiss available depending on the amount of acid and alcohol (Table 66.4). The manufacture of Koumiss therefore requires controlled lactic acid using *Lactobacillus delbrueckii* subsp. *bulgaricus* and alcohol fermentation using yeasts such as *Torula* spp. and others. In addition to acid and alcohol, carbon dioxide is also produced to impart fizziness to the final product.

Various regional products similar to koumiss are also made in central Asia on a relatively small scale. Examples

TABLE 66.4
Types of Koumiss

	Lactic Acid %	Alcohol %
Weak	0.7	1.0
Ordinary	1.1	1.8
Strong	1.8	2.5

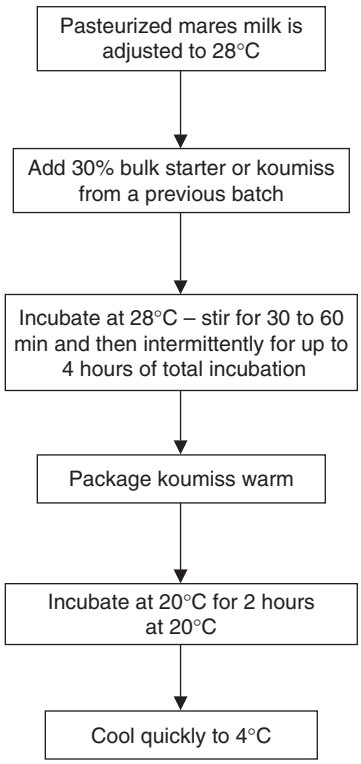

FIGURE 66.3 Manufacture of Koumiss from mares milk.

include Chal, which is manufactured from camels' milk, Kuban and Kurunga (4).

A. Manufacture of Koumiss

1. Mares' Milk

Koumiss can be manufactured using a previous batch as bulk starter or by preparing a bulk culture from pure strains. For preparing a bulk starter, yeast and lactic cultures are propagated separately (1). Two liters of nonfat cows' milk that has been heated to 70°C for 30 min and cooled to 30°C is inoculated with *Torula* spp. yeast. Incubation is for 15 hours at 30°C. A liter of similarly treated milk is inoculated with a lactic culture (*Lactobacillus delbrueckii* subsp. *bulgaricus*) and incubated at 37°C for 7 hours. The two separately fermented milks are mixed with a liter of mares' milk and incubated at 28°C. Additional mares' milk is added until about day four when the acidity is 1.4%. This mixture is then used as bulk starter for the production of koumiss as outlined in Figure 66.3. Aeration during incubation is important to allow the yeasts to grow. The three categories of acid-alcohol in koumiss cited in Table 66.4 can be achieved by adopting short or long ripening periods as follows: 1 day for weak, 2 days for ordinary, and 3 days for strong. Obviously, koumiss should be consumed quickly after production, as acid and alcohol production may continue during storage and the product will become stronger.

2. Cows' Milk

Koumiss that is similar in sensory and therapeutic qualities to mares' milk can be manufactured from cows' milk if appropriate adjustments are made for composition (43). As stated above, mares' milk has a significantly lower protein content and higher lactose content than cows' milk and the proportion of whey proteins is higher relative to casein in mares' milk. In one procedure utilizing cows' milk (1), 2.5% beet sugar is added to skim milk and pasteurized and a 10% culture consisting of *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus acidophilus,* and *Saccharomyces lactis* is added. The mixture is incubated at 27°C until curd forms and acidity is 0.8%. It is then held at 17°C with aeration via stirring until acidity is 0.9%. Aeration permits the growth of yeasts. The product is then packaged and ripened for a further 2 hours at 17°C before cooling to a storage temperature of 4°C.

In another procedure (23), cows' milk is first standardized as follows: 34.6 parts whole milk, 0.8 parts skim milk and 64.6 parts of cheese whey are mixed. Starter similar to the one described above for cows' milk is added to the mixture at the rate of 20%. Ascorbic acid is also added at the rate of 0.2 grams per kilogram. Standardization lowers the casein content, and raises the whey protein and lactose contents. Ascorbic acid is added as a supplement to match the vitamin C content of mares' milk. The mixture is incubated at 28 to 30°C for 3 to 4 hours under continuous stirring. When the titratable acidity is approximately 0.7%, it is cooled to 16 to 18°C and stirred for 1 to 2 hours. The product is then packaged and ripened at 6 to 8°C for 1 to 3 days.

A Swiss process (44) employs the ultrafiltration of whey prior to standardization of cows' milk to simulate the composition of mares' milk. The lactose in the mix is partly hydrolyzed by beta-galactosidase to improve yeast fermentation. The sensory quality and composition of the resulting koumiss were similar to that made from mares' milk.

3. Starters

In the early years, koumiss from a previous batch was used as starter but purified starters have since become available (14). Such purified starters may be in the form of concentrates and include *Lactobacillus bulgaricus* and *Saccharomyces lactis* (45). The microflora of commercial koumiss is a reflection of the microflora of the starter. Various strains of lactic acid bacteria and yeasts have been isolated from commercial koumiss. One study, for example, isolated 43 strains of lactic acid bacteria and 20 strains of lactose-fermenting yeasts (46) and another isolated 417 yeast cultures from 94 samples of koumiss (47).

TABLE 66.5
Microflora of Koumiss (Refs 14, 46, 47)

	Species
Yeasts	*Candida kefir*
	Candida buensis
	Kluyveromyces marxianus subsp. *lactis*
	Saccharomyces unisporus
	Saccharomyces cartilaginosus
	Other yeasts
Bacteria	*Lactobacillus causasicum*
	Lactobacillus curvata
	Lactobacillus delbrueckii subsp. *bulgaricus*
	Lactobacillus paracasei subsp. *paracasei*
	Lactobacillus paracasei subsp. *tolerans*
	Lactobacillus rhamnosus

Lactose-fermenting as well as lactose non-fermenting yeasts were isolated (Table 66.5).

V. THERAPEUTIC PROPERTIES OF LIQUID FERMENTED MILK PRODUCTS

The medicinal value of liquid fermented milk products has been suggested for hundreds of years and various studies have implied that individuals for whom fermented milks such as acidophilus milk, Bulgarian buttermilk and kefir is a part of the diet as in some parts of Russia, live long lives (1). This value goes beyond the accepted high nutritional quality of unfermented milk. The fermentation process apparently adds therapeutic qualities to milk that are not found in the original milk. These properties are imparted by the cultures used that have the ability to survive product manufacturing and storage procedures and the harsh environment in the gastric system and establish themselves in the intestinal tract. Through their activities in this environment they are able to perform functions that are of benefit to the consumer. Also, some metabolic products of their growth during the fermentation process add therapeutic value to the finished fermented product. For example, a pasteurized Japanese product (Ameal S) is produced by the fermentation of a milk-based medium with *Saccharomyces cereviseae* and *Lactobacillus helveticus.* The fermentation process produces two tripeptides, valine-proline-proline, and isoleucine-proline-proline, which have the ability to reduce blood pressure. In this product live bacteria do not exist and are not important but the products of their growth are (48).

Much has been written about studies on the therapeutic value of fermented milks involving in vitro, animal and human studies. Various benefits have been suggested including the reduction in risk of gastrointestinal illnesses such as diarrhea, lactose digestion, enhancement of the immune function, decreasing *Helicobacter pylori* infection, reduction of cholesterol and certain allergies, anticarcinogenic action, etc (49, 50). As a result of this, commercial fermented milks with health claims have been developed in some countries and in Japan the Ministry for Welfare developed FOSHU (Foods for specified health use) regulations in 1993 for such products (51).

Lactobacilli such as the types used in the manufacture of some liquid fermented milks described above have been linked to various therapeutic properties (12). *Lactobacillus acidophilus, casei* and *reuteri* are believed to control the growth of undesirable microorganisms such as *Escherichia coli* and Salmonella in the intestinal tract (50). A large amount of acid produced by these organisms is one method of such control, as is competitive exclusion, but these bacteria are also able to produce bacteriocins that are antagonistic against undesirable organisms. *Lactobacillus acidophilus* LB (52), *Lactobacillus johnsonii* LA1 and *Lactobacillus casei* YIT9209 (53) produce antimicrobial substances against *Helicobacter pylori*, which is a human gastric pathogen. The antibiotic reuterin produced by *Lactobacillus reuteri* is effective against a wide range of organisms including pathogens (50). Control of undesirable microorganisms that produce carcinogenic metabolites in the intestines may also result in anticarcinogenic effects by limiting the production of such metabolites (50).

Some lactic acid bacteria have been shown to stimulate immune functions by activating macrophages, increasing the levels of cytokines, and increasing immunoglobulin levels (especially those of IgA). Organisms identified in such functions include *Lactobacillus johnsonii* LA1, *Lactobacillus* GG, and *Lactobacillus casei* Shirota, among others (48).

The improvement of lactose digestion, for which *Lactobacillus acidophilus* has particularly been identified, is useful for individuals who are not able to digest lactose. *Lactobacillus acidophilus,* unlike yogurt bacteria, is able to survive and grow in the intestinal tract. Here the increased permeability of the bacterial cells allows for the permeation of lactose and subsequent hydrolysis by beta-galactosidase (50).

A reduction in serum cholesterol has also been linked to certain lactobacilli, including acidophilus, johnsonii and casei (50, 54). This activity is believed to occur by the assimilation of cholesterol or via deconjugation of bile acids in the small intestine and subsequent excretion from the body. Bile acids are precursors for cholesterol; hence their removal from the body helps in reduction of cholesterol.

The therapeutic properties of traditional kefir have been identified as an increase in the excretion of urea and some nitrogen metabolism products (14) and the treatment of atherosclerosis, allergic disease, and gastrointestinal disorders (55). The polysaccharides are able to decrease the cholesterol content of blood and bind toxins. Anti-cancer effects of kefir have also been suggested (14). The inclusion of pre- and probiotics, as stated earlier, and colostrum products has expanded the therapeutic value of kefir.

Koumiss made from mares' milk has been used widely in Russia for many years for the treatment of tuberculosis (56, 57), and chronic enteritis and gastrointestinal disorders (58). The first hospital specializing in koumiss therapy was established in 1858 in Samara, Russia. The intestinal microflora is apparently normalized with koumiss therapy and partly because of the intense yeast fermentation, the vitamin B12 absorption and levels in blood are raised (59). The dose for adults is 1.5 liters per day and 0.4 to 0.8 liters for children (1). Koumiss is readily digested and assimilated because of its lower casein content and a larger proportion of peptones and free fatty acids that are generated during fermentation.

Many of these therapeutic properties of fermented milks are strain specific, i.e., not all strains have all of the above characteristics. In the manufacture of fermented milk, therefore, it is important to use specific strains if health claims are made (60, 61, 62).

67 Semi-Solid Cultured Dairy Products: Principles and Applications

Dilip Patel and Marcia Walker
Food Science and Technology, Oregon State University

CONTENTS

I. SEMI-SOLID CULTURED DAIRY PRODUCTS

A. Introduction

Fermented semi-solid dairy foods have a long history of consumption worldwide. This category of dairy foods that include yogurt, sour cream, fromage frais and many variations continue to show increased sale because of their healthful reputation and convenience. The $2.9 billion yogurt industry saw a 10.5% increase in sales from 1999 to 2000 (1). Within the yogurt category, new product entries are continually appearing in marketplaces that promote probiotic-enhanced benefits. Innovative packaging concepts that target convenience and fun also drive the market surge.

Classification of fermented semi-solid dairy products is difficult because of the wide variety of products that can be manufactured. Traditional dairy products such as

cheese varieties have been classified based on moisture content (2). Although widely used, this system suffers a serious drawback in that dairy products with different characteristics and manufacturing protocols are grouped together. In other attempts products are classified based on similarities that exist, such as starting ingredients, the type of fermentation and rheology (3). However, it is important to define rheology, which is the mathematics of a set of behaviors rather than as a set of materials (4). Rheology of a product is related to the flow of fluids and the deformation of matter. Texture is defined as the tendency to resist flow, and is often used interchangeably with rheology. Typically, texture relates to solid foods and viscosity relates to fluid products. Many foods can exhibit characteristics of both solids and liquids (5). Fluid milk and cream are considered liquids and hard cheeses are classified as solids. Semi-solid fermented dairy foods show an intermediate behavior, with properties of both solids and liquids, and can be defined as viscoelastic (6). As viscoelasticity characteristics are very dependent on the protein network structure formed by casein micelles (6), a great deal of research has focused on processing parameters that optimize a network structure that favors good rheological properties and desired firmness without syneresis.

In this chapter, yogurt, fromage frais and sour cream are considered semi-solid fermented dairy products based on the consensus in the literature. Typical manufacturing protocols for these products require raw milk selection, milk pretreatments, ingredient blending and standardization, heat processing, starter addition and other technological procedures to produce satisfactory products with desired body, texture, flavour and organoleptic and rheological properties. Keeping these aspects in mind, principles and applications of fermented milk manufacture are discussed under two sections, Section I involving selection of raw milk, milk pretreatments, ingredient addition, heat processing, role of lactic starter system, gel formation during fermentation and proactive phage control program. Section II is devoted to probiotics in semi-solid dairy foods covering health issues, probiotic cultures and product development and production of probiotic dairy foods.

B. Selection of Raw Milk

As the old saying goes — there is no substitute for good quality raw milk. This is also true for milk destined for fermented milk manufacture. Quality criteria for raw milk should be based on compositional quality of milk, microbial count, somatic cell count, freedom from inhibitory substances and reception temperature (7). In the U.S., grade A milk is required for fermented milk manufacture. Such milk has a standard plate count of less than 100,000 cfu/ml and a storage temperature not exceeding 7°C (within 2 hr of milking). Somatic cells are indicators of udder health and individual states have set the limits for acceptable somatic cell count (8). Generally somatic cell counts above 750,000/ml are not acceptable. A high somatic cell count is indicative of mastitis conditions; and milk may also be abnormal in composition. Leucocytes in milk may cause inhibition of lactic starters by phagocytosis and abnormal composition can influence other technological parameters affecting quality of resultant fermented milks.

Good quality raw milk is free from all kinds of inhibitory substances including residual antibiotics, traces of detergents, sanitizers or insecticides. Mastitis treatment of cows involves application of various antibiotics, and milk from treated cows may occasionally contain residual antibiotics if it is not withheld for the recommended period. The resulting low-level contamination may be sufficient to inhibit starter microorganisms (9); for example, penicillin at 0.01 IU/ml of milk will inhibit thermophilic starters. Apart from the possibility of partial or complete inhibition of starter bacteria due to antibiotic action, antibiotic testing is also mandatory for consumer safety reasons due to potential allergic reactions in sensitive individuals (10). High levels of residual detergents and sanitizers can inhibit starter bacteria. Under good sanitation practices, the amount of residual sanitizers that might enter into milk from milk contact surfaces is not sufficient to cause culture inhibition except when the sanitizer solution is not completely drained from tanks or trucks (11). Quaternary ammonium compounds (QAC) present a potential problem due to their residual activity, and lactic-acid bacteria are sensitive to low concentrations of QAC. For example, Lactococus strains are inhibited at 10 μg/mL level of QAC (12) and thermophilic cultures are inhibited at 0.5 to 2 μg/mL of QAC (13).

C. Milk Pretreatments

Commonly employed pretreatments in the fermented milk manufacture include filtration, clarification and homogenization.

1. Filtration

Filtration is carried out by pumping milk through specially woven cloth. This results in the removal of extraneous matter. Filtration of the recombined dairy powders is also helpful in the removal of undissolved or scorched particles from base mix. This may be further helpful in minimizing wear and tear to the homogenizer orifice and minimizing the deposition of milk solids on the heat exchanger plates.

2. Clarification

Clarification refers to the process of centrifugal separation carried out in a specially designed separator, called a clarifier. This process removes extraneous matter such as straw, hay and large clumps of bacteria and thereby improves the aesthetic quality of fermented milks. A specially designed centrifuge can be used to carry out bactofugation. This

process can reduce bacterial load by about 80–90%. It is especially effective for removal of spores and leucocytes from milk (~98%).

3. Homogenization

Homogenization is a process of attaining homogeneous emulsions. This is achieved by passing the milk under high pressure through a small orifice; the shearing effect reduces the average diameter of the milk fat globules to less than 2 μm. As a result, globules are less inclined to coalesce into large units and do not rise to form a cream line.

Homogenization is an important processing step in order to improve consistency and viscosity of yogurt due to incorporation of the finely divided fat globules within the coagulum structure. Further, coagulum stability also improves due to adsorption of casein micelles onto fat globules. The increased number of small fat globules tends to enhance the ability of the milk to reflect light, and as a result the fermented milk appears whiter.

Use of unhomogenized milk leads to fat accumulation on top of the packaged product which is disliked by most customers except in products where cream line is specifically required, e.g., crusty yogurt in Greece.

Milk processing for fermented milk manufacture typically employs homogenization pressure in the range of 10–20 MPa at 50–70°C temperature. Homogenization preceding heat processing is preferable to avoid risk of contamination after heat processing.

D. Ingredient Addition and Blending

Optional ingredients can be added to base mix to improve viscosity and to minimize syneresis in fermented milk products. Additionally, with the development of low-fat dairy products, stabilizers are often added to improve mouthfeel and to reduce calories (14).

1. Stabilizers

Stabilizers serve two basic functions when added to semi-solid fermented dairy foods. Good stabilizer systems will have the ability to bind water, react with milk proteins to increase their level of hydration, and stabilize protein molecules into a network that prevents the movement of water. Gelatin and hydrocolloids such as guar gum, pectin, carageenan and pre-gelatinized starch are the most common stabilizers (15). A stabilizer is added as a single component or as a blend. Blends of stabilizers have the benefit of overcoming a limiting property of a single stabilizer. It is important to balance the desired level of stabilizer with undesirable flavor changes the stabilizer may impart. The stabilizer concentration will vary widely depending on the type of system chosen. Processing conditions may need to be considered when choosing the stabilizer system.

2. Sweeteners

Products are typically sweetened by sucrose, honey, high fructose corn syrup (HFCS), and aspartame. Some manufacturers use apple and pear concentrates when a healthier image is desired (15).

3. Fruits, Colorants, and Flavorings

Addition of fruit, colorants and flavorings are also common in fermented semi-solid dairy products and are typically added following fermentation. Typically, heat-treated purees that range from 30–50° Brix are used. Because fruit is commonly added after the dairy product is heat treated, the microbiological quality is critical to the safety and shelf life of the product. In set yogurts, a layer of gelled or pureed fruit is placed into the container prior to addition of cultured milk (14).

4. Other Ingredients

Recently, other less common ingredients are making their way into fermented dairy products. Addition of vitamins and minerals has become a method for increasing nutritional value. Adding calcium to the fermented milk base has been difficult due to solubility and bioavailability issues. Recent patents for methods of increasing calcium in fermented dairy products focus on technology that overcomes the low solubility of calcium salts in milk (16).

5. Prebiotics

Prebiotics are defined as "non-digestible food that beneficially affects the host by selectively stimulating the growth or activity of one or a limited number of bacteria in the colon" (17). Prebiotics, such as oligosaccharides, are therefore used to maximize the effectiveness of probiotic microorganisms. Based on their chemical structure, some oligosaccharides are resistant to digestive enzymes and are bioavailable to *bifidobacterium* in the large intestine as a carbon and energy source (18). Research suggests that fructo-oligosaccharides, lactose derivatives, galacto-oligosaccharides, and soybean oligosaccharides have commercial significance as prebiotic ingredients (19). Addition of the prebiotic fructo-oligosaccharide and galacto-oligosaccharide in combination with bifidobacterium in yogurt has been shown to increase the intestinal probiotic level by two log cycles. The current trend in yogurts marketed in Australia, Europe and Japan is to contain a prebiotic component (18).

E. Heat Processing

Pasteurization of milk is a legal requirement in the United States for manufacture of fresh cultured products (CFR Title 21, part 133:1995). Heat treatments typically employed for selected fermented milk products are depicted in Table 67.1.

TABLE 67.1
Typical Heat Treatments Employed for Fermented Milk Preparations

Product	Typical Heat Treatment(s)	Reference
Yogurt	90 to 95°C for 2 to 5 min	20
	80 to 85°C for 30 min	
Sour cream	74°C for 30 min	21
	85°C for 25s	
	80°C for 30 min	7
	90°C for 5 min	
Fromage frais	93 for 120s	

The most important impact of heat processing is microbiological. Due to heat treatment, most vegetative bacteria, yeast, molds and pathogens are destroyed ($\geq$5 log cycle reduction is required). This has a strong impact on safety and quality of the resultant product. Surviving spores are unlikely to cause problems, as *bacillus* and *clostridium* endospores do not germinate at the pH of most fermented milks, i.e., pH $<$ 4.5 (20). Heat-stable enzymes are reported to not pose a significant problem in semi-solid fermented milk products (21) with the exception of products like sour cream that may be critical for lipolytic or proteolytic spoilage. With regard to starter culture, reduced competition between surviving flora and starter organisms is beneficial for the growth of the latter. Due to high heat processing employed for milk destined for fermented milk preparation, germicidal activity of milk is destroyed along with natural inhibitors of milk making conditions more suitable for starter growth. Severe heat treatment denatures whey proteins in milk and α-lactalbumin and β-lactoglobulin become attached to casein micelles, especially k-casein. This leads to increased viscosity and enhanced water-binding capacity of coagulum (22).

F. Role of Lactic Starter System

In the limited context of fermented milks discussed in this chapter, starter culture systems can be defined as safe, pure, actively growing, selected lactic acid bacteria that bring about desirable changes to produce a satisfactory fermented product.

Typical starter microflora, inoculation rates, incubation temperature and incubation periods employed in fermented milk manufacture are summarized in Table 67.2. Typical starter flora for yogurt include: *Streptococcus thermophilus* (ST) and *Lactobacillus delbrueckii* ssp. *bulgaricus* (LB). In the United States, the National Yogurt Association recommends the level of at least 10 million live yogurt bacteria per g at the time of consumption if manufacturers wish to display the "Live and Active Cultures" symbol on yogurt packages (23).

The relationship between ST and LB is best described as that of protocooperation and antibiosis (24) as the former is stimulated by free amino acids and peptides produced by LB (25). In turn, LB is stimulated by formic acid, pyruvic acid and carbon dioxide produced by ST at low oxygen concentration (26). As a result, acid production is significantly enhanced in mixed cultures compared to ST and LB grown individually, and yogurt gel tends to set faster. The unique relationship between the two starter organisms also makes yogurt flavour unique compared to other dairy products. Unique flavouring compounds in yogurt include acetaldehyde (optimum flavour and aroma at 23 to 41 ppm), acetone and butanone (contributed from milk), diacetyl, and acetoin (27). Presence of diacetyl (0.5 ppm) contributes to delicate and full flavor and aroma. Acetaldehyde production is mainly attributed to LB. However, in association with ST, acetaldehyde production is considerably enhanced as compared to LB alone (28).

Typical starter flora of sour cream or cultured cream includes: *Lactococcus lactis* ssp. *lactis* (*LL*) *and/or Lactococcus lactis* ssp. *cremoris* (LC)*, Lactococcus lactis* ssp. *lactis biovar. diacetylactis* (LD), *Leuconostoc mesenteroides* ssp. *cremoris* (LeuC). The main sensory attributes of cultured cream are sour taste (lactic acid), buttery aroma (due to diacetyl) and nutty flavor. Starter flora in sour cream exhibit positive (mutually beneficial) association. LD and LC can ferment citrate under aerobic conditions to produce diacetyl. Acetaldehyde in cultured cream is not desirable because it imparts "green" flavor. In such cases inclusion of LeuC in the starter system is advantageous as it scavenges acetaldehyde produced by lactococci. Conversely*, Leuconostocs* that lack proteolytic activity and do not grow well in milk grow better in association with *Lactococci*.

During sour cream manufacture when the citrate level is depleted, diacetyl is reduced to acetoin. Increasing oxygen content in milk may enhance production of diacetyl, however, addition of citrate in milk (0.05 to 0.1%) is a preferable option. Production of cultured cream requires proper selection of bacteria as well as manufacturing conditions to induce the right balance of acid and flavour, because flavor producers are fastidious in their temperature requirements. If the temperature of incubation is maintained much above 22°C, insufficient diacetyl will be produced (29).

Purity and activity checks are very important for optimum performance of the starter system. Purity can be checked by microscopic examination of culture suspension or a catalase test to detect contamination. Starter flora are typically gram-positive, catalase-negative, nonsporulating rod or cocci. An activity test or vitality test can be conducted by monitoring rate of acid development (30). For active cheese culture, acidity development is expected to be at least 0.4% lactic acid after 3.5 hr incubation at 37.8°C with 3% inoculation. For cultured cream and cheese cultures, the activity test can be run at 30°C instead

TABLE 67.2
Typical Starter Microflora, Inoculation Rates, Incubation Temperature, and Incubation Period for Selected Fermented Milk Products

Product	Starter Microflora	Inoculation Rate	Incubation Temperature	Incubation Period
Yogurt	*Streptococcus thermophilus* and	2–3%	40–45°C	2.5–4 hr
	Lactobacillus delbrueckii ssp. *bulgaricus*		30°C	18 hr
Sour cream	*Lactococcus lactis* ssp. *lactis* and or	1–2%	18–21°C	14–20 hr
	Lactococcus lactis ssp. *cremoris*			
	Lactococcus lactis ssp. *lactis bio* var. *diacetylactis*			
	Leuconostoc mesenteroides ssp. *cremoris*			
Fromage frais	*Lactococcus lactis* ssp. *lactis* and or	0.5–3%	27°C	14–16 hr
	Lactococcus lactis ssp. *cremoris*			
	Lactococcus lactis ssp. *lactis bio* var. *diacetylactis*			
	Leuconostoc mesenteroides ssp. *cremoris*			

of 37.8°C. For checking aroma-producing starter bacteria in a mixed culture, a Voges-Proskauer or creatine test can be used. It is also useful to detect gas producing contaminants in a non-gas-forming culture (31).

G. Gel Formation during Fermentation

During the manufacture of semi-solid dairy foods, an irreversible gel is formed due to the destabilization of the casein micelle. The gel can be classified into one of the following groups based on whether it is enzymatic, acid induced, or salt/heat induced (14).

The gel or coagulum formation in fermented semi-solid dairy foods is primarily of the acid type, similar to that of acid-set cheeses. In acid-set cheeses, however, syneresis is desirable, whereas in yogurt or other semi-solid fermented foods it is not desirable.

In studies investigating the acidification of skimmed milk with glucono-δ-lactone at 30°C, the following changes were observed in the casein micelles:

- pH 6.6–5.9, casein micelles were homogeneously distributed with no appearance of change
- pH 5.5–5.2, appearance of micellar disintegration and at pH 5.2 or less, aggregation of casein micelles was observed
- pH 5.2–4.8, casein aggregates contracted and micelles were much larger than the native form
- pH < 4.5, protein network formed with rearrangement and aggregation of casein consisting of micellular chains and clusters with trapped water and milk constituents in the network (32)

H. Proactive Phage-Control Program

Current trend in the fermented milk industry is consolidation of smaller plants in to larger plants and increased production volume. Starter suppliers are now offering ranges of options like direct vat set cultures or frozen concentrated cultures. As a result, the problem of bacteriophage and other microbiological risk factors has been reduced considerably. Nevertheless, preparation of bulk culture cannot be entirely eliminated due to certain practical considerations and in such situations bacteriophage contamination remains a distinct possibility, especially during in-house handling.

In light of this, a proactive phage-control program is necessary. Such a program can be very helpful in maintaining consistent starter performance and thereby in assuring consistent quality of fermented milks.

Many strategies employed in bacteriophage control are summarized below.

- Good whey handling and processing practices. Whey is a principal site where phage multiplication and buildup can occur.
- Adequate heat treatment of bulk culture milk, e.g., 95°C for 30 min to inactivate phages in milk.
- Use of phage-resistant starter cultures or multiple-strain starter or mixed-strain starter used in rotation. Where feasible, direct-vat inoculation with deep-frozen or lyophilized concentrated bulk cultures.
- Use of phage-inhibitory media or phage-resistant media for bulk culture propagation.
- Use of exopolysaccharide-producing strains that are more resistant to phages (33).
- Use of a mechanically protected (e.g., Lewis Jones Alfa Laval) system to maintain asepsis and to avoid contamination of bulk culture.
- Good sanitation practices to ensure freedom from phage build-up on vat surfaces and other potential milk contact surfaces. Chlorine is a better sanitizer compared to iodine or acid sanitizers for phage control.

II. PROBIOTICS IN SEMI-SOLID DAIRY FOODS

A. Introduction

In the early 1900s, Nobel Prize-winning scientist Élie Metchnikoff was the first to propose that acid-producing organisms in fermented dairy foods offered a prolongation of life by preventing fouling in the large intestine (34). From his idea evolved the idea of functional foods as a marketing term in the 1980s. This term is used to describe foods fortified with ingredients capable of producing health benefits. The trend for healthful foods is becoming increasingly popular with consumers because of the awareness that diet can influence health. Probiotic foods are defined as foods containing live microorganisms in significant concentrations that actively enhance the health of consumers by improving the balance of microflora in the gut when ingested (18). This restricts probiotics to products that contain live microorganisms, improve health and well being of humans or animals, and can affect host mucosal surfaces, including the mouth and gastrointestinal tract, and the upper respiratory tract, and the urogenital tract (35). In Japan, a standard for probiotic foods was developed stipulating that a product contain more than 1×10^7 viable *bifidobacteria*/g or mL of product (36). The probiotic must be viable and available at a high enough concentration to effect health benefits (18). These factors are often overlooked or ignored and many of the commercially available probiotic products have shown low populations of probiotics (37).

Fermented dairy products have evolved as the predominant carriers of probiotics in foods. They already have a healthful image that facilitates recommendations of daily consumption, and consumers are aware that fermented foods contain live microorganisms (38). Many of the fermented dairy foods have been optimized for survival of the fermentative microorganisms, which creates important technological advantages for the use of dairy products as probiotic carriers (39).

B. Health Issues

Foods that help prevent disease are becoming increasingly popular with consumers, with 70% of American shoppers believing that certain foods contain components that reduce the risk of diseases and improve long-term health (35). Additionally, 97% of shoppers surveyed in the United Kingdom were willing to change their eating habits to better their health. The benefits of probiotics include inflammatory disease control, the treatment and prevention of allergies, cancer prevention, immune stimulation, and respiratory disease reduction. Many of the suggested benefits of probiotic dairy foods are based on the involvement of the gastrointestinal microflora in resistance to disease. Unfortunately, few well-controlled studies have looked at clearly defined health effects, and many of the reported health benefits are based on unsubstantiated reports. However, the use of probiotics for the treatment of lactose maldigestion, diarrheal disease, lowering of serum cholesterol, and prevention of cancer or formation of carcinogens appear to be well-substantiated (41). Lactose intolerance or maldigestion causing abdominal discomfort affects approximately 70% of the world's population to varying degrees (35). The probiotic bacterium *Lactobacillus acidophilus* has been clinically shown to alleviate the symptoms of lactose intolerance. The recent work in this area indicates that lactose in yogurt, possibly due to lactase-producing bacteria, can be utilized more efficiently than lactose in milk. Additionally, many of the probiotic strains that produce lactase have shown promise in alleviating symptoms of lactose intolerance (40).

Rotavirus is one of the leading causes of gastroenteritis worldwide (41). Gastroenteritis characterized by acute diarrhea and vomiting is a leading cause of death and illness among children, affecting approximately 16.5 million children annually (35). Ample evidence has shown that the probiotic strain *Lactobacillus GG* reduced the duration and severity of rotavirus infection. Oral administration of *Bifidobacterium bifdum* has shown potential for reducing the incidence of diarrhea in infants hospitalized for rotavirus infection (41). Other research suggests that the probiotic bacteria *Bifidobacterium longum* and *Saccharomyces boulardii* prevent antibiotic-associated diarrhea (35).

Much attention has been given to the cholesterol-lowering potential of probiotics. However, the influence of lactic-acid bacteria such as *Lactobacillus acidophilus*, although widely studied, remains controversial (42).

The role of lactic acid bacteria in reducing the incidence of DNA damage and other carcinogenic changes has also been investigated (43). In addition, microflora and composition of the intestinal flora with probiotics might suppress the growth of bacteria that convert procarcinogens to carcinogens. An important index of carcinogenic activity is the activity of enzymes that convert procarcinogens to carcinogens. Several studies have shown an inhibitory effect on these enzyme activities following the consumption of probiotics (41).

Additional research on the prevention or delay of tumor development by probiotic bacteria suggests that they might bind to mutagenic compounds in the intestinal tract. A reduction of mutagens in urinary excretions was found when meals were supplemented with fermented milk containing *Lactobacillus acidophilus*. This suggests that lactobacilli were binding to the mutagenic compounds, thereby reducing their absorption in the intestine. It is inconclusive whether this will lead to a decreased incidence of cancer, but research looks promising (41).

C. Probiotic Cultures

LB and ST are the bacteria traditionally used in yogurt manufacture. While these bacteria have some health benefits, they do not naturally inhabit the gastrointestinal tract.

They do not survive the acidic conditions of the stomach and the bile concentration of the GI tract (18). The probiotic bacteria used currently in commercial products include members of the genera *Lactobacillus (Lb) and Bifidobacterium (B).* The Lactobacillus (Lb) strains that are mainly used in commercial production include: *Lb. acidophilus*, *Lb. johnsonii, Lb. casei, Lb. rhamnosus, Lb. gasseri, Lb. reuteri, Lb. helveticus* and *Lb. plantarum. Bifidoacterium bifidum, B. longum, B. infantis, B. breve* and *B. lactis* are some of the *bifidobacterium* strains that are used commercially (38). Therefore, to be considered a probiotic product, many of these strains are incorporated into the fermented dairy product. Typically, combinations of these strains are used. A product manufactured entirely with probiotic bacteria would require a long incubation time and lowered taste quality. Therefore, it is common practice to manufacture products with both yogurt and probiotic cultures (39).

D. Product Development and Production of Probiotic Dairy Foods

1. Food Interactions and Probiotics

There are several basic requirements for the development of marketable probiotic products. The most basic requirement is that the probiotic bacteria survive manufacturing and storage in sufficient numbers in the product so that they are viable when consumed. Additionally, the probiotic of choice should not have an adverse effect on the sensory properties of the food product. The chemical composition of the food product will also be important in determining the metabolic activity of the probiotic and how successfully it will survive. The amount and type of carbohydrate available, the degree of hydrolysis of milk proteins (amino acid content) and the composition and availability of short-chain fatty acids are essential variables in developing a probiotic semi-solid dairy food.

The interaction between the probiotic organisms and the starter organisms is another important factor to consider in the production of semi-solid fermented dairy foods. Both synergistic and antagonistic effects between organisms exist. This will require the identification of specific strains of probiotics that work in synergy with the starter organisms to achieve efficient acidification and multiplication of organisms during the fermentation process. Antagonistic effects that cause the production of undesirable compounds, such as hydrogen peroxide, benzoic acid and bigenic amines, have been investigated and can be a limiting factor for combinations of starters and probiotics (38).

A critical factor in the development of probiotic dairy foods is the manufacturing procedure. When the probiotic is added following fermentation and before or after cooling, the interactions are kept to a minimum. The metabolic activity of both the starter organisms and the probiotic is drastically reduced at this point and will dramatically reduce interactions. It is critical to maintain cold storage of the product without fluctuations in temperature in order to maintain the quality of the finished product (38).

Another factor of considerable importance is the physiological state of the probiotic. When the probiotic culture is harvested, whether it is in the logarithmic or the stationary phase of its growth and how it is handled following harvesting are critical to it successful addition to a food product. Bacteria from the logarithmic phase have been shown to be much more susceptible to environmental stresses. Environmental conditions that signal to the bacteria the transition from the logarithmic phase to the stationary phase will have an effect on survival during the stationary phase.

2. Production of Semi-Solid Dairy Foods with Probiotic Properties

Because each semi-solid dairy product is manufactured differently, there is considerable variation with respect to starter culture, processing temperatures, ingredients and fermentation time and temperature. All of these factors influence the successful production of fermented dairy products containing probiotics. The methods used to manufacture stirred yogurt and yogurt drinks are best suited to probiotic incorporation following fermentation. Immediately before packaging, the probiotic can be stirred into the product. With set yogurts, the probiotic must be added during fermentation, because stirring in the final stages of manufacturing can destroy the products' consistency (38). The chosen strain must first meet the technological and functional requirements and thus might compromise the full expression of the health properties.

The addition of probiotics to the manufacturing of cottage cheese can also vary. When the probiotic is added with the starter culture during fermentation, a high amount of the probiotic organism will be lost from the coagulum during draining of the whey. It is therefore very difficult to control the concentration of probiotics in the final product. During manufacturing, the whey–coagulum mixture temperature is raised to 50–55°C; this temperature can be destructive to the probiotic organisms. The addition of the probiotics with the cream and spices in the final stages of manufacturing offers the best chance of survival for the probiotic bacteria (38).

III. CONCLUSIONS

Despite considerable advances in scientific understanding of semi-solid cultured dairy products, their manufacture involves fine art and skill. A full understanding of the complex interplay between biological, chemical and technological entities is slowly emerging. Cultured dairy products are different from other dairy products in that they contain deliberately added live lactic acid bacteria with or

without other probiotic bacteria. Therefore, the choice of starter cultures and control of the fermentation process are key parameters in producing quality products. The demand for probiotics-based foods is growing. However, it can be expected that consumer confidence will decrease, unless the dairy industry offers products that have been scientifically proven to exhibit probiotic effects. Thus, additional research on the mechanisms by which probiotic cultures exert their effects on the host is required.

68 Principles of Production of Cheese

E. Waagner Nielsen
Department of Food Science, The Royal Veterinary and Agricultural University

CONTENTS

Cheese, which can be considered as a nutritious and delicious concentrate of valuable nutrients of milk in a stable form, has been produced since prehistoric times. The basic steps of modern cheese production are the same as empirically based cheese making thousands of years ago. The present scientific knowledge on cheese production, however, has been developed mainly during the last 125 years.

I. BASIC PRINCIPLES OF CHEESEMAKING

A. Concentration

The first step in making cheese is coagulation of milk. Milk can be coagulated by the action of rennet enzyme or by acidification. The coagulum has a natural tendency toward syneresis — contraction and expelling of whey (i.e., water and water-soluble compounds of the milk (Fig. 68.1)). Larger particles such as fat globules and bacteria will be retained in the shrinking coagulum, the cheese curd. The syneresis can be accelerated by cutting up the gel and by heating. The resulting firm curd can be pressed and formed into cheeses of various shapes.

B. Preservation

The fresh curd contains valuable nutrients and can therefore be quickly spoiled by bacteria, yeasts and moulds if not preserved. The main factors contributing to preservation are low moisture content (concentration), acidification by adventitious or added lactic acid bacteria, and salting. Spoilage of the cheese by moulds on the surface can be prevented by drying and cleaning the surface or by exclusion of oxygen by immersion in brine or by coating the cheese with wax or synthetic film material.

C. Ripening

Cheese may be consumed as fresh curd or it may undergo ripening by means of enzymes from the milk, from the rennet and from microorganisms in the cheese or on its surface. During ripening, which may last for months, the organic solids of the cheese are gradually hydrolysed and metabolized, during which time the characteristic flavour, consistency and texture of the cheese is developed.

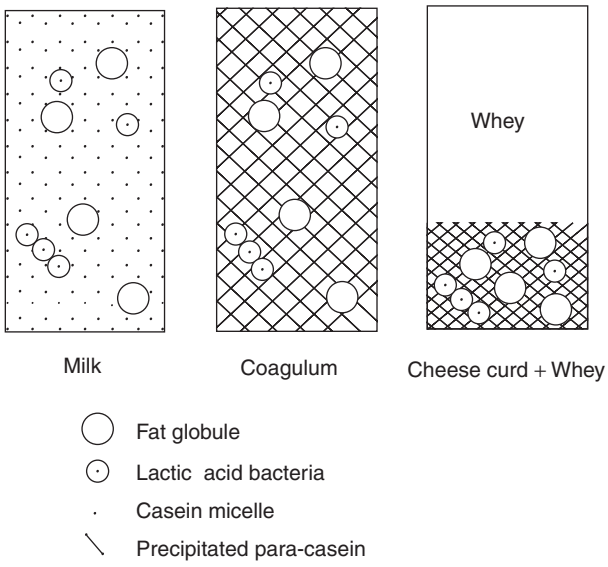

FIGURE 68.1 Outline of the structure of milk, rennet coagulum and cheese curd (1).

In Table 68.1 some of the important types of cheeses are listed and grouped according to method for coagulation of the milk, their firmness and the degree of acidification.

II. YIELD OF CHEESE

The majority of cheeses produced in the world are made from cow's milk. Substantial amounts of cheese, however, are also produced from milk of sheep, goat and buffalo. Many of the milk components vary quantitatively, both between and within species. Estimated mean component figures are shown in Table 68.2.

TABLE 68.1
Cheeses Grouped According to Method of Coagulation, Firmness, and pH Minimum

Coagulation of Milk By	Firmness (Moisture Content on Fat-Free Basis, MFFB)	Acidification, pH of Young Cheese	Examples of Cheese Types
Rennet	Extra hard (<51% MFFB)	5.10	Grana
	Hard (49–56% MFFB)	5.30	Emmentaler
		5.10	Cheddar
	Semihard (54–63% MFFB)	5.20	Gouda, Danbo, Edam, Jarlsberg, Herrgård, Fontina, Svecia, Havarti, Tilsiter
			Heated after acidification: Mozzarella, Kashkaval, Provolone
	Semisoft (61–69% MFFB)	6.10	Heated in whey: Halloumi
		5.20	Heated after acidification: Soft Mozzarella
		5.15	Esrom, Limburger, St.Paulin
		4.70	Blue-veined mould cheeses: Roquefort, Gorgonzola, Stilton, Danablu
	Soft (>67% MFFB)	4.60	White mould cheeses: Camembert, Brie
			Ripened in brine: Feta
			Milk salted: Domiati
Acid	Semisoft (61–69% MFFB)	4.50	Matured sour milk cheese:Gamal ost, Pult ost, Harzer Käse, Olomoucke tvaruzky
	Soft (>67% MFFB)	4.50	Fresh unmatured curd: Homogenous curd: Tvorog, Quarg, Skyr Curd in grains: Cottage cheese
Made from cheese whey:			
Proteins of whey are precipitated by heating			Ricotta, Anari, Whey protein cheese
Solids of whey concentrated by evaporation			Myse ost, Whey cheese

TABLE 68.2
Estimated Mean Figures for Gross Composition of Main Solids of Milk

Species	Fat	Total Protein	Lactose	Citrate	Ash
Cow	3,8	3,3	4,7	0,2	0,7
Buffalo	7,4	3,8	4,8	N.D.	0,8
Goat	5,6	3,8	4,8	N.D.	0,7
Sheep	7,4	5,5	4,8	N.D.	1,0

N.D.: not determined.

A. Recovery of Milk Solids and the Yield of Cheese

When milk is coagulated, either by rennet or by acid, the caseins form a three-dimensional network enclosing all the other milk constituents. When the coagulum contracts, water and water soluble constituents will be squeezed out, whereas fat globules and bacteria will be retained in the casein network as outlined in Fig 68.1.

1. Retention of Protein

The caseins, constituting about 75 to 80% of the milk proteins, are the basic structure-forming elements of coagulated milk and cheese curd. "Casein" is defined as those proteins of milk which become non-soluble when milk is acidified to pH of 4.6 (i.e., α_{s1}-casein, α_{s2}-casein, β-casein, κ-casein and γ-casein; see Table 68.3). The caseins in milk are aggregated in micelles 0.01 to 0.3 μm in diameter, and of the milk salts, much of the calcium, phosphate, magnesium and citrate are associated with these micelles. When cheese is made by means of rennet enzymes, coagulation takes place at about pH 6.6. The coagulation is brought about by enzyme-catalysed hydrolysis of a single peptide bond of κ-casein:

κ-casein ----> para-κ-casein + glyco-macro-peptide (GMP).

The glyco-macro-peptide (GMP) constitutes about one-third of the mass of the κ-casein. The para-κ-casein component of the κ-casein remains as a part of the para-casein in the curd. The GMP is soluble and separates with the other soluble compounds (whey proteins, lactose, water-soluble vitamins and the soluble salts) into the whey. Typical figures for the amount of the various groups of milk proteins as percent of total nitrogen, and their distribution on the non-soluble part (in the cheese curd) and the soluble part (in the whey) after precipitation of casein with acid at pH 4.6 or with rennet at pH 6.6, are listed in Table 68.3; 76% is given as a typical value for retention of protein for rennet cheese. Variations in the relative amounts of the various protein fractions can cause actual protein retention values to vary from about 75 to 78% of total protein (N x 6.38).

Heat treatment of the milk can cause denaturation of the whey proteins. Heat-denatured whey proteins precipitate together with the caseins, giving higher protein retention. *Higher* retention of protein can also be achieved by

TABLE 68.3
Typical Values for Distribution of Nitrogen Compounds (Protein Nitrogen and Nonprotein Nitrogen) of Whole Milk in the Nonsoluble Versus the Soluble (Whey) Components after Precipitation of Casein by Acid at pH 4.6 or by Rennet at pH 6.6

Percent of Total Nitrogen				
After Precipitation at pH 4.6			**After Precipitation by Rennet at pH 6.6**	
	Non-soluble		*Non-soluble*	
Fat globule membrane protein (FGMP)[a]	1		1	Fat globule membrane protein (FGMP)

κ-casein	10	→ para-κ-casein 6.5	6.5	Para-κ-casein
		→ GMP 3.5		
γ-casein[b]	3		3	γ-casein
β-casein[b]	27		27	β-casein
			1.5	Non-soluble proteose-peptone
Total *acid casein* + FGMP	78		76	Total rennet casein + FGMP
	Soluble		*Soluble*	
			3.5	Glyco-macro-peptide (GMP)
Proteose-peptone (pp)[b]	3	→ Non-soluble 1.5[c]		
		→ Soluble 1.5[c]	1.5	Soluble proteose-peptone
Whey proteins	13.5		13.5	Whey proteins
NPN (non-protein-N)	5.5		5.5	NPN (non-protein-N)
Total *acid-whey*-N	22		24	Total *rennet-whey*-N

[a] When cheese is made from whole or part skimmed milk the proteins of the fat globule membrane will be incorporated in the network of the precipitated caseins.

[b] I milk a part of β-casein may be hydrolysed by the action of the milk enzyme plasmin resulting in γ-caseins (the more hydrophobic parts of β-casein) and proteose-peptones (the more hydrophilic parts).

[c] A part of the proteose-peptones, which all are soluble at pH 4.6 , is precipitated with the caseins at pH 6.6. The partition of proteose-peptones on the soluble and the non-soluble parts, after precipitation by rennet at pH 6.6, which in the table is set to 1:1, may be somewhat lower or higher (3, 4).

Source: Data from various sources.

concentrating the protein by ultrafiltration. *Lower* retention of protein may be caused by inflammation of the udder or by growth of psychrotrophic, proteolytic bacteria during cold storage of cheese milk.

2. Retention of Fat and Bacteria

The fat globules with diameters 0.5 to 10 μm will be incorporated into the casein network. Consequently, the retention of fat is high (85 to 95%).

For bacteria the retention is of the same magnitude as for the fat globules.

3. Retention of Lactose

Lactose is dissolved in the water phase of milk and follows the whey out of the curd; hence retention of lactose in curd is low, usually in the range of 3 to 5%, depending on the final moisture content of the cheese and on the amount of water added.

4. Retention of Ash Compounds

Some of the minerals (K^+ Na^+, Cl^-) in milk are dissolved in the aqueous phase and these minerals separate with the whey. Others are present as colloidal particles integrated into the casein micelles (Ca^{2+}, Mg^{2+}, PO_4^{3-}). At the pH of fresh milk, these salts remain in the curd, but as the pH decreases during the syneresis these salts gradually become dissolved.

Some of the phosphate is covalently bound in the casein molecules as serin-phosphate. This phosphate, which accounts for about 2½% of the mass of casein, will be included in the ash in analysis of both milk and cheese, a fact which should be taken into consideration in calculations of cheese yield. The figures found for retention of ash typically are about 35 to 40% for hard and semihard rennet cheese. For Cheddar cheese, with a higher degree of acidification during syneresis, retention of ash is lower — 30 to 35%. For cheeses with acid precipitation of the casein at pH around 4.6 the retention of ash is low — 10 to 15% of total ash.

5. Retention of Citrate

Most of the citrate in milk is in aqueous solution, with 10% linked to the caseins together with calcium in the same way as with inorganic phophate. The retention of citrate therefore depends partly on the whey content of the cheese and

TABLE 68.4
Example of Calculation of Milk Solids in Cheese Curd, Yield of Cheese, and Composition of Cheese, Based on Typical Figures for Composition of Cheese Milk and for Retention of Milk Solids in Cheese Curd

	Milk Solids in Cheese Curd			
	In 1 kg Milk	Retention in Cheese Curd	Gross Calculated for Cheese Curd from 1 kg Milk	Net Calculated for Cheese Curd from 1 kg Milk, with Correction the Part of the Phosphate in the Ash Originating from Serine-PO4
Fat (standardized to give minimum 45% fat in dry matter of cheese)	30.0 g	0.92	27.60 g	27.60 g
Protein	34.0 g	0.76	25.84 g	25.84 g
Lactose (anhydride)	46.0 g	0.035	1.61 g	1.61 g
Ash	7.2 g	0.35	2.52 g	1.87 g
Citrate	1.8 g	0.10	0.18 g	0.18 g
Total solids in fresh cheese curd from 1 kg milk				57.10 g

Yield of cheese:
In addition to the milk solids, the cheese after salting includes extraneous NaCl. If the cheese after salting cheese contains 43% moisture and 57% dry matter, of which 2% NaCl and 55% milk solids, the yield of cheese per kg milk will be:
$57.1 \times 100/55 = 103.8$ g.
Then the composition of the salted cheese can be calculated:

Composition:		%
Fat:	$27.60 \times 100/103.8 =$	26.59
Protein:	$25.84 \times 100/103.8 =$	24.89
Lactose: (converted to lactic acid in cheese)	$1.61 \times 100/103.8 =$	1.55
Ash:	$2.52 \times 100/103.8 =$	2.43
Less the casein-PO_4 included in ash:		−0.62
Citrate:[a]	$0.18 \times 100/103.8 =$	0.17
Total milk solids in cheese		55.0
Plus extraneous NaCl		2.0
Total dry matter in cheese		57.0
Moisture in cheese[b]		43.0

[a] In cheeses like Danbo with citrate fermenting starter bacteria, the citrate is converted within 1 to 2 weeks to volatile compounds such as carbon dioxide, diacetyl and acetic acid.

[b] Under storage and ripening the moisture content of the cheese (and the weight of the cheese) will decrease because of evaporation, unless the cheese is packed in synthetic film or covered with cheese wax.

partly on the acidification during syneresis. For semihard cheeses the retention of citrate is typically around 10%.

B. Calculation of Composition and Yield of Cheese

Table 68.4 shows an example of the calculation of yield of cheese and of composition of cheese. The example is based on typical figures for production of a semihard cheese, e.g., Danbo or Gouda.

III. MILK FOR CHEESE

For production of cheese the milk has to be of good quality.

A. Storage of Milk for Cheese

Unless the cheese is made shortly after milking, the milk should be kept cool until the start of cheese production in order to prevent excessive growth of bacteria. During storage at low temperatures the rennetability may be slightly reduced.

B. Pasteurization

Cheese is often made of raw milk, and it is a common assumption that cheese made of raw milk of good quality can be more rich in flavour. Some pathogenic bacteria, however, such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*, can survive in cheese for months, and in many countries pasteurization of milk for cheese is mandatory. Pasteurization at 72°C for 15 seconds typically kills about 99% of the bacteria of the raw milk. Bacterial spores, however, will not be killed. About 95% of milk lipase will be inactivated at 72°C for 15 seconds, a fact which may help to explain a part of the assumed richer flavour of raw milk cheese. Most of the whey proteins remain unchanged by pasteurization at 72°C for 15 seconds, but at slightly more intensive heat treatment, the whey

proteins begin to denature. Denatured whey proteins precipitate together with the caseins by the action of rennet, or by acid at pH 4.6, yielding a higher total retention of the proteins. For most cheeses, however, a heating greater than 72°C for 15 seconds is normally not applied, because more intensive treatment entails certain drawbacks: slower renneting of the milk and a weaker coagulum; inactivation of the enzyme xanthine oxidase, which catalyzes the reduction of added nitrate to nitrite; and slower development of cheese flavour and texture during ripening.

C. Homogenization

For some types of cheese, e.g., Danablu and Feta produced by ultrafiltration, homogenization may be applied in order to whiten the cream and increase the water-binding capacity of the cheese curd. Homogenization also increases the lipolysis of the fat, provided active lipase is present.

D. Bactofugation and Microfiltration

These processes are widely used in the production of cheese types liable to damaging fermentation by the spore forming bacteria *Clostridium tyrobutyricum* (e.g., Emmental and Gouda/Danbo cheeses). With *bactofugation* a large part of the bacteria, and more than 90% of the spores, can be removed from the milk. With *microfiltration* more than 99.9% of all bacteria and spores can be removed from the skim-milk part of the milk. The cream of the milk then has to be heat-treated separately, as the fat globules otherwise would block up the filter membranes.

In both processes a part of the bacterial spores follow the cream, adhering to fat globules. In order to produce cheese with a low number of *Clostridium tyrobutyricum* spores, the cream can be pasteurised at about 120°C for a few seconds, prior to mixing cream with skim milk from bactofugation or with permeate from microfiltration. Both the retentate from microfiltration and the bactofugate from bactofugation contain most of the spores from the milk and also a part of the casein, and for utilization of this casein, the retentate/bactofugate can be mixed with the cream before the heat treatment.

E. Ultrafiltration

By ultrafiltration, milk can be separated into a *retentate* in which fat, bacteria, casein micelles and whey proteins are concentrated, and a *permeate* containing water and lactose. Salts linked to the caseins in the micelles (most of the calcium and phosphate and a part of the citrate) will be concentrated in the retentate, whereas other salts will follow the water into the permeate. Ultrafiltration thus resembles the natural filtration process in the curd grains in traditional cheesemaking, in which the casein network acts as a filter, with the exception that the ultrafiltration membranes also retain the whey proteins. Concentrating milk for cheese by ultrafiltration is utilized in large scale for production of UF-Feta cheese, where the retentate, with about 40% total solids after addition of starter culture and rennet, can be *cast* directly into tins. Because the whey proteins are retained in the retentate, the yield of cheese by ultrafiltration is higher than in conventional cheesemaking. By ultrafiltration of a part of the milk, the protein content of the cheese milk can be increased and standardized for conventional cheese production.

F. Standardization of Fat Content

Cheeses are usually classified by percent fat in dry matter (FDM) according to legal standards. The fat content of the cheese milk has to be adjusted according to the percent FDM desired and according to the protein content of the milk.

IV. ADDITIVES TO CHEESEMILK

A. Colouring Agents

The colour of cheese is determined by the carotene colour of the milk fat, which may vary with the seasons and with type of milking animals. Jersey milkfat, for example, is usually high in carotene, while sheep milk fat is low. Where colouring is permitted, the colour of cheese may be adjusted by means of annatto extract or carotene dye.

B. Salt

All cheeses are salted, either by addition of salt to milled curd after acidification and before moulding or by absorption of salt by diffusion after the cheese has been formed. A special case is Domiati cheese, where 8 to 15% salt is added to the milk, yielding coagulum and resulting cheese that is very soft.

C. Spore-Inhibiting Additives

For cheese of Gouda/Danbo type there is a risk of *Clostridium tyrobutyricum* spore growth during ripening, resulting in excessive gas production and the development of an unpleasant smell. The spores can be inhibited by means of nitrate added to the milk (0.1 to 0.2 g KNO_3/L); the nitrate is reduced to nitrite (NO_2^-) which inhibits the spores. This reduction is catalyzed by the milk enzyme xanthin oxidase, which is active in milk heated to about 72°C for 15 seconds but inactive at a slightly higher heat treatment. Other possible additives for inhibition of spores are the enzyme lysozyme (from hen's egg white) and nisin (bacteriocin). The use of spore-inhibiting additives is legally restricted in cheese-producing countries.

D. Starter Cultures and Acidification

For most cheese varieties, starter cultures of lactic-acid bacteria are added to the cheese milk. Where the curd is either

TABLE 68.5
Optimal pH Minima for Various Cheeses

Cheese	pH Minimum
Emmental	5.25
Gouda/Danbo group	5.20–5.25
Tilsiter/Havarti	5.15–5.20
Mozzarella	5.15–5.25
Cheddar	4.95–5.10
Feta, Danablu	4.65–4.7
Camembert	4.60–4.70

not heated or heated to about 40°C, starters with mesophilic *Lactococcus* sp. and *Leuconostoc* sp. are used. If formation of carbon dioxide is undesirable (e.g. for Cheddar cheese, and for Feta cheese destined to be put in tins) mesophilic starters without citrate-fermenting *Leuconostoc* sp. and *Lactococcus lactis* subsp. *lactis* biovar. *diacetylactis* (=*Lactococcus diacetylactis*) are utilized. In cheeses scalded at higher temperatures (e.g. Grana, Emmental), lactic-acid fermentation is performed by thermophilic cultures of *Streptococcus thermophilus* and *Lactobacillus helveticus*.

Starter cultures can be local natural starters or laboratory cultures from culture manufacturers either for propagation in the dairy or, as frozen or lyophilized starter concentrates, for direct inoculation in the cheese milk. The amount of starter culture added to the milk is typically about 1% for starter propagated in milk and about 0.01–0.05% for starter concentrates.

Slow acidification due to antibiotics in the milk or the development of bacteriophages can cause serious problems. Bacteriophages will not be destroyed by heat treatment of the milk at about 72°C for 15 seconds, so there will always exist a risk of development of bacteriophages, along with the starter bacteria, in a cheese factory. Counteractive measures include careful cleaning and disinfection with chlorine or disinfectants with peracetic acid (hydrogen peroxide has no effect on bacteriophages), preventing any contamination of milk and curd with whey, propagation of starter culture in highly heated milk in a separate room, the use of starter cultures with good bacteriophage resistance, and if necessary, change of starter culture. Fast development of lactic acid bacteria is of utmost importance for cheese quality. For each type of cheese there is an optimal range for minimum pH; Table 68.5 gives some examples.

The effects of lactic acid bacteria are:

1. *Coagulation and syneresis:* The lactic acid promotes the action of rennet enzyme and the acidification of the curd increases syneresis. In the production of sour milk cheese (Quarg, etc.) the milk is coagulated only by the acid produced by the starter bacteria.
2. *Inhibition of detrimental bacteria:* Lactic acid bacterial growth inhibits harmful bacteria by fermentation of the lactose and by the formation of lactic acid. Some of the lactic acid bacteria also produce bacteriocins which may inhibit other bacteria.
3. *Control of consistency:* The acidification controls the consistency and texture of the cheese. If the pH becomes too low, much of the calcium is dissolved from the casein network and the cheese will be brittle and less coherent. If the acidification is weak, little calcium is dissolved and the cheese mass will be rubbery. For semihard, sliceable cheese, the best consistency is obtained with a fresh cheese pH at about pH 5.2.
4. *Control of enzyme activity:* pH determines the activity of the various enzymes of the cheese during ripening.
5. *Taste:* The lactic acid is important for the fresh acid taste of young cheese.
6. *Low redox potential:* The lactic acid bacteria lowers the redox potential to about −150 mV, yielding cheese that can be kept for a long time without the development of off-flavours owing to oxidation of milk fat.
7. *Formation of proteolytic enzymes:* The lactic-acid bacteria have proteolytic enzymes important for the breakdown of proteins during ripening. Intracellular peptidases, released after autolysis of the cells, are responsible for the formation of free amino acids; starter bacteria may also contribute to conversion of amino acids into various flavour compounds.
8. *Formation of CO_2 and diacetyl:* If the starter contains citric-acid-fermenting bacteria, such as *Leuconostoc* sp. and *Lactococcus diacetylactis*, the citric acid will be converted to acetic acid, diacetyl/acetoin, and CO_2.

E. The Course of the Acidification of Cheese

As described above, acidification is of fundamental importance for the quality of cheese. The velocity of the acidification is also important. A too-rapid drop in pH may cause the cheese to become too sour and too hard (increased syneresis); on the other hand, slow acidification gives the opposite effects, and there will be a risk for growth of detrimental bacteria. Fig. 68.2, left, illustrates the rate of acid development during the first 24 hours for a typical semihard cheese such as Gouda/Danbo, for a blue-veined cheese (Danablu) and for milk, all starting with inoculation with 1% mesophilic starter culture at 30°C. Fig. 68.2, right, shows the rise in pH for both types of cheese during ripening owing to release of ammonia by the breakdown of proteins and by degradation of lactic acid. The faster increase in pH during ripening for Danablu compared to

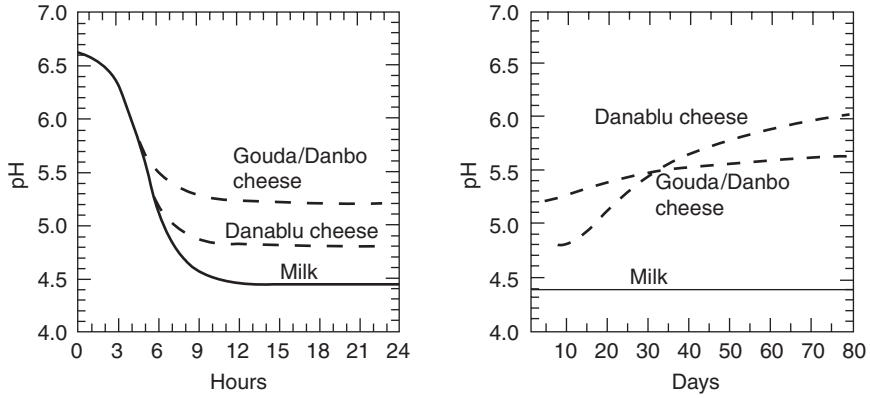

FIGURE 68.2 The course of acidification for a Gouda/Danbo cheese, for a blue-veined cheese (Danablu) and for milk, respectively, during the first 24 hours after inoculation with 1% mesophilic starter culture, all starting at 30°C (left). The graph to the right show pH changes during storage and ripening. The fall in pH during the first 24 hours is caused by the fermentation of lactose into lactic acid by the lactic acid bacteria. The rise during storage is caused by release of amino acids and ammonia by breakdown of proteins and by degradation of lactic acid. The bottom curve applies to milk inoculated with lactococci and which is protected from infection by yeasts and moulds during storage (1).

Gouda/Danbo is a result of very active proteolytic enzymes from the mould and aerobic degradation of lactic acid. In milk acidification stops at about pH 4.4 because the bacteria are completely inhibited by lactic acid at low pH, although there will still be surplus of nonfermented lactose. In cheese the inverse situation prevails: The growth of the bacteria and the decrease in pH end when all of the lactose is used up, not because pH has become too low.

For the Gouda/Danbo cheese the pH levels off at about pH 5.2, while for the blue-veined Danablu cheese pH continues to decrease until a minimum pH at 4.7. This difference is due to a difference in the lactose/buffering capacity ratio. The amount of lactose determines the amount of lactic acid formed, and the amount of buffers (i.e., protein and inorganic phosphate) determines the change in pH for a given amount of acid. In the young blue-veined cheese there is a higher moisture content compared to the Gouda/Danbo cheese, hence a higher content of lactose. At the same time, the blue-veined cheese has a lower content of buffers (protein and inorganic phosphate) than the Gouda/Danbo cheese.

A further important factor which contributes to a higher pH minimum in Gouda/Danbo cheese compared to the blue-veined cheese is that for Gouda/Danbo, water is added to the mixture of whey and cheese grain in order to dilute the whey, thereby reducing the lactose concentration.

However, the pH minimum is not solely a function of the ratio lactose/buffers. As long as the curd grains are dispersed in the whey, lactose can diffuse from the whey into the grains in replacement of that which has been fermented into lactic acid during stirring. (About 90% of the lactic bacteria are concentrated in the curd grains, hence the lactose fermentation mainly takes place here). Consequently, the total decrease in pH may be seen as two phases: Phase one, the decrease of pH in the curd grains until their final separation from the whey, and phase two, the decrease in pH in the cheese curd after it has been finally separated from the whey; in this phase the decrease in pH is determined solely by the lactose/buffers ratio.

An approximate calculation of pH minimum:

$$\text{pH minimum} = \text{pH}_1 - 0.8298 \times (\text{L/B}) \times (\text{pH}_1)^2 + 24.89 \times \text{pH}_1 \times (\text{L/B})^2,$$

where pH_1 is pH at moulding/start of pressing (when cheese grains are finally separated from the whey), L is % lactose hydrate of the pressed cheese, and B is buffering capacity = % protein of the pressed cheese + 19 x % inorganic phosphate (5). For Cheddar cheese the addition of salt to the milled curd may, depending on the concentration of salt, delay or stop the acidification before all lactose has been completely fermented (5). In the model it is assumed that all lactose is converted to lactic acid. Lactose is calculated here as hydrate; therefore, one weight unit of lactose corresponds to one weight unit of lactic acid.

Calculation:

$$\text{L} = \frac{\text{Lm(100-A(100-Tw-h*Pw)/(100-Tm-h*Pm)) *((100-Tc-h*Pc)/100)}}{\text{(100-Tm-h*Pm)-A(100-Tw-h*Pw)/100 + W}},$$

where Lm is % lactose hydrate in milk, Tm and Pm are % total solids and % protein, respectively, in milk, Tw and Pw are % total solids and % protein in whey, and Tc and Pc are % total solids and %protein in cheese (24 h). A is the amount of whey (% of milk by volume) removed during stirring,

W is Water (as % of milk by volume) added to the mixture of whey and curd grains during stirring. h (exclusion factor (2)) is the amount of water bound to protein in such a way that it cannot function as solute for lactose. h can be set to 0.3 g H_2O per g protein (6).

F. Non-Bacterial Acidification

In some countries it is allowed for certain types of cheeses (eg. Quarg, Cottage Cheese and Mozzarella) to acidify the curd by phosphoric, acetic or citric acid, or by gluconodelta-lactone which is slowly converted to gluconic acid.

G. Other Microorganisms

1. *Propionibacteria.* For Emmental cheese and other types with large eyes, cultures of *Propionibacterium* sp. are added in order to initiate fermentation of lactic acid to propionic acid, acetic acid and CO_2, the latter contributing to the formation of the large holes.
2. *Moulds.* For blue-veined mould cheeses, spores of *Penicillium roqueforti* are added to the milk. For white mould cheeses, spores of *Penicillium camemberti* and other *Penicillium* species are added to the milk or onto the surface of the cheese.
3. *Secondary flora of lactic acid bacteria.* In semi-hard cheeses the number of starter bacteria culminates at about 10^9 cells per gram after 1–2 days. Thereafter these bacteria gradually die out and autolyse. During the first month of ripening 99% of the lactococci may die out, and simultaneously a secondary flora of lactobacilli develops and may grow to a number of 10^7–10^8 cells per gram (7). These lactobacilli, mainly belonging to the group of facultatively heterofermentative lactobacilli (e.g., *Lactobacillus casei/paracasei*) develop spontaneously in the cheese and are found only in low numbers, e.g., 1–10 per mL or less, in pasteurized cheese milk; they may originate from the flora in the cheese factory or they may be lactobacilli surviving pasteurization. Pediococci have also been found in the secondary flora. Although the presence of a secondary flora in cheese has been known for more than hundred years, knowledge of their growth and their effects on the cheese is still relatively scarce. There are indications that the secondary flora may have positive effects on the quality of cheese, for example, by inhibition of detrimental bacteria such as heterofermentative lactobacilli (8) and *Clostridium tyrobutyricum* (9) and by the consumption of oxygen diffusing into the cheese (10).

H. Rennet

The primary effect of rennet is coagulation of the milk. Later, rennet enzymes play an important role in the hydrolysis of proteins during ripening. The coagulating activity of *calf rennet*, or *standard rennet*, is due to the enzyme chymosin. Traditionally rennet is made from the fourth stomach of calves, abomasum, which is sliced and extracted in a weak-acid/salt solution. The extract is filtered and the pH adjusted to 5.5. Finally, 15–20% salt and benzoic acid is added. Milk-coagulating enzymes can also be extracted from stomachs of oxen or from other animals, by the fermentation of certain moulds, or by microorganisms into which the gene for chymosin has been cloned.

1. The Enzymatic Coagulation Process

The coagulation takes place in two phases. First a negatively charged part of the κ-casein (1/3 of the κ-casein molecule) is split off by hydrolysis (catalysed by the rennet enzyme) of one peptide bond (no. 105, phenylalanin/no. 106, methionin) in κ-casein. The casein micelles thereby lose a part of the negative charge which otherwise prevents the micelles from coagulating. The casein (paracasein) is now insoluble in the presence of Ca^{2+}. In the second phase of renneting the paracasein micelles aggregate by hydrophobic attraction between hydrophobic amino acid residues in the caseins. With 30 mL standard rennet per 100 L and at 30°C, the first phase takes about 10 minutes and the second phase about 1 minute. It then takes about 20 minutes before the coagulum is sufficiently firm for cutting.

I. Addition of Calcium Chloride

Addition of $CaCl_2$, 5 to 20 g per 100 L, can increase the rate of renneting partly because the addition of $CaCl_2$ produces a slight reduction in pH.

V. PRODUCTION OF CHEESE CURD

After the milk has formed a firm coagulum, the next steps (cutting, stirring and heating/scalding) have the purpose of controlling the syneresis of the curd in order to achieve the appropriate level of moisture.

A. Cutting

The coagulum is cut in grains by means of knives or fine steel wires. The size of the grains influences the syneresis — the finer the cut, the lower the moisture content in the cheese. For soft cheese the grain size is 15 mm or larger, for semi-hard cheese 5 to 10 mm, and for hard cheese 2 to 5 mm.

B. Stirring

After cutting, whey begins to be squeezed out of the grains and the syneresis begins. The mix of whey and grains is

then stirred, at first gently, in order to enhance syneresis. The stirring is continued until the grains have reached the desired firmness. The stirring may take from one to two hours. The main factors for the syneresis are: fat content of milk, size of the grains, pH and temperature during stirring. Lower fat, smaller grains, lower pH and higher temperature increase syneresis.

C. Heating/Scalding

Heating during stirring is usually not applied for soft and semi-soft cheeses; however, for semi-hard cheese heating to 34 to 38°C is typical, for hard/semi-hard cheeses to 37 to 40°C and for hard cheeses 50 to 56°C (scalding). The heating/scalding can be done by heating the mixture of whey and grains by steam in the jacket of the cheese vat or by the addition of hot water to the whey. Addition of water reduces the lactose content of the curd and, consequently, the amount of lactic produced in the pressed cheese. Another effect of heating/scalding is that the lactic-acid bacteria, and their acid production under stirring, will be inhibited because the temperatures applied are above their optimum.

If a higher heating temperature for Gouda/Danbo cheese is used, the starter bacteria will grow more slowly in the cheese grains, and the pH at the end of stirring/moulding will consequently be higher. Although higher pH during stirring will in itself *reduce* syneresis, the higher heating temperature will *increase* syneresis. Experience shows that the net result will be lower moisture content in the cheese. A higher heating temperature will also cause a higher pH minimum of the cheese, because the cheese grains will have a higher pH at the end of stirring/at moulding and because the pressed cheese has a lower moisture content, and consequently, a lower content of lactose. In summary: Higher heating temperatures for a semihard cheese such as Gouda/Danbo type will result in a more firm, less acid cheese.

D. Final Treatment of the Cheese Curd

When the cheese grains have reached the desired firmness they must be separated from the whey. The curd can then be put directly in moulds or it can be given further treatment before final moulding.

On the whole, a few different moulding methods are used for the many varieties of cheese:

- Curd grains are pressed under whey before moulding (round-eyed cheeses).
- Curd grains are pressed under whey before moulding and boiled in whey (Halloumi cheese).
- Grains are separated from the whey before moulding (granular cheeses, soft cheeses).
- Grains are separated from the whey and the curd is left a few hours for continued acidification (cheddaring) and then milled, salted and moulded (Cheddar, Stilton) or milled and then warmed and kneaded before moulding (e.g. Mozzarella).
- After being concentrated by ultrafiltration and added rennet etc., the cheese is cast directly in moulds or in the package (e.g., UF-Feta).
- Sour-milk cheese: After acidification of the milk to about pH 4.6 the whey is separated from the precipitated curd, which can then be packed for consumption (Tvorog, Quarg, Skyr) or formed into small cheeses and ripened (Olmützer quargeln, Harzer käse, Pult ost).
- Grains of acid precipitated coagulum, gently cut and stirred and heated, are separated from the whey and the loose grains are packed for sale (Cottage cheese).

The following describes more in detail some of the above-listed principles for handling the curd.

1. *Round-eyed cheeses:* The curd grains are collected under whey, avoiding mixing with air, lightly pressed and cut in pieces, one for each cheese, placed in moulds, and finally pressed for 1 to 2 h or more. The moulds are equipped with clothes or perforated for drainage of whey and for formation of a closed rind on the cheese. This method results in a closed texture with only microscopic bubbles of air. The closed texture is an important factor for obtaining the desired structure of round-eyed cheeses. The starter cultures used for semi-hard round eyed cheeses, e.g., Gouda/Danbo, contain bacteria which in 1 to 2 weeks can ferment the citric acid, thereby producing CO_2.

   Initially CO_2 is dissolved in the cheese but eventually the combined pressure of CO_2, and that of the N_2 dissolved in the cheese begins to expand the largest of the microscopic air bubbles. If the velocity of the formation of CO_2 is suitable, the gas will expand only a few of the largest air bubbles because of the physical law

$$\text{Pressure in a bubble} = \frac{\text{surface tension}}{\text{radius of the bubble}},$$

   which states that less gas pressure is required for enlarging a large hole than a small one (11). The same applies for large-eyed cheeses, e.g., Emmental and Jarlsberg, where the eyes are expanded by CO_2 produced by propionic-acid bacteria by fermentation of lactic acid.
2. *Halloumi cheese.* After stirring, the grains are pressed under whey, then cut in 300-gram pieces, put into boiling whey and kept at about 90°C

for 30 minutes. After cooling, the Halloumi cheese is stored in brine.

3. *Granular cheeses, soft cheeses*. The whey is drained from the curd grains, which are then scooped into moulds. If the grains are relatively firm, as in semi-hard cheeses, e.g., Tilsiter, air will be mixed in between the grains, which then cannot fuse completely; therefore a large number of tiny air pockets will be incorporated, giving a granular texture. When CO_2 is formed during ripening, the gas enlarges the air pockets, producing irregularly shaped holes.

   In blue-veined cheeses, e.g., Roquefort and Danablu, the air pockets, enlarged by CO_2 from bacteria and yeasts, make up the spaces in which *Penicilium roqueforti* can grow provided atmospheric oxygen is given access via openings in the cheese. If the curd grains are large and soft when put in moulds, as for Camembert and Brie, the texture of the cheese can be without mechanical openings between the grains. Production of CO_2 may produce holes, but most of the CO_2 will diffuse out of small-sized cheeses. Soft cheeses are usually pressed only by their own weight.
4. *Cheddar and "Pasta filata" cheese — Provolone, Mozzarella and Kashkaval*. The curd grains are separated from the whey and the curd is left for a few hours for continued acidification (cheddaring) until a pH value about 5.1 to 5.3. Then the curd is milled into chips.

   For Cheddar, salt is added (2–2½%). Some of the whey, which dissolves about 25% of the added salt, is squeezed out from the chips, while the remaining 75% of the salt is absorbed in the cheese. Finally the curd is hooped, pressed, wrapped in plastic film and packed in cartons and placed in storage for ripening.

   In the production of Provolone, Mozzarella and Kashkaval, the chips of milled, acidified curd are conveyed or shovelled into a container filled with hot water or brine at 75 to 85°C and the curd is kneaded until it is smooth and elastic. The curd then is formed in moulds and cooled.

VI. SALTING OF CHEESE

Salt is important for conservation of cheese and for a balanced, pleasant taste and for consistency. For many cheeses salting also plays a role in reduction of the moisture content. For most semi-hard and semisoft cheeses, 1.5 to 2% NaCl is suitable. For Emmental and other large-eyed cheeses the salt content is lower, 0.8 to 1.4% , in order to facilitate the growth of propionic-acid bacteria. For blue-veined cheese, 3 to 3.5% NaCl is suitable.

The salting can be achieved either by adding salt to the curd before moulding, or by diffusion of salt into the cheese after moulding, by immersion in brine or by dry salting. The lactic-acid bacteria are sensitive to salt and will be severely inhibited if the cheese is salted before acidification has finished.

A. Salting before Moulding

For Cheddar cheese and Stilton, the curd is allowed to continue acidification until about pH 5.2 during the cheddaring process. Then the curd is milled, salted and moulded.

B. Salting after Moulding

For most other cheeses made without a cheddaring process, the curd is put in moulds and pressed shortly after the end of stirring. At that point the pH typically will be about 6.2 to 6.4, and, if more than a small amount of salt is added, the growth of starter bacteria and the acidification will be severely inhibited; the formed cheese therefore has to be salted by absorption of salt from dry salt or from brine.

1. Dry Salting

For dry salting the surface of the cheese is rubbed with dry salt or a salt paste.

2. Brine Salting

For salting in brine, cheeses are immersed in brine (20 to 22% NaCl) at 10 to 15°C. Salt is taken up by the cheese while at the same time some moisture is forced out. The loss of moisture, which is higher than the uptake of salt, gives the cheese a firm rind. The uptake of salt and loss of moisture depends on the geometrical dimensions of the cheese, its moisture content, and its fat content and on the concentration of the brine.

Some examples for salting duration in brine with 20 to 22% salt:

- Grana cheese, high cylinder, 45 kg, 1.7% NaCl: 3 weeks.
- Emmental cheese, flat cylinder, 100 kg, 0.8 to 1% salt: 3 days.
- Semi hard cheeses (Gouda/Danbo etc.), 2 to 12 kg, 1.6 to 2.2% NaCl: 1 to 3 days.
- Soft cheeses (Camembert, Brie etc.), 0.1 to 1 kg, 1.5 to 2.5% NaCl: 0.5 to 3 hours.

The uniform diffusion of the absorbed salt throughout the cheese may take up to several week depending on the weight, moisture content and dimensions of the cheese.

VII. RIPENING OF CHEESE

Although cheeses like cottage cheese and Quarg are consumed fresh, most cheeses require a ripening period (from

a few weeks up to several years) for development of characteristic flavour, consistency and appearance. The changes during ripening are brought about by enzymes and microorganisms. The effects of the enzymes and the microorganisms depend on pH and temperature, on the content of moisture and salt and the surface treatment.

Examples of regimens for storage for ripening:

- Emmental: 2 weeks at 12°C; 3 to 6 weeks at 20 to 24°C; then at 8 to 10°C.
- Cheddar: 4 to 12 months at 6 to 10°C.
- Semihard cheeses, Gouda/Danbo, etc.: 2 to 4 weeks at 12 to 18°C; then at 6 to 10°C.
- Blue-veined cheese: 3 to 5 weeks at 8 to 12°C; 1 to 3 months at 2 to 6°C.
- White mould cheese: 1 to 2 weeks at 12 to 15°C; 1 to 2 weeks at 6 to 10°C; 2 to 6 weeks at 2 to 5°C.

A. Fermentation of Lactose and Citric Acid

The fermentation of lactose to lactic acid by lactic-acid bacteria and the fermentation of citrate by citrate using bacteria in DL-starters are described in the sections above. In cheeses such as Emmental and other large-eyed cheeses lactic acid is further fermented by propionic acid bacteria to propionic acid, acetic acid and CO_2.

B. Proteolysis

The caseins are gradually hydrolysed by rennet proteinase enzymes and by plasmin, an indigenous milk protease, which yields a number of large polypeptides, but which do not influence the flavour of the cheese (some hydrophobic peptides may be astringent or may have a bitter taste, however). These first steps of the proteolysis are important for changing the structure of semi-hard cheeses from a rubber-like to a sliceable consistency.

Some of the peptide bonds in the polypeptides can be further hydrolyzed by enzymes from the lactic-acid bacteria to yield smaller peptides and free amino acids, contributing to the basic taste of cheese. Amino acids may be further converted to smaller molecules — ammonia, organic acids, amines, esters, low molecular sulphur compounds, etc., contributing to the aroma of ripened cheese.

1. Extent and Depth of Proteolysis

The speed of the breakdown of proteins and the amounts of resulting compounds produced during ripening are very different for the various kinds of cheese and depend on a range of factors: Type and amount of rennet, type of starter bacteria, level of moisture, pH of the cheese, salt percentage and storage temperature.

The progression of proteolysis can be monitored by electrophoresis, by HPLC and by separation of the casein and its breakdown products into groups according to their solubility. In the classical ripening analysis the *extent* of proteolysis is defined as the amount of total nitrogen which is soluble at pH 4.4 (12). The *depth* of the ripening is defined as the amount of the nitrogen present as amino acids and low molecular nitrogen compounds. The amount of free amino acids can be estimated by nitrogen determination in the filtrate after precipitation with phosphotungstic acid (13) or by a titration with formaldehyde (14) or by other methods (15).

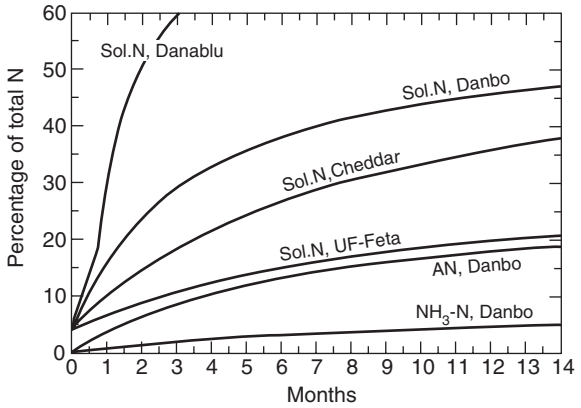

FIGURE 68.3 Typical development of soluble nitrogen at pH 4.4 during ripening as percent of total nitrogen for Danablu cheese, for semihard Danbo cheeses and similar Danish cheeses with moderate smear ripening, for Cheddar cheese and for Feta cheese (made by ultrafiltration). For Danbo and similar Danish cheeses curves are also shown for typical development for amino nitrogen (determined by precipitation with phosphotungstic acid or by formol titration) and for NH_3 nitrogen during ripening. (Based on data from (5) and (17)).

Fig. 68.3 shows curves for soluble nitrogen production during ripening for blue-veined Danablu cheese, for semi-hard Danbo cheese with moderate smear ripening, for Cheddar cheese and for Feta cheese. For the Danbo curves are also given for amino nitrogen (determined by phospho-tungstic acid or by formol titration) and for NH_3 nitrogen. (Based on data from (5) and (16)).

2. Surface-Ripening

Aerobic microorganisms may develop on the surface of cheese. If the surface is moist, bacteria and yeasts may form a red-brownish smear, in which protein and fat is catabolized, producing fatty acids, amino-acid breakdown products such as ammonia, and various low molecular sulphur compounds; these compounds diffuse into the cheese and impart a spicy flavour to the cheese, the intensity of which depends on the growth of the surface flora, the dimensions of the cheese, its moisture content, and the temperature and duration of surface ripening.

3. Feta and Similar Cheeses

Feta and similar cheeses are acidified to a low pH, about 4.4 to 4.6, and kept in brine. The enzymes of rennet retain

some activity; the peptidases of the lactic-acid bacteria, however, are practically inactive at this low pH. Hence proteolysis in Feta is rather limited, and the amounts of free amino acids and ammonia produced are low and there is no increase in pH during ripening.

4. White Mould Cheeses

Like Feta, fresh white mould cheeses are low in pH, about 4.5 to 4.7. The ripening of a Camembert cheese is dependent on the growth of white mould on its surface, which consumes lactic acid and produces ammonia from proteins. The pH of the rind soon rises to pH >7, and a pH gradient is created from the surface to the center (17). The pH increases gradually throughout the cheese, thereby activating peptidases of the lactic acid bacteria and releasing amino acids from the peptides. The ammonia and other metabolic products from the mould diffuse into the cheese and contribute significantly to the flavour.

5. Blue-Veined Mould Cheeses

The pH of fresh blue-veined cheeses is rather low, about 4.6 to 4.8, so a complete ripening process is dependent on the growth of mould, analogous to that described above for white-mould cheeses. *Penicillium roqueforti* is able to grow at rather low oxygen tension, hence it can develop in openings and caves inside the cheese, if there is oxygen access via perforations of the cheese. The moulds in blue-veined cheeses produce highly active protein- (and fat-) degrading enzymes.

C. Lipolysis

By lipase enzymes the triglycerides of milk fat can be hydrolysed into free fatty acids and glycerol. The short-chain fatty acids have a sharp, pungent flavour, which although undesirable in milk and butter, may contribute to a balanced flavour in some ripened cheese because of these fatty acids and other metabolites, such as metyl ketones and esters. In some cheeses, lactones, produced from hydroxy acids of the fat, may also contribute to flavour.

1. Lipolytic Activity in Cheese

a. *Milk lipase.* The indigeneous lipase of milk can produce a significant lipolysis in cheese made from raw milk (Table 68.6). Pasteurization of the milk at 72°C for 15 seconds inactivates about 95% of the milk lipase.
b. *Rennet and starter bacteria.* Standard rennet do not contain lipase and the starter cultures of lactic acid bacteria do not produce enzymes which can liberate fatty acids from milk triglycerides.

TABLE 68.6
Examples of Typical Acid Degree Values for Cheese Fat (16)

Cheese	Acid Degree* (BDI)
Non hydrolyzed milk fat	0.5–0.8
Flavour threshold value for milk	1.2
Semi hard cheese from raw milk, ripened 6 months	3–5
Semi hard cheese, made of pasteurized milk of good quality, ripened 6 months	1–2
Semi hard cheese, made of pasteurized milk with 500,000 of psychrotrophic bacteria per mL before pasteurization, ripened 6 months	3–5
Blue-veined cheese (Mycella) made of raw milk, ripened 3 months	10–20
Blue-veined cheese (Danablu) made of raw homogenized milk, ripened 3 months	30–50

* mL 1 N alkali per 100 g fat

Consequently there will be only slight lipolytic acitivity in cheese made of good quality pasteurized milk.

c. *Added enzyme preparations.* Traditional rennet paste, made by macerating the stomachs and pregastric regions of lambs or kid goats, contains pregastric lipases with high specificity for the liberation of short-chain fatty acids, which in cheese can contribute to a piquant flavour, e.g., Provolone and Feta (18).
d. *Lipases from psychrotrophic bacteria.* In raw milk psychrotrophic, Gram negative bacteria may produce lipases (and proteases). These bacteria are killed by pasteurization, but their enzymes may persist (19). If the milk is high in psychrotrophic bacteria before pasteurization, thermoresistant bacterial lipases can split fat during ripening. Concomitantly an unclean flavour may develop, owing to thermoduric protein degrading enzymes from the psychrotrophic bacteria.
e. *Lipases from surface microflora.* Bacteria and yeasts in the smear on surface-ripened cheeses can hydrolyse fat on the surface and the liberated fatty acids can diffuse into the cheese (20) and contribute to the flavour, in combination with ammonia and other low molecular compounds from degraded proteins of the surface smear.
f. *Mould lipases.* The moulds of blue-veined and white-mould cheeses produce very active lipases. However, in Camembert, for example, the contribution of free fatty acids to the flavour is reduced because of the dissociation of the acids at the high final pH.

2. The Influence of Homogenization on Lipolysis

Homogenization increases the effect of lipase dramatically. If raw milk is homogenized, e.g., for blue-veined cheese, then significant lipolysis, catalyzed by the milk lipase, will occur quickly in the cheese vat. The combined effect of milk lipase and the mould lipases during ripening is also increased by homogenization of the milk (21).

3. Extent of Lipolysis

The hydrolysis of fat can be measured by titration of fat extracted from the cheese, e.g., by boiling with BDI-reagent after adjustment of pH to 4 (21). This method recovers about 70% of the free fatty acid. Table 68.6 give some examples for acid degree of fat from various cheeses.

D. Finishing the Cheese

Hard and semi-hard cheeses after a stable rind has been formed are often given a layer of cheese wax in order to prevent further loss of moisture. For semi-hard cheeses with surface ripening, the smear should be removed after 2 to 3 weeks, and the cheese dried carefully, before waxing can be applied. Mould cheeses, soft cheeses and formed, ripened sour-milk cheeses usually are packed in aluminium foil. Feta-type cheeses and Halloumi, kept in brine in containers, are sold directly from the container or packed in plastic bags with brine.

ACKNOWLEDGMENT

69 Yeast

Bernard Poitrenaud
Lesaffre International

CONTENTS

I. INTRODUCTION

The general public is often confused between baking powder, incorrectly called "chemical yeast," and baker's yeast, which is biological in origin. The availability of active dried yeast, a staple product, only adds to the confusion. The packaging is similar and contains a powder, whilst the baker retails or sells small 42-gram cubes of a semi-moist product, with a plastic appearance.

The craft baker, however, knows that the bread he makes will not be as light, or have the same texture and organoleptic properties as the first product. Bread is a symbolic food about which there is universal agreement, despite the different ways it is made, because a special production method is used: fermentation.

Fermentation is a 5,000-year-old process which was based on the renewal of a previously risen dough: the starter dough (levain). Since earliest antiquity, the manufacture of bread and beer went hand in hand. In the palaces of ancient Egypt, leavens were activated by collecting the foam which rose to the surface of mash tubs. Pliny the Elder, a 1st century Roman naturalist, writes that the bread made in Gaul and on the Iberian peninsula owed its incomparable lightness to the addition of this foam. This method, which was taken up again in the 17th century to make a soft bread and was much talked about, was subsequently widely used (1). When brewers in the 16th century opted for low-fermentation yeast, instead of high-fermentation yeast, it was not at all suitable for bread manufacture. Distiller's yeast filled the gap. It soon opened the door in Europe to a fledgling industry, which expanded, particularly in Austria in 1846 with the Mautner process, then in England in 1886, with continuous aeration of a culture medium. This was the beginning of the biotechnology era, although people were unaware of this at the time. In fact, it was only in the years between 1857 and 1863 that Louis Pasteur demonstrated the role of yeast as the microorganism responsible for fermentation. The yeast industry made a crucial advance between 1910 and 1920 when Sak, a Dane, and Hayduck from Germany developed the continuous sugar-feed process in the presence of oxygen, known as "Zulaufverfahren" or feed-batch process (2).

TABLE 69.1
Yeasts for Different Baking Applications

Applications	Genus	Species
Multipurpose	*Saccharomyces*	*Cerevisiae*
High sugar doughs	*Saccharomyces*	*Rosei*
	Saccharomyces	*Rouxii*
Flavor enhancement	*Saccharomyces*	*Delbrukii*
	Candida	*Lusitaniae*
Sourdough starters	*Saccharomyces*	*Exiguus*
	Torulopsis	*Holmii*
	Candida	*Milleri*

Source: G. W. Sanderson (1985).

Worldwide production of baker's yeast was about 2.8 million tonnes a year in 2003. This is the largest quantity of microorganisms produced, thanks to the enormous technical and scientific progress this industry has been able to exploit and develop. As a result of the innovative processes it uses, the yeast industry has also supplied all the fermentation industries, which are a feature of biotechnology today: production of enzymes, amino acids, vitamins, and substances with a therapeutic use: hormones, antibiotics, vaccines, and more.

II. YEAST: A LIVING ORGANISM MADE UP OF A SINGLE CELL

A. BIOLOGY

1. Its Place in the Living World

The yeasts found in the flora of cereals belong to different genuses: *Pichia, Candida, Saccharomyces*. The latter is the most common comprising the species *cerevisiae* (80%), *exiguus, minor, uvarum, ellipsoïdus, turbidans* (3).

Although the *Saccharomyces* genus is generally used in brewing, wine-making and baking, the *cerevisiae* species does not give the best results in each of these applications. This is why *S. carlsbergensis* (which became *S. uvarum*) is used in the first instance and *S. bayanus* in the second. Within the *cerevisiae* species, some varieties have been improved by genetics, giving rise to new strains which are better suited to their specific applications. Although *Saccharomyces cerevisiae* is used throughout the world in bread-making, there are other groups of yeasts which have very specialized applications in baking (Table 69.1) (4, 5, 6).

Saccharomyces cerevisiae is undoubtedly the most cultivated yeast. All research and development work focuses on it because it has the cell characteristics of higher organisms, simple nutritional requirements, and a beneficial multiplication rate, although it does not multiply quite as fast as bacteria. From an economic point of view, its suitability for industrial production and its wide range of applications make it unique. Strains are generally stable, can be improved, and pose no risk in terms of food safety. Some of the different genuses and species of yeast listed above for special applications cause production problems, such as flocculation or very low yields.

Yeasts as a whole are microorganisms which have a high nutritional value and are completely harmless. However, a few of them are pathogenic. This applies to some species belonging to the *Candida* genus. Yeast producers are very cautious about using some genuses whose taxonomy is uncertain. They can be classified more accurately using very delicate genetic techniques when morphological or biochemical characteristics are not sufficient.

2. The Cell: Organized in a Similar Way to Higher Life Forms

A baker's yeast preparation, through the electron scanning microscope, reveals a multitude of distinctive cells (Fig. 69.1), ovoid in shape. Some of them have buds or scars which they have left. They vary in size from 6 to 8 micrometers. One cm^3 of compressed yeast with a 30% dry matter content contains about 10 billion cells!

Transmission electron microscopy reveals the following ultrastructure (Fig. 69.2), from the outside toward the inside:

- The cell wall: composed of glucans and mannans bound to proteins, it provides physical external protection. It is completely permeable to water, minerals and small organic molecules.

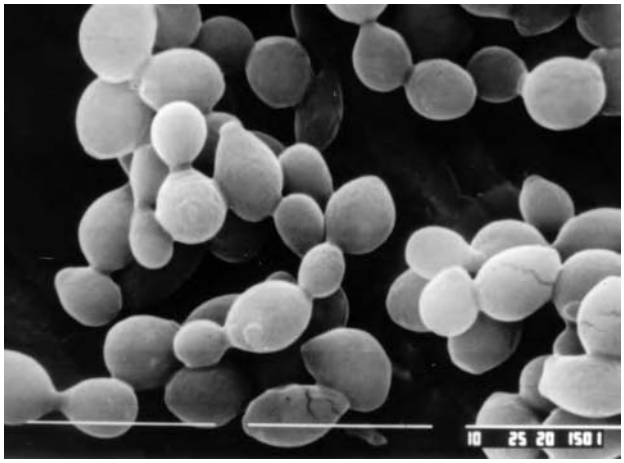

FIGURE 69.1

- The cytoplasmic membrane: made up of glycolipids and glycoproteins, it controls the exchanges between the intracellular and extracellular media. It is characterized by a selective permeability, i.e. it allows water and some solutions to circulate, whilst retaining the large molecules.
- The cytoplasm: a colloidal substance in which a multitude of biochemical reactions take place and which contains organelles in suspension:
  - The nucleus, which contains the chromosomes (carriers of genetic information) which transmit hereditary characters and control the synthesis of proteins.
  - The ribosomes, sites of protein synthesis.
  - The endoplasmic reticulum and Golgi bodies, a network of membranes involved in the secretion of proteins.
  - The mitochondria, energy-producing bodies in the cell in the presence of oxygen.
  - The vacuoles, places where different storage substances are found.

B. Biochemical Composition

The composition of yeast depends on its type and the conditions in which it is stored. Table 69.2 gives average indicative values for samples of fresh European yeast.

- The proteins contribute to a considerable degree of potential metabolic activity as they are made up of a high proportion of enzymes. The protein content is therefore directly related to fermenting power and the ability to produce biomass (Cf. § III.C. et IV.B.).

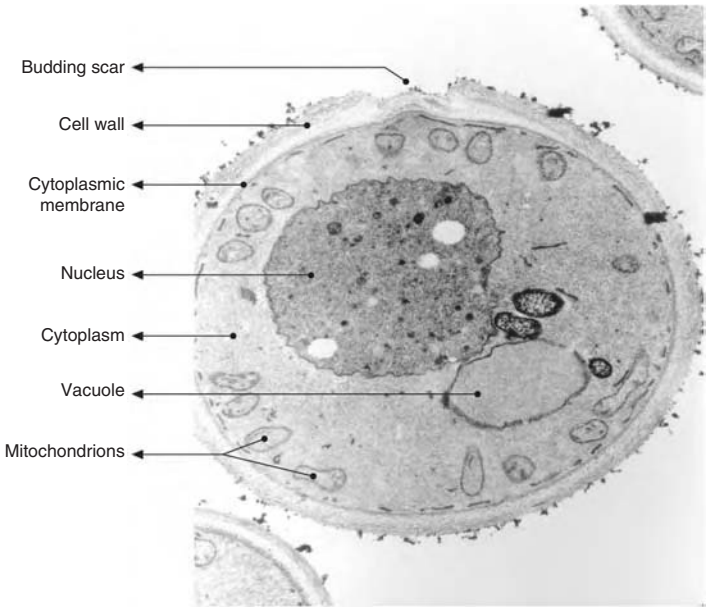

FIGURE 69.2

TABLE 69.2
Average Composition of European Yeasts

Dry Matter * (DM)	30.0 to 33.0 (%)			(%)
Nitrogen/DM	6.5 to 9.30			
Proteins/DM (nitrogen x 6.25)	40.6 to 58.0	of which	Glutathione	0.5 to 1.5
Carbohydrates/DM	35.0 to 45.0	of which	Glycogen	5 to 10
			Trehalose	8 to 20
Cell lipids/DM	4.0 to 6.0	of which	Phospholipids	1 to 2
Minerals/DM	5.0 to 7.5	of which	Potassium	0.8 to 2.0
			Sodium	0.01 to 0.2
			Calcium	0.02 to 0.15
			Magnesium	0.04 to 0.18
			Phosphorus	0.8 to 1.3
			(P_2O_5)	2.0 to 3.0
Vitamins		of which	Thiamin (B1)	0.002 to 0.015
			Riboflavin (B2)	0.002 to 0.008
			Pyridoxine (B6)	0.002 to 0.006
			Niacin (PP)	0.010 to 0.050

- The carbohydrates are mainly:
  - glucans and mannans, wall constituents;
  - glycogen, a storage macromolecule usually found in animal cells, which is used when there is a long-term deficiency of nutrients;
  - trehalose, a disaccharide which is called up preferentially when there is a short-term deficiency. The storage of this sugar is very important whenever the yeast cell has to undergo stress, such as drying, high osmotic pressure or freezing.
- The lipids, particularly lipoproteins and phospholipids, are involved in the make-up of the cytoplasmic membrane and in maintaining its properties in the various processes used for drying active dried yeast.
- The minerals, including phosphorus which is essential as it is involved in the formation of nucleic acids, molecules with a high energy potential (ATP) and membrane phospholipids.

Due to its high number of proteins with the presence of all the essential amino acids in addition to phospholipids, minerals and vitamins, deactivated yeast is regarded as a top quality food supplement.

III. BEHAVIOR OF YEAST DURING BREAD FERMENTATION

A. The Roles of Yeast in Bread-Making

1. Dough Rising

This is the most obvious phenomenon for anyone who is unfamiliar with bread manufacture. Air is incorporated into dough during mixing and the yeast is able to establish respiratory-type metabolism. A few minutes after mixing, all the oxygen which has been introduced is used up by the yeast. Due to the anaerobic conditions, yeast metabolism is geared towards fermentation. The carbon dioxide produced firstly dissolves in the free water in the dough. When it reaches a saturation point, it accumulates in gaseous form, exerting internal pressure on the impermeable gluten network. This network, which is elastic and extensible, enables the dough to rise, whilst the external structure is maintained. Contrary to what is generally thought, the pores in the crumb of bread have nothing to do with the distribution of yeast cells but correspond to the dilatation of the CO_2 they produce. This diffuses into the air bubbles which are incorporated and dispersed in the dough during mixing and various mechanical operations.

2. Acidification

The formation of carbon dioxide and organic acids results in a lowering of pH and an increase in the total titratable acidity (TTA) of the dough during fermentation, in spite of the high buffering capacity of proteins in the flour. This acidification confirms that bread fermentation is working properly. It is often measured (pH and TTA) in routine checks in industrial bakeries using prefermentation processes as water brew, stiff or liquid sponge. (Cf. § II.D.4.).

3. Flavor Production

The alcohol formed, the lowering of pH, and the release of metabolites from secondary fermentation are directly involved in, or act as precursors to, the development of bread taste and flavor (7, 8, 9). Long fermentation times, slightly low dough temperatures and sensible quantities of yeast result in a bread with excellent organoleptic properties. This assumes, of course, that the dough has not been subjected to excessive oxidation which is the result of high-speed mixing and the presence of bean or soya flour.

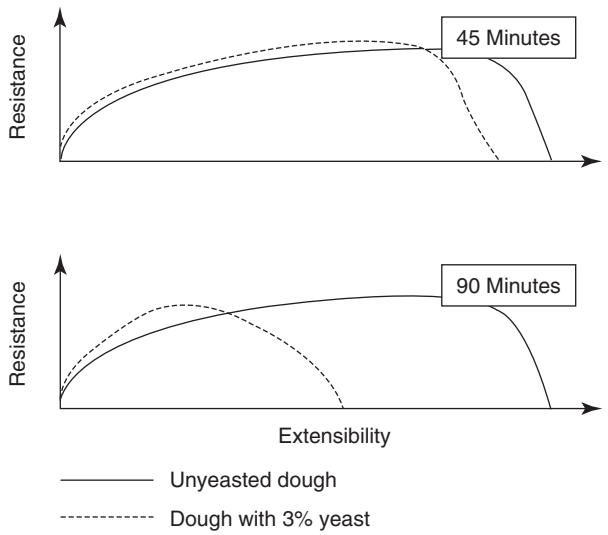

FIGURE 69.3

Particular genuses and species of yeast have metabolisms which result in bread products with very characteristic flavors (Cf. § 1.A.1.).

4. Change in Dough Rheology

Apart from the physical changes dough undergoes during the various operations of mixing, dividing, rolling or moulding, its viscoelastic properties are transformed throughout the fermentation process. This is a very familiar phenomenon to the craft baker, for whom the effects of bread fermentation do not simply mean the inflation of dough (10). The dough strengthening to which bakers refer, and which is occurring during bulk fermentation, is a perfect illustration of this. It involves a reduction in gluten extensibility combined with an increase in its elastic resistance (Fig. 69.3).

The causes are known but it is difficult to find a scientific explanation for the mechanisms because of the complexity of the dough system. It involves:

- Firstly, a purely mechanical effect which is the result of gluten development, namely, its extension and organization into a three-dimensional network under gaseous pressure;
- Secondly, the formation of physicochemical bonds, strengthening the cohesion of the gluten network. The lowering of pH, reactions with the different metabolites produced by secondary fermentation and variations in surface tension between the different dough phases seem to play a part in these phenomena. According to K. Hoseney, the phenomenon is essentially oxidative, involving the production of oxygen peroxide by the yeast (11).

Understanding the notion of dough strength is complicated by certain factors which can cause confusion, particularly in long fermentation processes. After a long first fermentation, or the fermentation of a sponge, the dough softens, which seems to go against this idea of strength. This effect, which is real, is heightened by the undermixing inherent in this type of dough. In fact, it is linked to the gradual hydration of gluten and to the action of enzymes in the flour: the amylolytic activity, which contributes to the release of water previously fixed by the starch, a slight proteolysis affecting the gluten; and possibly the reducing effect of the glutathione excreted by some types of dried yeast.

These changes in no way preclude the strengthening of dough elasticity that takes place in the gluten and is evident during the moulding operations. Too much strength will affect the external and internal characteristics of the finished product, so the baker's skill lies in knowing how to control fermentation processes to fit the characteristics of the flours and the type of mixing used. This skill is somewhat restricted by high-speed mixing methods and the use of dough conditioners. The fact remains that in reality the technology is complex, making it difficult for bakers and technicians or engineers in the world of industry or applied research to communicate. The only way forward is for the latter to "get their hands dirty" if they wish to establish a fruitful dialogue based on mutual trust.

B. Use of Fermentable Substrates: The Enzymes Involved

- Monosaccharides, simple sugars with six carbon atoms (such as glucose, fructose and galactose), are preferentially used by *S. cerevisiae*. Nevertheless, the assimilation of galactose depends on the concentration of glucose, with the latter exerting catabolic repression. It is generally acknowledged that glucose and fructose can penetrate the cell by facilitated diffusion, involving phosphorylation.
- Disaccharides can be assimilated after enzymatic hydrolyses.
  - The sucrose already present in flour or added to the ingredients is converted to glucose and fructose by invertase in the yeast. This reaction takes place in the periplasmic space between the wall and the cytoplasmic membrane. The two hexoses then diffuse into the cytoplasm, where they are metabolized. Invertase acts very quickly, practically doubling the osmotic pressure in the region next to the cell.
  - Maltose, which mainly comes from the conversion of starch by action of the α- and β-amylases in flour, is split into two glucose molecules by maltase, an enzyme in yeast cells. However, the maltose must have previously been carried inside the cell by maltopermease.

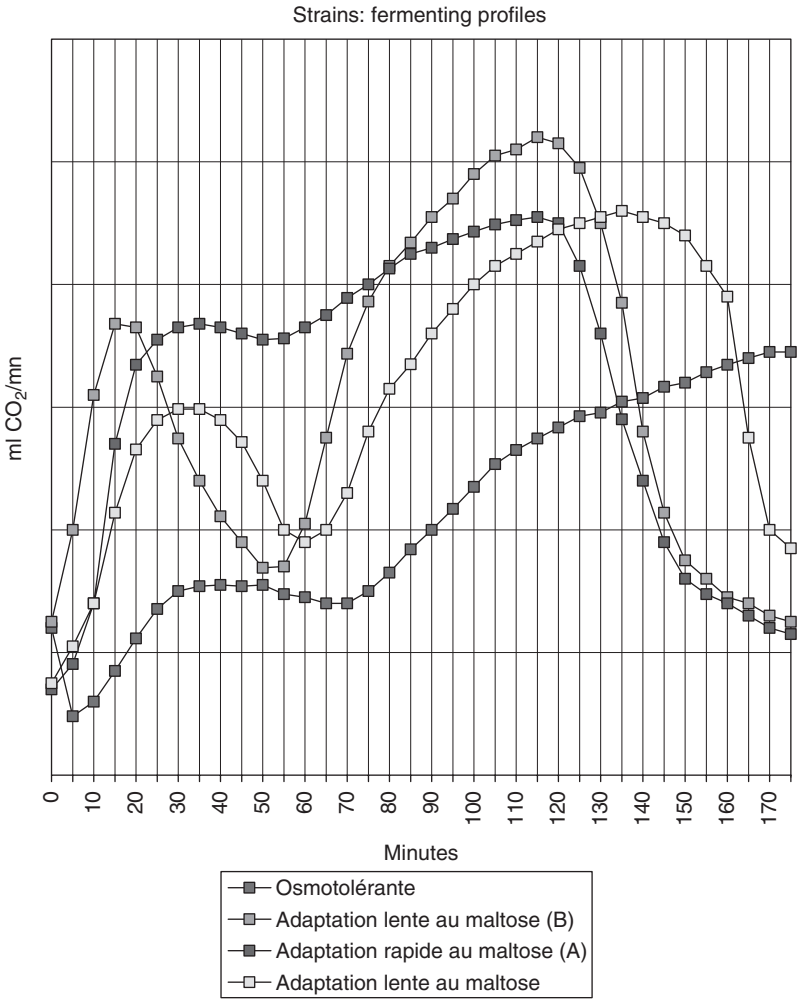

FIGURE 69.4

Not all strains of yeast have the same ability to ferment maltose. Strains used in the U.S. and in Japan have adaptive maltopermease and maltase. The synthesis of these enzymes is catabolically repressed by glucose and induced by maltose. So the cell can only produce the two enzymes which enable it to use the maltose present in the medium after the glucose has been exhausted (13, 14).

In Europe, most industrial baker's yeasts have constituent maltopermease and maltase. These strains were developed in Great Britain in the early 1960s for the Chorleywood Bread Process. They were then used on the continent, where high-speed mixing was catching on. These types of strains were able to rapidly adapt to maltose in bread-making processes with no added sugar, since mechanical dough development replaced first fermentation in straight doughs, or sponge in sponge-and-dough processes. The risk of exhausting the fermentable sugars in the dough was thus eliminated by systematically supplementing flours with malt or α-amylases.

- There are also small quantities of tri- and polysaccharides which are fermentable to varying degrees.

C. Fermentative Profiles

This ability to ferment maltose is easily demonstrated by the rheofermentometer, a device for recording the variations in a yeast's rate of fermentation as a function of time (for example, CO_2 released per min). The dough used must have no sugar added to the flour (so-called "normal" dough).

Depending on the quantity of yeast, its fermentative capacity, and the fermentation temperature, a "depression of adaptation to maltose" varying in size can be seen on the curve. This depression in fermentation speed is linked to the exhaustion of directly fermentable sugars already present. If the yeast contains constituent maltase and maltopermease, the depression is much less pronounced or non-existent, depending on the above-mentioned conditions.

If there is added sugar (sucrose, glucose/fructose syrup), the depression disappears as yeast preferentially uses these substrates (Figs. 69.4 and 69.5).

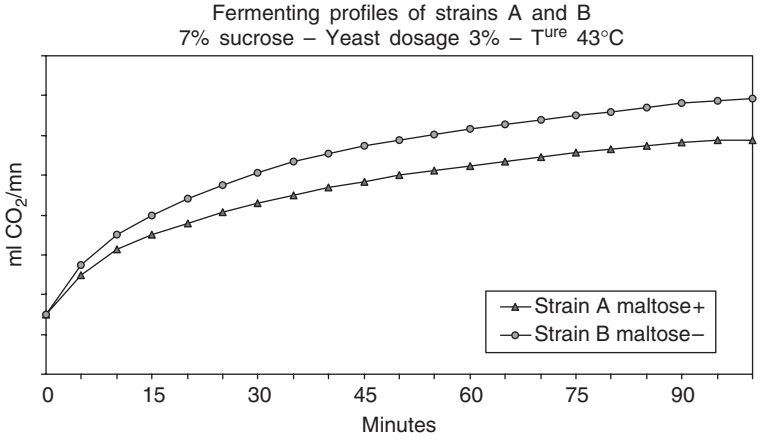

FIGURE 69.5

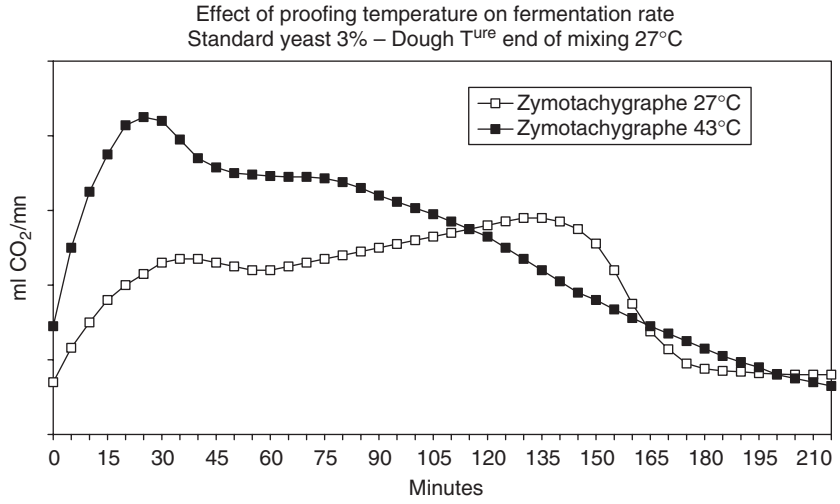

FIGURE 69.6

D. Influence of Various Factors on Fermentative Activity

For a strain with a given biochemical composition, the conditions of the medium affect the rate of fermentation of yeast. The effects must be taken into account in baking, not only for the sake of productivity and economics but also for technological reasons. For example, there are the problems with varying dough density when it is passed through a volumetric divider, or variations in dough strengthening between the start and end of moulding (the larger the dough mass being divided, the greater the difficulty).

Although numerous factors have a bearing on the fermentative activity of yeast, we should remember that the baker judges this activity by the rising of the dough. This is the result of the force exerted by the increase in internal pressure (impermeability plus CO_2 production) and the resistance of the dough to deformation. Extensibility, elastic resistance, permeability, viscosity of dough (cold or warm, soft or firm) are among the many parameters which affect the rate of dough rising, regardless of the activity of the yeast itself. This is clearly demonstrated by observing a dough piece as it rises in a mould, in a fermentation chamber at 43°C and 85% relative humidity. The dough "moves" slowly at first but its volume grows more and more quickly. Over a final fermentation period of one hour, the last five minutes are crucial as, in that time, there is a spectacular increase in the height of dough in the mould. This is related, amongst other things, to a reduction in internal pressure as the dough swells, as can be seen on the alveograph curve.

1. Effect of Temperature

Enzymes activity in the yeast depends on the temperature of the medium. Within the range of 20 to 40°C, an increase in dough temperature of 1°C results in an increase in fermentation speed of 8 to 12% according to the type of yeast (Fig. 69.6). In production conditions, therefore, it is vital to check and control dough temperatures very

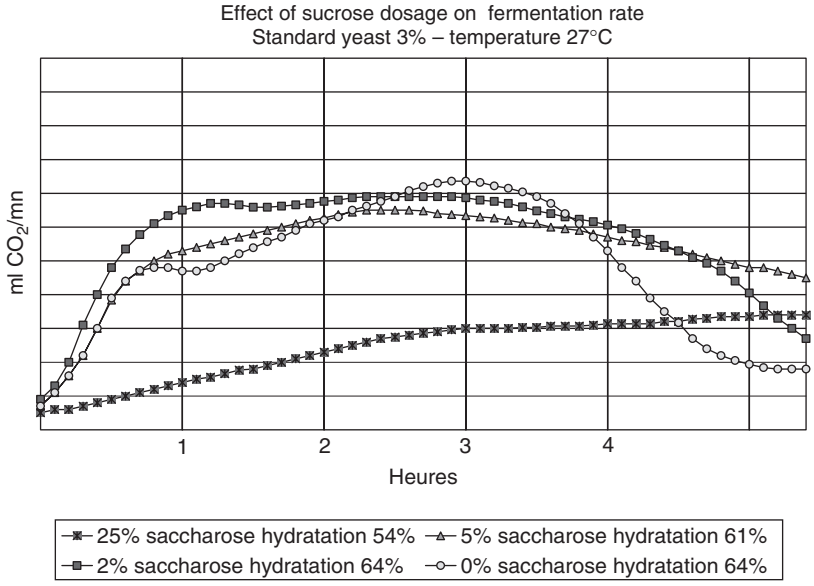

FIGURE 69.7

accurately at the end of mixing, and particularly in the laboratory when comparative studies are being carried out.

This explains the variations of dough and fermentation temperatures required for various applications. Cooler doughs are needed for baguette production (22 to 24°C) in order to restrict dough strength, an excess of which would hinder moulding, and to encourage certain flavors to develop. When working with raw frozen doughs, temperatures of between 18 and 20°C restrict the start-up of yeast activity. At 4°C fermentation is held up. Whilst final fermentation temperatures of 30 to 35°C are used for tinned sandwich bread in France, the general average in the U.S. is 48°C, which increases productivity but at the expense of the overall quality of the finished product. In the United Kingdom, fermentation temperatures of 55°C for soft bun manufacture are quite common, and can be as much as 75°C in the case of industrially produced pizza crusts, all at a relative humidity of 95%. It should be noted that yeast is very quickly killed when the internal dough temperature exceeds 55°C.

2. Effect of Osmotic Pressure

The semi-permeable cytoplasmic membrane of the cell delimits two compartments. When there is a difference in concentration between the medium inside and outside the cell, water gradually moves from the less concentrated medium to the more concentrated one so that equilibrium can be established. This transfer is influenced by a force which exerts a virtual pressure linked to the semi-permeability of the membrane. This movement of water can be prevented by exerting hydrostatic pressure. The difference in pressure between the two media defines the *osmotic pressure*. This is in proportion to the number of dissolved particles per unit of volume. A solution containing 1 mmol/l of sodium chloride (58 mg/l) will release 2 ions per molecule, and the osmotic pressure can be twice that of a glucose solution also containing 1 mmol/l (180 mg/l).

In a dough, osmotic pressure mainly depends on the proportions of sugar and salt used. It can be very high, as much as 35 to 100 atmospheres. This explains the slowdown in the activity of yeast in which metabolism cannot take place normally because water has leaked outside the cell and fewer fermentable sugars can enter.

In bread-making, sugar, often added with fat, is responsible for a reduction in dough consistency. It then becomes necessary to decrease dough hydration, which accentuates the concentration phenomenon in the medium. The baker compensates for the drop in fermentative activity by increasing dough and fermentation temperatures, reducing the quantity of salt and increasing the amount of yeast. The rheofermentometer shows the fermentation rate of yeast with different levels of sucrose, or salt (with or without calcium propionate added in the dough) (Figs. 69.7, 69.8). For a standard French yeast, there is a low level of sugar stimulating fermentation and prolonging it, whilst from 5% of sugar upwards, the rate of fermentation is slowed down and tends to decrease. The rapid accumulation of alcohol, to which the yeast is very sensitive, could be the reason for this. The higher the fermentation temperature, the more obvious this phenomenon is.

There are some bread-making processes where the concentration of sugars is such that the methods described above cannot guarantee that dough will rise within a reasonable time using ordinary yeasts. This has led to the development

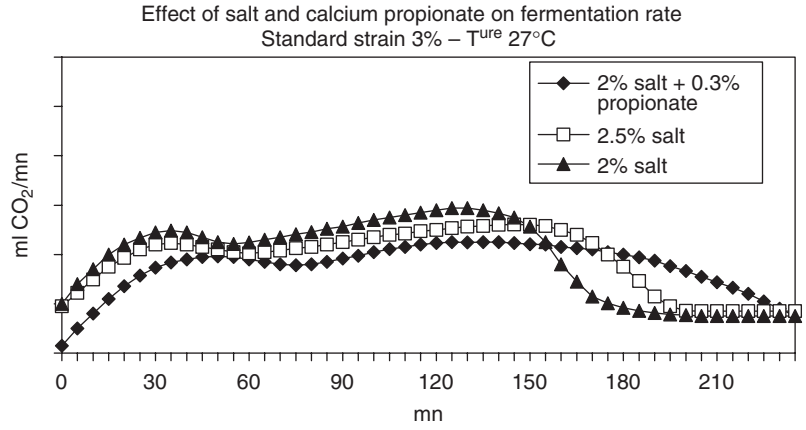

FIGURE 69.8

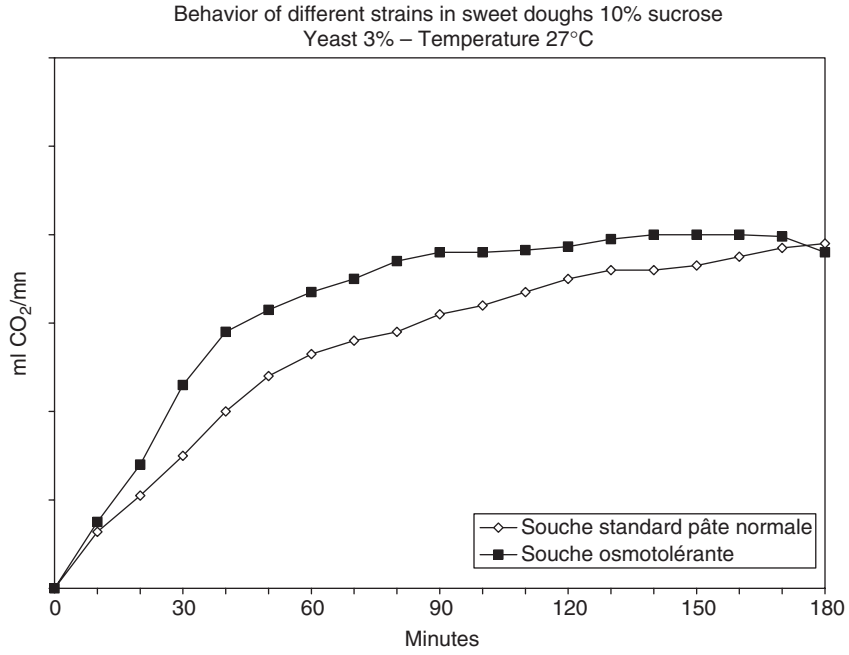

FIGURE 69.9

of osmotolerant strains (Fig. 69.9) which are used in France, (Vendée brioche), the U.S. (Danish pastries, sweet doughs, Hawaiian sweet bread), Indonesia (roti mani), and Japan (kashipan), and where the levels of sugar vary from 20 to 50% based on flour weight.

The osmotolerance of these strains is associated with various characteristics, including:

- a low level of invertase so that sucrose is gradually converted to glucose and fructose, resulting in fewer dissolved molecules at a given moment. Obviously, this ability does not apply to sugars such as glucose/fructose syrups.
- the capacity to synthesize molecules such as glycerol or trehalose, so that the exit of water from a cell is counterbalanced when the concentration of the medium outside the cell is too high.
- the propagation conditions on which, regardless of strain, the osmotolerance of a yeast depends.

3. Effect of Yeast Dosage

At a given temperature, the rate of fermentation depends on the quantity of yeast used (Fig. 69.10). We can see a depression in the curves in the 1st hour because the sugars already present are being used up more quickly.

If no sugar is added, the quantity of maltose resulting from amylolysis is a limiting factor. When the amount of yeast is too high, a flour with low levels of damaged starch

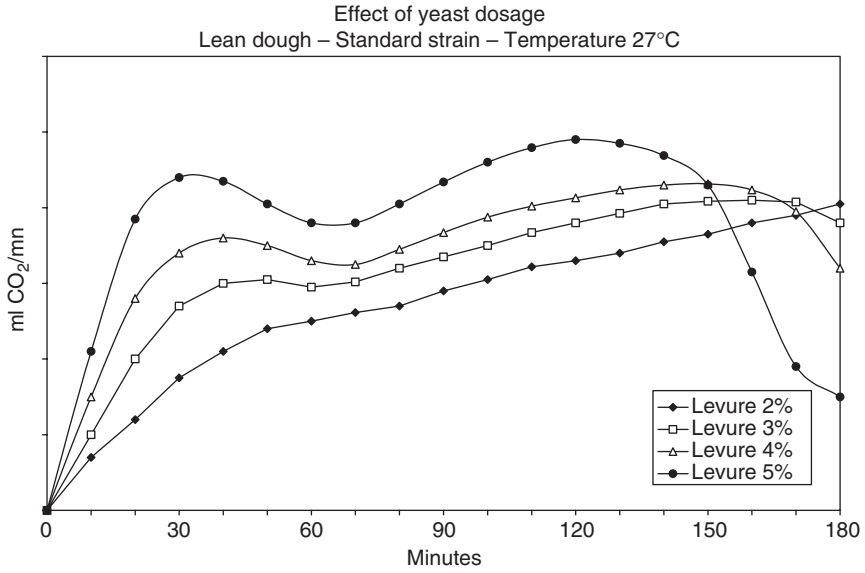

FIGURE 69.10

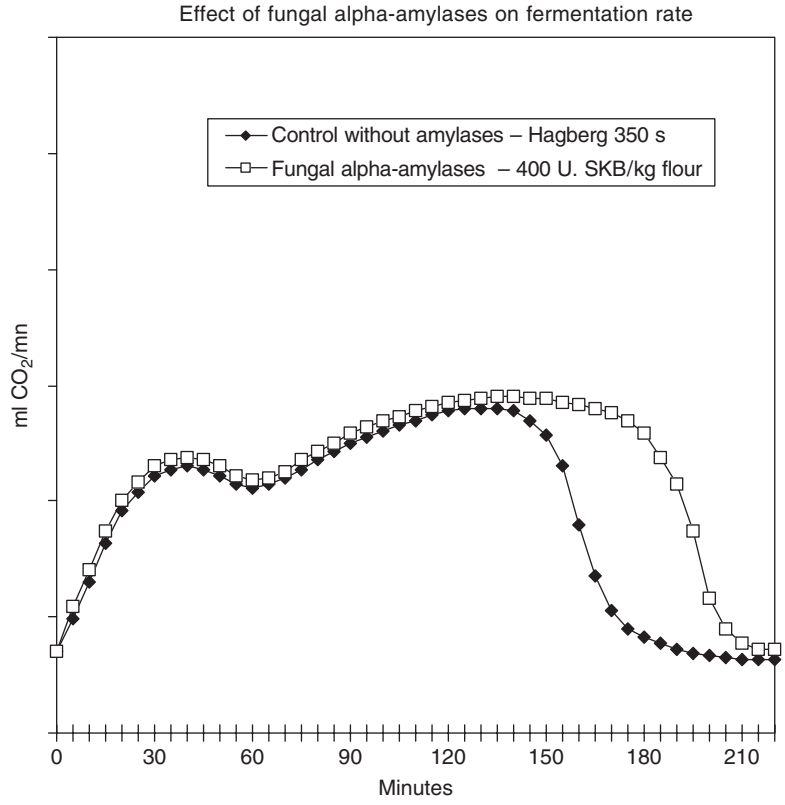

FIGURE 69.11

or α-amylases can be exhausted before proofing is completed. Adding fungal α-amylases at a level of 40,000 SKB units per 100 kg of flour prolongs fermentation by about 1 hour in standard bread-making conditions (Fig. 69.11).

4. Effect of pH

The internal pH of a yeast cell is of the order of 5.6 to 5.8 and varies very little. The enzyme systems involved in the metabolism of *S. cerevisiae* are intracellular as a whole,

TABLE 69.3
Changes in Dough Acidity at Different Stages of Fermentation

	pH	TTA
American Sandwich Bread		
Sponge (70% flour)	4.8	4.6
Dough at start of proofing	5.2	4.0
Dough at end of proofing	5.0	5.3
American Sandwich Bread		
Liquid preferment (20% flour)	4.5	12
Liquid preferment (50% flour)	4.8	10
French Bread — Straight Dough		
Dough at end of mixing	6.1	1
Dough at end of proofing (2 h 1/2 fermentation)	5.8	1.5
French Bread — 30% Sourdough		
Dough at end of mixing	5.3	2.0
Dough at end of proofing (6 h fermentation)	4.2	7.0

which explains why yeast is very tolerant to variations in the pH of a medium, within the range of 2 to 8.

At pH of between 4 and 6, the fermentative activity of yeast is at its optimum. These conditions are found in most bread-making processes with yeast, where the pH at the end of final fermentation is of the order of 5.2 ± 0.2. This pH can be lower when using sourdough starters (cf. chapter II, § III. 1), deactivated sourdoughs or organic acids, particularly for rye bread manufacture. Unlike glucose, the fermentation of maltose is affected when the pH is less than 4.

The actual acidity of a dough cannot be assessed by pH alone due to the high buffering capacity of flour proteins. It is often associated with titratable total acidity which is an arbitrary notion often used in the U.S. (TTA) and Germany (Säuergrad). In the first case, it corresponds to the quantity of 0.1 N sodium hydroxide (4 g/l) needed to neutralize a ground mixture of 15 g of dough in 100 ml of distilled water to pH 6.6. In the second, the pH is 8.5. This method enables plant bakers to control the consistency of their fermentation processes (Table 69.3).

Volatile organic acids and their salts inhibit fermentative activity in their non-dissociated form. A low pH, which shifts the balance of dissociation toward the non-dissociated form, means that the acetic acid or propionates used as anti-mould agents will have a much more detrimental effect. The critical zone falls right inside the range of pH (4 to 5) found at the end of fermentation in most types of bread-making methods (Table 69.4).

5. Inhibiting Ions

In the cases, fortunately rare, where bread fermentation is inhibited, water is often responsible as a carrier of certain ions which are toxic to yeast. Cu^{++} from the copper in old pipes, quaternary ammoniums in antiseptic products from poorly rinsed equipment, and excess Cl^{-} in city supply water have often been blamed.

TABLE 69.4
Dissociation of Acetic and Propionic Acids at Different pH

	Non-Dissociated Fraction (%)					
	pH 2	pH 3	pH 4	pH 5	pH 6	pH 7
Acetic acid	99.8	98.2	84.7	35.7	5.3	0.6
Propionic acid	100	99	88	42	6.7	0.7

IV. INDUSTRIAL PRODUCTION OF YEAST

In 2003, an estimated 2.8 million tonnes of baker's yeast, expressed as compressed yeast, was produced throughout the world. Half was produced on the continent of Europe, with the other half equally divided between the Americas and the rest of the world. Regardless of their physical forms (compressed, dried, etc.), the yeasts produced are not the same in the various regions of the globe as manufacturers have to adapt them to the local bread-making conditions. However, they have one problem in common, ensuring that the fermenting capacity of the product they supply is consistent and stable. This is achieved by controlling the quality of raw materials, production technology and logistics.

A. Raw Materials

The raw materials used must satisfy the nutritional requirements necessary for the growth and multiplication of yeast cells.

Molasses are the substrates of choice both economically and technically. Viscous, highly colored liquids, their composition varies according to the sugar-making process from which they derive, and the quality of the sugar-beet or cane harvest. 77 to 82% of dry matter essentially provides: sucrose as a source of carbon (45 to 55%), minerals, trace elements and vitamins. However, they supply very little nitrogen for protein synthesis (the betaine they contain cannot be assimilated) and not enough minerals such as phosphorus, magnesium and often zinc. The problems they cause are rarely related to any deficiencies but are more likely to be due to the presence of elements which are toxic to yeast. They may be substances which derive from farming methods or sugar-producing processes: fungicides, quaternary ammonium, sulfites, but also an excess of minerals (Na^{++}), short chain fatty acids and a great many trace elements.

In order to homogenize the composition of the nutrient medium and reduce the risks of toxicity, all batches are analyzed and tested before they are mixed (up to 10 or 12 different sources).

After an initial filtration to remove coarse foreign elements, the molasses are diluted and heated to reduce the viscosity. Clarifiers continuously remove the fibers and colloids by centrifugation. The next is flash pasteurization when the molasses are heated to 130°C under pressure for a very short time. This treatment removes vegetative forms of microbial contaminants as well as *Clostridium* and *Bacillus* spores, without caramelizing or degrading the sugars. After they have cooled down on plate exchangers, the molasses are stored in a buffer tank, ready for use.

Cane molasses, which contain a lot of fibers and colloids, are difficult to process but have a very high nutrient content. When they are mixed at a level of 20% with sugar beet molasses, biotin does not need to be added.

Minerals which are added as nutrients (phosphoric acid, ammonium salts, ammoniac) or to control pH (sulfuric acid, soda) comply with food standards, in particular for heavy metal content. The water for diluting the medium is potable and chlorinated to avoid any contamination.

B. Storage and Protection of Strains

Thousands of strains have resulted from research studies but fewer than about ten are used in large-scale industrial production. Manufacturers store them in their own laboratories but also, as a precautionary measure, in public collection centers. With the development of identification methods, the claims of patent applications dealing with the creation and improvement of strains can be described more accurately.

The methods of storing strains vary, for example −80°C on a glycerol medium with subcultures made after 1 to 5 years, or 4°C on a gelose medium and subcultures after 1 to 3 months.

C. Propagation

How yeast cells multiply (wrongly called "fermentation") is of major importance in carrying out the yeast manufacturer's two objectives.

The first relates to quality. A specific strain must satisfy several criteria:

- the best fermentative power in a specific application ("normal", sweet, or acid doughs….), or fermentation kinetics which are most suited to a given bread-making method (sponge and dough, Chorleywood bread process, etc.);
- the nature of the finished product: compressed yeast, rehydratable dry yeast or instant yeast;
- the stability of fermenting power.

The second objective has to do with economics. The manufacturer must achieve the quality dough for the best price. The result is a compromise between:

- yields (% of yeast obtained in proportion to the substrate used);
- productivity (rate of multiplication and optimum use of tank equipment).

It is evident, therefore, that there are many complex — and sometimes contradictory — obstacles. To untangle the knot, engineers and researchers rely on data on the biochemistry and physiology of cells. Although attempts at modeling have been made in order to optimize production, experience and a certain degree of pragmatism are still called for.

Yeast is propagated in sequences during which cells multiply under different conditions. Multiplication has two aims which follow from each other:

- to massively increase the cell population so that a final so-called "commercial" generation can be seeded;
- to multiply the yeast so that its biochemical composition and physiological condition meet the requirements of producer and user.

The number and method of these stages can differ noticeably from manufacturer to manufacturer, but the principle is the same. In each stage, enough yeast is produced to inoculate the next stage (Fig. 69.12). This is carried out using a series of containers, from lab to plant, whose contents must be managed extremely well when the industrial stage is reached.

The third industrial generation (commercial generation) must finish with a maturing phase, the aim of which is to ensure the yeast is stable. It means making the yeast, at the end of the manufacturing process, synthesizing as many stock sugars as possible (trehalose and glycogen) and reducing the rate of budding to very low levels. In order to do this, the yeast is deprived of nitrogen, and is supplied with molasses only, and the temperature is slightly increased above the 32 ± 2°C which is the average temperature during production.

Next comes the separation of yeast cells from the wort. This operation takes place continuously using centrifugal equipment where the yeast is washed and a cream is obtained, i.e., a suspension of cells in water at a dry matter concentration of between 15 and 20%. This figure is equivalent to about 50% of cells, in volume. Above 23% dry matter, the suspension becomes too viscous and cannot be pumped. This cream is cooled down to 4°C in a plate exchanger and kept at this temperature in storage tanks. About 400 tonnes of yeast (compressed yeast equivalent) will be finally collected 10 days after the first test tube was cultured in the laboratory. The principle of yeast manufacture is summarized in Fig. 69.13.

French yeast producers, who are concerned about environmental regulations, have concentrated on investing in methods of pollution control. After the yeast cream has been separated, there is a great deal of effluent which cannot be discharged, as is, into the environment. The most diluted effluent is treated by aerobic or anaerobic

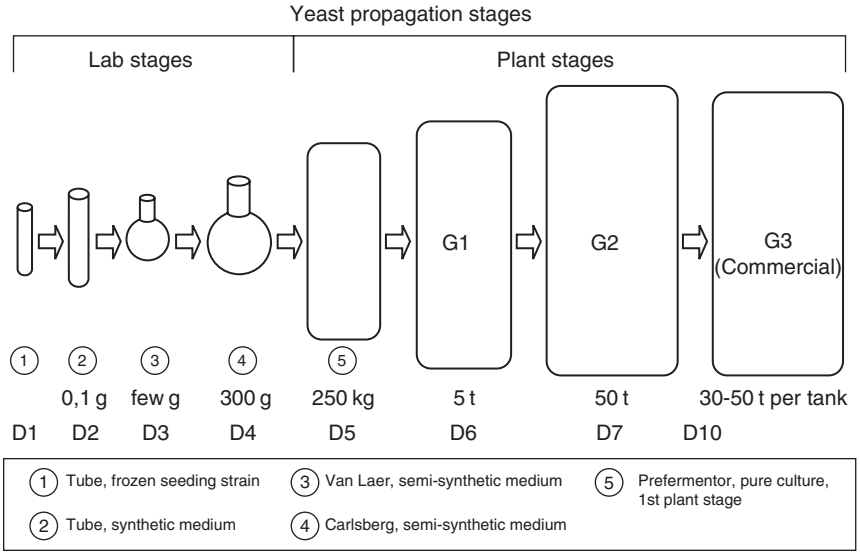

FIGURE 69.12

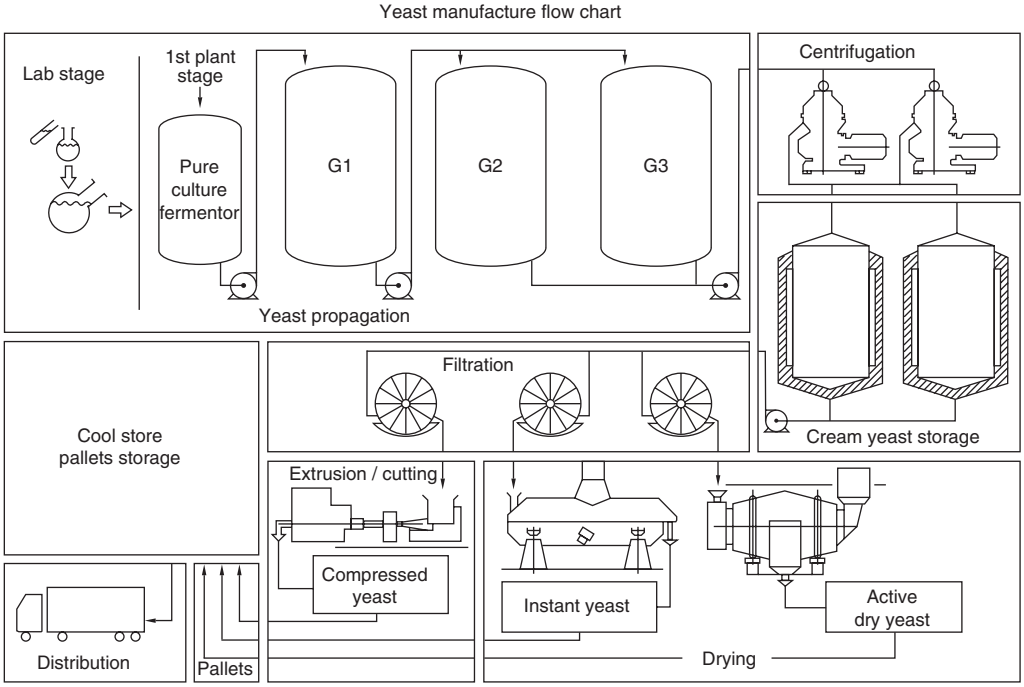

FIGURE 69.13

biological methods. The must from which the yeast has been removed and which still contains non-assimilated organic nitrogen (betaine) and mineral salts rich in potassium sulfate is very highly concentrated by evaporation and inverse osmosis. The vinasse obtained is used as a fertilizer, spread on directly as manure or in the form of potassium extracts after crystallization, decantation and drying. It can also be used in animal feed after treatment to reduce the potassium content. Pollution control treatments have a considerable effect on production costs.

V. COMMERCIAL YEASTS

A. Strains

The strains used in France and in Europe as a whole are of the "rapid adaptation to maltose" type. They were developed in the early 1960s in response to straight bread-making methods which had appeared as a result of high-speed mixing used in bread-making with no added sugar. Because of their poor performance in very sweet doughs (over 15% of sucrose/flour), osmotolerant strains already

TABLE 69.5
Comparison of Commercial Strains and Wide-Range Laboratory Strains

Type of Yeast and Strain	Fermenting Power Lean Dough (Base 100)	Fermenting Power 25% Sweet Dough (Base 100)	Invertase Activity (Ui)*
Commercial — Rapid Adaptation to maltose	100	60	60 to 200
Commercial — Osmotolerant	50	100	5 to 10
Lab — Hybrid wide range	85	105	<5
Lab — Genetic engineering Wide range	90	100	<10

Source: P. Clément, ICC Conference, Paris 1992.

*1 Unit invertase = 1 µmole of reducing sugar released/5min/mg of yeast DM.

TABLE 69.6
Change in the Fermenting Power of Various Types of Yeast in Accelerated Storage Tests

Yeast Quality	DM (%)	Nitrogen/ DM (%)	Fermenting Power Lean Dough (Base 100)	Loss After Storage 7 Days/26°C
"Standard"	≃33	7.0	100	−10%
"Rapid"	≃32	7.3	110	−25%
"Ultra rapid"	≃31	8.2	125	−50%
"High activity"	≃29	9.3	165	Autolysed

used for the large export markets were introduced onto the French market at the end of the 1980s. The difficulty bakeries had in using several qualities of yeast resulted in research work into strains with a wide range of applications (Table 69.5).

B. Biochemical Compositions Adapted for Applications

The need to increase the rate of fermentation, particularly in an industrial environment, is met by yeasts with a high nitrogen — and therefore protein — content. The major drawback of these yeasts is their instability, which is due to higher enzyme activity and a storage sugar content which is proportionally lower. In the case of compressed yeast, as has been mentioned earlier, the increase in protein level calls for a decrease in DM content so that the product maintains its physical cohesion. The stability of its fermentative activity is affected by this, which means that low temperatures must be maintained. The higher the protein level, the more rigorously these low temperatures need to be observed. An increase in temperature accelerates the consumption of trehalose, then glycogen to cover the needs of energy metabolism. When these carbohydrates are exhausted, the yeast attacks its own proteins. This autolysis is responsible for the degradation of yeast activity and its physical appearance (Table 69.6). The nitrogen content of the various types of dried yeast is restricted to the maximum level, which is unlikely to be detrimental to them during drying.

C. Controls on The Finished Product

A yeast, regardless of its form, must comply with several criteria before it can be marketed:

- Physical and organoleptic: consistency and friability in the case of compressed yeast, shape and size of particles in the case of dried yeast, color and smell.
- Biochemical: dry matter, nitrogen and phosphorus composition, stocks carbohydrates.
- Bacteriological: appearance of cells, budding rate; most attention is given to identifying and counting foreign microflora.
- Fermenting power: most of the methods used measure the release of carbon dioxide which is produced over a given time, by fermentation of a medium with known characteristics. Mostly, it is a wheat flour dough whose consistency varies from liquid to very firm. Various levels of sugar can also be used to evaluate the behavior of yeast at increasing osmotic pressure (18).
- Suitability of yeast for storage: the stability of the fermenting power of various types of yeast can be evaluated in storage tests, at temperatures of between 20 and 43°C. There are correlations between the results of these accelerated tests and those obtained in real time, at temperatures found in different markets.
- Bread-making tests: for specific applications, laboratory fermentation tests, although useful, do not supply enough information about the overall yeast activity (cf. § II.A.). Bread-making tests can result in a better understanding of the effect of yeast on dough rheology, on dough behavior during proofing and baking, and finally on its effect on bread properties: color, structure, crumb texture, and flavor. Monitoring the dough in a rheofermentometer at the same time can provide a wealth of information.

D. Commercial Forms and Methods of Use

The different commercial forms of baker's yeast can be discussed in the order in which they appear in the manufacturing process, which corresponds to a continuity in their historical development. And although the 1990s saw a sudden demand for liquid yeast in industry, this was

no revolutionary product unless we are thinking of the mechanical meaning of the term revolution: a return to the point of origin!

1. Liquid Yeast

Until 1825, when compressed yeast was introduced by Tebbenhof, yeast was sold in liquid form (2) . The return to this form correlates with the demand from plant bakeries. In general use in Australia, it is used much less widely in the U.S. and Canada and has its followers in the United Kingdom and Ireland.

- Advantages
  - dosage of the yeast can be automated, as it is for the other raw materials, resulting in improved control and stock management;
  - no handling and no packaging materials to dispose of;
  - even dispersion in the dough during high-speed mixing;
  - yeast activity is standardized: the producer controls fermenting power using a substitution rate, for example 1.5 liters of cream per 1 kg of compressed yeast;
  - stability is noticeably improved compared with other forms, because the cream is cooled immediately on a plate exchanger. This stability is ensured by monitoring the storage temperature (Table 69.7). However, a temperature of less than 4°C must be maintained to prevent any bacteriological contamination.
- Specific points
  - the installation must be specially designed for each user;
  - profitability is guaranteed when the quantity of yeast used at the same site is sufficiently large;
  - hygiene, cleaning and disinfection conditions must be strictly observed.

The installation made entirely of stainless steel consists of two double-walled storage tanks with separate cooling systems, as well as feed systems for the tanks and mixers. The metering systems must be accurate and reliable. The whole unit is supplemented by a cleaning plant and equipment for discharging liquids: soda, antiseptics, rinsing water. The capacity of each tank must allow at least one week's production.

The liquid yeast is stirred in the tank and circulates continuously through the distribution system so that it remains homogeneous and there is no risk of infection. The temperature is strictly controlled and held at between 2 and 4°C. The system must be cleaned and disinfected once a week or whenever the installation is shut down, hence the need for two tanks. The receiving circuits must be cleaned each time there is a delivery. Procedures should be put in place and followed meticulously by operators.

2. Compressed Yeast

This is the most widely used form in industrialized countries, for economic and practical reasons. It comes in the form of compact blocks so that there is limited contact with the oxygen in the air. White in color and very friable in France, it can have a deeper color and a plastic consistency in other countries. The packaging of "waxed paper" or "sulfurized paper and cellophane" restricts gaseous exchanges and controls the migration of moisture, giving a longer shelf life.

TABLE 69.7
Change in the Fermenting Power of Different Quality Liquid Yeasts, Stored at Different Temperatures

Yeast Quality	Length of Storage (Days)	Loss of Fermenting Capacity Lean Dough (%)		Loss of Fermenting Capacity Sweet Dough (%)	
		4°C	12°C	4°C	12°C

	14	3	4	5	10
"High activity" A	7	0	0	–	–
(Great Britain)*	14	0	4	5	10
"High activity" B	7	0	3	5	10
(Great Britain)*	14	5	30	15	50

* Yeasts made using two different propagation methods. The stability of yeast B can only be achieved by positive temperatures of less than 4°C.

TABLE 69.8
Change in the Properties of Compressed Yeast after Freezing

Properties	t 0	11 Months at −18°C
Dry matter %	32.9	30.5
Nitrogen %/DM	7.2	–
Fermenting power %	100	97
Appearance	White, Friable	White, Very Friable, Normal Smell

The stability of the fermenting power of yeast in its packaging depends on the storage temperature. One month is guaranteed for a "standard" quality French yeast stored at 10°C maximum (ideally 4°C). At 20°C, its activity is stable for two weeks but is reduced by 60% after 1 month; the DM loses 4 points, which corresponds to the consumption of storage sugars and to the product drying out; there is considerable contamination from mould. At 35°C compressed yeast is only stable for 24 hours; after 3 days the loss of activity is equivalent to that found after 1 month at 20°C, and the product becomes brown, soft and sticky.

The performance of "high activity" English yeast is guaranteed for 17 days if the storage temperature is strictly kept at a maximum of 2°C.

No special precautions are necessary when using compressed yeast; it can be easily crumbled into the mixer and there are no repercussions when it is dispersed in cold water. It should not be in contact with salt for too long, although this is not actually harmful in practice, contrary to common ideas.

Compressed yeast tolerates slow freezing very well (<1°C/min) and maintains its initial performance after a year's storage at −18°C (Table 69.8), provided that when it is used, it is thawed at positive temperatures (°C) and is used within 24 hours.

It is worth noting that there is an increase in the friability of yeast due to the evaporation of free water and a loss of dry matter as a result of storage sugar consumption.

3. Crumbled Yeast

This is in the form of relatively fine, free flowing particles which means that it can be either weighed or measured automatically. It is packed in 25-kg, multi-layer polyethylene-lined paper sacks which are sealed to keep the product airtight. Crumbled yeast is very sensitive to oxygen in the air because of its large surface of contact. Respiration which continues in a very active manner after extrusion and during the bagging operation causes the yeast to heat up, making it very difficult to cool it down. However, the carbon dioxide released creates an inert atmosphere which stabilizes it.

The storage temperature must be under 10°C. Under these conditions, the crumbled yeast loses 5% of its initial fermentative power after a week and 10% after a month (losses are much higher in sweet dough).

TABLE 69.9
Change in the Temperature of Crumbled Yeast, Not Refrigerated

Conditions	Time	Temperature (°C)
"Standard" Quality yeast	t 0	8

	5H00	50
	5H30	47

Opened sacks should be used up within a day, as the product heats up quickly (Table 69.9).

Crumbled yeast is often used by plant bakers as a suspension in water so that metering can be automated. The installation includes a storage tank with identical characteristics to those previously described for liquid yeast. Upstream, a smaller tank with a very vigorous stirring action is used to disperse the yeast in water.

4. Rehydratable Active Dry Yeast

Rehydratable active dry yeast (Fig. 69.13) is packed in air in 125-g or 500-g containers (metal or plastic), 10- or 25-kg sacks, or 25-kg plastic drums. It is packed in 5 to 11 g sachets for the consumer market. It is stored at ambient temperature. This rustic product is very stable, a fact appreciated in parts of the world where the climatic conditions are unfavorable (high temperature and humidity).

When reconstituted, the yeast undergoes a rehydration stage in about 5 times its weight of water, at a temperature between 35 and 42°C, the optimum being 38°C. Rehydration takes 15 minutes, during which time attempts should not be made to disperse the yeast mechanically or it will be damaged. After this resting time, it goes into suspension very easily and forms a cream.

Observing the rehydration temperature is vital as it ensures that the enzymatic mechanisms by which the cell membranes become semipermeable again are functioning properly. If the temperature is too low (<5°C), the membranes do not regain these properties quickly enough and the cells release their contents, resulting in their death. At 20°C, the loss of gassing power is about 30 to 40%.

In view of its dry matter content and fermentative capacity, its rate of substitution compared with "standard" quality French compressed yeast is about 40 to 50%,

i.e., 1 kg of rehydratable dried yeast instead of 2 to 2.5 kg of compressed yeast.

Rehydratable dried yeast releases enough glutathione to change dough consistency and reduce its development time during mixing. Adjustments are therefore necessary; in particular, the quantity of oxidizing agent may need to be increased.

5. Instant Dry Yeast

Instant dry yeast vermicelli-like particles are vacuum packed in 125-g or 500-g sachets, or in packs of 10 kg or more. There are also 7- to 12-g sachets packed with inert gas for home bread-making. The vacuum-packed sachets are hard: They ensure that the product is stable at ambient temperature. (Strict checks after packing eliminate sachets which no longer have this vacuum.) At temperatures of under 20°C, a loss of fermentative activity is apparent during the first month, and then stabilizes; after 1 year it is about 10% ± 2. At 35°C, 1/3 of activity is lost in 1 year. Sachets which have been partially used should be kept in a cold place, carefully closed: the yeast's normal activity will be maintained for at least a week.

Instant dry yeast owes its name to the fact that it does not need to be rehydrated before it is added to flour. It is as easy to use as compressed yeast. In most applications, the fineness and porosity of the particles mean that the yeast can be dispersed quickly and evenly in the dough. However, the use of very high-speed mixers (mixing times of less than 3 min) can pose some dispersion problems.

Nevertheless, when using instant dry yeast, it should not come into direct contact with cold water, ice or the refrigerated walls of mixers. It should just be mixed dry with the flour or sprinkled over the dough during mixing at first speed. In these conditions, the water heats up before it reaches the yeast cells, the membranes of which can regain their biological properties normally. However, it is less sensitive to cold than rehydratable dried yeast (−15% at 20°C/38°C).

The high fermentative power and dry matter content mean that it can be substituted at 33% for compressed yeasts with an equivalent composition. In other words, 1 kg of instant dry yeast can be used instead of 3 kg of compressed yeast. In view of the difference in dry matter content, it is essential to compensate for the difference in weight of water, i.e., 2 kg in the example given.

As a small amount of glutathione may be released, it is advisable to reduce the mixing time slightly or increase the quantity of oxidizing agent in some applications.

Because of the additional energy costs arising from drying and packaging technology, instant dry yeast is a product which cannot compete economically with compressed yeast when the latter is of good quality and the distribution networks are effective.

6. Free-Flowing Frozen Dry Yeast with Intermediate Moisture

In applications such as frozen dough, the results achieved with instant dry yeast are only comparable to those obtained with compressed yeast (CY) when the dough is stored for about two weeks. In fact, the yeast membranes, weakened by drying, cannot withstand being frozen in the dough, then stored, and thawed again without damage. At lower dry matter contents (≃75%) the yeast membranes remain intact. In its physical appearance as a powder, it has the characteristics of CY. It can be packed in air and frozen. It can be stored for long periods and exported to distant regions where there is no compressed yeast, and used in applications where instant dry yeast is unsuitable.

7. Dry Yeast with Reducing Power

- Active
  In the form of small granules packed in air in plastic containers, this yeast is used by pizzerias. Its moderate, consistent fermenting power gives the tolerance during fermentation which is necessary for this type of application. The quantity of glutathione released means that pizzas can be easily moulded, dough extensibility is increased and shrinkage phenomena are reduced.
- Deactivated
  This yeast has no fermenting capacity at all. In dough, the membranes which have been made completely permeable, allow all the cell contents through including glutathione which has a reducing effect on the gluten.

  The quantities used vary from 0.3 to 1%, depending on the flour type and the effects required. The reducing effects work in the following way:
  – by improving the machinability of doughs which are too stiff or very strong;
  – by accelerating dough development during mixing, which requires a 15 to 20% reduction in mixing time. In the absence of lipoxygenase (from bean or soya flour), this property can be exploited to preserve the flavor of bread by limiting the oxidation of the flavor compounds.

Deactivated dried yeast is packed in polyethylene-lined paper sacks. As the product is very hygroscopic, sacks should be closed carefully after use to prevent it becoming lumpy and to ensure it retains all its functions.

VI. CONCLUSIONS

Very little is known about yeast by the people who use it and its true worth is certainly underestimated. Indeed, it is

a product which has become banal in industrial countries, perhaps because the manufacturing process is well controlled and problems are therefore quite rare. Nevertheless, the yeast industry is a high-tech industry in the field of biotechnology where progress has been made due to intensive research and development work. As a result of genetic techniques, strains are being improved all the time. There have been advances in methods of culturing strains as we have gained a better understanding of biology and cell physiology. A good grasp of raw materials and manufacturing methods, intensive automation, and logistical controls are guarantees of product quality in a world increasingly concerned by food safety issues.

ACKNOWLEDGMENTS

To Eric Duquenne for his help with laying out the artwork, and Dorothy Ellerington, for her remarkable translation from French into good English of this unusual topic. The information in this chapter has been derived from "Yeast," Bernard Poitrenaud, In *Handbook of Food and Beverage Fermentation Technology*. Editors: Y. H. Hui et al. Marcel Dekker, New York, 2004.

70 Pickle Manufacturing in the United States: Quality Assurance and Establishment Inspection

Nanna Cross
Chicago, Illinois

CONTENTS

I. QUALITY ASSURANCE

A. Introduction

This section is not designed to explain how pickles are manufactured in the United States. Rather, it is designed to show you the critical factors you should look for in assuring the quality of your pickles. The information has been modified from a document issued by the United States Department of Agriculture: *United States Standards for Grades of Pickles*. Consult the original document for complete details.

This section contains 11 tables of reference data, numbered 1 to 11, and they do not appear in the same order as the text.

B. Product Description

Pickles means the product prepared entirely or predominantly from cucumbers (*Cucumis sativus* L). Clean, sound ingredients are used that may or may not have been previously subjected to fermentation and curing in a salt brine. The product is prepared and preserved through natural or controlled fermentation or by direct addition of vinegar to an equilibrated pH of 4.6 or below. The equilibrated pH value must be maintained for the storage life of the product. The product may be further preserved by pasteurization with heat or refrigeration, and may contain other vegetables, nutritive sweeteners, seasonings, flavorings, spices, and other permissible ingredients defined by the U.S. Food and Drug Administration (FDA). The product is packed in commercially suitable containers to assure preservation.

C. Styles of Pickles

1. *Whole style* means the pickles are whole and are relatively uniform in diameter as indicated in a later discussion (Table 70.2).
2. *Whole, mixed sizes style* means the pickles are whole pickles of mixed sizes.
3. *Sliced lengthwise style* means the pickles are cut longitudinally into halves, quarters, or other triangular shapes (spears, strips, or fingers), or otherwise into units with parallel surfaces with or without ends removed.
4. *Sliced crosswise, Crosscut, or Waffle-cut style* means the pickles are cut into slices transversely to the longitudinal axis. The cut surfaces may have flat-parallel or corrugated-parallel surfaces.
5. *Cut style* means the pickles are cut into chunks or pieces that are of various sizes and shapes.
6. *Relish style* means finely cut or finely chopped pickles containing no less than 60 percent of cucumber ingredient and possibly containing other vegetable ingredients (cauliflower, onions, pepper, tomatoes, cabbage, olives, mustard or any other suitable vegetable).

D. Types of Pack

1. Cured Type

The pickles are cured by natural or controlled fermentation in a salt brine solution and may contain the dill herb or extracts thereof. The pickle ingredient may be partially desalted. The pickles may be further processed or preserved by the addition of vinegar and may contain other ingredients (spices, flavorings, firming and preserving agents) that constitute the characteristics of the particular type of pickle. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. The characteristics of the various types of cured pickles are as follows:

1. *Dill pickles (natural or genuine)* are cucumbers that are cured in a brine solution with dill herb and other flavoring agents.
2. *Dill pickles (processed)* are brine-cured pickles that have undergone a freshening process and are packed in a vinegar solution with dill flavoring and other flavoring agents.
3. *Sour pickles* are cured pickles that are packed in a vinegar solution with or without spices.
4. *Sweet pickles* and *mild sweet pickles* are cured pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s).
5. *Sour mixed pickles* are cured pickles that are packed in a vinegar solution. The pickles may be of any style or combination of styles other than relish and may contain other vegetable ingredients as outlined in Table 70.1 or any other suitable vegetable.
6. *Sweet mixed pickles* and *mild sweet mixed pickles* are cured pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s). The pickles may be of any style or combination of styles other than relish and may contain other vegetable ingredients as outlined in Table 70.1 or any other suitable vegetable.
7. *Sour mustard pickles* or sour chow chow pickles are cured pickles of the same styles and ingredients as sour mixed pickles except the pickles are packed in a prepared mustard sauce of proper consistency with or without spices and flavorings.
8. *Sweet mustard pickles* or sweet chow chow pickles are cured pickles of the same styles and ingredients as sweet mixed pickles except the pickles are packed in a sweetened, prepared mustard sauce of proper consistency with or without spices and flavorings.
9. *Sour pickle relish* consists of finely cut or chopped cured pickles that are packed in a vinegar solution. Sour pickle relish may contain other chopped or finely cut vegetable ingredients as listed in Table 70.1, and may contain a stabilizer such as a starch or gum.
10. *Sweet pickle relish* and *mild sweet pickle relish* are finely cut or chopped cured pickles that are packed in a vinegar solution with a suitable nutritive sweetening ingredient(s). Sweet pickle relish and mild sweet pickle relish may contain other chopped or finely cut vegetable ingredients as listed in Table 70.1 and may contain a stabilizer such as a starch or gum.

TABLE 70.1
Proportions of Pickle Ingredients in Certain Types and Styles

Pickle Ingredients and Styles	Cured; Fresh-Pack; and Refrigerated Types (Percent by Weight of Drained Weight of Product)	
	Sour Mixed; Sweet Mixed; and Mild Sweet Mixed; Sour Mustard or Sour Chow Chow; Sweet Mustard or Sweet Chow Chow	Sour Pickle Relish; Sweet Pickle Relish; Dill Relish; Hamburger Relish; Mustard Relish
Cucumbers, and style other than relish	60 to 80%	
Cucumbers, chopped or finely cut	60 to 100%	
Cauliflower pieces	10 to 30%	
Cauliflower, chopped of finely cut		30% maximum (optional)
Onions, whole (maximum diameter of 1-1/4 inches), sliced or cut	5 to 12%	
Onions, chopped or finely cut		12% maximum (optional)
Green tomatoes, whole or pieces	10% maximum (optional)	
Green tomatoes, chopped or finely cut		10% maximum (optional)
Red, green, or yellow peppers, or pimientos, cut, finely cut, or pieces	Optional	Optional
Celery	Optional	Optional
Cabbage	Optional	Optional
Olives	Optional	Optional
Tomato paste	Optional	Required in hamburger relish
Mustard or prepared mustard	Required in chow chow and mustard pickles	Required in mustard relish, optional in hamburger relish

11. *Hamburger relish* consists of relish style pickles and other chopped or finely cut vegetable ingredients as listed in Table 70.1 with tomato product added.
12. *Mustard relish* consists of sweet pickle relish with mustard and other chopped or finely cut vegetable ingredients as listed in Table 70.1.
13. *Dill relish* consists of relish style pickles containing dill flavoring and other chopped or finely cut vegetable ingredients as listed in Table 70.1.

2. Fresh-Pack Type

The pickles are prepared from uncured, unfermented cucumbers and are packed in a vinegar solution with other ingredients to produce the characteristics of the particular type of pack. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. In addition, the pickles are sufficiently processed by heat to assure preservation of the product in hermetically sealed containers. The distinguishing characteristics of the various types of fresh-pack pickles are as follows:

1. *Fresh-pack dill pickles* are pickles that are packed in a vinegar solution with dill flavoring.
2. *Fresh-pack sweetened dill pickles* are pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s) and dill flavoring.
3. *Fresh-pack sweetened dill relish* consists of finely cut or chopped pickles packed in a vinegar solution with suitable nutritive sweetening ingredient(s) and dill flavoring. The relish may contain other finely cut or chopped vegetable ingredients as listed in Table 70.1.
4. *Fresh-pack sweet pickles* and *fresh-pack mild sweet pickles* are pickles that are packed in a vinegar solution with nutritive sweetening ingredient(s).
5. *Fresh-pack sweet pickle relish* and *fresh-pack mild sweet pickle relish* consists of finely cut or chopped pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s). The relish may contain other finely cut or chopped vegetable ingredients as listed in Table 70.1.
6. *Fresh-pack hamburger relish* consists of relish style pickles and other chopped or finely cut vegetable ingredients as listed in Table 70.1 with tomato product added.
7. *Fresh-pack mustard relish* consists of sweet pickle relish with mustard and other chopped or finely cut vegetable ingredients as listed in Table 70.1.

8. *Fresh-pack dill relish* consists of relish style pickles containing dill flavoring and other chopped or finely cut vegetable ingredients as listed in Table 70.1.
9. *Fresh-pack dietetic pickles* are pickles that are packed with or without the addition of sweetening ingredient(s), salt (NaCl), or other suitable ingredient(s) as declared and permitted under FDA regulations.

3. Refrigerated Type

The pickles are prepared from fresh cucumbers and are packed in a vinegar solution with other ingredients to produce the fresh crisp characteristic of refrigerated type. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. They are stored, distributed, and displayed under refrigeration and may or may not contain one or more chemical preservatives. The various types of refrigerated pickles are the same as the types listed for fresh-pack type in earlier discussion with respect to ingredients except that they conform to the requirements for refrigerated type.

E. Sizes of Whole Pickles

Sizes of whole pickles are based on the diameter and the relationship of diameter to the count per gallon. Size designations, applicable counts, and diameters are outlined in Table 70.2 of this subpart. The diameter of a whole cucumber is the shortest diameter at the greatest circumference measured at right angles to the longitudinal axis of the cucumber.

F. Definitions of Terms

For an interpretation of this standard, some definitions of terms are:

Analytical definitions refer to analytical laboratory requirements.

1. *Acid* means total acidity calculated as acetic acid in accordance with the Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC).
2. *Brix value* (Brix) means the percent sugar, by weight, corrected to 20°C (68°F), as determined with a sugar scale, Brix hydrometer or other instrument that gives equivalent results.
3. *Degrees Baumé* means the density of the packing medium determined with a Baumé hydrometer (modulus 145) corrected to 20°C (68°F).
4. *Equalization* means the natural (osmotic) or simulated blending between the soluble solids of the pickle ingredient and the packing medium.

   Natural equalization means equalization brought about after a period of time has elapsed after processing as follows. *Sweetened pickles* are considered to be equalized 15 days or more after processing. If the pickles have been sweetened in a tank prior to packing, the pickles will be considered equalized 15 days after the sweetening process began. *Sour and dill pickles* are considered to be equalized 10 days or more after processing.

   Simulated equalization means a method of simulating equalization by comminuting the finished product in a mechanical blender, filtering the suspended material from the comminuted mixture and making the required tests on the filtrate.
5. *Total chlorides or salt* means the salt content expressed as grams NaCl (sodium chloride) per 100 milliliters packing medium; except that total chlorides in mustard pickles and chow is determined and expressed in grams NaCl per 100 grams of product.

Blemished means any unit that is affected by discoloration, pathological injury, insect injury, or similar causes to the

TABLE 70.2
Sizes of Processed Whole Pickles

Word Designation	Diameter	Approximate Counts In			Glass	Metal
		1 qt	1/2 gal	1 gal	No. 10	No. 12 (1 gal)
Midget	19 mm (.75 in) or less	67 or more	135 or more	270 or more	202 or more	270 or more
Small gherkin	Up to 2.4 cm (.94 in)	33–66	67–134	135–269	101–201	135–269
Large gherkin	Up to 2.7 cm (1.06 in)	16–32	32–36	65–134	48–100	65–134
Small	Over 2.7 cm (1.06 in) but not over 3.5 cm (1.38 in)	10–15	20–31	40–64	30–47	40–64
Medium	Over 3.5 cm (1.38 in) but not over 3.8 cm (1.50 in)	6–9	13–19	26–39	19–29	26–39
Large	Over 3.8 cm (1.50 in) but not over 4.4 cm (1.73 in)	4–5	9–13	18–25	13–18	18–25
Extra large	Over 4.4 cm (1.73 in)	2–3	6–8	12–17	9–12	12–17

extent that the appearance or edibility of the product is adversely affected:

1. Slightly — those blemishes which detract only slightly from the appearance of the unit;
2. Seriously — those blemishes which strongly detract from the appearance or edibility of the unit.

1. Color

1. Good color in cured type means the typical skin color of the pickles ranges from a translucent light green to dark green and is practically free from bleached areas. Not more than 10 percent, by weight, of the pickles may vary markedly from such typical color. In mixed pickles, chow chow pickles, and pickle relish, all of the ingredients possess a practically uniform color typical for the pertinent ingredient. The pickles and other vegetable ingredients are free of off-colors.
2. Good color in fresh-pack and refrigerated types means the typical skin color of the pickles ranges from an opaque yellow-green to green. Not more than 15 percent, by weight, of the pickles may vary markedly from such typical color. In pickle relish, all of the ingredients possess a good uniform color typical for the pertinent ingredient. The pickles and other vegetable ingredients are free of off-colors.
3. Reasonably good color in cured type means the typical skin color of the pickles ranges from light green to dark green and is reasonably free from bleached areas. Not more than 25 percent, by weight, of the pickles may vary markedly from such typical color. In mixed pickles, chow chow pickles, and pickle relish, all of the ingredients possess a reasonably uniform color typical for the pertinent ingredient. The pickles and other vegetable ingredients are free of off-colors.
4. Reasonably good color in fresh-pack and refrigerated types means the typical skin color of the pickles ranges from light yellow-green to green. Not more than 30 percent, by weight, of the pickles may vary markedly from such typical color. In pickle relish, all of the ingredients possess a good, fairly uniform color typical for the pertinent ingredient. The pickles and other vegetable ingredients are free of off-colors.
5. Poor color in all types of pickles means the pickles fail to meet the requirements for good or reasonably good color for the pertinent type.

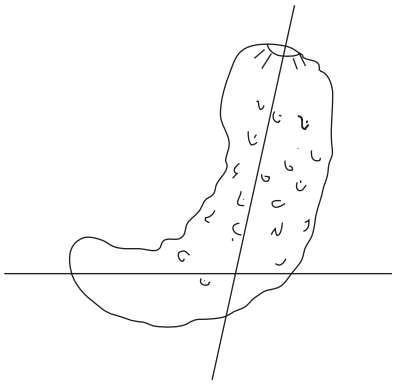

FIGURE 70.1 Crooked pickles (also see the definition of misshapen).

Also see the definition of misshapen.

Crooked pickles mean whole pickles that are curved at an angle greater than 60 degrees, as illustrated by Figure 70.1.

Curved pickles mean whole pickles that are curved at an angle of 35 to 60 degrees when measured as illustrated by Figure 70.2.

Diameter in whole style means the shortest diameter measured transversely to the longitudinal axis at the greatest circumference of the pickle. Diameter in cross-cut style is the shortest diameter of the largest cut surface.

Defect means an imperfection such as curved, misshapen, mechanically damaged, discolored, and other imperfection that affects the appearance or edibility of the product.

End cut means a pickle unit intended for crosscut (sliced crosswise) style that has only one cut surface.

Extraneous Vegetable Material (EVM) means any harmless vegetable material, other than stems, that is not

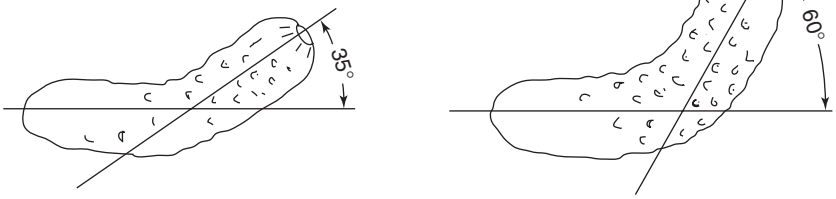

FIGURE 70.2 Curved pickles.

normally part of the pickle ingredient. EVM such as leaves or other vegetable material not associated with proper pickle preparation or packaging is considered a defect if it affects the appearance or edibility of the product either:

Slightly — Practically free of EVM and does not more than slightly affect the appearance or edibility; or

Materially — Reasonably free of EVM and does not more than materially affect the appearance or edibility.

2. Flavor and Odor

1. Good flavor and odor means characteristic flavor and odor (e.g. characteristic dill flavor or the like) typical of properly processed pickles, for the type, that is free from objectionable flavor and odor of any kind.
2. Reasonably good flavor and odor means flavor and odor that may be lacking in characteristic flavor for the type but is free from objectionable flavor and odor.
3. Poor flavor and odor means flavor and odor that fails to meet the requirements for good or reasonably good flavor and odor.

Length in sliced lengthwise style means the longest straight measurement at the approximate longitudinal axis.

Mechanical damage refers to crushed or broken units that affect the appearance of the units. In relish, mechanical damage refers to units that are poorly cut and have a ragged or torn appearance.

Misshapen pickles mean whole pickles that are crooked or otherwise deformed (such as nubbins). Also, see the definition for crooked pickles.

Nubbin is a misshapen pickle that is not cylindrical in form, is short and stubby, or is not well developed.

Texture means the firmness, crispness, and condition of the pickles and any other vegetable ingredient(s) and freedom from large seeds, detached seeds, and tough skins that may be present. The following terms also relate to texture:

1. Hollow centers in whole style, means the pickles, when cut transversely to the longitudinal axis, are missing 1/3 or more of the seed cavity.
2. Soft, shriveled, and slippery units refers to pickles that are wrinkled, not crisp, slick, flabby, or lack firmness.
3. Good texture means the pickle units have been properly processed and possess a texture that is firm and crisp.
4. Reasonably good texture means the pickle units have been properly processed but lack some of the firmness and crispness that is characteristic for the style and type of pack.
5. Poor texture means the pickle units do not meet the requirements for good or reasonably good texture.

3. Uniformity of Size (Relish Style Only)

1. Practically uniform in size means the size of the units may vary moderately in size but not to the extent that the appearance or the eating quality is seriously affected.
2. Poor uniformity of size means the units fail the requirements for practically uniform.

Unit means one whole, half, slice, or piece of pickle as applicable for the style.

Units missing one third or more of the seed cavity in crosscut style means pickles that have lost a substantial portion of the seed cavity such as a crosscut unit missing one third or more of the seed cavity portion.

G. Recommended Fill of Container

The recommended fill of container is not a factor of quality for the purposes of these grades. Each container of pickles should be filled with pickle ingredient, as full as practicable, without impairment of quality. The product and packing medium should occupy not less than 90 percent of the total capacity of the container.

H. Quantity of Pickle Ingredient

The recommended minimum quantity of pickle ingredient is designated as the percentage of the declared volume of product in the container for all items except pickle relish. Minimum quantity of pickle relish is designated as a relationship of the drained weight of the pickle ingredient to the declared volume of the container. The minimum quantities

TABLE 70.3
Recommended Pickle Ingredients

All Styles Except Relish	
Type of Pack	**Minimum Fill (Volume)**
Cured	55 percent
Fresh-Pack	57 percent
Refrigerated	57 percent

TABLE 70.4
Recommended Drained Weight to Container Volume, Relish

Type of Pack	Minimum Fill (Weight/Volume)
Cured:	
Sweet	92 percent
Other than sweet	88 percent
Fresh-Pack:	
Sweet	85 percent
Other than sweet	80 percent

recommended in Tables 70.3 and 70.4 are not factors of quality for the purposes of these grades.

The percent volume of pickle ingredient is determined for all styles, except relish, by one of the following methods in accordance with the procedures prescribed by the USDA:

1. Direct displacement (overflow-can method)
2. Displacement in a graduated cylinder
3. Measurement of pickle liquid
4. Any other method that gives equivalent results and is approved by the USDA

Drained weight/volume. The percent weight/volume (w/v) of relish shown in Table 70.4, is determined as follows: The drained weight of pickle relish of all types is determined by emptying the contents of the container upon a U.S. Standard No. 8 circular sieve of proper diameter containing 8 meshes to the inch (0.0937 inch ±3 percent, square openings) so as to distribute the product evenly, inclining the sieve slightly to facilitate drainage, and allowing to drain for 2 minutes. The drained weight is the weight of the sieve and the pickles less the weight of the dry sieve. A sieve 8 inches in diameter is used for 1 quart and smaller size containers and a sieve 12 inches in diameter is used for containers larger than 1 quart in size.

I. Sample Unit Size

For all styles of pickles and types of pack, the sample unit used in analyzing the quality factors is the entire contents of the container unless otherwise specified in 7 CFR Part.

J. Grades

1. *U.S. Grade A* is the quality of pickles that meets the applicable requirements of Tables 70.5–11 and scores not less than 90 points.
2. *U.S. Grade B* is the quality of pickles that meets the applicable requirements of Tables 70.6–11 and scores not less than 80 points.
3. *Substandard* is the quality of pickles that fails the requirements of U.S. Grade B.

K. Factors of Quality

The grade of pickles is based on the following quality factors:

1. Analytical requirements in Table 70.5
2. Flavor and odor
3. Color
4. Uniformity of size
5. Defects
6. Texture

L. Requirements for Grades

See tables 70.5–11.

II. ESTABLISHMENT INSPECTION

The FDA has issued guidelines for the inspection of a pickles processing plant. Some of the information is provided in this chapter. The quality control officer in

TABLE 70.5
Analytical Requirements [a]

Cured Type Pickles, All Styles	Totally Acidity Expressed as Acetic Acid Grams/100 mL, Unless Otherwise Indicated — Maximum	Total Chlorides Expressed as NaCl Grams/100 mL, Unless Otherwise Indicated — Maximum	Degrees Brix — Minimum	Degrees Baumé — Minimum
Dills (natural, genuine or processed)	1.1	5.0		
Sour, sour mixed, dill pickle relish, sour relish	2.7	5.0

such a plant should use the information to implement its in-plant inspection procedure.

The information is presented in the teacher/student format for ease of reference.

1. Direct special attention to the following areas when inspecting these types of food establishments. If the establishment is producing acidified fresh-pack pickles, determine if the establishment is complying with the requirements of 21 CFR 114, Acidified Foods.
2. Salt Stations and Salt Stock Tanks.
3. Insects which breed in decomposed pickles or other decaying organic matter such as the lesser or little house fly, the latrine fly, the house fly, the rat-tailed maggot, and *drosophila* spp are of major sanitary significance. Examine 25% of the tanks for insect filth.

[b] Pickles that are substandard for uniformity of size cannot be graded above U.S. Grade B, regardless of the total score.

4. "Mill run" salt may be used but workers should not walk in the salt.
5. Tanks should be skimmed daily for debris and insects, and the skimmings should be properly disposed of.
6. Newly salted stock ferments: scum growth should be removed regularly and disposed of so that insects are not attracted.

A. Pickle Products

Examination of raw materials used in relish.

1. Obtain the usual composition of relish in percent by weight of cucumbers as well as other ingredients to help appraise the filth load found in the sample.
2. Salt stock used for relish may consist of poor quality pickles, i.e., deformed, bloated, or blemished. However, in the absence of filth, grit, or partly or wholly rotted pickles, there is no objection to their use. Mushy pickles are caused by certain pectin-splitting enzymes during fermentation. Soft pickles may be invaded by bacteria and fungi, but it is

frequently difficult to determine if any mold or bacteria are present by field examination.

3. Examination of cucumber salt stock for relish: When whole pickles or large pieces are used, examine a representative sample of 100 units going to chopper.
4. Segregate and list objectionable pickles as follows:

Class	Number	Percent
– with rot spots over 1/2 in.	_____	_____
– insect-infested or damaged	_____	_____
– mushy or very soft	_____	_____

5. For class 1 pickles, make a further determination of the surface area of the rot spots by size; up to 1 inch; from 1 inch to half of the pickle; and over half of the pickle. Take close-up color photographs of objectionable pickles. Collect exhibits of pickles showing typical rot and insect damage.
6. Laboratory examination of mushy pickles for mold is necessary to establish if they are objectionable. If over 5% of the units are mushy, cut a thin cross-section from each pickle. Place the slices in a quart jar with water and add 20 cc formaldehyde for later examination.
7. When small pieces of salt stock cucumbers, cauliflower, and peppers are used, rot determination by count is impractical. If rotten pieces are observed, collect a separate quart of each pickled vegetable. Preserve the samples with 20 cc formaldehyde. At the same time, collect a sample totaling half a gallon of finished relish.

B. Peppers

1. Check for insect larvae (maggots or larvae of pepper weevil) in fresh and salt stock peppers and figure percent of infestation on a representative sample. Examine any fresh pack peppers in which infested stock was used.
2. If peppers with rot are found, evaluate in the same fashion as for cucumbers.
3. Examine vinegar storage tanks for drosophila infestation and for vinegar eels.
4. Insect filth in sweet stock pickles: insects, particularly drosophila, are attracted to the sweetening tanks, and may be found in the finished sweet pickle products.
5. Sweet brine is frequently circulated within a tank and from one tank to another dispersing insects in the circulating brine. It is sometimes difficult to estimate the number of insects and parts in such circulating brine. Close examination of the inside tank walls may reveal drosophila above the brine level. These are the best indices of infestation in a tank.

When insects are found in a sweetening tank:

1. Determine whether sweet brine in the tank is an intermediate or finishing brine and if it is circulated within the tank or between sweetening tanks.
2. If the finishing brine is used as a packing medium, determine whether it is filtered prior to use and evaluate the filtration step.
3. If sweet stock is held in infested tanks, determine anticipated date of packing.
4. Evaluate tank covers used.
5. List quantitatively, the extent of insect infestation by the collection of representative samples of filth from a definite area, e.g., square feet of the walls of the tank on the sweet stock and in a specified amount of brine from different areas of the tank if the infestation is widespread. If infestation seems to be isolated, collect specimens showing the types of insects.

C. Other Points of Interest

1. Grit in pickles: Excessive grit is frequently found in fresh pack pickles and in midget sweet pickles. Salt stock may occasionally contain excessive grit. If dirty cucumbers are packed, collect in-line and finished product samples.
2. Use of color and preservatives: Green artificial color is sometimes used in relish without label declaration. Ascertain if the color is permitted for use and declared on the label.
3. Sorbic acid may be used in salt stock, to prevent yeast growth, and in finished pickle products, as a preservative. Where sorbic acid is present in the finished product, determine if it is declared on the label.
4. Examination of warehouse stocks: Examine for evidence of spoilage, particularly in fresh pack pickles that may have been inadequately pasteurized.
5. If heavy insect infestation is found, examine 24 jars of the pickle product (other than relish) most likely to contain insects by inverting jars under strong light. Collect jars containing insects as a factory sample.

D. Sample Collection

1. Bulk Salt Stock for Filth

If in barrels, collect a minimum of 12 half-gallon jars of salt with their brine; 2 from each of 6 previously unopened

barrels to make 6 duplicate subs. Collect 1 sub from the top and the other sub from the bottom, if possible. If in tank cars, collect a minimum of twelve 1/2 gallon jars of salt stock and brine. If live flies are observed inside tank during sampling, note and estimate their number.

2. Finished Pickle Product — All Types

Filth and Grit

Quarts and smaller jars	*Minimum to collect*
Up to 100 cases in lot	24 jars
More than 100 cases	48 jars
Gallon jars	*Minimum to collect*
Up to 100 cases	12 jars
More than 100 cases	24 jars

3. Undeclared Color and Chemical Additives

Collect 6 quarts or 12 pints for examination.

Food and Workers Safety, Food Security

71 U.S. Food Standards and Food Grades

Nanna Cross
Chicago, Illinois

CONTENTS

I. INTRODUCTION

In the United States, three federal agencies have responsibility to make sure that processed foods (excluding meat and poultry) in the market are safe and do not pose any economic fraud. The U.S. Food and Drug Administration (FDA) issues regulations or mandatory requirements to achieve both goals. The U.S. Department of Agriculture (USDA) and U.S. National Marine Fisheries Service (NMFS) issue voluntary guides to achieve the same goals. However, "voluntary" can become "mandatory" under certain circumstances.

When studying information in this chapter, please note the following premises:

1. It is most useful for food companies of all sizes that sell products across state lines.
2. It is most useful for small food companies, especially new ones.
3. Although the information is designed for domestic food companies, it is definitely beneficial for foreign food manufacturers that export food to the United States.
4. Abbreviations used:
   CFR = U.S. Code of Federal Regulations.
   21 CFR 113 = U.S. Code of Federal Regulations, Title 21, Part 113.

II. FDA FOOD STANDARDS

Food standards are a necessity for both consumers and the food industry. They maintain the general quality of a large part of the national food supply and prevent economic fraud. Without standards, different foods could have the same names or the same foods could have different names. Both situations would be confusing and misleading to consumers and create unfair competition.

Section 401 of the Federal Food, Drug, and Cosmetic Act requires that whenever such action will promote honesty and fair dealing in the interest of consumers, regulations shall be promulgated fixing and establishing for any food, under its common or usual name so far as practicable, a reasonable definition and standard of identity, a reasonable standard of quality, and reasonable standards of fill-of-container. However, no definition and standard of identity or standard of quality may be established for fresh or dried fruits, fresh or dried vegetables, or butter, except that definitions and standards of identity may be established for avocados, cantaloupes, citrus fruits, and melons.

Standards of identity define what a given food product is, its name, and the ingredients that must or may be used in the manufacture of the food. Standards of quality are minimum standards only and establish specifications for quality requirements. Fill-of-container standards define

how full the container must be and how this is measured. FDA standards are based on the assumption that the food is properly prepared from clean, sound materials. Standards do not usually relate to such factors as deleterious impurities, filth, and decomposition. There are exceptions. For example, the standards for whole egg and yolk products and for egg white products require these products to be pasteurized or otherwise treated to destroy all viable Salmonella bacteria. Some standards for foods set nutritional requirements, such as those for enriched bread, or nonfat dry milk with added vitamins A and D, etc. A food which is represented as, or purports to be, a food for which a standard of identity has been promulgated must comply with the specifications of the standard in every respect.

The standards that have been promulgated by the FDA are listed below.

A. 21 CFR 131 — Milk and Cream

1. Requirements for Specific Standardized Milk and Cream

21 CFR.110 — Milk.
21 CFR.111 — Acidified milk.
21 CFR.112 — Cultured milk.
21 CFR.115 — Concentrated milk.
21 CFR.120 — Sweetened condensed milk.
21 CFR.125 — Nonfat dry milk.
21 CFR.127 — Nonfat dry milk fortified with vitamins A and D.
21 CFR.130 — Evaporated milk.
21 CFR.147 — Dry whole milk.
21 CFR.149 — Dry cream.
21 CFR.150 — Heavy cream.
21 CFR.155 — Light cream.
21 CFR.157 — Light whipping cream.
21 CFR.160 — Sour cream.
21 CFR.162 — Acidified sour cream.
21 CFR.170 — Eggnog.
21 CFR.180 — Half-and-half.
21 CFR.200 — Yogurt.
21 CFR.203 — Lowfat yogurt.
21 CFR.206 — Nonfat yogurt.

B. 21 CFR 133 — Cheeses and Related Cheese Products

1. Requirements for Specific Standardized Cheese and Related Products

21 CFR 133.102 — Asiago fresh and Asiago soft cheese.
21 CFR 133.103 — Asiago medium cheese.
21 CFR 133.104 — Asiago old cheese.
21 CFR 133.106 — Blue cheese.
21 CFR 133.108 — Brick cheese.
21 CFR 133.109 — Brick cheese for manufacturing.
21 CFR 133.111 — Caciocavallo Sicilian cheese.
21 CFR 133.113 — Cheddar cheese.
21 CFR 133.114 — Cheddar cheese for manufacturing.
21 CFR 133.116 — Low sodium cheddar cheese.
21 CFR 133.118 — Colby cheese.
21 CFR 133.119 — Colby cheese for manufacturing.
21 CFR 133.121 — Low sodium Colby cheese.
21 CFR 133.123 — Cold-pack and club cheese.
21 CFR 133.124 — Cold-pack cheese food.
21 CFR 133.125 — Cold-pack cheese food with fruits, vegetables, or meats.
21 CFR 133.127 — Cook cheese, Koch kaese.
21 CFR 133.128 — Cottage cheese.
21 CFR 133.129 — Dry curd cottage cheese.
21 CFR 133.133 — Cream cheese.
21 CFR 133.134 — Cream cheese with other foods.
21 CFR 133.136 — Washed curd and soaked curd cheese.
21 CFR 133.137 — Washed curd cheese for manufacturing.
21 CFR 133.138 — Edam cheese.
21 CFR 133.140 — Gammelost cheese.
21 CFR 133.141 — Gorgonzola cheese.
21 CFR 133.142 — Gouda cheese.
21 CFR 133.144 — Granular and stirred curd cheese.
21 CFR 133.145 — Granular cheese for manufacturing.
21 CFR 133.146 — Grated cheeses.
21 CFR 133.147 — Grated American cheese food.
21 CFR 133.148 — Hard grating cheeses.
21 CFR 133.149 — Gruyere cheese.
21 CFR 133.150 — Hard cheeses.
21 CFR 133.152 — Limburger cheese.
21 CFR 133.153 — Monterey cheese and Monterey jack cheese.
21 CFR 133.154 — High-moisture jack cheese.
21 CFR 133.155 — Mozzarella cheese and scamorza cheese.
21 CFR 133.156 — Low-moisture mozzarella and scamorza cheese.
21 CFR 133.157 — Part-skim mozzarella and scamorza cheese.
21 CFR 133.158 — Low-moisture part-skim mozzarella and scamorza cheese.
21 CFR 133.160 — Muenster and Munster cheese.
21 CFR 133.161 — Muenster and Munster cheese for manufacturing.
21 CFR 133.162 — Neufchatel cheese.
21 CFR 133.164 — Nuworld cheese.
21 CFR 133.165 — Parmesan and reggiano cheese.
21 CFR 133.167 — Pasteurized blended cheese.
21 CFR 133.168 — Pasteurized blended cheese with fruits, vegetables, or meats.
21 CFR 133.169 — Pasteurized process cheese.
21 CFR 133.170 — Pasteurized process cheese with fruits, vegetables, or meats.
21 CFR 133.171 — Pasteurized process pimento cheese.
21 CFR 133.173 — Pasteurized process cheese food.

21 CFR 133.174 — Pasteurized process cheese food with fruits, vegetables, or meats.
21 CFR 133.175 — Pasteurized cheese spread.
21 CFR 133.176 — Pasteurized cheese spread with fruits, vegetables, or meats.
21 CFR 133.178 — Pasteurized Neufchatel cheese spread with other foods.
21 CFR 133.179 — Pasteurized process cheese spread.
21 CFR 133.180 — Pasteurized process cheese spread with fruits, vegetables, or meats.
21 CFR 133.181 — Provolone cheese.
21 CFR 133.182 — Soft ripened cheeses.
21 CFR 133.183 — Romano cheese.
21 CFR 133.184 — Roquefort cheese, sheep's milk blue-mold, and blue-mold cheese from sheep's milk.
21 CFR 133.185 — Samsoe cheese.
21 CFR 133.186 — Sapsago cheese.
21 CFR 133.187 — Semisoft cheeses.
21 CFR 133.188 — Semisoft part-skim cheeses.
21 CFR 133.189 — Skim milk cheese for manufacturing.
21 CFR 133.190 — Spiced cheeses.
21 CFR 133.191 — Part-skim spiced cheeses.
21 CFR 133.193 — Spiced, flavored standardized cheeses.
21 CFR 133.195 — Swiss and Emmentaler cheese.
21 CFR 133.196 — Swiss cheese for manufacturing.

C. 21 CFR 135 — Frozen Desserts

1. Requirements for Specific Standardized Frozen Desserts

21 CFR.110 — Ice cream and frozen custard.
21 CFR.115 — Goats milk ice cream.
21 CFR.130 — Mellorine.
21 CFR.140 — Sherbet.
21 CFR.160 — Water ices.

D. 21 CFR 136 — Bakery Products

1. Requirements for Specific Standardized Bakery Products

21 CFR.110 — Bread, rolls, and buns.
21 CFR.115 — Enriched bread, rolls, and buns.
21 CFR.130 — Milk bread, rolls, and buns.
21 CFR.160 — Raisin bread, rolls, and buns.
21 CFR.180 — Whole wheat bread, rolls, and buns.

E. 21 CFR 137 — Cereal Flours and Related Products

1. Requirements for Specific Standardized Cereal Flours and Related Products

21 CFR 137.105 — Flour.
21 CFR 137.155 — Bromated flour.
21 CFR 137.160 — Enriched bromated flour.
21 CFR 137.165 — Enriched flour.
21 CFR 137.170 — Instantized flours.
21 CFR 137.175 — Phosphated flour.
21 CFR 137.180 — Self-rising flour.
21 CFR 137.185 — Enriched self-rising flour.
21 CFR 137.190 — Cracked wheat.
21 CFR 137.195 — Crushed wheat.
21 CFR 137.200 — Whole wheat flour.
21 CFR 137.205 — Bromated whole-wheat flour.
21 CFR 137.211 — White corn flour.
21 CFR 137.215 — Yellow corn flour.
21 CFR 137.220 — Durum flour.
21 CFR 137.225 — Whole durum flour.
21 CFR 137.250 — White corn meal.
21 CFR 137.255 — Bolted white corn meal.
21 CFR 137.260 — Enriched corn meal.
21 CFR 137.265 — Degerminated white corn meal.
21 CFR 137.270 — Self-rising white corn meal.
21 CFR 137.275 — Yellow corn meal.
21 CFR 137.280 — Bolted yellow corn meal.
21 CFR 137.285 — Degerminated yellow corn meal.
21 CFR 137.290 — Self-rising yellow cornmeal.
21 CFR 137.300 — Farina.
21 CFR 137.305 — Enriched farina.
21 CFR 137.320 — Semolina.
21 CFR 137.350 — Enriched rice.

F. 21 CFR 139 — Macaroni and Noodle Products

1. Subpart B — Requirements for Specific Standardized Macaroni and Noodle Products

21 CFR 139.110 — Macaroni products.
21 CFR 139.115 — Enriched macaroni products.
21 CFR 139.117 — Enriched macaroni products with fortified protein.
21 CFR 139.120 — Milk macaroni products.
21 CFR 139.121 — Nonfat milk macaroni products.
21 CFR 139.122 — Enriched nonfat milk macaroni products.
21 CFR 139.125 — Vegetable macaroni products.
21 CFR 139.135 — Enriched vegetable macaroni products.
21 CFR 139.138 — Whole-wheat macaroni products.
21 CFR 139.140 — Wheat and soy macaroni products.
21 CFR 139.150 — Noodle products.
21 CFR 139.155 — Enriched noodle products.
21 CFR 139.160 — Vegetable noodle products.
21 CFR 139.165 — Enriched vegetable noodle products.
21 CFR 139.180 — Wheat and soy noodle products.

G. 21 CFR 145 — Canned Fruits

1. Requirements for Specific Standardized Canned Fruits

145.110 — Canned applesauce.
145.115 — Canned apricots.

145.116 — Artificially sweetened canned apricots.
145.120 — Canned berries.
145.125 — Canned cherries.
145.126 — Artificially sweetened canned cherries.
145.130 — Canned figs.
145.131 — Artificially sweetened canned figs.
145.134 — Canned preserved figs.
145.135 — Canned fruit cocktail.
145.136 — Artificially sweetened canned fruit cocktail.
145.140 — Canned seedless grapes.
145.145 — Canned grapefruit.
145.170 — Canned peaches.
145.171 — Artificially sweetened canned peaches.
145.175 — Canned pears.
145.176 — Artificially sweetened canned pears.
145.180 — Canned pineapple.
145.181 — Artificially sweetened canned pineapple.
145.185 — Canned plums.
145.190 — Canned prunes.

H. 21 CFR 146 — Canned Fruit Juices

1. Requirements for Specific Standardized Canned Fruit Juices and Beverages

146.114 — Lemon juice.
146.120 — Frozen concentrate for lemonade.
146.121 — Frozen concentrate for artificially sweetened lemonade.
146.126 — Frozen concentrate for colored lemonade.
146.132 — Grapefruit juice.
146.135 — Orange juice.
146.137 — Frozen orange juice.
146.140 — Pasteurized orange juice.
146.141 — Canned orange juice.
146.145 — Orange juice from concentrate.
146.146 — Frozen concentrated orange juice.
146.148 — Reduced acid frozen concentrated orange juice.
146.150 — Canned concentrated orange juice.
146.151 — Orange juice for manufacturing.
146.152 — Orange juice with preservative.
146.153 — Concentrated orange juice for manufacturing.
146.154 — Concentrated orange juice with preservative.
146.185 — Pineapple juice.
146.187 — Canned prune juice.

I. 21 CFR 150 — Fruit Butters, Jellies, Preserves, and Related Products

1. Requirements for Specific Standardized Fruit Butters, Jellies, Preserves, and Related Products

150.110 — Fruit butter.
150.140 — Fruit jelly.
150.141 — Artificially sweetened fruit jelly.
150.160 — Fruit preserves and jams.

J. 21 CFR 152 — Fruit Pies

1. Requirements for Specific Standardized Fruit Pies

152.126 — Frozen cherry pie.

K. 21 CFR 155 — Canned Vegetables

1. Requirements for Specific Standardized Canned Vegetables

155.120 — Canned green beans and canned wax beans.
155.130 — Canned corn.
155.131 — Canned field corn.
155.170 — Canned peas.
155.172 — Canned dry peas.
155.190 — Canned tomatoes.
155.191 — Tomato concentrates.
155.194 — Catsup.
155.200 — Certain other canned vegetables.
155.201 — Canned mushrooms.

L. 21 CFR 156 — Vegetable Juices

1. Requirements for Specific Standardized Vegetable Juices

156.145 — Tomato juice.

M. 21 CFR 158 — Frozen Vegetables

1. Requirements for Specific Standardized Frozen Vegetables

158.170 — Frozen peas.

N. 21 CFR 160 — Eggs and Egg Products

1. Subpart B — Requirements for Specific Standardized Eggs and Egg Products

§160.100 — Eggs.
§160.105 — Dried eggs.
§160.110 — Frozen eggs.
§160.115 — Liquid eggs.
§160.140 — Egg whites.
§160.145 — Dried egg whites.
§160.150 — Frozen egg whites.
§160.180 — Egg yolks.
§160.185 — Dried egg yolks.
§160.190 — Frozen egg yolks.

O. 21 CFR 161 — Fish and Shellfish

1. Requirements for Specific Standardized Fish and Shellfish

161.130 — Oysters.
161.136 — Olympia oysters.

161.145 — Canned oysters.
161.170 — Canned Pacific salmon.
161.173 — Canned wet pack shrimp in transparent or nontransparent containers.
161.175 — Frozen raw breaded shrimp.
161.176 — Frozen raw lightly breaded shrimp.
161.190 — Canned tuna.

P. 21 CFR 163 — Cacao Products

1. Requirements for Specific Standardized Cacao Products

163.110 — Cacao nibs.
163.111 — Chocolate liquor.
163.112 — Breakfast cocoa.
163.113 — Cocoa.
163.114 — Lowfat cocoa.
163.117 — Cocoa with dioctyl sodium sulfosuccinate for manufacturing.
163.123 — Sweet chocolate.
163.124 — White chocolate.
163.130 — Milk chocolate.
163.135 — Buttermilk chocolate.
163.140 — Skim milk chocolate.
163.145 — Mixed dairy product chocolates.
163.150 — Sweet cocoa and vegetable fat coating.
163.153 — Sweet chocolate and vegetable fat coating.
163.155 — Milk chocolate and vegetable fat coating.

Q. 21 CFR 164 — Tree Nut and Peanut Products

1. Requirements for Specific Standardized Tree Nut and Peanut Products

164.110 — Mixed nuts.
164.120 — Shelled nuts in rigid or semirigid containers.
164.150 — Peanut butter.

R. 21 CFR 165 — Beverages

1. Requirements for Specific Standardized Beverages

165.110 — Bottled water.

S. 21 CFR 166 — Margarine

166.40 — Labeling of margarine.
166.110 — Margarine.

T. 21 CFR 168 — Sweeteners and Table Sirups

1. Requirements for Specific Standardized Sweeteners and Table Sirups

168.110 — Dextrose anhydrous.
168.111 — Dextrose monohydrate.
168.120 — Glucose syrup.
168.121 — Dried glucose syrup.
168.122 — Lactose.
168.130 — Cane syrup.
168.140 — Maple syrup.
168.160 — Sorghum syrup.
168.180 — Table syrup.

U. 21 CFR 169 — Food Dressings and Flavorings

1. Requirements for Specific Standardized Food Dressings and Flavorings

169.115 — French dressing.
169.140 — Mayonnaise.
169.150 — Salad dressing.
169.175 — Vanilla extract.
169.176 — Concentrated vanilla extract.
169.177 — Vanilla flavoring.
169.178 — Concentrated vanilla flavoring.
169.179 — Vanilla powder.
169.180 — Vanilla-vanillin extract.
169.181 — Vanilla-vanillin flavoring.
169.182 — Vanilla-vanillin powder.

III. USDA STANDARDS FOR GRADES OF PROCESSED FRUITS AND VEGETABLES

Voluntary U.S. grade standards are issued under the authority of the Agricultural Marketing Act of 1946, which provides for the development of official U.S. grades to designate different levels of quality. These grade standards are available for use by producers, suppliers, buyers, and consumers. As in the case of other standards for grades of processed fruits and vegetables, these standards are designed to facilitate orderly marketing by providing a convenient basis for buying and selling, for establishing quality control programs, and for determining loan values.

The standards also serve as a basis for the inspection and grading of commodities by the Federal inspection service, the only activity authorized to approve the designation of U.S. grades as referenced in the standards, as provided under the Agricultural Marketing Act of 1946. This service, available as on-line (in-plant) or lot inspection and grading of all processed fruit and vegetable products, is offered to interested parties, upon application, on a fee-for-service basis. The verification of some specific recommendations, requirements, or tolerances contained in the standards can be accomplished only by the use of on-line inspection procedures. In all instances, a grade can be assigned based on final product factors or characteristics.

In addition to the U.S. grade standards, grading manuals or instructions for inspection of several processed fruits and vegetables are available upon request for a

nominal fee. These manuals or instructions contain detailed interpretations of the grade standards and provide step-by-step procedures for grading the product.

Grade standards are issued by the Department after careful consideration of all data and views submitted, and the Department welcomes suggestions that might aid in improving the standards in future revisions.

Those products with such grade standards are listed below. They are all located in 7 CFR 52.

A. Canned Fruit

Apples
Apple Butter
Apple Juice
Applesauce
Apricots, Regular and Solid Pack
Blackberries and Other Similar Berries
Blueberries
Cherries, RTP
Cherries, Sweet
Cranberry Sauce
Figs, Kadota
Fruit Cocktail
Fruit Jelly
Fruit Preserves (Jams)
Fruits for Salad
Grapefruit
Grapefruit Juice, from Concentrate and Concentrated Grapefruit Juice for Manufacturing
Grapefruit and Orange for Salad
Grapefruit Juice and Orange Juice (Blend)
Grape Juice
Grapes
Lemon Juice
Lemon Juice, Concentrate for Manufacturing.
Orange Juice: from Concentrate, Pasteurized, Concentrated, and Concentrate for Manufacturing
Orange Marmalade
Peaches, Clingstone
Peaches, Freestone
Pears
Pineapple
Pineapple Juice and Pineapple Juice from Concentrate
Plums
Prunes, Dried
Raspberries
Tangerine Juice
Tangerine Juice Concentrate for Manufactuing

B. Canned Vegetables

Asparagus
Beans, Baked, Dried, Pork and
Beans, Green and Wax
Beans
Beets
Carrots
Celery
Chili Sauce
Corn, Cream Style
Corn, Whole Kernel
Hominy
Leafy Greens
Mushrooms
Okra
Okra and Tomatoes and Tomatoes and Okra
Olives, Green
Olives, Ripe
Onions
Peas
Peas and Carrots
Peas, Field and Blackeye
Pickles
Pimientos
Potatoes, White
Pumpkin (Squash)
Sauerkraut
Spinach
Squash (Summer type)
Succotash
Sweet potatoes
Tomatoes
Tomato Catsup
Tomato Juice and Tomato Juice from Concentrate
Tomato Juice, Concentrate
Tomato Paste
Tomato Puree (pulp)
Tomato Sauce

C. Frozen Fruit

Apple Juice, Concentrate
Apricots
Berries (Black, Boysen, etc.)
Blueberries
Cherries (red tart pitted)
Cherries, Sweet
Cranberries
Grape Juice, Concentrate, Sweetened
Grapefruit
Grapefruit Juice
Conc. Grapefruit Juice
Conc. Grapefruit Juice for Manufacturing
Grapefruit Juice and Orange Juice Concentrate, Blended
Lemonade, Concentrate
Limeade, Concentrate
Melon Balls
Orange Juice
Orange Juice from Concentrate

Pasteurized Orange Juice
Concentrate Orange Juice
Concentrate Orange Juice for Manufacturing
Reduced Acid Orange Juice, Concentrate
Peaches
Pineapple Juice
Pineapple Juice from Concentrate
Pineapple
Plums
Raspberries
Strawberries

D. Frozen Vegetables

Asparagus
Beans, Green and Wax Beans, Lima
Beans, Speckled Butter (Lima)
Broccoli
Brussels Sprouts
Carrots
Cauliflower
Corn, Whole Kernel
Corn on the Cob
Leafy Greens (includes Spinach)
Okra
Onion Rings, Breaded
Peas
Peas and Carrots
Peas, Field and Black-eye
Peppers
Sweet Potatoes
French Fried Potatoes
Hash Brown
Rhubarb
Squash (Cooked)
Squash (Summer)
Succotash
Sweet Potatoes
Tomato Juice
Tomato Juice from Concentrate
Turnip Greens with Turnips
Vegetables, Mixed

E. Dried Dehydrated Products

Apples, Dehydrated
Apples, Dried
Apricots, Dehydrated
Apricots, Dried
Dates
Figs
Grapefruit Juice, Dehydrated
Orange Juice, Dehydrated
Peaches, Dehydrated
Pears, Dried
Prunes
Prunes, Dried
Raisins, Processed

F. Sugar Products

Honey, Comb
Honey, Extracted
Maple Syrup
Molasses, Sugarcane
Syrup, Refiners'
Syrup, Sugarcane

G. Miscellaneous Products

Cherries, Sulphured
Olive Oil
Peanut Butter
Potatoes, Peeled
Sauerkraut, Bulk

IV. NMFS STANDARDS FOR GRADES OF FISHERY PRODUCTS

The regulatory agency, the National Marine Fisheries Service (NMFS), has issued some minimal criteria for several seafood and seafood products: what they are, what types and styles are available, and so on. A product grade is established to achieve two objectives: assure product safety and minimize economic fraud. The fishery products with standards for grades include the following.

A. 50 CFR 261 — United States Standards for Grades of Whole or Dressed Fish

Whole or Dressed Fish
Frozen Headless Dressed Whiting

B. 50 CFR 262 — United States Standards for Grades of Fish Steaks

Frozen Halibut Steaks

C. 50 CFR 263 — United States Standards for Grades of Fish Fillets

Fish Fillets
Cod Fillets
Flounder and Sole Fillets
Haddock Fillets
Ocean and Pacific Perch Fillets

D. 50 CFR 264 — United States Standards for Grades of Frozen Fish Blocks and Products Made There from

Frozen Fish Fillet Blocks
Frozen Minced Fish Blocks
Frozen Raw Fish Portions
Frozen Raw Breaded Fish Sticks
Frozen Raw Breaded Fish Portions
Frozen Fried Fish Sticks
Frozen Fried Fish Portions

E. 50 CFR 265 — United States Standards for Grades of Crustacean Shellfish

Fresh and Frozen Shrimp
Frozen Raw Breaded Shrimp

F. 50 CFR 266 — United States Standards for Grades of Molluscan Shellfish

Frozen Raw Scallops
Frozen Raw Breaded Scallops and Frozen Fried Scallops

G. 50 CFR 267 — United States Standards for Grades of North American Freshwater Catfish and their Products

ACKNOWLEDGMENT

72 Standards for Meat and Poultry in the United States

Nanna Cross
Chicago, Illinois

CONTENTS

I. INTRODUCTION

In the United States, the federal government has total control over the safety of all land muscle foods, i.e., beef, pork, chicken, and many others. This approach is similar to that of major Western countries. The federal agency is called Food Safety Inspection Service (FSIS). FSIS is one arm of the United States Department of Agriculture (USDA). FSIS has the major responsibility of assuring that nation's meat supply and other land muscle foods are save for the public to consume. However, apart from safety, the FSIS has another responsibility, assuring that economic fraud is kept to a minimum. Because meat and many land muscle foods are high-priced items, many dishonest food operations cannot resist the temptation to cheat the consumers when the opportunities arise. Fortunately, most operators are honest businessmen. Still the FSIS has spent an enormous amount of effort to prevent economic fraud.

All information in this chapter has been derived from publication documents issued by the USDA, with legal citation and languages removed. To obtain original documents, please consult the USDA with respect to standards and labeling of products under USDA jurisdiction.

II. DEFINITIONS

For ease of reference, some important terms are defined here.

Red Meat

Required percentages of meat required for red meat products are shown on the basis of *fresh uncooked weight* unless otherwise indicated. Whenever the terms beef, pork, lamb, mutton, or veal are used they indicate the use of skeletal muscle tissue from the named species (9 CFR 301.2).

Poultry

Required percentages for poultry products are based on a *cooked deboned* basis unless otherwise stated. When the standards indicate "poultry," the skin and fat are not to exceed natural proportions per (9 CFR 381.117(d)).

IV. STANDARDS, LABELS, AND OTHER INFORMATION

Andouille (FR)

Made with pork and/or pork byproducts stuffed into large intestines. Product can be sold cooked or uncooked. Andouille is a coined name and must be accompanied by a true product name, e.g., "sausage" or "pudding" depending on formulation. If beef is used, it must be shown in the product name, e.g., "Beef Andouille Sausage" or "Beef Andouille Pudding."

Arroz Con Pollo (SP)

The product must contain at least 15% cooked chicken meat. The label must show, the true product name, in English, i.e., "Rice with Chicken," except if the product is distributed solely in Puerto Rico.

Au Gratin Potatoes and Bacon

At least 8% fully cooked bacon (based on 40% yield).

Baby Food

High Meat Dinner — At least 26% meat. High Meat Poultry Dinner — At least 18.75% cooked poultry meat, skin, fat and giblets. Meat and Broth — At least 61% meat. Vegetable with Meat — At least 8% meat. Poultry with Broth — At least 43% cooked poultry meat, skin, and giblets. Poultry and Rice — At least 5% cooked deboned poultry meat.

Note: Wine, mechanically separated species, nitrites, and nitrates are not acceptable in baby and toddler foods.

Baby Food with Fresh Ham or Bacon

Ham or bacon without nitrates or nitrites must be shown in the ingredients statement as ham or bacon (water, salt, sugar, etc., without nitrates or nitrites).

Bacon

The term "bacon" is used to describe the cured belly of a swine carcass. If meat from other portions of the carcass is used, the product name must be qualified to identify the portions, e.g., "Pork Shoulder Bacon." "Certified" refers to products that have been treated for trichinae.

Bacon and Pork Sausage

Product is formulated with a high percentage of bacon (usually bacon ends and pieces) with at least 20% pork.

Bacon Arkansas and Arkansas Style Bacon

Product which is identified as Arkansas Bacon or Arkansas Style Bacon is produced from the pork shoulder blade Boston roast. The pork shoulder blade Boston roast includes the porcine muscle, fat and bone, cut interior of the second or third thoracic vertebrae, and posterior of the atlas joint (first cervical vertebrae), and dorsal of the center of the humerus bone. For Arkansas Bacon, the neck bones and rib bones are removed by cutting close to the underside of those bones. The blade bone (scapula) and the dorsal fat covering, including the skin (clear plate), are removed, leaving no more than one-quarter inch of the fat covering the roast. The meat is then dry cured with salt, sugar, nitrites, and spices, and smoked with natural smoke. The meat may not be injected or soaked in curing brine, nor may any artificial or liquid smoke be applied to the meat. Product that is prepared outside the state of Arkansas but in the manner prescribed may be identified as "Arkansas Style Bacon." The true product name must be shown as "Boneless Cured Pork Shoulder Butt."

Bacon (Canned — Pasteurized)

A shelf stable item, which must have at least 7% brine concentration.

Bacon (Canned, Prefried)

In "Canned Prefried Bacon," e.g., "Bacon Crumbles," the following criteria should be applied:

1. M/SP Index of 0.4 or more. M/SP = Moisture/(Salt × Protein).
2. A Brine Ratio of 9.0 or less. Brine Ratio = Moisture/Salt.
3. A Brine concentration of 10% or more. Brine concentration = Salt/(Moisture + Salt).
4. Maximum 40% yield.

Bacon (Cooked)

Not to yield more than 40% bacon — 60% shrink required. BHA and BHT may be used as antioxidants in precooked bacon at level of 0.01% individually or 0.02% collectively, based on fat content. TBHQ can be used in products as an antioxidant in combination with BHT and BHA; but it can not be used alone except in cooked bacon.

Bacon Dressing for Stuffing

The product must contain at least 8% bacon.

Bacon-Like Products

Bacon-like products, including poultry bacon, labeled with "bacon" in the name must follow the same requirements as those applied to pork bacon. These requirements include, but are not limited to, limits on restricted ingredients and the requirement that the bacon must return to green weight.

Beef bacon is a cured and smoked beef product sliced to simulate regular bacon. It is prepared from various beef cuts and offered with a variety of coined names, including "Breakfast Beef," "Beef Bacon," etc. A common or usual name is required, e.g., "Cured and Smoked Beef Plate," and should be shown contiguous to the coined name.

Poultry bacon products are acceptable and may be designated as (Kind) Bacon. However, a true descriptive name must appear contiguous to (Kind) Bacon without intervening type or design, in letters at least one-half the size of the letters used in the (Kind) Bacon, and in the same style and color and on the same background. An example of an acceptable designation is "Turkey Bacon-Cured Turkey Breast Meat-Chopped and Formed."

The descriptive name can serve alone as the product name.

Bacon Products

The bacon products intended for further cooking before consumption, i.e., slab bacon for deli slicing, can be labeled "certified," "roasted" or "partially cooked" provided the product is cooked to 148°F and the labeling clearly indicated the product is intended to be further cooked before consumption.

Bangers

A sausage-like product prepared with meat and varying amounts of rusk or other cereals. The label must show percentage of rusk (or other cereal) adjacent to product

name in prominent lettering. May be labeled British, Scottish or Irish Style.

Barbecue (BBQ) Products

Barbecue (BBQ) products that are composed of uncured red meat products that are injected, massaged, tumbled, etc., and which are cooked back to or below the weight of the raw meat product (green weight), must use the term "seasoned" or "flavored," in conjunction with the meat product in the product name, e.g., "BBQ Seasoned Pork," or "Sliced Seasoned Beef with Barbecue Sauce."

The labeling for uncured red meat products containing some solutions that are used to make BBQ products (9 CFR 319.312 or 319.80) which are not cooked back to green weight or are not in compliance with the cooking yield must have a containing statement on the label. A containing statement is required in the product name when the cooking yield is not met, e.g., "BBQ Pork Containing up to 15% of a solution." Similarly, a containing statement is required in the product name when the product does not have sufficient quantities of meat minus the solution to meet the minimum meat requirement. However, in limited situations when the minimum meat requirement (minus the solution) is met and when cook yield is compensated for by adding additional meat, the containing statement can either be placed in the product name or attached to the meat component in the ingredients statement, e.g., "Ingredients: Beef Containing up to 25% … sugar, spices."

Red meat components that contain binders and extenders and do not meet one of the barbecue standards (9 CFR 319.80, 319.312) shall be descriptively labeled to include the extender, nomenclature in the product name, e.g., "BBQ Seasoned Beef, Modified Food Starch and Gelatinized Wheat Starch," "Pork and Binder Product with Barbecue Sauce", or "BBQ Cooked Beef and Binder Product" followed by a parenthetical list of all of its ingredients. Bone-in red meat products do not have to comply with Federal meat regulation, 9 CFR 319.312 or 319.80 with regard to cooking yield and must indicate the presence of bones in product name, e.g., "Seasoned Cooked Pork Ribs with Barbecue Sauce" or "Barbecue Beef Ribs."

When bone-in red meat products are injected, massaged, tumbled, etc., and do not return to green weight after cooking, the containing statement shall appear once on the label in (1) the ingredients statement as part of the red meat component (only if there is enough Beef Ribs without solution to meet the requirement for "Beef Ribs and BBQ Sauce"), or (2) in the product name, e.g., "Beef Ribs, containing 10% of a solution and BBQ Sauce."

Barbecue (Infrared Cooked)

The label must indicate heat source, e.g., "infrared cooked," with lettering no less than one-half the size of the largest letter in the word "barbecue."

Barbecue Meat or Poultry "Eastern North Carolina Style"

Acceptable identification for a product that is enhanced in a vinegar-based solution, apple or white. The solution is seasoned with pepper, i.e., black pepper, red pepper, or cayenne pepper. Other ingredients may include salt, sugar, and hot pepper sauce.

Barbecue Sauce with Chicken

The product must contain at least 15% cooked chicken meat. Changing the size of the term "Chicken" does not change the 15% cooked chicken meat requirement.

Barbecue Sauce with Meat

The product must contain at least 35% cooked meat. When the name of the product shows meat in smaller letters, not more than one-half the size of the largest letter in the product name, 25% cooked meat is required.

Beef a La King

The product must contain at least 20% cooked beef.

Beef a La Mode

A product consisting of sliced beef (marinated in wine, cognac, vegetable stock) with carrots, onions, and other ingredients covered with wine sauce. The product must contain at least 50% beef.

Beef Almondine with Vegetables

The product must contain at least 18% cooked meat on the ready-to-serve basis. The product must contain almonds.

Beef and Dumplings with Gravy

The product must contain at least 25% meat and not more than 25% water blanched dry dumplings.

Beef and Gravy

The product contains at least 50% cooked beef.

See: Gravy and Beef

Beef Blood

This is an acceptable ingredient for beef patties provided the product name is qualified, such as "Beef and Blood Patties" or "Beef Patties with Blood."

Beef Blood Glaze

A coating of beef blood is permitted on cured products (e.g., ham, hamette, etc.) if the product name is prominently

qualified to reflect the coating. Nitrite is not permitted in the glaze.

Beef Brisket (Canned)

The minimum brine concentration required is 5.5%.

Beef Burgundy or Bourguignonne

The product must contain at least 50% beef. Product contains beef cubes, mushrooms, onions, and red wine or burgundy gravy. May include other vegetables, e.g., carrots, shallots, tomato paste, or potatoes. Other acceptable names include "Beouf A La Bourguignonne," "Beef Burgundy Style," "Beef Burgundy," and "Burgundy Beef."

Beef Burgundy with Noodles

The product must contain at least 50% beef in the beef burgundy portion. Total product should not contain more than 50% cooked noodles.

Beef Cheek Meat and Beef Head Meat and Pork Cheek Meat and Pork Head Meat (Use and Labeling as an Ingredient in Meat Food Products)

Beef cheek meat and pork cheek meat refers to beef and pork cheeks from which the glandular material has been removed.

Beef head meat and pork head meat refer to muscle tissue remaining on the beef and hog skull after removal of the skin, cheeks, tongue, and lips. The meat normally attached to and considered as part of the tongue trimmings when detached from the tongue trimmings may also be included as beef head meat or pork head meat although it can be labeled as "beef" or "pork."

When beef cheek meat and/or beef head meat are included in boneless beef, its presence must be specifically declared. Examples include: "Boneless Beef — Contains Beef Cheek Meat and Beef Head Meat," "Boneless Beef Head Meat," "Boneless Beef — Ingredients: Beef, Beef Head Meat, Beef Cheek Meat," or "Boneless Beef — 20% Beef Head Meat, 15% Beef Cheek Meat."

Beef cheek meat and/or beef head meat may be used in unlimited quantities and identified as "beef" in meat food products unless restricted by regulatory standards for specific products as indicated in 9 CFR 319.15(a) (Chopped beef, ground beef), 319.15(b) (Hamburger), 319.15(d) (Fabricated steak), 319.81 (Roast Beef parboiled and steam roasted), 319.100 (Corned beef), 319.300 (Chili con carne), 319.301 (Chili con carne with beans), and 319.303 (Corned beef hash).

The presence of pork head meat is not required to be identified on the labeling of boneless pork. However, pork cheek meat and/or pork head meat may be used in unlimited quantities and identified as "pork" in meat food products, unless restricted by regulatory standards as indicated in 9 CFR 319.300 (Chili con carne) and 319.301 (Chili con carne with beans).

Beef Concentrate and Salt

Broth derived from cooking fresh beef containing 3% to 4% solids is centrifuged and evaporated to approximately 60% solids under vacuum. The water fraction is salted to a level of 25.5% of the water weight (100 lbs. concentrated stock at 60% will have 10.2 lbs. of salt added, making a total weight of 110.2 lbs.). There is no need for refrigeration.

Beef Consomme

The standard requires beef as an ingredient and a minimum protein content of at least 3% in the finished product.

"Beef stock" or "beef broth" (or mixture of both) may be used to comprise the beef ingredient. Additional optional ingredients are gelatin, beef extract, tomato puree, hydrolyzed plant protein, and seasoning.

Beef (Dried or Air Dried)

Product name is "Air Dried Beef" or "Dried Beef." MPR 2.04:1. It is usually cured by rub and/or stitch pump followed by cover pickle for 4 to 8 weeks with several overhauls (turned over for the application of additional cure), then placed in smokehouse or drying chambers for 3 to 10 days.

Beef Fibrin

This is a component mixture of beef fibrinogen and beef thrombin plasma protein used to bind pieces of meat or poultry together. It is limited to ten percent.

1. If used from seven percent of ten percent, it must appear in the product name, e.g., "Bacon Wrapped Beef Tenderloin Steak Formed with Beef Fibrinogen and Thrombin." Therefore, the smallest letter in the product name must be at least 1/3 size of the smallest letter in the product name.
2. If used at less than seven percent, it must be a product name qualifier, e.g., "Formed with Beef Fibrinogen and Thrombin." As a product name qualifier, there is no size requirement, however, it must contiguous to the product name and be prominent and conspicuous. Additionally, the terms "Beef Fibrin" or "Fibrin" may be used in the product name as a qualifier and its components identified elsewhere on the principal display panel. In this situation, the terms "Beef Fibrin" or "Fibrin" and its components are linked to each other by means of asterisks.

Acceptable terminology's for the components are "Beef Fibrinogen and Thrombin Plasma Protein," or "Beef Fibrinogen and Thrombin."

Beef Gravy Mix

The product must contain at least 15% dried beef.

Beef Marsala

The product must contain at least 50% beef. Product contains beef cubes, Marsala wine sauce, and usually mushrooms and onions. White wine may be used, but it may not replace Marsala wine.

Beef Oriental or Oriental Beef

The product must contain at least 12% meat and oriental style vegetables and sauce. The label must show true product name, e.g., "Beef Oriental with Vegetables."

Beef Roulade

The product must contain at least 50% cooked meat. Usually a thin strip of flank meat wrapped around vegetables and cooked.

Beef Slices a-La-Pizzaiola

The product must contain at least 50% cooked beef.

Beef Stroganoff

A dish with a creamy sauce prepared with beef cut into narrow strips or cubes and sautéed. Product labeled "Beef Stroganoff" should be prepared with a formula, which includes at least 45% beef, or 30% cooked beef.

1. The product must contain at least 10% sour cream, or
2. 7.5% sour cream, and 5% wine, or
3. 9.5% whole milk, 2% sour cream, and 2½% wine.

Beef Stroganoff with Noodles

Meat and sauce portion must meet the standard for Beef Stroganoff. Total product shall contain no more than 50% cooked noodles.

Beef Sukiyaki

The product must contain at least 30% meat based on total product. Consists of thinly sliced beef and various vegetables cooked in a flavored beef stock. This is not a stew as the vegetables and components are mixed during the cooking process. Vegetables used with this food are celery, bean sprouts, leeks, onions, mushrooms, Chinese cabbage, carrots, spinach, water chestnuts, bamboo shoots, and bean curds.

Beef Tripe Stew

There are two versions of this product. One is of Mexican origin and merchandised in association with the term "Menudo."

Corn is a prominent ingredient in its formula. The standard for an item of this nature requires that it contain not less than 33% beef tripe computed on the basis of the uncooked tripe in relation to total ingredients.

The second product is popular in Puerto Rico. It is referred to as "Mondungo." The product is made with 25% raw beef tripe. The remainder consists principally of potatoes, a squash with pumpkin-like appearance and flavor, and a native vegetable called "Tanier." When the vegetables are not distinguishable, this product can be labeled as "Dominican Style Mondungo."

Beef Wellington

It is made with beef tenderloin that is roasted very rare. It is then spread with a liver pate, covered with pastry, and baked in a hot oven until pastry is brown. The product must contain at least 50% cooked meat and no more than 30% pastry.

Alternatively, mushroom duxelle is an acceptable substitute for liver pate, but a true descriptive product name is required, e.g., "beef tenderloin covered with mushroom duxelle and wrapped with pastry."

Beerwurst, Bierwurst

A cooked smoked sausage. Same requirements as beef salami, with the exception that pork may be used.

Berliner

A cooked smoked sausage usually made from coarsely cut cured pork in large casings. When beef is used, it shall not exceed 50% of the meat block. Pork stomachs or beef tripe not permitted.

Berliner Blood Sausage

A cooked blood sausage containing diced bacon. After cooking it is dried and smoked. Ham fat, snouts, and lips are not permitted.

See: Blood Sausage

Bier Schinken (GR)

The literal translation is "Beer Ham." If product is made of all pork, it may be labeled "Bier Schinken."

Binders in Poultry, Boneless, Raw, or Cooked

Binding agents may be added individually or collectively in amounts not to exceed 3% for cooked poultry products and 2% for raw poultry products based on total finished product. When binders are added in excess of these levels,

the common or usual name of the binder or the generic term "Binders Added" shall be included in a product name qualifier, e.g., "Turkey Breast-Gelatin Added." In all cases, the presence of these ingredients must be shown in the ingredients statement.

This policy is intended to apply to binders which are used in chopped or chunked poultry products that are formed into rolls, loaves, etc., but not to binders added directly into whole muscle by injection, massaging, tumbling, etc., which then act as extenders.

Blockwurst

A semi-dry type sausage. The maximum MPR is 3.7:1.

Blood and Tongue Sausage

Same as blood sausage, except cured and cooked pork or beef tongues are used.

Blood Sausage

A cooked sausage formulated with blood and some meat. Usually contains pork skins and/or pork jowls. May also contain sweet pickled ham fat, snouts, and lips. If the product does not contain meat, it must be labeled as "Blood Pudding."

Boingghetti

This label must show a true product name, "Spaghetti with Chicken Sauce." The product must contain at least 6% cooked chicken meat.

Bone-In Meat with Sauce

Must have at least 50% meat (cooked basis). Product with barbecue sauce must comply with 9 CFR 319.312.

Boneless Breast Trimmings

Boneless breast trimmings (turkey or chicken) are defined as trimmings that are removed from the breast portion only. When a product is formulated with boneless breast trimmings, the amount of skin should be indicated in order to determine that the meat requirement is met for a standardized product and that the product is properly labeled. Trimmings from the ribs may be identified as white turkey or white chicken trimmings, or white turkey or white chicken rib meat (excluding skin).

Breakfast Links or Patties

The names "Breakfast Links" and "Breakfast Patties" can be considered fanciful names, which must be followed by a descriptive product name. Such products are acceptable without compliance with the fresh pork sausage or breakfast sausage standard. If the names "Breakfast Links" or "Breakfast Patties" are used without further qualification, the products must meet either the fresh pork sausage standard or the breakfast sausage standard.

Breakfasts (Containing Meat)

The product must contain at least 15% cooked meat or poultry or meat or poultry food product based on the total net weight of breakfast.

Broth, Beef or Pork

No distinction has been made between "broth" and "stock." They may be used interchangeably as the resulting liquid from simmering meat and/or bones in water with seasonings. Both products have an MPR of 135.1 or a 67.1 MPR for concentrate.

Brotwurst

A cured and cooked sausage that may be smoked.

Brown and Serve Sausage

The standard is based on one of the four options as listed below:

1. Moisture Protein Ratio (MPR) is no more than 3.7:1, fat limited to 35%, and 10% water at formulation.
2. No more than 10% added water at formulation and a yield of no greater than 80%.
3. No more than 8.8% added water at formulation and a yield no greater than 85%.
4. Product must meet fresh sausage standard before cooking. The label must show true product name, e.g., "Brown and Serve Pork Sausage."

Brown and Serve Sausage (Canned)

A cooked sausage, usually without cure, and not more than 8% water. The weight of the sausage at canning shall not exceed weight of fresh uncured meat ingredients plus weight of curing and seasoning ingredients.

Brunswick Stew

The product must contain at least 25% (fresh basis) of at least two kinds of meat, one of which may be poultry. Product must contain corn as one of the vegetables.

See: Poultry Brunswick Stew

Buffalo Style

Buffalo style is acceptable on any product (e.g., poultry parts other than wings, chicken patties, nuggets etc.) that is cooked and coated with a mild or spicy sauce containing, Cayenne red pepper, vinegar, salt and garlic. It is no longer

exclusive to chicken wings only. It would also be acceptable on any product made in Buffalo, NY.

Burgundy Sauce with Beef and Noodles

The product must contain at least 25% cooked beef in the product, with up to 20% cooked noodles. Product must contain enough wine to characterize the sauce.

Burritos

A Mexican style sandwich-like product consisting of a flour tortilla, various fillings, and at least 15% meat or 10% cooked poultry meat. The flour tortilla is rolled and may or may not have tucked ends. Fillings may contain, in addition to meat or poultry meat, such major ingredients as beans, potatoes, cheese, rice, tomatoes, and chilies.

Examples of product names are "BEEF BURRITO," "TURKEY BURRITO," "CHICKEN FAJITA BURRITO," AND "CHILI VERDI WITH BEANS BURRITO." If ingredients, e.g., rice or beans, are declared in the product name, they must appear in the proper order of predominance. Ingredients cannot be mentioned in the product name unless all other ingredients present in amounts equal to or above the declared ingredient are included in the name, e.g., "BEANS, BEEF, TOMATO, ONION, AND RICE BURRITO."

The use of "Red Chili" or "Green Chili" or a similar designation of the chili content in a starburst, flag, or similar display, separated from the product name, is acceptable. If such designations are used as part of the descriptive name, the presence of the chilies must appear in the correct order of predominance, and all other ingredients present in amounts equal to or greater than the chilies must appear in the product name.

A claim or name that identifies the use of shredded meat or shredded poultry meat is permitted. However, if ground meat or ground poultry meat is also used, its presence must also be identified in the claim or name, e.g., "Shredded Beef and Ground Beef Burrito."

"BURRITO" alone, may be used to name the product without a descriptive name. However, the ingredients statement must appear directly beneath "burrito."

Burritos with Sauce or Gravy

Product must contain at least 50% burritos.

Butifarra-Sausage

An uncured sausage. Labeling that features the term "Butifarra" would require an additional product name:

Pork Sausage — for those products that meet the fresh pork sausage standard.

Fresh Sausage — for those products that include byproduct but do not meet the standard for pork sausage.

Sausage — for those products that are incubated or fermented. The term Puerto Rican Style would be applicable if manufactured in Puerto Rico.

Caddies

Caddies or display cards used to display fully labeled product shall not bear an inspection legend and, therefore, can be reused. The caddies or display cards may contain a picture of a product that has a legend on it.

Cajun

Refers to product made in Louisiana.

Cajun Style/Cajun Recipe

Acceptable identification for products containing onion/onion powder/dehydrated onion, garlic/garlic powder/dehydrated garlic, white pepper, red pepper, and black pepper.

Calabrese (IT)

A salami originating in Southern Italy. Usually made entirely of pork seasoned with hot peppers.

Calzone, Calzoni (IT)

Turnover-like product made with dough stuffed with meat or poultry, cheese, and seasonings and baked. It must contain 25% meat or 14% poultry meat. The label must show a true product name, e.g., "Sausage and Cheese Calzone."

Canadian and Canadian Style Bacon

"Canadian Bacon" and "Canadian Style Bacon" are synonymous and should not be considered geographical terms.

The term "Canadian Style Bacon," when featured on the label as a product name or part of a product name (i.e., as a description, etc.), may stand alone without an additional qualifier indicating the true geographical origin of the product.

"Chunked and Formed" and "Water Added" products are permitted, provided proper labeling is applied.

Uncooked and/or unsmoked "Canadian Style Bacon" is also permitted, provided labeling describes the product as uncooked and/or unsmoked.

Product which is identified as "Canadian Style Bacon" is made from a trimmed boneless pork loin. On the shoulder end, the cross section of the longissimus dorsi muscle shall be equal to or larger than the combined cross sectional areas of the splenius and semispinalis capitis muscles. The ham end shall be removed anterior to the ilium. The exposed faces shall be approximately perpendicular with the skin surface. The dorsal and ventral side on each end of the "Canadian Style Bacon" shall not be more

than 1.0 inch different in length. The belly is removed adjacent to the longissimus dorsi muscle. All bones and cartilage shall be removed. The tenderloin and the flesh overlying the blade bone are excluded. The surface fat (and false lean when necessary) shall be trimmed to 0.3 inches thick at any point. The fat on the ventral and dorsal sides is neatly beveled to meet the lean.

Canadian Style Bacon Made with/from Pork Sirloin Hips

The sirloin is obtained by removing a 5- to 7-inch section of the pork loin immediately in front of the hip or pelvic bone. The sirloin hip is obtained by removing the half of the sirloin which comprises the posterior end of the pork loin. The tenderloin is not included and surface fat shall be trimmed to 0.3 inches in thickness.

The labeling for these Canadian Style Bacon products must bear a qualifying statement, adjacent to the product name, clarifying that pork sirloin hips are included or that the product is made entirely from pork sirloin hips, e.g., "Canadian Style Bacon — Includes Pork Sirloin Hips" or "Canadian Style Bacon — Made from Pork Sirloin Hips." The smallest letter in the qualifier should not be less than one-third the size of the largest letter in the product name. The qualifier must be of equal prominence to the product name.

Chunked (or chopped) and formed varieties and substances controlled by the protein fat free (PFF) regulation for cured pork products 9 CFR 319.104 shall be labeled in accordance with applicable guidelines.

Use of this type of product in a secondary product, e.g., a pizza, requires complete identification only in the ingredients statement; the product name of the secondary product need only refer to Canadian Style Bacon, e.g., Canadian Style Bacon Pizza.

Canned Chopped Beef or Pork

Cured product with no more than 3% water in formula.

Canned Meat

"Canned meat with Natural Juices;" is acceptable for product that has been pumped or contains up to 10% of a solution before canning and processing. Processed canned uncured meat products, when water or broth is added to the can may not be called "with natural juices," but the acceptable name would be "with juices."

Cannelloni (IT)

Product must contain at least 10% meat or 7% cooked poultry meat. Cannelloni is an Italian term referring to a product with the same characteristics as "Ravioli" except Cannelloni has a tubular form. The product name should show the type of species, e.g., "Beef Cannelloni."

Cantonese Style Species

Marinated in a solution of soy sauce, cooked and returned weight. In addition, product is mildly seasoned with sugar, salt, wine, and spices.

Capacollo, Cooked (Capicola, Capocolla, Capacola, Capicollo, Cappicola, Capacolo) (IT)

Boneless pork shoulder butts which are cured and then cooked. The curing process may be dry curing, immersion curing, or pump curing. The cured product is coated with spices and paprika before cooking. This product shall always be labeled with "Cooked" as part of the product name. Water added is permitted.

Caramel Coloring

Caramel is considered a natural color. However, when caramel coloring is added to a product, the product name must be qualified to indicate the presence of artificial coloring, e.g., "Cooked Roast Beef-Caramel Coloring Added" or "Artificially Colored." This requirement does not apply to gravies, sauces, and similar products where the use of such coloring is customary. Seasoning mixes containing small quantities of caramel coloring may be used if the caramel coloring does not impart color to the finished product.

Caramel coloring may be used on the surface of raw products, e.g., beef patties, if the name is appropriately qualified. However, caramel coloring may not be added directly to the formulation of a raw product where the caramel coloring becomes an integral part of the total product.

Carbonade (FR)

Product must contain at least 50% meat. It may contain beef, pork, or mutton, and beer or wine. Product is slowly cooked, either by braising or stewing.

Label must show a true product name, e.g., "Beef Carbonade."

Carriers

Substances, as defined by the Food and Drug Administration, that carry flavoring compounds, e.g., essential oils, on their surface, and are not expected to provide a functional effect, e.g., binding and emulsifying, in the finished food product and are considered incidental. Some substances, e.g., maltodextrin and modified food starch, are not carriers but actually diluents or bulking agents, and must be declared in the ingredients statement. Dextrose and/or sugar are commonly used as carriers for spice extracts and resins of spices. The

carrier must be declared in the ingredients statement, except in those cases where a sweetening agent is used separately in formulating the meat or poultry product and the use of the spice mixture will not result in the quantity of the carrier being more than 0.75% of the seasoning mix. When a determination cannot be made from the information on the label application, declaration is required.

Salt, when used as a carrier, will always be declared regardless of amount used.

Casing, Artificial

Frankfurters packaged in retail containers with the artificial casing left on must bear a prominent statement, e.g., "Remove casing before eating," contiguous to the product name on the label.

Casserole

Product must contain at least 25% meat or 18% cooked meat.

Cassoulet (FR)

Product must contain at least 25% meat. A complex stew consisting of dried white beans and a combination of pork, lamb, game, and sausages. The ingredients are cooked, then put into a casserole, usually covered with crumbs, and baked. Label must show true product name, e.g., "Beans and Bacon in Sauce."

Center Slice

When the term "Center Slice" is used on labels for slices of ham from smoked and cooked, smoked, or water cooked hams, product must be sliced from an area of the original ham positioned about 1 inch on each side of a center cut.

Certified

With the exception of the term "Certified Pork" the term "certified" implies that the United States Department of Agriculture (USDA) and the Agriculture Marketing Service (AMS) have officially evaluated a meat product for class, grade, or other quality characteristics. When used under other circumstances, the term should be closely associated with the name of the organization responsible for the "Certification" process (e.g., "XYZ Company's Certified Meat," or "Our Certified Meat").

Cervelat

A cured and cooked sausage, often a semi-dry or dry summer sausage. Hog stomachs, beef tripe and extenders are permitted. There is no MPR (moisture protein ratio) requirement.

Cha Shu Bow (CH)

A steamed bun with a dry roasted pork filling requiring 15% cooked pork. Label must show true product name, e.g., "Steamed Bun with a Pork and Cabbage Filling."

Cheek Meat, Beef

Natural proportions are considered to be 2%.

See: 9 CFR 319.15.

The use of cheek meat is limited to 25% in ground beef, chopped beef and similar type products. If cheek meat exceeds 2% (natural proportions), its presence must be declared.

Cheese

1. When cheese is declared in the ingredients statement of a fabricated product, cheddar cheese must be used in the product's formulation.
2. Swiss, Gruyere: The term "Gruyere" pertains to a cheese that closely resembles "Swiss Cheese" both in its appearance and on analysis, although it has smaller holes than Swiss Cheese. FDA advises that Gruyere Cheese is a suitable substitute for Swiss Cheese and gives the same character to a finished food product, e.g., "Chicken Cordon Bleu."
3. The term Cheese may appear in the product name, e.g., "Ham and Cheese Loaf," provided the common name is declared in the ingredients statement.
4. When a cheese product and meat or poultry food product are packaged together, the product name shown on the label must show the name of each component product.

   For example, if slices of ham and slices of a cheese product are packaged together, the product name should include "Ham" and the name of the cheese product (e.g., Ham and Pasteurized Processed American Cheese). Alternatively, the Pasteurized Processed American Cheese could be parenthetically qualified contiguous to the product name (e.g., "Ham and Cheese (Pasteurized Processed American Cheese"). The name "Ham and Cheese" alone would be acceptable if the cheese used was "Cheddar Cheese."
5. Use of substitute or imitation cheese in products where real cheese is expected (e.g., Cordon Bleu) requires the product name be changed or qualified to indicate the presence of the ersatz cheese. Substitute and imitation cheeses cannot be described as "cheese" in the product name. There is no limitation on the amount of ersatz cheese used.

6. Reduced fat cheeses may be identified on the label as "Reduced Fat Cheese." However, the name of a standardized cheese may not be associated with the phrase "Reduced Fat Cheese" (e.g., Reduced Fat Cheddar Cheese).
7. Cheese is a standardized product. See: 21 CFR 130.10 and 133 for a listing of standardized cheeses.

Cheese (Pasteurized Processed Cheese Food or Spread)

A cheese food product with a standard of identity, but is not considered a cheese. Therefore, it cannot be used in meat food products where cheese is an expected ingredient, e.g., "Cheesefurters" or "Veal Cordon Bleu." It is acceptable in non-specific loaves, etc.

Cheese Products Containing Meat

Homogeneous cheese products, e.g., cheese balls, must contain more than 50% meat to be amenable. When cheese and meat are separate components, the products are amenable with 2% meat.

Cheese Standardized Products

Cheese standardized products that require real cheese, e.g., chicken cordon bleu, must use FDA standardized cheese or those FDA standardized cheeses specified. Use of a substitute, imitation cheese or other non FDA standard cheeses, if permitted, must be declared in the product name, or a suitable qualifier, e.g., chicken cordon bleu made with reduced fat cheese. The 90/10-cheese rule is only applicable to pizza.

Chicharrones (PR)

The Spanish name for fried pork skins. Product must have an English product name, "Fried Pork Skins" except in Puerto Rico.

Chicharrones de Pollo (PR)

An acceptable product name for "Marinated Cut-up Fried Chicken" sold in Puerto Rico. When product is destined for sale only in Puerto Rico, "Chicharrones de Pollo" can be the product name. When destined for sale in other places, "Chicharrones de Pollo" must be explained with true product name.

Chicken, Aloha

"Aloha Chicken" is acceptable as a coined name which must be followed by a true product name, e.g., "Chicken and Sauce with Rice." The standard for the product is 22% cooked poultry meat.

Chicken and Noodles Au Gratin (FR)

Product must contain at least 18% cooked chicken meat.

Chicken Cordon Bleu (FR)

Product must contain not less than:

1. 60% chicken breast meat (sliced). If it is made from any other part of the chicken, then the product name must be qualified to indicate the part used.
2. 5% ham or Canadian Style Bacon.
3. Cheese (either Swiss, Gruyere, Mozzarella, or Pasteurized Processed Swiss).
4. Not more than 30% batter and breading (if used).

Chicken Enchilada Suiza

The product consists of chicken enchiladas with a cream sauce. The sauce used must be made with sour cream, heavy cream, or whipping cream in an amount sufficient to characterize the sauce. The label must show a true product name, e.g., "Chicken Enchilada with Cream Sauce."

Chicken Ova

These can not be used for human consumption without first going to an egg products plant for pasteurization (because of problem with potential Salmonella contamination). Chicken Ova can not use the poultry inspection legend.

Chicken Paprika

Product must contain at least 35% chicken. A Hungarian dish. Sauce must contain either sour or sweet cream and enough paprika to give a pink color.

Chicken Tocino

Acceptable with a true product name such as sliced, marinated, cured chicken thigh meat.

Chicken Wellington

It is made with roasted chicken that is spread with liver pate, covered with pastry, and baked in a hot oven until pastry is brown. The product must contain at least 59% cooked meat and no more than 30% pastry.

Chili

1. "Brick Chili" or "Condensed Chili" requires 80% meat. Cereal is limited to 16%.
2. Chili with reconstitution directions should meet the chili standard when reconstituted.
3. When beef heart meat, cheek meat, or head meat is used in excess of 25% of the meat

block, it must be reflected in the product name, e.g., "Chili with Beef and Beef Heart Meat."
4. When beef appears in the product name, BEEF MAY BE THE ONLY MEAT SOURCE USED. Beef Chili may not contain beef fat or other beef byproducts.
5. "Chili Gravy with Meat" requires at least 40% fresh meat and no more than 8% cereals.
6. Cured meats are not an expected ingredient in chili; when used, they must be shown as part of the product name.
7. The terms "Chili" or "Chili con Carne" may be used interchangeably.
8. Since "con carne" means "with meat," products labeled as chili con carne should include only red meat and not poultry. Products which meet the chili standard and include poultry may be labeled "beef and chicken chili," "beef chili, chicken added," etc., as appropriate. The binder and extender limitation of 8% is based on total formulation.

See: 9 CFR 319.300.

Chili Colorado

Product must meet 9 CFR 319.300 requirements. Chili peppers must be exclusively of the red variety. If a prepared chili powder is used, it must be prepared exclusively from red chili peppers.

The term "Colorado" is used for red more than "Rojo" in Mexico. The term "Rojo" is used more in Spain, Puerto Rico, and Cuba.

Chili-Mac

Product must contain at least 16% meat. The label requires a true product name, e.g., "Bean, Macaroni and Beef in Sauce."

Chili Pie

Chili component of the total product must have at least 40% fresh meat.

Chili Pups

An emulsion stuffed in casing and smoked. Label requires a true product name, e.g., "Chili con Carne and Ground Beans Product." Product must contain at least 60% fresh meat in total formulation.

Chili Relleno

Product must contain at least 12% fresh meat and be coated with a batter and then fried. Sometimes product is called "Chili Pepper Relleno." Relleno means stuffed.

Chili Spaghetti

Product must contain at least 16% meat.

Chili Verde (SP)

Product must meet 9 CFR 319.300 requirements. Chili peppers must be exclusively of the green chili or Verde chili pepper varieties. If a prepared chili powder is used, it must have been prepared exclusively from green chili or Verde chili peppers. Products, e.g., "Chili Verde with Beans" shall comply with 9 CFR 319.301 and the above requirements for "Chili Verde."

Chili with Beans

1. "Brick Chili with Beans" or "Condensed Chili with Beans" requires 50% meat and cereal is limited to 16%.
2. Chili with Beans with reconstitution directions should meet the Chili with Beans standard when reconstituted.
3. When beef heart meat, cheek meat, or head meat is used in excess of 25% of the meat block, it must be reflected in the product name, e.g., "Chili with Beef and Beef Heart Meat with Beans."
4. When beef appears in the product name, beef may be the only meat source used. Beef Chili with Beans may not contain beef fat or other beef byproducts.
5. Cured meats are not an expected ingredient in Chili with Beans; when used, they must be shown as part of product name.
6. "Chili with Beans" formulae usually contain up to 25% of beans in a product. About one-fourth of these beans may be incorporated in the product as ground beans and should be listed in the ingredients statement as ground beans.
7. The terms "Chili with Beans" or "Chili con Carne with Beans" may be used interchangeably.
8. The binder and extender limitation of 8% is based on total formulation.

See: 9 CFR 319.301.

Chimichanga

Product must contain at least 15% meat or 10% poultry meat. A Mexican specialty from the State of Sonora. Like burritos, product is made by wrapping a flour tortilla around a filling; but unlike the burrito, chimichanga is fried until brown and crisp. "Fried Burritos" is acceptable.

Chinese Brand Links

Raw nonspecific sausage-like products. These products are permitted to contain artificial red coloring; however, if pork is used it must be certified. Unlike the term "links,"

"Chinese Brand Links" is considered a coined or fanciful name, and [as a] nonspecific product, it must be accompanied by an ingredients statement. Furthermore, "made in USA" must be contiguous to the word "brand" but cannot intervene between "links" and the ingredients statement.

Chinese Pepper Steak

A Chinese main dish, usually served with rice, must contain at least 30% cooked beef. Beef steak is cut into thin strips, browned in fat or oil, and added to a soy flavored sauce. Vegetables are also added to the sauce. Green pepper strips are always used and other vegetables may be included.

Chinese Style Barbecue Meat

Acceptable identification for a product that is enhanced in a solution with soy sauce, grain alcohol or dry sherry wine, and a sweetener, i.e., sugar or honey. Other ingredients may include garlic or scallions, ginger or ginger juice, sesame or peanut oil. The product may be artificially colored. If artificially colored, a qualifier is needed.

Chinese Style Beef

Product must contain grain alcohol and soy sauce.

Chinese Style Sausage

Product must contain grain alcohol and soy sauce.

Chipped Beef

Beef that is dried, chipped, or sliced and may be cured or smoked. An MPR 2.04:1 is required. It may be chunked, ground, chopped, and formed. If so, the product name must be qualified, e.g., "Chipped Beef, Chunked and Formed."

Acceptable fill:

1. 2 oz. in a 4 fluid oz. glass, or
2. 2 1/2 oz. in a 5 fluid oz. glass, or
3. 5 oz. in a 9-5/8 fluid oz. glass.

Chitterlings

Approved label must identify the species of food animal from which the product is derived. Hog bungs may be labeled "Pork Chitterlings." The purge under normal conditions should not exceed 20% of the net weight of frozen chitterlings.

See: 9 CFR 317.8(b)(30).

Choice Grade, Fancy Grade Poultry

"Choice" or "Fancy" may not be used in conjunction with "Grade" on poultry labels. These terms and others like "Prime" and "Top Quality" on poultry labels indicate only that product is equal to U.S. Grade A.

Chopped Chicken Livers

Total product must contain at least 50% cooked chicken livers. Wheat flour and similar ingredients are acceptable.

Chopped Chicken Livers Combined with other Characterizing Components

Product must contain at least 30% cooked livers, e.g., "Chopped Chicken Livers with Eggs and Onions."

Chopped Ham

A total of 15% shank meat is permitted. This is 3% above the normal proportion of 12% shank meat found in a whole ham.

See: 9 CFR 319.105.

Chop Suey, American

Product must contain at least 25% fresh meat in total formulation. A stew-like dish prepared with beef, pork, or veal. Vegetables include onion and celery. Macaroni, noodles, or rice are usually incorporated in the product, although recipes suggest serving chop suey over one of these.

Chop Suey (Vegetables with Meat)

Product must contain at least 12% fresh meat.

Chorizo (SP)

The product name "Chorizo" can be used for any type of chorizo sausage that is cooked, dry, semi-dry, cured and fresh without further product name qualification. Other requirements for various types of chorizo apply, including the sausage standard. It is seasoned with Spanish pimento and red pepper.

Partially defatted pork fatty tissue is acceptable in Chorizo. Wine is considered a flavoring and need only appear in the ingredients statement. However, the liquid is credited as added water.

Chorizo, Fresh

These products may contain vinegar. The vinegar used must have a strength of no less than 4 grams of acetic acid per 100 cubic centimeters (20°C).

See: 9 CFR 318.7(c)(1).

Chorizo in Lard

Product must contain at least 55% chorizo.

Chorizo in Lard, Canned

Canned chorizos that are packed hot, usually in lard, and are not thermally processed must have a moisture protein ratio of 1.8:1 and a pH of not more than 5.5. An alternative standard is a water activity (Aw) of 0.92.

Chow Mein with Meat

Product must contain at least 12% fresh meat.

Chulent (Cholent)

Product must contain at least 25% fresh meat. A meal-in-one dish of Jewish cuisine made in various ways. The product name can stand without qualification.

Coarse Ground Meat Trimmings

Coarse ground trimmings may be shipped from an establishment without meeting the 30% fat limitation if a specific fat content is declared, e.g., "Coarse Ground Beef Trimmings — 40% fat beef." If the labeling terminology is "Coarse Ground Beef" or "Ground Beef," the 30% fat limitation shall apply.

Colored Casing

Colored casings on meat and poultry products which do not transfer color to the product, but which change and give a false impression of the true color of the products, must be labeled to indicate the presence of the casings. Acceptable terminology includes "Casing Colored" or "Artificially Colored." These phrases must appear contiguous to the product name.

Casings which are the same color as the product and not misleading or deceptive, e.g., a white opaque casing on a summer sausage, do not have to be so labeled. Also, products consisting of whole muscle bundles, e.g., hams, pork butts, etc., packaged in colored wrappings where a cut surface is not visible through the casing are exempt. The color agent must be specifically identified on the label either in the product name qualifier or ingredient statement.

See: 9 CFR 319.15(d).

Composite Ingredients Statement

Processors who use a multi-ingredient product, e.g., pepperoni from various sources, as an ingredient, may identify all the ingredients that may be present from all the various formulations (i.e., a composite ingredients statement). However, the ingredients identified as those that may be present can only be those ingredients that are minor in nature and cannot include ingredients, e.g., the meat component that have a bearing on the overall characteristics or value of the product. The minor ingredients must be identified using one of the following examples of acceptable formats:

1. pepperoni (pork, beef, water, salt, spices, sodium nitrite. May also contain lactic acid starter culture, sugar, and sodium ascorbate).
2. bacon bits (cured with water, salt, dextrose and/or sugar, sodium nitrite).
3. pepperoni, pork, beef, water, sweeteners (contains one or more of the following: sugar, dextrose, fructose, corn syrup), salt, spices, sodium nitrite).

Labeling records must identify all the ingredients of each type of component that is used so the accuracy of the composite ingredients statement can be determined. All labeling for meat and poultry products must either comply with this type of format or, alternatively, accurately list all ingredients used in the product.

Cooked Beef, Equivalency

In lieu of fresh beef, a 70% yield figure is used if no yield information is provided.

Cooked Breakfast Sausage

Antioxidants are permitted when product is formulated on a raw basis (no more than 3% water).

Cooked Red Meat Products Containing Added Substances

Cooked corned beef products and cooked cured pork products not addressed by the cured pork products regulation (9 CFR 319.104), that weigh more than the weight of the fresh uncured article, may be prepared if they are descriptively labeled to indicate the presence and amount of the additional substances. Acceptable product names include: "Cooked Corned Beef and X% Water" or "Cooked Cured Pork and Water Product, X% of Weight is Added Ingredients," and "Cooked Pastrami and Up to 20% of a Solution." The ingredients of the solution may accompany the product name or appear in locations prescribed for ingredient statements. Product name prominence guidelines are found in Policy Memo 087A and Policy Memo 109. If product name qualifiers, such as "X% of Weight is Added Ingredients," are used, the labeling prominence guidelines used for cured pork products as found in 9 CFR 319.104(b) apply.

Uncured red meat products that weigh more than the weight of the fresh article after cooking should be labeled with a qualifying statement indicating the amount of solution remaining after cooking, e.g., "After cooking, contains X% of a seasoning solution of …." The ingredients of the solution may accompany the qualifying statement

or appear in locations prescribed for ingredient statements. The qualifying statement must be one-fourth the size of the largest letter in the product name. If the ingredients of the solution accompany the qualifier, they must appear in print one-eighth the size of the most prominent letter in the product name. Other labeling prominence guidelines are found in Policy Memo 087A.

If cooked, uncured red meat products that contain added solutions/substances prior to cooking are cooked back to or below the weight of the fresh (green weight) article, words, such as "seasoned" and "flavored," are to be used to reflect the addition of the added substances, e.g., "Seasoned Cooked Beef."

For cooked products, the percent added substances for the label statement is determined by subtracting the fresh (green) weight of the article from the weight of the finished cooked product, (i.e., after injecting, marinating, etc., and cooking), dividing by the weight of the finished product, and multiplying by 100. This policy is intended to apply to solutions that impart favorable flavor and other sensory characteristics, but not to solutions containing ingredients used to extend a product, such as isolated soy protein and carrageenan.

Uncooked red meat products containing added substances are addressed in Policy Memo 066C.

Corn Dog or Korn Dog

A coined name which must be accompanied by a true product name, e.g., "Batter Wrapped Franks on a Stick." Product is limited to 65% batter and a minimum of 35% frankfurter.

Corn Dog or Korn Dog (Poultry)

"Corn Dogs" made from poultry cooked sausage, e.g., poultry franks or poultry frankfurters, must show the "kind" of poultry used in conjunction with the coined name "Corn Dogs," e.g., "Chicken (or Turkey) Corn Dogs." The "kind" name should be shown in type size at least one-third the size of the largest letter of the coined name. A descriptive name, e.g., "Batter Wrapped Chicken Frank on a Stick," must accompany the coined name. If the descriptive name is at least one-third the size of the coined name, the "kind" name need not precede the coined name.

Corn Meal Mush with Bacon

Product must contain at least 15% cooked bacon.

Corned Beef and Cabbage

Product must contain at least 25% cooked corned beef.

Corned Beef (Canned, Cooked with Natural Juices)

Canned product labeled "Cooked Corned Beef with Natural Juices," is limited to 10% added solution before cooking. If the added solution is greater than 10%, the label must indicate the total added solution, e.g., "Cooked Corned Beef and Water product-X% of weight is added ingredients."

See: Cooked Corned Beef Products with Added Substances.

Corned Beef, Gray

Gray corned beef is not a cured product but one that contains water, salt, sugar, flavorings, etc. It should be labeled as "Gray Corned Beef," "Gray Corned Beef Rounds," etc. The label must show an ingredients statement rather than a curing statement as shown on other corned beef labels.

Corned Beef with Juices

Uncooked corned beef with juices (or without juices and spices) is unacceptable terminology for corned beef products meeting standards in 9 CFR 319.101 and 319.102 for corned beef brisket and corned beef round (and other cuts). The presence of free flowing juices in a package does not change this policy. The net weight includes free flowing juices.

Cornish Style Pasty

Product must contain at least 25% beef. Product consists of a round or square of piecrust with a filling of chopped beef, potatoes, and onions.

Cotechino (IT)

Pork skin sausage. Meat and meat by-products other than pork skin can be used in this product. It could also be given the name of pork skin sausage in parentheses as a common name. Italian sausage. A variety of cooked sausage.

See: 9 CFR 319.140.

Country

A geographical term that refers to an unincorporated area. To use country, the product must be made in the country.

Country Fried

Refers to a fried product that is usually breaded. It is not considered a geographical term.

Country of Origin

Statement, "Product of …" need only appear beneath the product name on the principal display panel on imported product.

Country Style Chicken

Cut up chicken in which the wishbone is left whole.

Country Style (Farm Style) Sausage

When sausage products are labeled "farm style" or "country style," they must be prepared with natural spices with the exclusion of oleoresins, essential oils, or other spice extractives. Sugar is the sweetening agent for "farm style" or "country style." HVP, MSG, and antioxidants are permitted ingredients. Products so labeled are not necessarily prepared in the country (on the farm) but are expected to have these characteristics.

See: 9 CFR 317.8(b)(2).

Creamed Beef (Chipped or Dried)

Product must contain at least 18% dried beef. It may be produced using a cured beef, or beef product which has been chopped, pressed, or cooked.

Creamed Cheese with Chipped Beef

Product consists of cream cheese, chipped beef, cream and chopped onions. The meat component must be at least 12% of the total formulation.

Creamed Sauce with Meat or Creamed Meat Products (Chipped Beef, Cooked Beef, Sausage, Ham, Franks, Meatballs, etc.)

Product must contain at least 18% meat or meat products (on a cooked basis). The kind of meat product used should be reflected in the product name (e.g., "Creamed Cured Beef, Chopped, Pressed, Cooked").

Creole Style

Term applies to many dishes made with tomatoes, spices, and green peppers. Spices include onion, garlic, bell pepper, white pepper, red pepper, black pepper, parsley, and other Louisiana seasonings, e.g., bay leaf, filét, paprika, or pepper sauce.

Crepe Filling

Must contain at least 40% cooked meat or 20% cooked meat if filling has one other characterizing ingredient, e.g., cheese, and at least 14% cooked meat when the filling has two other characterizing ingredients, e.g., cheese and mushrooms. This is based on the total weight of the filling.

Crepes

Product must contain:

1. At least 20% cooked meat when the filling contains no other major characterizing component.
2. At least 10% cooked meat when the filling contains one other major characterizing component (e.g., cheese).
3. At least 7% cooked meat when the filling contains two or more other major characterizing components (e.g., cheese and mushrooms).

These percentages are based on the total weight of the product.

Croissant

A crescent shaped roll requiring 18% cooked meat. Label must show a true product name, e.g., "Croissant with a ham and cheese sauce filling."

Croquette

Product must contain at least 35% cooked meat, based on total formulation. Beef, ham, etc., must appear as part of the product name.

Curdlan

A substance identified by the common or usual name "curdlan" has been approved for use in foods (see 12/16/1996 Federal Register), and for non-standardized meat products, poultry products, and in Policy Memo 123 and 121B products as a binder/stabilizer/thickener/texturizer.

Cured Meat Products — Labeling of Mechanically Reduced

The traditional names of cured meat products, e.g., bacon, may be used even though mechanical reduction-like chopping or chunking has taken place before the product has acquired the characteristics expected of the product, provided the finished product acquires the characteristics expected. Furthermore, the mechanical reduction must be noted in the product name or in a qualifier to the product name (e.g., chopped bacon or bacon-chopped and formed).

Cured Meat Products — Packed in Brine

Cured meat products, e.g., pork tails, pork snouts, and cured boneless beef brisket, that contain 120–200 PPM nitrite and are packed and sold in brine solution, do not require a handling statement, e.g., "Keep Refrigerated," provided the finished product has at least 10% brine concentration, and the packing medium contains a sufficient quantity of salt to maintain the 10% brine concentration in the product.

Cured Pork Bellies

Such products are assumed to be further processed into bacon. Therefore, cured pork bellies must meet the restricted ingredients requirement for bacon.

Cured Pork

Cured pork products, that contain modified food starch, X% solution ISP, carrageenan or sodium caseinate, that fall into the PFF value of "Ham, Water Added" and the "Ham and Water product X% solution" category, must be labeled with the appropriate PFF Nomenclature, Descriptive Labeling, e.g., "ham, water and binder product," will be used if:

1. Binders are at levels above those permitted by the regulations
2. Binders other than those permitted are used
3. Two or more binders are used in combination or
4. The PFF value of the finished product falls in the "ham" or "ham with natural juice" category which do not permit binders.

Cured Turkey Thigh Meat

A product labeled "cured turkey thigh meat" (without turkey ham in the name) must follow the turkey ham standard. The product "cured turkey thighs" (which includes skin and bone), is not required to meet the standards for turkey ham and cannot be labeled "turkey ham."

Curried Sauce with Meat (Poultry) and Rice Casserole

Product must contain at least 35% cooked meat or poultry meat based on the sauce and meat portion only.

Curry Product

1. Meat Curry — Must contain at least 50% meat (lamb, beef, etc.)
2. Poultry Curry — Must contain at least 35% cooked poultry meat.

Cutlet, Beef

Beef cutlet may be chopped and formed.

Cutlet, Pork

"Pork Cutlet" may consist of pork temple meat, inside masseter muscles, and small pieces of lean from the tip of pork jaws. These are flattened and knitted together in "cutlet" size products by means of "cubing" or "Frenching" machines, or by hand pounding with "cubing hammers." The term "cutlet" relates to thin slices of meat. They can be identified as sliced pork meat product when the designation clearly states the specific part of the carcass from which the meat in the product is derived (e.g., "Pork Loin Cutlets"). All of the terms should be conspicuously displayed on labels.

Cutlet, Poultry

Poultry cutlets may be fabricated as opposed to using whole pieces of poultry meat. However, the term "cutlet" must be properly and distinctly qualified to describe the product, e.g. "Turkey Cutlet from a Turkey Loaf" "Chicken Cutlet from Chicken Roll" "Turkey Cutlet, Chopped and Formed"

Cooked poultry cutlets, which are solid pieces and contain added water, should not be labeled as patties. A solution statement is not needed.

Cutlet Veal

Must be a solid piece of meat from the round; slice thickness may vary. However, combining several thin slices to represent a single cutlet is not permitted.

Dehydrated Meat Calculation Factor

The fresh meat equivalent based on a given amount of dehydrated meat can be found by multiplying the weight of the dehydrated beef by the factor 2.8. This factor was derived as follows: Assuming canners and cutters grade beef was used, the composition of meat would be approximately 12% fat, 18% protein, 69% water, and 1% ash. Then 100 pounds of beef, when dehydrated to 5% moisture, would be 100 less 64 or 36 pounds dehydrated meat. Thus, 100 divided by 36 equals 2.8.

Assuming that the amount of dehydrated beef equivalent of 100 pounds of fresh beef is that quantity containing 18 pounds of protein, then 18 divided by the percentage of protein found by analysis of dehydrated beef would be the amount of dehydrated beef equivalent to 100 pounds of fresh meat.

Dehydrated Poultry Calculation Factor

The moist deboned cooked poultry or poultry meat equivalent based on a given amount of dehydrated poultry or poultry meat which can be found by multiplying the weight of the dehydrated poultry or poultry meat by the factor of 4.0.

Dehydrated Products when Water is Added

Three methods are acceptable for listing dehydrated products. Listing of the ingredients (1) As "water, dehydrated potatoes" or "dehydrated potatoes, water," whichever is the proper order, (2) As "reconstituted potatoes," or (3) As "rehydrated potatoes." If the reference was to meat instead of potatoes, the word beef, pork, or whatever was appropriate would be substituted for the word "potatoes."

Deviled Poultry

Is a semi plastic cured poultry food product made from finely comminuted poultry in natural proportions and containing

condiments. Deviled poultry may contain poultry fat, provided that the total fat content shall not exceed 35% of the finished product and the moisture content shall not exceed that of the fresh unprocessed poultry. When skin is in excess of natural proportions, skin must be included in the product name (e.g. "Deviled (Kind) with (Kind) Skin Added").

Dinner Dog

A coined name — must show true product name, e.g., "A Meat and Soy Protein Concentrate Product."

Dinners and Suppers, Frozen

Frozen products labeled as "dinner" or "supper" must weigh at least 10 ounces and shall contain at least 3 components consisting of the following: meat, poultry, cheese, eggs, vegetables, fruit, potatoes, rice or other cereal-based products (other than bread or rolls). This is not intended to include products like casseroles and stews that have all of the components combined. Sauces and gravies are not considered one of the components. They may also contain other servings of food, e.g., soup, bread or rolls, appetizer, beverage, and dessert, and these components may be included in the minimum 10-ounce net weight requirement. If meat is featured in the product name, e.g., Beef Dinner, the requirement is 25% or 2.5 ounces cooked meat. If a meat food product is featured in the product name, e.g., Beef Burgundy Dinner, then 25% or 2.5 ounces of meat food product is needed. If poultry is featured in the name, e.g., Chicken Dinner, the standard is 18% or 2 ounces cooked deboned poultry meat, whichever is greater. However, if a poultry food product is featured in the product name, e.g., Chicken a La King Dinner, the 25% or 2.5 ounces of poultry food product, whichever is greater, is needed. The meat requirement for products with net weights greater than 10 ounces may be established exclusive of the appetizer, bread, and dessert, provided the remaining components weigh not less than 10 ounces.

The name for dinner and supper products shall consist of or include a listing of each of the dish components in descending order of predominance by weight, for example, Fried Chicken Dinner — Fried Chicken, Mashed Potatoes, Peas and Carrots. Dinner or supper identification may appear on side panels without the complete product name shown, for example, "Fried Chicken Dinner" or "Beef Dinner."

When a dessert is one of the components of a frozen dinner or supper, i.e., a multi-component item, it may appear out of the order of predominance in the product name and appear as the last component in the product name.

Dipped Steaks

Steaks made from a solid piece of meat may be dipped in a solution of water and flavoring. The result in gain shall not be more than 3% above the weight of the untreated product. A prominent statement, like "Dipped in a Solution of contiguous to the product name," shall show.

Dixie Bacon

True product name, e.g., "Pork Jowl Dixie Bacon, Cured and Smoked" shall appear on the label.

Dixie Square

Same as for Dixie Bacon.

Dog Food

See: 9 CFR 355.29.

Dough Conditioner

A generic or class name that cannot stand alone in the ingredients statement. The term "Dough Conditioner" must be followed immediately by the common or usual name of all ingredients present.

Dried Egg White Added

See: **Wheat Gluten Dried Soup Mixes (Meat)**.
Dried meat soups are not amenable. Poultry — See: 9 CFR 381.15.

Dry Aged

Fresh Meat is held (without vacuum packing) for various periods of time (usually 10 days to 6 weeks) under controlled temperatures (34°F to 38°F), humidity, and airflow to avoid spoilage and ensure flavor enhancement, tenderness, and palatability.

There is a difference of opinion regarding the best cooler humidity. Some prefer low humidity of from 70 to 75% so that exposed surfaces of meat remain dry. Others use humidity's up to 85 to 90% in order to purposely develop a mold growth on the outside of the meat and reduce evaporation losses. Ultraviolet light may be used to reduce microbial load in the aging room. The number of days aged does not have to appear on the label when the product is identified as "Dry Aged" (e.g., "Dry Aged Beef").

Dry Cured

Product labeled as "dry cured" shall not be injected with a curing solution or processed by immersion in a curing solution.

Dry Milk Products

Approved dry milk items include whole dry milk, nonfat dry milk, calcium-reduced dried skim milk, dried whey and lactose-reduced dried whey. If nonfat dry milk is reconstituted prior to addition to product, it would be declared on the label as "Reconstituted Skim Milk."

Dry Salt Cured

Dry salt cured product may contain a curing solution injected directly into the tissue but not through the circulatory system before it is covered with a dry curing mixture. It may be momentarily moistened to facilitate initial salt penetration but shall not be immersed in a curing solution.

Dual Weight Requirement for Stuffed Poultry Labels

Poultry products that consist solely of bone-in poultry and stuffing, e.g., a "Stuffed Turkey," shall bear weight statements on the label indicating the total net weight of the product and a statement indicating the minimum weight of the poultry in the product.

When a stuffed poultry product is a component of a dinner or an entree, only the total net weight needs to be shown on the label.

Duck, Salted

This product should reach an internal temperature of 155°F.

Dumplings with Beef

The product must contain at least 18% meat in total formulation.

Dutch Brand Loaf

A nonspecific loaf that must be qualified as "Made in USA."

Easter Nola

Salami that is made with pork that is coarsely chopped and mildly seasoned with black pepper and garlic.

Egg Foo Young with Meat

The product must contain at least 12% meat.

Egg Foo Young with Poultry

The product must contain at least 3% poultry meat.

Egg Roll, Vietnamese Style

The product must contain soy bean noodles or cellophane noodles, and fish sauce or anchovy extract. They are usually rolled in a thin spring roll skin or a dry rice paper skin.

Eggs Benedict

The product must contain at least 18% cured smoked ham. A poached egg on a toasted English Muffin, topped with a slice of ham, and covered with hollandaise sauce.

Eggs, Fresh

For breakfast-type foods the egg portions may be referred to in the product name and the ingredients statement as "Fresh U.S. Grade A Large." The eggs must be received in shells or broken and blended and not in dry or frozen form.

Empanadillas (SP)

A turnover containing 25% fresh meat or poultry (raw basis). The species or kind is part of the product name, e.g., "Beef Empanadillas." The product may vary in size from large to hors d'oeuvre size.

Empanadillas Chorizo

An empanadilla that contains at least 25% fresh chorizo or 17% dry chorizo.

Encapsulation

An encapsulated additive, e.g., salt is an acceptable name. It does not require a sublisting if encapsulated in vegetable oil. If encapsulated in an animal fat, the specific animal fat must be identified in the ingredient statement.

Encapsulated lactic acid starter culture does not need to be sublisted.

Enchilada (SP)

The product must contain at least 15% meat or 10.5% poultry meat. A Mexican type food consisting of a "tortilla" which has been filled with a variety of fillings and then rolled. The species must appear in the product name, e.g., "Beef Enchilada."

Enchilada with Beef Chili Gravy or Enchilada Prepared with Meat and Sauce

The product must contain at least 50% Enchilada.

Enchilada — Sonora Style

The product consists of two or more tortillas stacked "pancake style" with filling spread between each tortilla. Cheese may be mixed into the tortilla dough prior to frying.

Entree (Principal Dish or Main Course)

Product labeled entree should fall into one of the following categories:

1. All meat or meat food product — 100% meat or meat food product.
2. Meat or meat food product and one vegetable; or meat or meat food product and gravy — 50% cooked meat or meat food product.

3. Meat and Vegetable with Gravy — 30% cooked meat portion; meat and gravy portion at least 50%, (e.g., Salisbury Steak with Potatoes and Gravy).
4. Meat or Entree portion of a meal type — 25% cooked meat or meat food product, (e.g., Meat Loaf Dinner would require 25% meat loaf).

Enzyme Treated Product

Product from carcasses of animals injected with papain; liver, heart, tongue, cheek and head meat, trimmings, boneless beef, tenderloin, tails, tripe and cuts of meat not showing an imprint of the roller brand reading, "tenderized with papain," shall be properly identified and kept separate from other product. Kidneys must be segregated and properly labeled.

When such product leaves an official establishment, the immediate container shall bear a label showing, in addition to the other required labeling, a statement like "tenderized with papain" prominently displayed contiguous to the product name.

The establishment will furnish retail dealers handling such product with labels bearing the statement, "tenderized with papain" prominently displayed contiguous to the product name for use by such dealers on consumer packages or on product prepared from carcasses of animals injected with papain. Inspection personnel visiting retail markets should observe the effectiveness of this requirement. When retail outlets do not follow this identification, these facts should be immediately reported to the Food Labeling Division.

Enzyme Trimmings from Ante-Mortem Injected Beef

Beef trimming from this operation may be used in fresh meat products without label declaration.

Enzymes — Proteolytic

A 3% limit permitted pickup on dipped items, e.g., steak and solid pieces of meat. The label must declare the presence of the enzyme, e.g., "Tenderized with Papain." Trimmings from this method may be used in fresh meat products up to 25% of the formula, provided the finished product is immediately frozen and that distribution is limited to institutional use only. The labeling record should state the conditions and means of inspection control. Meat from this method may be used in cooked ground beef products up to 25% of the formula without showing the ingredients of the solution.

See: 9 CFR 317.8(b)(25) 9 CFR 318.7(a)(1) 9 CFR 381.120.

Exotic/Non-Amenable Products — Use of Cure Agents

Only amenable meat/poultry products can contain curing agents (i.e., nitrites etc.), with the exception of ratites (ostrich, rhea, emu) and squab. The prior function of nitrite and nitrate, according to FDA regulations, applies only to those species that were considered "meat" or "poultry" prior to September 1958. Therefore, amenable species that can contain cure agents are identified as the following:

1. Poultry — (domesticated birds) chicken, turkey, duck, geese, and guineas.
2. Meat — cattle, sheep, swine, and goat. Non-amenable products, such as buffalo, reindeer and pheasant, can not contain curing agents; such products are considered to be regulated under FDA regulations. However, if non-amenable products are included in an amenable product, curing agents would be permitted. The curing agents would be calculated based on both the amenable meat/poultry product and non-amenable meat/poultry product. For example, the formula includes 3 lbs. Cooked chicken and 97 lbs. buffalo. The calculation for the curing agents would be based on 100 lbs. of meat. In addition, in those situations where the meat block consists of an amenable product and a nonamenable product (refer to the example), the appropriate inspection legend should represent the amenable product. Therefore, using the example above, the label would have a poultry legend.

   Product derived from exotic/non-amenable species that contain over 3% raw meat (cattle, sheep, swine, goat, horses or other equine) are subject to inspection. The game meat used in these products must be derived from carcasses slaughtered under the Food Safety and Inspection Service. Products made with meat from exotic and non-amenable exotic species with 3% or less of meat or edible portion from cattle, sheep, swine, goat, horses or other equine, or up to 30% fat from these species are non-amenable provided the only reference to meat or meat byproducts on the labeling is in the statement of ingredients and the product name includes the term "flavored with (amenable species)."

   Custom prepared products composed of meat from exotic/nonamenable species and up to 30% animal fat are not amenable. Labeling such products with the term applies (see: 303.1 (a) (2)).

   Products made with meat from game animals with 3% or less of meat or edible portion from cattle, sheep, swine, goat, or up to 30% meat fats provided the only reference to meat or meat

byproducts on the labeling is in the statement of ingredients or referred to as "flavored with."

Custom prepared products composed of meat from game animals and up to 30% animal fat. Labeling "Not For Sale" applies.

See: 303.1 (a)(2)

Buffalo and venison must be federally or state inspected; however, venison may also be produced under the supervision of inspection officials of a country approved to export meat products into the United States. All other meat from exotic/non-amenable species that is used in formulating amenable products must be derived from carcasses slaughtered under the Food Safety and Inspection Service.

Extra and More Than

The terms "extra" or "more (component) than" may be used provided the following guidelines are followed:

1. There is at least a 10% increase in the particular component of interest over the amount that is found in the usual or "regular" formulation.
2. Information must be provided with the label application that compares the product formulation containing the "extra" amount of the component to the regular formulation of the same product to establish that at least a 10% increase in the component has occurred. Therefore, the usual or "regular" component claims at the time of label review must be presented so that the necessary comparison of formulations can be made.
3. In the situation where production of the "regular" product formulation ceases, the "extra" or "more (component) than" product labels would be given a 6-months temporary approval.
4. A comparison to a similar product on the market may be made to support the "extra" or "more/than" type claim, provided suitable market basket data are submitted with the label application that establish the similarity of formulations and show the increased amount of the component over the "usual" amount.

Fabricated Steak

1. Steaks that include large sections or pieces of meat that are molded or shaped to form one large piece and the sliced. A qualifier such as "formed" must be included in the product.
2. Fabricated steaks may contain added solutions if labeled in accordance with Policy Memo 066B.
3. Antioxidants are permitted.
4. When made from simulated fat covering and or marbling, the name must reflect this fact, e.g., artificially marbled-simulated fat covered.

Fajitas

The Spanish translation is "little belts" or strips of meat. Fajitas are strips of seasoned or marinated red meat or poultry meat, which have been cooked. Red Meat Fajitas require labeling in accordance with the current policy memo on added solutions. Fajitas may also be sandwich-like product, requiring 15% strips of cooked meat or poultry meat (excluding the marinade), topped with onions, peppers, and sauce, and rolled in a flour tortilla. Fajita, including the name of the meat or poultry, may stand alone, e.g., "Beef Fajita," "Chicken Fajita."

Farm Style Sausage

See: Country Style (Farm Style) Sausage.

Farmer Sausage Cervelat

Is usually a semi-dry sausage; but may be made in dry form. Usually made of equal parts of pork and beef delicately seasoned without garlic.

Farmer Summer Sausage

This is a special type of sausage made of beef and pork, salt, spices, nitrite or nitrate, and heavily smoked. It is classed as "Cervelat," and no extenders are permitted. It is dry with an MPR of 1.9:1. The word "Farmer" is considered a generic term, and labels can be approved without any qualifying words like "Style" or "Brand." Such labels are not required to bear a statement identifying the place of manufacture. The product must be trichina-treated.

Fiber Products

Fiber products such as bran are acceptable only in non-specific products. Fiber type foods are permitted in meat and poultry products and must be identified by their common or usual name, such as oat bran. However, fiber is not permitted in meat or poultry products, e.g., soy fiber, oat fiber, and wheat fiber. Presently, there is no recognized definition for fiber.

Fillet Style

"Fillet style" must be qualified, e.g., "chunked and formed," if the meat or poultry product is not made from a solid piece of meat or poultry. The term "fillet" is defined as a solid piece of meat or poultry.

Flanken in the Pot

The product must contain at least 25% beef. Product is made from beef plates and may contain such components as Matzo Balls, Noodles, and Vegetables. True product

name, e.g., "Flanken in the Pot with Matzo Balls, Noodles and Vegetables" must be used.

Flavored with

Any product with a standard in Section 9 CFR 319 and 9 CFR 381 of the regulations must meet that standard and may not be designated "flavored with." If a product does not meet the standard as it appears in the Policy Book it can be labeled "Flavored with." "Flavored with" can be anything from over 3% fresh meat or 2% cooked meat to below the standard for the product.

Flavoring

Ingredients, e.g., thiamine hydrochloride, monosodium glutamate, disodium inosinate, disodium guanylate, hydrogenated vegetable oil, and other commonly used materials must be listed separately.

Such ingredients as diacetyl, hexanal, ethyl alcohol, dimethyl sulfide, diallyl sulfide, and furfuryl mercaptan may be declared as artificial flavors or artificial flavorings without naming each.

When spices and/or flavorings are presented on labels coming from foreign countries, the identity of the spices and/or flavorings must be made known.

Foie Gras Products, Duck Liver and/or Goose Liver

Goose liver and duck liver foie gras (fat liver) are obtained exclusively from specially fed and fattened geese and ducks. Products in which foie gras is used are classified into the following three groups based on the minimum duck liver or goose liver foie gras content:

(A) French Product Name	Acceptable English Product Name
Foie Gras d'Oie Entier	Whole Goose Foie Gras
Foie Gras de Canard Entier	Whole Duck Foie Gras

These are products in which goose liver or duck liver foie gras are the only animal tissues present. They may contain added substances, e.g., seasonings and cures and when truffles are featured in the product name, they are required at a minimum 3% level.

(B) French Product Name	Acceptable English Product Name
Foie Gras d'Oie	Goose Foie Gras
Foie Gras de Canard	Duck Foie Gras
Bloc de Foie Gras d'Oie	Block of Goose Foie Gras
Bloc de Foie Gras de Canard	Block of Duck Foie Gras
Parfait de Foie Gras d'Oie	Parfait of Goose Foie Gras
Parfait de Foie Gras de Canard	Parfait of Duck Foie Gras

These products are composed of a minimum 85% goose liver or duck liver foie gras, although "parfaits" may contain mixtures of goose liver and/or duck liver foie gras. These products may also contain a wrapping or stuffing consisting of the lean or fat of pork, veal, or poultry, pork liver, and/or aspic jelly. When these ingredients are used, their presence must be indicated in a product name qualifier. Truffles, when featured in the product name, are required at a minimum 3% level.

(C) French Product Name	Acceptable English Product Name
Pate de Foie d'Oie	Pate of Goose Liver
Pate de Foie de Canard	Pate of Duck Liver
Galantine de Foie d'Oie	Galantine of Goose Liver
Galantine de Foie de Canard	Galantine of Duck Liver
Puree de Foie d'Oie	Puree of Goose Liver
Puree de Foie de Canard	Puree of Duck Liver

These products must contain a minimum of 50% duck liver and/or goose liver foie gras and may also contain a wrapping or stuffing of the lean or fat of pork, veal, or poultry, pork liver, aspic jelly, extenders, and/or binders. When these ingredients are used, their presence must be indicated in a product name qualifier. Truffles, when featured in the product name, are required at a minimum 1% level.

In all groups, an English translation of the term "foie gras" is not required, although all other product name terms must be translated into English. The kinds of poultry liver(s) used must be indicated in the product name. Also, other species and/or binders used must be indicated in a product name qualifier immediately following the product name, while the ingredients statement must follow the product name or qualifier as the case may be.

For Further Processing

Products which require further processing at another federally inspected plant may leave a federally inspected plant under one of the following three conditions:

1. With the name of the finished product qualified by a "For Further Processing" statement (e.g., Turkey Ham For Further Processing); or
2. With a fully descriptive name (e.g., uncooked ham contains up to 30% of a solution).
3. Not acceptable on a label when a product is formulated or processed in a manner contrary to the regulations.

"Fresh," "Not Frozen" and Similar Terms when Labeling Poultry Products

The word "fresh" may *not* be used to describe:

1. Any cured product, e.g., corned beef, smoked cured turkey, or prosciutto.

2. Any canned, hermetically sealed shelf stable, dried, or chemically preserved product.
3. Any raw poultry, poultry part, or any edible portion thereof whose internal temperature has ever been below 26 degrees Fahrenheit.
4. Any injected, basted, marinated poultry, poultry part or any edible portion thereof whose internal temperature has ever been below 26 degrees Fahrenheit.
5. Any other finished processed poultry product (including cooked poultry products) where its temperature has ever been below 26 degrees Fahrenheit, e.g., turkey sausage, chicken meatballs, cooked breaded chicken nuggets, etc.
6. Any uncured red meat product permitted to be treated with a substance that delays discoloration, such as, ascorbic acid, erythorbic acid, or citric acid.
7. Any product treated with an antimicrobial substance or irradiated.
8. The phrase "never frozen" or similar verbiage is not permitted on an unprocessed or processed poultry product where the internal temperature of the product has ever been below 0 degrees Fahrenheit or on any red meat product that has ever been frozen. Further, the phrase "never frozen" or similar verbiage is not permitted on refrigerated secondary products where the meat or poultry component has ever been frozen, e.g., multi-component meals, dinners, etc.

Generally, trademarks, company names, fanciful names, etc., containing the word "fresh" are acceptable, even on products produced in a manner described in one through seven above, provided the term is used in such a manner that it remains clear to the purchaser that the product is not fresh.

Secondary products, e.g., pizza, multi-component meals, dinners, etc., sold in the refrigerated state, i.e., not frozen or previously frozen, may be labeled as "fresh" when the term is used to describe the product as a whole even when made from components processed in a manner described in one through seven above.

This entry cancels Policy Memo 022C dated January 11, 1989, since 022C is out of date.

Fresh Thuringer

Not an acceptable name.

Fried Noodles with Pork

The product must contain at least 12% fresh pork in total formulation.

Fried Products

1. Frying medium need not be shown on the label.
2. Breading is not limited to 30% unless breaded is in the product name.
3. Fried chicken labels do not need to state "fully cooked" or refer to breading because fried denotes fully cooked and breading is expected. Fried poultry products in dinners are limited to 30% breading.

Fried Rice with Meat

The product must contain at least 10% meat; may contain eggs and vegetables.

Fries

1. Beef testicles may be labeled as "Beef Fries." They are not permitted to be used as an ingredient in meat food products.
2. "Fries" is not a required part of the product name, "species mountain oyster."

Fritters

The product must contain at least 35% raw red meat/poultry or red meat/poultry food product in the total formulation depending on the name, i.e., "Beef Fritter" must contain 35% beef and a "Chicken Patty Fritter" must contain 35% chicken patty. Fritters can contain up to 65% batter/breading (coating). If "breaded" is included in the product name, the batter/breading is limited to 30%.

Frizzes

An acceptable name. Similar to pepperoni but not smoked. MPR of 1.6:1.

Galician Sausage

Cured beef and pork is seasoned and stuffed into beef rounds. It is then smoked at a high temperature. Cooling is done in a blast of air which produces a wrinkled appearance which is characteristic of Galician sausage.

Gelatin

Gelatin is a binder/extender and is only permitted in a few meat and poultry products. Examples where gelatin is permitted include:

1. Non-specific products
2. Jellied products, e.g., souse, jellied beef loaf and head cheese
3. As a covering for products such as paté, to bind two pieces of meat together and in products where "gelatin" would be part of the product name

Gelatin is permitted as a thickening agent in menudo (i.e., beef tripe stew). If it is used in red meat paté products, its presence must be indicated by product name qualification.

It is not permitted in products like sausage, luncheon meat, and meat loaves. Gelatin is an acceptable ingredient in souse, jellied beef loaf, headcheese. Canned whole hams require qualifier if gelatin is added.

Gelatin in Poultry Rolls

If gelatin or some other binder comprises more than 3% of the formula, the name of the product must be qualified by wording, e.g., "Gelatin Added."

General Offices

The company's grant of inspection permits the general office address to be used in the signature line for any firm "doing business as."

Genoa or Genoa Salami

Is a dry sausage product with an MPR not in excess of 2.3:1. It is prepared with all pork or with a mixture of pork and a small amount of beef. The meat is given a coarse grind and enclosed in a natural casing. No smoke is used in its preparation.

Geographic and Related Terms (Requirements for the Use on Product Labels)

Any label representation that expresses or implies a particular geographical origin of the product, or any ingredient of the product, shall not be used except when such representation is:

1. A truthful representation of geographical origin, e.g., "Virginia Ham" for a ham produced in the State of Virginia; or
2. A trademark or trade name which:
   a. has been so long and exclusively used by a manufacturer or distributor that it is generally understood by consumers to mean the product of the particular manufacturer or distributor, e.g., "Swiss Chalet;" or
   b. is so arbitrary or fanciful that it is generally understood by the consumer not to suggest geographical origin, e.g., "Moon Sausage;" or
3. A part of the name required or allowed by an applicable Federal law, regulation or standard, e.g., "Frankfurter," "Vienna;" or
4. A name whose market significance is generally understood by consumers to connote a particular class, kind, type or style of product, or preparation rather than to indicate geographical origin of the product, e.g., "Mexican Style Dinner," "Italian Style Pizza." Such terms must be qualified with the word "style" or "type," unless specifically approved by the administrator as a generic term, e.g., "Lebanon Bologna," "Genoa Salami," "Milan Salami."

Any geographical representation that does not meet the aforementioned guidelines should be qualified by the word "brand," provided that the word "brand" is not used in such a way as to be false or misleading. A qualifying statement identifying the place where the product was actually made is required in proximity to the brand name, e.g., "Milwaukee Brand Bacon, Made in Chicago, Illinois." The word "Brand" must be in the same size and style of type as the geographical term. If the product has a foreign brand name, it may be identified as having been made in this country, e.g., "Scandinavian Brand Bacon, Made in U.S.A."

Geographic Terms

1. Country, Ranch, and Farm in Trade, Branch and Fanciful Names: Trade names, brand names, or fanciful names that include the words country, ranch, or farm, e.g., "Country Kitchen," "Ranch House," "Hickory Farms," or "Carabeef Ranch Brand" do not invoke section 9 CFR 317.8 of the regulations regarding the use of the term "Country" or "Farm." However, if the terms are used alone in conjunction with the product name, e.g., "Country Stew," then such products must be prepared in the country or on the ranch or farm and meet any other requirements prescribed.
2. Southern: The term "Southern" is restricted to use only in areas south of the Mason-Dixon Line and east of the Mississippi River as well as Arkansas, Louisiana, and Missouri, which are also considered southern states.

German Potato Salad with Bacon

The product must contain at least 14% cooked bacon in total formulation.

See: Salad–German Potato Salad.

German Sausages with Milk

Whole milk is a permitted ingredient in the following meat food products when the ingredients statement is shown immediately under the name of the product or the milk is shown in a qualifying statement contiguous to the product name: Speckblutwurst, Kalbsbratwurst, Langblutwurst, Blutwurst, Gelbwurst, Zengenwurst, Brand Tongue and Blood Pudding Kalbslebenwurst. (Swiss Liver Sausage, Kalbslebenwurst should be considered on the same basis as Bockwurst (e.g., no limit on water or milk).)

Milk is a characterizing ingredient in German sausages and not an extender. Products which contain milk should be called by their proper names.

Giblet Gravy (Kind)

Requires 7.25% giblets. The product must contain an equal number of livers, hearts, and gizzards.

Giblets and/or Necks Sold with Carcasses

Poultry giblets consist of approximately equal numbers of hearts, gizzards, and livers, as determined on a count basis.

Although often packaged with them, the neck is not a giblet. Rabbit giblets consist of the liver and heart. Giblet packs are expected within the cavities of eviscerated whole birds or eviscerated whole rabbits or when packaged with cut-up whole birds or cut-up whole rabbits, therefore, qualifying the presence of giblets is not required on labeling. However, when giblets are not expected, therefore, a product name qualifier is required, e.g., "Packed with Giblets."

In situations where parts of giblets are missing, a product name qualifier is required, e.g., "Parts of Giblets Missing" or "Parts of Giblets May Be Missing." In situations where the giblets are missing entirely from an eviscerated carcass or a cut-up whole carcass, a product name qualifier is required, e.g., "Packed Without Giblets." In addition, an excess of one of the giblet components can be added to make up for another missing giblet component. In this case, a proper qualifying statement is required, e.g., "Packed with 2 Gizzards, 1 Liver."

A neck, when not attached to the carcass of a whole bird, is also expected to be present within the carcass or packed with the cut-up whole carcass. Accordingly, a product name qualifier is not required to flag the presence of the neck. Rather, when the neck is missing, a product name qualifier is required, e.g., "Without Neck."

See: 9 CFR 381.170 (b) (21) and 9 CFR 354 (m).

Glazes

If a glaze component contributes to the flavor profile of the product, we will allow the ice glaze coating to be counted toward the total net weight of the finished product. However, the coating and coating percentage must be included as part of the descriptive product name in accordance with Policy Memo 044A, e.g., "chicken breast filets with rib meat, coated with a butter garlic flavoring and containing up to 22.5% of a solution of…" or "chicken breast filets with rib meat, coated with a 6.5% butter garlic flavoring and containing up to 16% of a solution of…."

Glycerin

May not be added to any product as such; may be used in proprietary mixes.

Goetta

An oatmeal product similar to scrapple. Goetta is prepared with a formula containing not less than 50% meat and meat byproducts. The cereal component should consist of oats or oat products and just enough water to prevent product from sticking and burning during the preparation process. The term "Old Fashioned" when noted on a label for "Goetta" refers to the round shape.

Goettinger Cervelat

A dry cervelat with no byproducts or binders.

Goose Liver or Goose Liver Sausage

At least 30% cooked goose liver. When pistachio nuts are added, product name must be qualified, i.e., "pistachio nuts added."

Gorditas, Meat/Poultry

The product must contain at least 15% cooked meat/poultry based on the weight of the total product. The "species" or "kind" gorditas name (Beef Gordita, Chicken Gordita) may stand alone. If other characterizing ingredients such as potatoes, rice, beans, etc, are included in the name, they must be reflected in their order of predominance, e.g., Beef and Potato Gorditas, Rice and Chicken Gorditas, as determined by the formula.

Goteborg

A Swedish dry sausage made of coarsely chopped beef and sometimes pork. Mildly seasoned with thyme. It has a somewhat salty flavor and is heavily smoked, usually in long casings and air dried.

Gothaer Cervelat

Originated in Gotha, Germany. Usually made of very lean pork finely chopped and cured.

Goulash

A stew-like product with at least 25% meat or 12% poultry meat. Unless designated "Hungarian," generally means stew, whether veal, pork, beef, turkey, etc., are used. Product may be just meat and gravy or meat and gravy with vegetables served with or without rice, potatoes, or noodles.

Goulash, Hungarian Style

The product must contain paprika and at least 25% meat or 12% poultry meat. May not contain noodles, potatoes or dumplings.

Grade Marks

There are no acceptable grade marks for products imported from foreign countries. Foreign countries do not have a grading service exactly like AMS.

The grading term "good" on poultry is considered puffery and is acceptable.

Red meat grading terms, "prime," "choice," "select," may not be used immediately preceding "kind" poultry, unless the poultry is equivalent to USDA Grade A. For example, "Choice Turkey" or "Select Chicken" must come from Grade A birds.

Gravies

The product must contain at least 25% meat stock or broth, or 6% meat. Mono and diglycerides allowed in amount of 1% in gravies.

Gravy and Beef

The product must contain at least 35% cooked beef (beef same size lettering as gravy). For 25% cooked beef (beef lettering no larger than one-half size gravy).

Gravy and Dressing with Pork or Gravy and Pork with Dressing

The product must contain at least 14% cooked pork.

Gravy and Poultry Salisbury Steak

Not more than 65% gravy and at least 35% poultry salisbury steak.

Gravy and Swiss Steak

The product must contain at least 35% cooked meat.

Gravy and Yankee Pot Roast

The product must contain at least 35% cooked beef. Beef is cooked with or without vegetables.

Greek Sausage

The product must contain orange peel.

Ground Beef

May not contain added fat. Maximum total fat 30%. Cheek meat is permitted up to 25% and must be declared in the ingredients statement. For more than 25%, show as "Ground Beef and Cheek Meat," all the same size.

Beef of skeletal origin, or from the diaphragm or esophagus (weasand) may be used in the preparation of chopped beef, ground beef, or hamburger. Heart meat and tongue meat as organ meats are not acceptable ingredients in chopped beef, ground beef, or hamburger.

Ground Beef Chuck and Round

Product to be labeled "Ground Beef Chuck" or "Ground Beef Round" must comply with the following guidelines:

1. "Ground Beef Chuck" must be derived from all or part of the primal part of the beef carcass commonly referred to as the "Beef Chuck," except as provided for in 3. The product must comply with the fat requirements of 9 CFR 319.15(a).
2. "Ground Beef Round" must be derived from all or part of the primal part of the beef carcass commonly referred to as the "Beef Round," except as provided for in 3. The product must comply with the fat requirements of 9 CFR 319.15(a).
3. Generally, shank meat may be added but may not exceed the natural proportion of the beef carcass, which is considered to average 6%. Higher quantities of shank meat may be used if the shank meat remains attached during the cutting and boning of the boneless chuck or round, or if the processor can demonstrate that a higher percentage is applicable.

Ground Beef — Hamburger and Soy Products

Combinations of ground beef or hamburger and soy products may be descriptively labeled, e.g., "Hamburger and Textured Vegetable Protein Product" or "Ground Beef and Isolated Soy Protein Product" if the combination product is not nutritionally inferior to hamburger or ground beef. If the combination products are nutritionally inferior, they are to be labeled as Imitation Ground Beef (or Imitation Hamburger) or Beef Patty or Beef Patty Mix in accordance with Section 9 CFR 317.2(j)(1) and Section 9 CFR 319.15(c) respectively.

Gum Arabic

May be used up to 2% in breading and batter mixes.

Gum Tragacanth

A carrier and stabilizer in liquid spice extractives not to exceed 0.1% in finished product. Not permitted in sausage products.

Gum-Vegetable

Spice extractive products which employ vegetable gums as emulsifiers have been approved. The addition of vegetable gum is limited to no more than 15% in the seasoning blend emulsion.

Gumbo

A Creole word for okra. It is now recognized as meaning a dish or a soup thickened with okra. To qualify, the dish must have okra as an ingredient. Either the soup or the stew standard would apply, depending on product name ("Chicken Gumbo"). Product identified as "Creole Style — Gumbo" does not contain okra; however, it must contain a roux (flour, milk, or water, etc.) or gumbo file (dried powder from young leaves and leaf buds of sassafras).

Gyros

Products identified with this term must contain at least 65% meat and no more than 12% extenders and binders. Examples include gyro loaf, gyro cone, gyro portions, and gyro slices.

Halal and Zabiah Halal

Products prepared by federally inspected meat packing plants identified with labels bearing references to "Halal" or "Zabiah Halal" must be handled according to Islamic law. The federal meat and poultry inspection program does not certify to the "Halal" or "Zabiah Halal" preparation of products, but rather accepts the statements and markings in this regard offered and applied under the supervision of any Islamic organization. The words "Halal" or "Zabiah Halal" may be used only on the labeling of meat and poultry products prepared under such Islamic authority. The identity of the Islamic organization should be available upon request by agency official. Qualification of the words "Halal" or "Zabiah Halal" by such terms as "style" or "brand" does not negate these requirements.

Ham a La King

Must contain at least 20% ham (cooked basis).

Ham and Bacon Loaf

There is a limit of 3% water in this product.

Ham and Cheese Loaf

Nonspecific loaf. Cheese is chopped into small cubes and combined with finely ground ham.

Ham and Cheese Salad

Product must contain at least 25% ham (cooked basis).
See: Salads.

Ham and Cheese Spread

Product must contain at least 25% ham (cooked basis).

Ham and Dumplings and Sauce or Gravy

Product must contain at least 18% cooked ham.

Ham, Boiled

A fully cooked, boneless product which must be cooked in water and may be processed in a casing or can. The product may be of various shapes and may be partially cooked in boiling water.

Hamcola

Not an acceptable product name; should be accompanied by true product name, i.e., "Boneless Cooked Ham Coated with Spices."

Ham Capacolla, Cooked

Ham that has been cured and then cooked.

Ham Chowder — Condensed

Product must contain at least 10% cooked ham.

Ham, Cooked — Sectioned and Formed

The qualifying phrase "sectioned and formed" is no longer required on boneless ham products, e.g., "ham" and "ham-water added." The addition of small amounts of ground ham added as a binder to such products may be used without declaration. The amount of ground ham that may be used can represent no more than 15% of the weight of the ham ingredients at the time of formulation. Products containing more than 15% ground ham trimmings must be labeled to indicate the presence of the ground ham, e.g., "a portion of ground ham added." Policies regarding the required use of terminology such as "chunked and formed" and "ground and formed" will continue.

Whole hams require a cooking temperature to differentiate the ready-to-eat products from trichinae-treated products. The reason that the temperature is required is to determine the label requirements (e.g., safe handling) and proper serving size.

Ham Croquettes

Product must contain at least 35% cooked ham. If chopped ham is used, the product name must be "Chopped Ham Croquettes."

Ham, Fresh (or Uncured)

Ham that does not contain a cure must be labeled either "Fresh" or, if the ham meets the requirements of 9 CFR 319.2, "Uncured." This also applies to cooked product, and must be labeled cooked product "Cooked Uncured Ham."

Ham Half

"Half Ham" is permitted on labels for semi- boneless ham products which during their processing have had the shank muscles removed. The two halves of the finished product have approximately an equal amount of bone. The term "No Slices Removed" has also been deemed suitable for use with a ham item referred to as "Half Ham."

Ham Omelet

Product must contain at least 18% cooked ham.

Ham/Parma Ham/Prosciutto Di Parma

Ham, when labeled "Parma Ham" and/or "Prosciutto di Parma," would have to be produced in the region of Parma, Italy, in accordance with Italian Law, which defines the denomination of origin, the territorial limits of production, characteristics of the product, and the method of manufacture.

Ham, Quarter, Semi-Boneless (No Slices Removed)

The product consists of a ham prepared as a "Regular Semi-Boneless, Half Ham" which is sectioned again to result in four pieces just about equal not only in weight but also in content of bone.

Ham Roll Sausage

Ham trimmings and ham shank meat are permitted.

Ham Salad

Product must contain at least 35% cooked ham. Chopped ham may be used without it appearing in the product name.

See: Salads.

Ham, Scotch Style

A cured, uncooked, boned, and rolled whole ham either tied or in a casing.

Ham, Shankless

When the term, "shankless" is used in reference to a ham, it indicates that the shank has been removed by a cut through the joint at a right angle to the femur bone. The distal tip of the semitendinous muscle may be severed above its tendinous attachment, leaving an extension approximately 2 inches long. The extension is considered an integral part of the ham's body and is usually folded over the femur's end.

Ham Shortcake

Product must contain at least 25% cooked ham.

Ham, Smithfield

This is an aged, dry cured ham made exclusively in Smithfield, Virginia. The use of the words "brand" or "style," e.g., "Smithfield Brand Ham," "Smithfield Style Ham," does not eliminate this requirement.

Ham Trimmings

Ham trimmings, to be labeled as ham, cannot contain excess shank meat. The fat content will not exceed 35%. It will consist of at least 65% lean meat as determined by chemical analysis.

Ham, Westphalian or Westphalian Style Ham

Ham is cut with bone in, the hip bone cut out, cured in a combination of dry and pickle cure but not a pickle alone. It is smoked in a medium warm (no greater than 100°F.) smokehouse until a shining red brown or chestnut color is acquired. Beechwood may be used and will impart the characteristic Westphalian flavor. Other hard woods are also acceptable. Juniper berries are permitted.

Handling Statements

Acceptable handling statements, in addition to those required in sections 9 CFR 317.2(k) and 9 CFR 381.125, include "Keep Refrigerated — May be Frozen" or "Keep Refrigerated — Can be Frozen."

Handling Statements on Retorted Products

Handling statements may appear on labels for shelf stable product, even though such product does not have to be refrigerated or frozen, and provided the statement will accurately reflect conditions of distribution and sale. These products are to be handled in the plant as shelf stable items including incubation and condition-of-container examinations. Once the product is refrigerated or frozen for shipment, distribution, and display for sale it is to be handled as a refrigerated or frozen item.

The statement "previously handled frozen for your protection, refreeze or keep refrigerated" is now acceptable on poultry products under the usual restriction of use for such statements.

Head Meat

After removal of the cheeks, lips, snout, skin, and tongue from the head, there remains small pockets and areas on the skull to which muscle tissue is attached. This muscle may be removed and used in product and declared on

labeling as beef or pork as the case may be. However, there are a few standardized products in which the regulations limit the amount of this meat that may be used and require that it be specifically declared on the label (e.g., chili, chili with beans, and corned beef hash).

See: Beef Cheek Meat and Beef Head Meat (Use and Labeling as an Ingredient in Meat Food Products).

Headcheese

A jellied product consisting predominantly of pork byproducts and seasoning ingredients. It must contain some product from the head. Extenders like cereal, soy derivatives, nonfat dry milk, etc., are not permitted ingredients of headcheese.

Hearts/Heart Meat

Hearts/heart meat may not be labeled as "beef," "pork," etc. in the ingredients statement. When used in a product, they must be identified by species, e.g., "Beef Hearts." Hearts/Heart Meat, including the heart cap, may be considered meat for calculating the meat to textured vegetable protein ratios.

Heat and Eat Sausage

Not the same as Brown and Serve Sausage. When the "heat and eat" term is used, product must comply with cooked sausage regulations, e.g., limitation of 10% added water and not more than 3½% binder.

Hickory Smoked

"Hickory flavored" ad "hickory taste" are acceptable terms on products that have been smoked with some hickory in the sawdust. They do not need to be smoked with 100% hickory smoke.

High Fructose Corn Syrup (HFCS)

HFCS may be used to flavor meat or poultry products in amounts sufficient for its intended purpose, provided the following conditions are met:

1. HFCS must contain not less than 40% fructose on a solids basis.
2. HFCS must have a dextrose equivalence (D.E.) of not less than 93.
3. HFCS must have a sweetening power greater than or equal to sugar (sucrose).
4. HFCS must be identified on the label as High Fructose Corn Syrup in the ingredients statement, curing statement, etc.

Holstein or Holsteiner

Product is the same as **Farm Style Sausage**, except that it is stuffed into wide casings and heavily smoked, usually in long casings, and air dried. No extenders are permitted.

Honey Claim in Product

A honey claim may be made or implied on a product label if:

1. The product contains at least 3% honey.
2. Honey contains at least 80% solids, U.S. grade C or above.
3. When other sweeteners, (sugar, dextrose, maltose, invert sugar, corn syrup solids, and similar ingredients) are used, the quantity may not exceed one-half that of the honey, e.g.. If 3% honey is used, then no more than 1½% of all other sweeteners may be used.
4. Product to be identified as "Honey Glaze" must contain honey to other sweeteners at a ratio no less than 2:1. If dried honey is used, the ratio is to be no less than 1.6:1.
5. When honey is included in a breading, a honey claim may be made regardless of the quantity of honey used.

Honey Cured or Sugar Cured

"Honey Cured" may be shown on the labeling of a cured product if:

1. the honey used contains at least 80% solids or is U.S. grade C or above;
2. honey is the only sweetening ingredient or when other sweetening ingredients are used in combination with honey, they do not exceed one-half the amount of honey used; and honey barbecue — touch of honey.
3. honey is used in an amount sufficient to flavor and/or affect the appearance of the finished product.

Traditionally, cured products which are labeled to indicate the presence of honey, e.g. Honey ham, must meet the parameters prescribed herein.

"Sugar Cured" may be used on the labeling of a cured product if:

1. the sugar used is cane sugar or beet sugar;
2. sugar is the only sweetening ingredient or when other sweetening ingredients are used in combination with sugar, they do not exceed one-half the amount of sugar used; and
3. sugar is used in an amount sufficient to flavor and/or affect the appearance of the finished product.

"Honey and Sugar Cured" or "Sugar and Honey Cured" may also be used on labeling if:

1. the honey and sugar are of the nature described above;
2. the honey and sugar are the only sweetening agents or when other sweetening ingredients are used in combination with the honey and sugar, they do not individually exceed either the amount of honey or sugar used and collectively do not exceed one-half the total amount of honey and sugar; and
3. the honey and sugar are used in amounts sufficient to flavor and/or affect the appearance of the finished product.

Hors d'oeuvre (Snack)

Product must contain at least 15% cooked meat or 10% bacon (cooked basis). True product name must be shown, e.g., "Puffed Pastry Wrapped Frank."

Hot Dog Chili Sauce with Meat

Product must contain at least 6% meat.

Hot Dog Chili with Meat

Product must contain at least 40% meat. Sausages and bologna rework not permitted.

Hunan Style Seasoned Pork

Acceptable for pork shoulder sliced into one inch pieces and marinated in a solution of soy sauce, garlic, and ginger, cooked and returned to green weight. The product may be flavored with other seasoning ingredients, e.g., star anise and coriander.

Hydrolyzed Beef Stock

A beef stock which has been treated with acid, alkali, or enzymes to digest the protein. The protein molecules are broken down into amino acids, peptides, polypeptides, and peptones. As the digestion is carried out for longer periods of time, more and more of the larger molecules are broken down into amino acids, with free alpha-amino groups. By analyzing these alpha-amino nitrogens one can determine the degree of hydrolysis. 100% hydrolysis would mean that all the nitrogen (protein) is in the form of amino acids. 10% of hydrolysis would mean that only 10% of the nitrogen is in the form of free amino acids, while the rest is still present in polymeric form.

The label should indicate the degree of hydrolysis. This is determined from the ratio of amino nitrogen to total nitrogen.

$$\textit{amino nitrogen} = \%\ \text{hydrolysis total nitrogen}$$

A product labeled 50% Hydrolyzed Beef Stock must, therefore, have 50% of the total nitrogen present as amino nitrogen. Adding % solids is optional. The % solids would not necessarily be the same % as hydrolysis depending on the thickness (consistency) of product.

Hydrolyzed Gelatin

Hydrolyzed gelatin is permitted in frankfurters and similar products (9 CFR 319.180) at levels typically used for flavorings (less than 2%). Hydrolyzed gelatin may currently be used a 2% in 9 CFR 319.180 and like products as a flavoring. If gelatin is used in a product, make sure it is permitted for use in the product. Hydrolyzed gelatin is acceptable in poultry franks 9 CFR 319.180 and like products at levels not to exceed 2% of total formula until otherwise notified.

Hydrolyzed gelatin is recognized as a binder rather than flavoring and may be used at levels of 2% or less in 9 CFR 319.180 type products.

Hydrolyzed Oat Flour

Hydrolyzed oat flour is safe and may be used in non-standardized meat/poultry products as a binder at below typical binder use levels, i.e., 3%. It may be used in low fat hamburger, water, and hydrolyzed oat flour product as per Policy Memo 121.

Hydrolyzed Protein

"Hydrolyzed Protein (milk, egg, soy)" is an acceptable common or usual name provided all components are hydrolyzed. "Hydrolyzed Protein (potato, gelatin)" is an unacceptable ingredient declaration and must be declared as "hydrolyzed potato protein and hydrolyzed gelatin."

Salt is present in hydrolyzed protein and must appear in the sublisting of the hydrolyzed protein if it does not appear elsewhere in the ingredients statement.

Hydroxypropyl Methylcellulose (HPMC)

Emulsifying agent, binder, thickener, and a stabilizer. This is accepted for its emulsifying qualities when prepared as a solution and applied as a dip.

1. Not more than 2% in solution
2. Not more than 4% weight gained in product
3. Not more than .08% hydroxypropyl methylcellulose in finished product
4. Must be identified in the ingredients statement for purpose
5. Approved on individual basis only

Ice-Glazed Breaded Chicken Nuggets

If an ice glaze is applied for the purpose of setting the breading, the term "ice glazed" needs to appear in close contiguous to the product name. The water cannot be included as part of the net weight statement and the transmittal form should indicate this.

Imitation Flavors

Imitation beef flavor, imitation mushroom flavor, flavor base for gravies and similar substances which enhance, fortify, or help to simulate a flavor are usually composed of food additives and, as such, are not "artificial flavors" for labeling purposes. This class of imitation flavors can be composed of such ingredients as flour, fats, oils, salt, hydrolyzed vegetable protein, vegetable gums, thiamine hydrochloride, beta alanine, disodium inosinate, glutamic acid, and a host of other ingredients. These flavorings must be identified on labels by showing each individual ingredient by its common name. Class names, e.g., amino acids are not acceptable. Each specific amino acid must be listed.

Incidental Additives

As defined in the Food and Drug Administration regulations (21 CFR 101.100(a)(3)), incidental additives are substances present in foods at insignificant levels and that do not serve a technical or functional effect in that food. In determining whether a substance is an incidental additive, the following criteria may be applied:

1. Substances that are present in a food as a result of having been present in an ingredient added to the food and have a technical or functional effect on the ingredient but not on the finished food, or
2. Substances that are processing aids, defined as:
   a. substances added during processing but removed before the food is packaged in its finished form, or
   b. substances added during processing but that are converted to constituents normally present in the food, and do not significantly increase the amount of those constituents naturally found in the food, or
   c. substances that are added to a food for their technical or functional effect in the processing but are present in the finished food at insignificant levels and do not have any technical or functional effect in that food.

Ingredient Labeling

1. All ingredients in FDA standardized products, e.g., Cheddar Cheese (Water, salt, cheddar, etc.), and on standardized products, e.g., Soy sauce, Worcestershire sauce, require complete disclosure of all ingredients on the labels of meat and poultry products.
2. Protein hydrolysates must identify the common and usual names and identify the source from which the protein is derived, e.g., "hydrolyzed vegetable protein" would be declared as "hydrolyzed corn protein."
3. FDA certified color additives require the listing of the common or usual names, e.g., FD&C Blue No. 1, Blue 1, or Blue 1 Lake. Color additives not subject to certification may be declared as "artificial color," "artificial color added," or "color added." Alternatively, color additives not subject to certification may be declared as "colored with _____," or "_____ color," with blank space filled in with the name of the color additive listed in 21 CFR 73, e.g., "colored with annatto" or "caramel color."
4. Cured meat products used as ingredients, regardless of their level of use, require complete disclosure of all ingredients in the formulation of meat and poultry products.

Insert Labels for Use at Retail Stores

No inspection legend is permitted on insert labels.

Inspection Legends (Dual)

Products consisting of mixed meat and poultry ingredients shall bear either the official meat inspection legend or poultry legend, depending on which ingredients are present in the greater amounts. If meat or poultry ingredients exist in equal proportions, either official legend may be used. If meat and poultry ingredients exist in exact proportions and both appear in the product name, the official legend must reflect the ingredient appearing first in the product name.

Containers of products intended for sale to household consumers can bear only the official mark of inspection of the product enclosed. Containers of products intended for distribution to other than the retail trade may bear both the official meat inspection legend and the official poultry products inspection legend.

Inspection Mark on Wing Tag

When the inspection mark is shown on a wing tag, either the plant number or the firm's name and address must also appear.

Intestines

Intestines can be prepared as edible product and bear the mark of inspection.

Irish Stew

Product does not require a geographical qualifying statement nor the words, "Style," "Type," or "Brand." Usually it contains lamb or mutton but beef may be used. It must meet the stew standard. Vegetables include onions, carrots, potatoes, and turnips. Dumplings are often used. Beans are not acceptable in "Irish Stew."

Isolated Soy Protein

This food ingredient is similar to soy protein concentrate except that additional extraction has removed more of the non-protein fraction, thereby increasing its protein content. It is prepared by alkaline solubilization of the soy protein and then precipitation of same in an acid bath. It may be powdered, extruded, or spun into fibrils and has a protein content of 90 to 95%. Products of spun fibrils may be referred to as "Textured Soy Protein Isolate," "Isolated Soy Protein Fibers," or "Spun Isolated Soy Protein." The PER of isolated soy protein is about 1.9 and indicates a poorer quality protein than that of soy flour or soy protein concentrate (PER 2.2). When hydrated textured (structured) protein isolate is added to meat food products, the ingredients statement should read "Hydrated Textured (Structured) Isolated Soy Protein."

Italian Sausage

Beef and pork Italian sausage is acceptable. Tomato products and other unexpected ingredients can be added if the product name indicates their presence. Red pepper permitted under 9 CFR 319.145(b)(1).

See: 9 CFR 319.145.

Italian Style

Acceptable term for products containing anise or fennel or Italian type cheese (e.g., Mozzarella, Parmesan, Provolone, Ricotta, Romano) or at least three of the following: basil, garlic, marjoram, olive oil, or oregano. Sausage products must meet the Italian Sausage requirements as per Regulation 9 CFR 319.145.

Italian Style Smoked Sausage

This is a smoked sausage (10% added water) and is not a 9 CFR 319.145 (Italian sausage) product. However, the product must contain Italian style ingredients found in the policy book under Italian style.

Jagwurst

The product is the same as yachtwurst (The Americanized name for the item). It is a cooked sausage made from a fine emulsion with cubes of lean meat rather than fat (as in mortadella).

Jamaican Style

Term may be used to identify meat and poultry food products made with allspice, garlic, onion, red pepper, and thyme. The name of the product must be further qualified with a statement, like "with Jamaican Style Seasoning," e.g., "Jamaican Style Chicken Wings-with Jamaican Style Seasonings." If the product formula contains textured soy product, then the ration rules apply.

Jamaican Style Patties

Product has at least 25% meat enclosed in a crust. The label must show true product name, e.g., "Beef Turnover." If the formula contains textured soy product, then the ratio rules apply.

Jambalaya

Product must contain at least 25% cooked ham and one other meat or seafood must be included. A New Orleans dish involving rice and ham and usually tomatoes (shrimp or other shellfish, other meat or poultry), together with seasonings. Must show true product name, e.g., "Ham and Shrimp Jambalaya."

Jamon

Spanish word for "ham." In the usage of Spanish-speaking people outside Spain, it has come to mean cured pork. "Jamon di Cocinar" is cured pork for cooking as opposed to slicing. When the term "Jamon" appears before the name of a limb, it means the product is cured. With the exception of products available for sale in Puerto Rico, all Spanish product names followed with the English translation.

Examples of acceptable product names are:

Jamon de Paleta — Cured Pork Shoulder
Jamon de Pierna — Cured Pork Leg

Jardiniere (FR)

Must contain at least 50% cooked meat based on total product. It means "in the manner of the gardener." The term applies to dishes made with diced garden vegetables which have been cooked with meat. Jardiniere should be followed by a true product name, e.g., "Beef with Vegetables."

Jerk or Jerk Style

The terms "Jerk" or "Jerk Style" can be used to describe red meat or poultry whole muscle, fabricated products, and other meat poultry food products, that are mixed or placed in a "spicy seasoning." The seasoning usually contains scallion, onion, thyme, allspice (pimento), hot peppers, and usually contains at least one or more of the

following: nutmeg, cinnamon, sugar, brown sugar, garlic, and rice or wine vinegar. The seasoning may be in the form of paste, marinade, sauce, or dry seasoning mixture. The product is mixed or placed in the spicy hot seasoning raw or the product may be grilled, cooked, or smoked. Examples of acceptable product names are, e.g., "Oven Roasted Jerk Chicken," "Jerk Pork Sausage" or "Jerk Style Smoked Beef Sausage."

Jerky

All Jerky products must have a MPR of 0.75:1 or less; "species" or "kind" must be in the name. Products may be cured or uncured, dried, and may be smoked or unsmoked, air or oven dried. A reference to the particular type of drying method is not a labeling requirement.

1. "Beef Jerky" — Produced from a single piece of beef. May also be classified as "Natural Style Beef Jerky" provided this product name is accompanied by the explanatory statement "made from solid pieces of beef" or comparable terminology. When a "Natural" claim (not natural style) is made, the policies as outlined in Policy Memo 055 are to be applied.
2. "Beef Jerky Chunked and Formed" — Produced from chunks which are molded and formed and cut into strips.
3. "Beef Jerky Ground and Formed or Chopped and Formed" — Produced as described, molded and formed and cut into strips.
4. Jerky products that contain over 3½% binders (2% ISP) must reflect the binder in the product name, i.e., "Beef Soy Protein Concentrate jerky, ground and formed. Jerky products that contain binders at levels below 3½% should express the binder in a qualifying statement, e.g., beef jerky — soy protein added.
5. "Species (or Kind) Jerky Sausage." The word "Jerky" can appear on labels for product in which the "species" or "kind" has been processed by chopping or grinding and stuffed into casings under the following conditions only:
   a. The word "Sausage" must appear immediately contiguous to "Jerky" whenever it is shown. "Sausage" must be in type at least one-third as high as "Jerky" in the same color ink and on the same background. The words "stick," "piece" etc. cannot be used as substitutes for "sausage" in the product name. "Sausage" means that the product has been chopped.
   b. The product may be dried at any stage of the process.

Junior Meat Snacks

Product must conform to the sausage standards going into the jar before processing. Limited to 3½% extenders.

Juniper Berries

Juniper berries and twigs are normally thrown on the fire from which dry cured hams are smoked. Juniper berries have been approved in the curing ingredients of Westphalian Ham.

Kabobs

Product consists of chunks of red meat or poultry and vegetables placed on a metal or wooden skewer. "Kabob" may be included in the descriptive name, e.g., "Beef, Mushrooms, and Onion Kabob." A kabob may be cooked or uncooked, but the label must clearly indicate this. This product may contain but does not require vegetables.

Kalbelwurst

Product is similar to Bockwurst with no limit on water or milk.

Katrifitas

A coined word used to describe a type of empanadillas. The product consists of dough containing yucca made to resemble a meat turnover and has a special meat filling. The product must contain at least 25% raw meat (beef) in total formulation. Label must include a true product name in conjunction with "Katrifitas," e.g., "Katrifitas, Beef Turnover made with Yucca Shell," or similar wording.

Kelco-Gel

A thickening agent used in sauces. It contains sodium alginate, calcium carbonate, and disodium phosphate. The amount of disodium phosphate in the finished product is approximately 0.099%. Its use should be judged on an individual basis.

Kidneys from Enzyme Injected Beef

Product may be exported to other countries. They must be labeled "Beef Kidneys, Tendered with Papain — For Export Only."

Kielbasa

A sausage that is cured, cooked, and usually smoked. Kolbassy is Czechoslovakian spelling; other variations include Kielbassy, Kolbasa and Kolbase. Kielbasa is made from coarsely ground pork or coarsely ground pork with added beef or mutton. "Hungarian Style Kolbase" is finely ground product, seasoned and stuffed into casings.

The 70/30 rule can be used, however, pork must always be the predominant meat ingredient. "Beef Kielbasa" is prepared with only beef as the meat ingredient. Byproducts are not permitted ingredients in these sausages.

An uncured (fresh), uncooked variety, with no more than 3% water exists. "Fresh" shall be used in the name when the product is uncured. When fresh Kielbasa is cooked or smoked, then cooked or smoked is required in the product name. The requirements of Policy Memo 110 apply when these perishable, cooked, uncured products are packaged in hermetically sealed containers.

Kippered Beef

A cured dry product similar to beef jerky but not as dry. MPR of 2.03:1 is applied to product.

Kiska; Kisba, Kishka, or Stuffed Derma

Ingredients statement is part of the product name. A meat food product prepared two ways:

1. Prepared with meat byproducts, including beef blood, pork snouts, pork livers, pork cheeks, etc. Packaged in fully labeled retail size packages or individually banded. When beef blood is used, it must be shown as part of product name.
2. Prepared with no more than 30% animal fat, mixed with farinaceous (consisting of or made of flour or meal) materials containing no other meat byproducts and ordinarily stuffed into beef casings and cooked. Product containing 30% or less fat is not considered amenable to the Federal Meat Inspection Act.

Knishes

Product must contain at least 15% cooked meat or poultry or 10% bacon (cooked basis). Same as snack standard. The type of meat or poultry should be identified in a true product name, e.g., "Chicken Knishes."

Konjac Flour

Food ingredient that provides the effects of thickening, gelling, texturizing, and water-binding, e.g., "binder," similar to that of starch vegetable flours, such as potato flour. Konjac flour can be used in meat and poultry products in which starch vegetable flours are permitted, e.g., 3.5% in cooked sausage products such as frankfurters and bologna.

Kosher and Kosher Style

Products prepared by federally inspected meat packing plants identified with labels bearing references to "Kosher" or Rabbinical markings must be handled under Rabbinical supervision. The Federal meat and poultry inspection program does not certify to kosher preparation of products, but rather accepts the statements and markings in this regard offered and applied under the supervision of the Rabbinical authority. The word "Kosher" may be used only on the labeling of meat and poultry products prepared under Rabbinical supervision. The identity of the Rabbinical authority must be made available upon request from agency official. Qualification of the word by such terms as "Style" or "Brand" does not negate the requirement.

Kosher (Product Containers)

Containers must be labeled "Kosher tags attached" when used for hearts, livers, and other products or tissues with attached metal tags indicating kosher inspection.

Krakow

Acceptable name for a cooked sausage similar to "Berliner."

Kreplach

Product must contain at least 20% meat. The type of kreplach should be identified in a true product name, e.g., "Beef Kreplach."

Kubbee

Other acceptable names are: Kubbe, Kibbe, Kabeda, Kilin, Kibbes, Kibby, Kabbo, or Kabe." A product popular in Syria and Lebanon. It must contain at least 25% meat based on total formulation; it must contain soaked cracked wheat and show the true product name, e.g., "Fried Cracked Wheat and Beef Balls," "Baked Stuffed Wheat and Beef Patty." Products may be shaped like a hamburger and fried or shaped into balls and fried.

Kuemmelwurst

An acceptable name. The product is the same as Carawaywurst and is a cooked sausage of the ring variety, with whole caraway seeds. Usual ingredients are beef, pork, salt, caraway, flavorings, and cure.

Kurma

Product must contain at least 50% meat or at least 35% poultry meat.

Labeling, Check-Off Blocks

The use of check-off blocks on immediate containers for identifying products that look alike but are different in composition is not permitted.

Examples of product that may look alike but are different in composition are as follows:

- Ground Beef and Beef Patty Mix
- Partially Defatted Chopped Beef and Partially Defatted Beef Fatty Tissue
- Frankfurters and Frankfurters with Variety Meats
- Finely Ground Chicken and Finely Ground Chicken Meat
- Comminuted Chicken and Comminuted Chicken With Kidney and Sex Glands Removed

However, exceptions to this policy may be granted. Exceptions would require that the establishment operators develop a procedure which the assigned inspector can readily monitor to ensure correct labeling. Such procedures, accompanied by written comments from the assigned inspector and where possible, the circuit supervisor, must be forwarded to the area supervisor for review and approval.

Approved procedures must be attached to the label records accompanying new or modified labels submitted for approval.

Labeling for Substitute Products

If a product fails to comply with a standard only because the meat or poultry content is lower than required and the product has generic identity as a nonmeat product (e.g., pizza, stew, pies), then the product may be designated by the nonmeat terminology in the standardized name (e.g., "Pizza," "Stew," "Pie"), provided the meat/poultry content of the product is conspicuously disclosed contiguous to the product name along with a statement of the amount of meat/poultry in the standardized product. (For example, Pizza contains 5% sausage; Sausage Pizza contains 12% sausage.) Such product may not be nutritionally inferior to the standardized product it resembles. For this purpose, nutritional inferiority is defined, consistent with the requirement of 21 CFR 101.3(e)(4), as any reduction in the content of an essential nutrient that is present at 2% or more of the U.S. RDA per serving of protein or any of the vitamins or minerals for which U.S. RDAs are established. A quality control procedure must be approved for such products by the Processed Products Inspection Division before the label can be used.

If a product is nutritionally inferior to the standardized product it resembles, it must be labeled "imitation" in accordance with 9 CFR 317.2(j) and 9 CFR 381.1(b).

Labeling of Modified Breakfast Sausage, Cooked Sausage, and Fermented Sausage Products Identified by a Nutrient Content Claim

Modified breakfast sausage, cooked sausage, and fermented sausage products are substitute versions of the standardized or traditional products that have been formulated and processed to reduce the fat contents to qualify for use of nutrient content claims, but do not comply with the standard of identity or composition as described in the meat and poultry regulations or the Standards and Labeling Policy Book (Policy Book) because of the use of ingredients used for fat replacement which are precluded or restricted by these standards. The deviation from the standard or the traditional, i.e., "regular product," is conveyed by associating an expressed nutrient content claim for the appropriate reduction in fat content and the standardized or traditional product name, e.g., "Reduced Fat Frankfurter" or "Low Fat Pepperoni." The nutrient content claims that may be used are those related to a reduction in fat contents that are identified in the regulations for meat products in 9 CFR Part 317 and for poultry products in 9 CFR Part 381.

1. Maintaining Product Integrity

The following guidelines must be applied to assure that the modified versions of the subject meat and poultry sausage products do not violate the integrity of the standardized or traditional product for which they purport to be substitutes: (1) the product must be similar in shape, flavor, consistency, and general appearance to the product as prepared according to the regulatory or traditional standard, (2) the meat or poultry used to formulate the modified product must come from the same anatomical location when the standardized term is related to an anatomical region on an animal, e.g., "ham" is expected to be from the hind leg of the hog and cured; thus, "lean smoked ham sausage" would be comprised of meat from the hind leg of a hog that has been smoked and cured, (3) the modified sausage product must result from the same processing procedures as those specified for the subject sausage products described by regulatory or Policy Book standards, (4) there must not be deviations from product safety criteria (e.g., salt content, curing agents, pH, water activity and/or moisture/protein ratio) that are provided in the regulatory or Policy Book standards for sausages, and (5) the modified product must achieve the appropriate reduction in fat content to be eligible to use a nutrient content claim in conjunction with the standardized or traditional product name.

2. Performance Characteristics

In producing modified, substitute versions of sausages, the deviations from ingredient provisions of the regulatory and Policy Book standards should be the minimum necessary to qualify for the nutrient content claim while maintaining the performance characteristics similar to the standardized or traditional product, i.e., similar preparation, cooking, and handling characteristics. If a modified version of the standardized or traditional sausage does not perform in substantially the same way as the standardized

or traditional item, the label must include a prominent statement informing the consumer of such differences. For example, a "low fat frankfurter" that essentially has all of the characteristics of a frankfurter, but cannot be grilled, would indicate "not recommended for grilling." A "reduced fat pepperoni" that displays essentially all the characteristics of pepperoni, but cannot be cooked, would, for example, indicate "not recommended for cooking" or "do not cook."

3. Safe and Suitable Ingredients

A modified, substitute sausage product must be formulated with approved safe and suitable ingredients, e.g., those identified in 9 CFR 318.7(c)(4) and 9 CFR 381.147(f)(4), and those determined to be safe and suitable by the Food Standards and Ingredients Branch, Product Assessment Division. Such ingredients are to be used at the lowest level necessary to achieve the intended effect of reducing fat as compared to the standardized or traditional product. Safe and suitable ingredients are those used to replace fat, improve texture, and prevent syneresis.

An ingredient or component of an ingredient that is specifically required by the regulatory or Policy Book standard for characterizing purposes, e.g., cheese in a cheesefurter, fresh livers in liver sausage, cured ham in a ham sausage, and fennel or anise in an Italian sausage, shall be present in the required amount, if applicable, or otherwise in a significant amount to provide a characterizing identity to the product. Moreover, an ingredient or component of an ingredient that is not permitted by regulations for use in any meat or poultry sausage product, e.g., sodium benzoate, shall not be added to a modified, substitute product.

4. Product Identity

The name of the modified version of the standardized or traditional product that complies with all parts of the policy prescribed herein is the appropriate expressed nutrient content claim for the meat and/or poultry product with a reduction in fat content and the applicable standardized or traditional term, e.g., "Lean Sausage," "97% Fat-Free (or "Low Fat") Kielbasa," "Low-Fat Frankfurter Made with Beef, Pork and Turkey," "Reduced Fat Pepperoni," "Extra Lean Turkey Italian Sausage," and "Lite Genoa Salami." The size and style of type must conform to the nutrition labeling regulations.

5. Ingredients Statement

To assist the consumer in differentiating between the standardized or traditional sausage product and the modified, substitute version, ingredients that are not provided for by regulatory or Policy Book standards, or used in excess of the allowable levels specified, must be appropriately identified with an asterisk in the ingredients statement. The statement(s) defining the asterisk(s), e.g., "*Ingredient(s) not in regular" (fill in name of the standardized or traditional product), or "*Ingredients(s) in excess of amount permitted in regular" (fill in name of the standardized or traditional product), or both as appropriate, must be legible and conspicuous, and shall immediately follow the ingredients statement in the same size and style of type.

Labeling of Meat and Poultry Stick Items

Stick items such as beef jerky, pepperoni sticks, and beef sticks must be labeled (i.e., contain the required label features as outlined in 9 CFR 317 and 9 CFR 381, Subpart N) according to the following guidelines:

1. If sold in *fully labeled* bulk containers, i.e., canisters, caddies, or similar containers, stick items do not have to be fully labeled unless they are individually wrapped. This type of container cannot be reused.
2. If sold in bulk containers, i.e., canisters, caddies, or similar containers that are not *fully labeled*, stick items must be fully labeled. Bulk containers such as these may only be refilled with fully labeled product.
3. If sold in small, fully labeled cartons, boxes, or similar containers (e.g., 3 oz., net weight) that are only intended for retail sale intact, stick items may be individually wrapped and unlabeled.

Labeling of Modified Substitute Versions of Fresh (Species) Sausage, Hamburger, or Ground Beef Products

This policy allows modified versions of fresh (species) sausages, ground beef, or hamburger to contain non-meat or poultry, "fat-replacing ingredients" (e.g., binders such as carrageenan, modified food starch) and to be identified by certain nutrient content claims in accordance with nutrition labeling regulations effective on August 8, 1994, in conjunction with descriptive labeling, e.g., "Lean Pork Sausage with a X% Solution of …," or "Low Fat Ground Beef, Water, and Carrageenan Product."

This policy allows for the use of terms defined in regulations, e.g., "Lean," "Reduced Fat," "Low Fat," etc., to be used to describe fresh (species) sausage, ground beef, or hamburger products with a reduction in fat content resulting from the use of added ingredients (i.e., "fat replacers" such as carrageenan and isolated soy protein). These products must meet the criteria for use of the nutrient content claim associated with the fat reduction. The nutrient content claim may be used in conjunction with the standardized name provided the consumer is informed of the actual components of the product through labeling,

i.e., descriptive product name, ingredients statement, and Nutrition Facts.

Meat products, including those that meet the criteria established for claims, such as "Lean," "Low Fat," "Lower Fat," "Reduced Fat," etc., that combine fresh (species) sausage, ground beef, or hamburger, and other safe and suitable ingredients, for the principal purpose of replacing fat, may be descriptively labeled. Examples of such products are "Lean Ground Beef, Water, and Carrageenan Product," "Low Fat Ground Beef With a X% Solution of …," "Lean Beef Sausage, Water, and Carrageenan Product," or "Reduced Fat Pork Sausage, Water, and Binders Product," provided conditions prescribed in the regulations, viz., 9 CFR 317, for use of the nutrient content claim are satisfied. In contrast, modified versions of fresh (species) sausage, ground beef or hamburger product containing added ingredients that do not qualify for use of a nutrient content claim prescribed in the nutrition labeling regulations must be labeled as Imitation Pork Sausage, Imitation Beef Sausage, Imitation Ground Beef, Imitation Hamburger, Beef Patty or Beef Patty Mix in accordance with 9 CFR Section 317.2(j)(1) and Sections 9 CFR 319.141 (Fresh pork sausage), 319.142 (Fresh beef sausage), and 319.15 (Miscellaneous beef products), respectively.

Descriptively labeled, modified, substitute versions of fresh (species) sausage, ground beef, or hamburger product with a reduction in fat content must comply with the following guidelines:

1. The descriptive name of a modified, substitute product with a reduction in fat content is the applicable nutrient content claim used in conjunction with the appropriate standardized name and fat-replacing ingredients, e.g., "Low Fat Ground Beef, Water and Carrageenan Product," or "Lean Pork Sausage With a X% Solution of Water, Modified Food Starch, Spices, and Salt." Words in the descriptive name may be of a different size, style, color, or type but, in all cases, the words must be prominent, conspicuous, and legible. Moreover, no word in the descriptive name should be printed in letters that are less than one-third the size of the largest letter used in any other word in the descriptive name. The solution statement, when used, is considered to be part of the descriptive product name and must comply with descriptive name sizing requirements.
2. Fat-replacing ingredients (e.g., binders and water) and fat in the finished product may not exceed 30% of the product as formulated for the modified, substitute ground beef, hamburger, or fresh beef sausage product, and no more than 40% of the product formulation for the substitute fresh pork sausage. The fat content must be in accordance with requirements for use of the applicable nutrient content claim.
3. The product includes mandatory nutrition labeling prescribed in the meat inspection regulations, viz., 9 CFR 317.
4. The product is formulated with approved safe and suitable ingredients, e.g., those identified in 9 CFR 318.7(c)(4), and which are determined to be safe and suitable by the Labeling and Consumer Protection Staff, that are used at the lowest level necessary to achieve the intended effect as a fat-replacing ingredient (i.e., binder).

Labeling of Product Names, Fanciful Names, Word Size

Words in product names or fanciful names may be a different size, style, color, or type, but in all cases, the words must be prominent, conspicuous, and legible. Moreover, no word in a product name, i.e., a common or usual name, a standardized name, or a descriptive name should be printed in letters that are less than one-third the size of the largest letter used in any other words of the product name. The same guidelines apply to letters of words in fanciful names that may accompany the product name.

For example, for a product labeled Chili Mac — Beans, Macaroni and Beef in Sauce, "Chili Mac" is the fanciful name and "Beans, Macaroni and Beef in Sauce" is the product name. No letter in "Chili Mac" may be smaller than one-third the size of the largest letter in "Chili Mac." Similarly, no letter in the descriptive name may be smaller than one-third the size of the largest letter in the descriptive name. This policy is not intended to address the relative size of words in fanciful names versus product names. The size of words in qualifying statements, e.g., "Water Added," "Contains up to …," "Smoke Flavoring Added," etc., are not affected by this policy memo.

Labeling of Products Containing Meat with Added Solutions or other Nonmeat Ingredients in Secondary Products

In those situations where meat containing an added solution or other nonmeat ingredients, e.g., Ham-Water Added, Corned Beef and Water Products, Beef — Containing up to 10% of a solution, are used in secondary products in sufficient quantities to meet the minimum meat requirement without including the added solution, or nonmeat ingredients, the product name need not include any reference to the added solution or nonmeat ingredients; e.g., Corned Beef and Cabbage would be an acceptable name for a product if the corned beef portion of the corned beef and water product was present in a sufficient quantity to satisfy the 25% cooked corned beef requirement. The

ingredients statement, however, must include nomenclature as required by the regulations or policy. In this example, the ingredients statement would list "Corned Beef and Water Product — X% of added ingredients are …"

For products in which the added solution ingredient as a whole is used to meet the minimum meat requirement, the product name must include nomenclature required for the component, e.g., Beef (containing up to 10% of a flavoring solution) Burgundy. The ingredients statement must also include the same nomenclature for the meat ingredient.

Labeling of Products which are Artificially Colored

Labels of products which are artificially colored either by artificial colors or natural colors must bear a statement to indicate the presence of the coloring, e.g., "artificially colored" or "colored with annatto." Products whose true color is disguised by packing media, e.g., colored pickling solutions, must also have labels that include a statement that indicates the presence of the color. The statement must appear in a prominent and conspicuous manner contiguous to the product name. When a component within a product is artificially colored, e.g., breading, sauce, and sausage, a qualifying statement is necessary. However, in all cases, the presence of the coloring must appear in the ingredients statement. Whenever FD&C Yellow No. 5 is used, it must be declared in the ingredients statement by FD&C Yellow No. 5 or Yellow 5. Some products, e.g., chorizos and some of the sausages of the longaniza variety, are expected to be characterized by coloring. In these situations, the presence of the coloring need only be indicated in the ingredients statement.

Labeling of Products which Include Packets of other Components

Wording indicating that the product contains, in addition to the meat or poultry product, another component, e.g., a gravy, sauce, or seasoning packet must appear in conjunction with the name of the product in such a manner that it is obvious to the purchaser that he or she is also purchasing that packet along with the meat and/or poultry product. The wording must be shown in print no smaller than one-third the size of the largest letter in the rest of the product name, of such color that will insure it not being overlooked at point of purchase, and positioned contiguous to the rest of the product name, so as not to appear in whole or part on any panel except the main display panel. The net weight individual components may be shown but are not required.

Labeling of Safe Thawing Instructions on Consumer Packages

Thawing instructions which appear on the label of a frozen meat or poultry product must be given in accordance with FSIS' recommendations for safe thawing procedures. These procedures are as follows:

1. Thawing product in the refrigerator.
2. Thawing product in cold water, changing water every 30 minutes until product is thawed.
3. Thawing product in a microwave oven for less than 2 hours. Cook immediately.

Upon request, alternative thawing procedures may be considered. However, scientific evidence which thoroughly establishes the safety of an alternative thawing procedure must be presented with the procedure when it is submitted for review.

Labeling Prominence Guidelines for Cured, Cooked Products with Added Substances that Do Not Return to Green Weight

The cured, cooked products covered by sections 9 CFR 319.100 ("corned beef"), 319.101 ("corned beef brisket"), 319.102 ("corned beef round and other corned beef cuts"), and 319.104(a) ("cured pork products" under PFF) of the Federal meat inspection regulations; and by Policy Memos 057A ("Labeling Turkey Ham Products Containing Added Water") and 084A ("Cooked Corned Beef Products and Cured Pork Products with Added Substances"), whose weights after cooking exceed the weight of the fresh uncured article, shall bear the product name and qualifying statements on the principal display panel using the following guidelines:

1. The product name and the qualifying statements must be prominent and conspicuous.
2. The label will bear the product name on the principal display panel in lettering not *less than* one-third the size of the largest letter in terms commonly associated with the product name, e.g., cooked, boneless, chopped, pressed, smoked, or words which could be a part of the product name, e.g., steak, butt portion, shank portion.
3. The product name will be judged prominent if the lettering is of the same style and color, and on the same color background as that which is used for the terms commonly associated with the product name or words which could be a part of the product name [see guidelines (2)]. If other styles, colors, and/or backgrounds are used, the prominence must be judged equal to those terms and words which could be associated with or part of the product name.
4. The product name must be distinct and separate from other label information. Thus, the product name should not be part of or embedded in

qualifying phrases or descriptions that include a list of added solution ingredients.

Examples of acceptable terminology are "Corned Beef and Water Product" and "Cured Pork and X% of a Solution."

5. The label for the products covered by this policy memo must also bear qualifying statements that conform to established policies on the size of the lettering in these statements in relation to product name (as outlined in Policy Memo 087A, FSIS Directive 7110.2, and Policy Memo 057A).

Labeling Requirements for Pump-Cured Bacon Products Treated with D- or D1-Alpha-Tocopherol in Surface Applications

Pump-cured bacon treated on the surface with d- or d1-alpha-tocopherol must be labeled with a product name qualifier which identifies the substances involved and the method of application. The qualifier must identify both the carrier and active substance in their order of predominance. The specific names, d- or d1-alpha-tocopherol, or the term, Vitamin E, may be used in the name qualifier. Examples of acceptable name qualifiers are "Sprayed with a solution of vegetable oil and Vitamin E" or "Dipped in a solution of corn oil and d-alpha-tocopherol." The name qualifier must be contiguous to the product name and printed in a style as prominent as the product name. The type used for the statement must be at least one-fourth the size of the most prominent letter in the product name, except that the ingredients of the mixture may be in print not less than one-eighth the size of the most prominent letter in the product name. The specific name of the ingredients, d-alpha-tocopherol or dl-alpha-tocopherol, and of the carrier must be listed as such in the ingredients statement or curing statement, as required by 9 CFR 317.2(f)(1).

Lamb Curry

Product must contain at least 50% fresh meat.

Landjaeger Cervelat

A semi-dry sausage that originated in Switzerland. It is about the size of a large frankfurter but pressed flat, smoked and dried giving it a black appearance.

Lard Continuous Process

This nomenclature identifies the commodity produced from clean and sound edible tissues of swine by a low-temperature separation process in which the oil is separated from the fatty tissue by means of a combination of heat and centrifugal force. Labeling records containing the above designation should identify in detail the process and equipment used in producing the commodity.

Lard — Cured Pork Tissue Use

Cured pork trimmings may be rendered to produce lard manufactured in compliance with the lard and leaf lard standard. Rendered bacon is not acceptable in lard.

Lard Refined

This term is applied to open-kettle rendered, prime steam, or dry-rendered lard put through a filter press, with or without bleaching agent.

Lasagna

Sauce is an expected ingredient of lasagna products and its declaration in the product name is optional.

Cheese Lasagna with meat: 12% meat
Lasagna with Meat and Sauce: 12% meat
Lasagna with Meat Sauce: 6% meat in total product
Lasagna with Poultry: 8% poultry meat
Lasagna with Tomato Sauce, Cheese, and Pepperoni: 8% pepperoni
Meat Lasagna: 12% meat
Poultry Lasagna: 8% poultry meat

Lau–Lau

Product must contain at least 25% meat. A Hawaiian dish made with pork and fish, wrapped in taro leaves. Label must have a true product name, e.g., "Pork and Fish Stuffed Taro Leaves."

Lebanon Bologna

A coarse ground, fermented, semi-dry sausage. If the product has a MPR of 3.1:1 or less and a pH of 5.0 or less, no refrigeration is required. It is made with beef. No extenders or hearts are permitted in the product. This is not a 9 CFR 319.180 product.

Legends

Products consisting of mixed meat and poultry ingredients shall bear either the official meat inspection legend or poultry legend, depending on which ingredients are present in the greater amounts. If meat or poultry ingredients exist in equal proportions, either official legend may be used. If meat and poultry ingredients exist in exact proportions and both appear in the product name, the official legend must reflect the ingredient appearing first in the product name.

Lentil Soup with Bacon — German Style

Acceptable name for a lentil soup containing only bacon. The bacon requirement is 4.0% for condensed and 2.0% for ready to eat.

Leona

An acceptable name. A coarse ground cooked sausage.

Lima Beans with Ham or Bacon in Sauce

Product must contain at least 12% ham or bacon.
See: 9 CFR 319.310.

Linguica

A Portuguese type sausage containing pork and excluding other meat and meat byproducts. Usually contains nonfat dry milk and condiments, e.g., vinegar, cinnamon, cumin seed, garlic, red pepper, salt, and sugar. Paprika and cures are acceptable in this product.

Links

This designation falls into four categories:

1. "Links" without further qualification refers to an all pork fresh sausage in links.
2. "Links Sausage" can be used to designate any sausage type formulation usually cured and smoked in links, except for those formulations containing poultry.
3. "Links cereal and nonfat dry milk added" usually formulated with meat and meat byproducts cured and smoked, and approved with the understanding each link is banded with an approved band label.
4. "Links, A pork and textured vegetable protein product" followed immediately by the ingredients statement is acceptable. "Links," "Top's Links," "Joe's Links" are coined names and must be followed immediately by true product name.

Little Smokies

A smoked small variety sausage link made with beef and pork.

Liver and Onions

Product must contain at least 45% liver.

Liver, Chopped

Product must contain at least 50% liver.

Liver, Onions, and Eggs

Product must contain at least 40% liver.

Liver Products

The product name does not have to include the species for multi-ingredient liver products, such as chopped liver, liver pate, and pureed liver. However, the species must be identified in the ingredients statement. For single ingredient liver products, such as sliced beef liver, the species must be identified in the product name. "Kind" of liver must always be identified.

Products with liver in the name (except for products listed) must contain a minimum of 30% liver.

Liver Spread (Streich Leberwurst)

The product name "Liver Spread (Stretch Leberwurst)" is acceptable. Product name must contain at least 30% liver in total formulation.

Liverwurst or "Pate De Foie — Style Liverwurst"

Product must meet liver sausage requirements. (See Regulation 9 CFR 319.182.)

Loaf

A "Loaf" (other than meat loaf) consists of meat in combination with any of a wide range of nonmeat ingredients. These products are not identified with the term "Meat Loaf," "Beef Loaf," or the like but with designations, e.g., "Olive Loaf," "Pickle and Pimiento Loaf," "Honey Loaf," "Luxury Loaf," and others that are descriptive.

Loaf, Canned, Perishable

Canned perishable products in the loaf category must:

1. Meet the perishable requirements. (See 9 CFR 317.2(k).)
2. Show a brine concentration of not less than 3.5% in finished product. Show a brine concentration of not less than 6.0% when the products contain cereal, starch, or other extenders.
3. Be cooked to a minimum internal temperature of at least than 150°F.
4. When extenders are added the product name must be qualified, e.g., "(Name of extender) added."

Lola and Lolita (IT)

Dry sausage products of Italian origin. Consists of mildly seasoned pork and contains garlic. Lolita comes in 14 oz. links, while Lola comes in 2 1/2 lb. links.

London Broil

Name can only be applied to a cooked product. Products including the expression "London Broil" on labels must be prepared with beef flank steak. Uncooked product must be labeled to indicate this, e.g., "Beef Flank Steak for London

Broil." If prepared from another cut, the identity of that cut must accompany the term "London Broil," e.g., "Sirloin Tip London Broil."

Long Island Style or Type

Not acceptable for poultry products.

Longaniza

Longaniza is a fresh sausage product. If it is prepared otherwise, the product name must indicate its nature, e.g., "Cured Longaniza." Paprika is an acceptable ingredient because it is expected.

Longaniza and Puerto Rican Style Longaniza

Longaniza is an acceptable name for Puerto Rican sausage made from pork which may contain beef but does not contain annatto. Added fat is not permitted.

Puerto Rican Style Longaniza is acceptable labeling for sausage made from pork which may contain beef and does contain annatto. Added fat is not permitted, although up to 3% lard may be used as a carrier for annatto. When annatto is used, it should be included in the ingredients statement as "annatto" in accordance with Section 9 CFR 317.2(j)(5) of the meat inspection regulations.

Loukanika

An acceptable name for cooked fresh Greek sausage. It is usually made with lamb and pork, oranges, allspice, whole pepper, and salt.

Lumpia or Loompya

A Philippine style or Filipino style egg roll. There are no special ingredient requirements, it refers to a shape of the egg roll. Lumpia or Loompya are generally longer and thinner than traditional egg rolls.

Luncheon Meat

1. "Luncheon Meat" cannot contain livers, kidneys, blood, detached skin, partially defatted pork or beef tissue, or stomachs.
2. On the label the meat components of "Luncheon Meat" are identified in the ingredients statement as "beef," "pork," "beef tongue meat," "pork tongue meat," "beef heart meat," and "pork heart meat."
3. In the ingredients statement "Beef" and "Pork" means lean meat with overlying fat and the portions of sinew, nerve, and the blood vessels which normally accompany muscle tissue and which are not separated in the process of dressing but not including bone and skin. Up to 10% of the meat portion of the formula can consist of cured and smoked meat trimmings which does not require special declaration in the ingredients statement except included under "pork" and "beef."
4. Heart or heart muscle, tongues, or tongue meat and cheek meat can be included in "Luncheon Meat" under the following restrictions:
   a. Hearts or heart meat or tongues or tongue meat must be declared individually by species in the ingredients statement on the label.
   b. No restriction on the percentage limits of hearts, heart meats, tongues, and tongue meats in the formulation.
   c. The terms "heart meat" and "tongue meat" refer to the muscle tissue remaining after heart caps, glands, nodes, connective tissue, etc. are trimmed away.
5. Water added to "Luncheon Meat" during manufacture cannot exceed 3% by weight of the total ingredients, this is controlled by weighing ingredients and not by analysis. Care must be used to see that water is not added indirectly through the use of undrained hearts and tongues.
6. The only ingredients permitted in "Luncheon Meat" are curing ingredients, sweetening agents, spices, and flavoring. All of these substances must be declared in the ingredients statement by name, except the various "flavorings" and "spices" which need not be named individually. "Spices" refer to natural spices and not to extracts.

Lyoner Wurst

A cooked, smoked, and finely ground sausage originating in Germany. It is usually made with beef, pork, (no chicken) flavoring, cure, and contains green peppercorns.

Lyons Sausage (FR)

A dry sausage made exclusively of pork (four parts finely chopped lean and one or two parts small diced fat) with spices and garlic which is stuffed into large casings, cured and air-dried.

Macaroni and Beef in Sauce

Product must contain at least 12% beef.

Macaroni and Cheese with Ham

Product must contain at least 12% cooked ham.

Macaroni Salad with (Meat or Poultry)

Product must contain at least 12% cooked meat or poultry meat.

Made with … Qualifiers

Need only mention the species or kind in the statement even when only a byproduct of the specific species or kind is used, e.g., pork, chicken and beef hearts in a sausage would carry a qualifier "made with pork, chicken and beef."

Made with 100% Real Cheese

This statement is acceptable on products as long as the cheese components are all 100% real cheese. It is not acceptable if a cheese food product or imitation cheese is included in the formula.

Malic Acid

Malic acid has been used extensively for many years as part of flavoring/seasoning mixtures which are added to components of meat or poultry products. It may be approved as a flavoring agent, and is acceptable as a component in a seasoning mix, e.g., in marinades and sauces, but may not be added alone to a product.

Manicotti (IT)

Product must contain at least 10% fresh meat. An Italian main dish consisting of rectangular-shaped pasta spread with a filling of meat (e.g., sausage, ground beef, or chopped prosciutto) and/or cheeses (e.g., ricotta and mozzarella). The pasta is rolled, edges pressed to seal, and covered with grated parmesan cheese and tomato sauce. A true product name must be shown, e.g., "Beef Manicotti in Sauce."

Margarine Substitutes

Meat food products that are substitutes for margarine because they contain less than 80% fat and/or oil need not be labeled "imitation" if the product has a fully descriptive name and the finished product contains 15,000 international units of Vitamin A per pound.

The descriptive name of the product may include the term "Spread" (or "Spred"), which has been widely adopted as a generic fanciful name for this class of product.

The following guidelines shall be used in selecting the appropriate descriptive product name:

1. "Animal Fat Spread (or Spred)" is an acceptable product name for a product prepared from animal fat as the sole source of fat.
2. "Animal Fat and Vegetable Oil Spread (or Spred)" is an acceptable product name for a product prepared with a combination of animal fat(s) and vegetable oil(s) in which the vegetable oil(s) content is greater than 20% of the total of the fat(s) and oil(s) used but less than 50% of the total.
3. "Animal Fat Spread (or Spred) — Vegetable Oil Added" is an acceptable product name for a product prepared with a combination of animal fat(s) and vegetable oil(s) in which the vegetable oil(s) content is 20% or less of the total of the fat(s) and oil(s) used but greater than 2% of the total.
4. The fanciful name "Spread" (or "Spred") accompanied by a list of all ingredients individually identified by their common or usual name in order of decreasing predominance is acceptable regardless of the nature and amount of fat(s) and/or oil(s) used.

In 1, 2, and 3 above, the descriptive product name may include the % of each fat and/or oil and may include the common or usual name of each fat and/or oil used.

Marengo

Product must contain at least 35% cooked meat or poultry meat. It has chicken or veal in a sauce containing tomatoes, mushrooms, onions, and wine, and label must show true product name, e.g., "Chicken Marengo."

Marinated

To be labeled "marinated," a product must use a marinade that is a mixture in which food is either soaked, massaged, tumbled, or injected in order to improve taste, tenderness, or other sensory attributes, e.g., color or juiciness. Time allotted in a marinade depends on many factors, e.g., thickness and size of the meat and strength of the marinade. Marinade should be that amount necessary to affect the finished product, and limited to 10% pickup in red meat, 8% pickup in boneless poultry and 3% in bone-in poultry.

Marine Oil

Herring oil and other marine species oils found by FDA to be satisfactory may be combined with animal and mixture of animal and vegetable oils processed as meat food products. Labels will bear statements identifying the presence of such substances, e.g., a shortening consisting of 50% herring oil and the remainder equal amounts of animal and vegetable oils would be "Shortening, Prepared with Herring Oil, Animal and Vegetable Oils."

Marking

Labeling may consist of a combination of printing, stenciling, box dyes, etc. for large true containers and for shipping containers. Crayons are unacceptable for applying required labeling features except for figures indicating content quantity. Approval of official marks appearing in newspaper advertisements, billboards, etc. is not necessary; however,

such marks may be reviewed locally before publication. Such markings should conform to the illustrations in the regulations and not be misleading.

"May Contain" Statements

The use of "may contain" or "and/or" labeling may be used in the ingredients statement's sublisting of sliced and/or diced products from various sources.

See: "Composite Ingredients Statement."

Meat and Dressing

Product must contain at least 50% cooked meat.

Meat and Dressing with Gravy

Product must contain at least 30% cooked meat.

Meat Base

A granular, paste-like product which is shelf-stable primarily because of its high salt content (30–40%).

1. Beef Base — 15% beef or 10.5% cooked beef
2. Pork Base — 15% pork or 10.5% cooked pork
3. Ham Base — 18% ham

Meat Broth or Meat Stock

MPR 135:1. Condensed 67:1.

Meat Byproducts

Byproducts must be individually declared by species and specific name in the ingredients statement, e.g., Pork Liver, Beef Tripe, and Beef fat.

Meat Casseroles

Product must contain at least 25% meat or 18% cooked meat.

Meat Curry

Product must contain at least 50% meat.

Meat Flavoring

Meat flavoring — when characteristic meat flavorings such as bacon are added in amounts less than 2% in addition to the required meat component of a product, such meat flavorings need not appear in the product label.

Meat Foldover Mit Dressing

Product must contain at least 50% meat (chopped and formed).

Meat Food Products Containing Poultry Ingredients — Labeling

Meat food products containing poultry ingredients in amounts that exceed 20% of the total livestock and poultry product portion of the meat food product must have product names that indicate the presence of the poultry ingredients, e.g., "Beef and Chicken Chili" or "Chili made with Beef and Chicken."

Meat food products containing poultry ingredients in amounts at 20% or less of the total livestock and poultry product portion of the meat food product must have product names that are qualified to indicate the presence of the poultry ingredients, e.g., "Beef Stew — Turkey Added."

However, meat food products that do not meet specified minimum livestock ingredient requirements because poultry ingredients are replacing any part of the required livestock ingredients must have product names that indicate the presence of the poultry ingredients, e.g., "Beef and Turkey Stew" or "Stew Made with Beef and Turkey."

This policy does not apply to: (1) red meat products that are expected to contain poultry ingredients, e.g., "Brunswick Stew and Potted Meat Food Product" (Section 9 CFR 319.761); (2) cooked sausages identified in Section 9 CFR 319.180 of the meat regulations (Policy Memo 005A); or (3) nonspecific loaves, rolls, logs, etc., e.g., Pickle and Pimento Loaf.

Meat Loaf

Uncooked or cooked pork, beef, veal or lamb, and other ingredients in loaf form, but not canned.

1. Ingredients, e.g., cracker meal, oatmeal, bread crumbs, nonfat dry milk, soy ingredients (untextured), milk, and whole eggs are not required in the product name.
2. Product may contain:
   a. Head meat, cheek meat, heart meat, and tongue meat under label declaration in the ingredients statement only.
   b. Not more than 12% extenders and binders.
   c. Partially defatted chopped beef or pork up to 25% and declared as meat in the ingredients statement.
3. Product must contain at least 65% meat.
4. Onion, tomato juice, water, and other liquid extenders are not directly controlled.

Meat Loaf, Canned (Perishable)

Canned perishable products in the loaf category must:

1. Meet the perishable labeling requirements. See: 9 CFR 317.2(k),

2. Be cured with at least 1 ounce nitrate per 100 pounds of product and 1/2% dextrose or 1% sugar.
3. Have a brine concentration of at least 3.5% in the finished product. Products that contain cereal, starch, or other extenders must have a brine concentration of at least 6.1%.

Meat Loaf, Canned (Sterile Packed)

No head, cheek, heart, or tongue meat permitted. Other requirements are the same as uncanned cured meat loaf. Binders and extenders must be shown in the product name, e.g., "Meat Loaf, cereal added."

Meat Pasty or Pasties

Product must contain at least 25% meat. The label must show the true product name, e.g., "Beef Pasty."

Meat Pie Filling

Product must contain at least 37% meat.

Meat Pies (or Vegetable Meat Pies)

Product must contain 25% meat; meat in gravy may be counted towards meat content.

Meat/Poultry Extended Products

These should always be listed in the ingredients statement of the secondary product by their correct name, e.g., "Beef, water and binder product," unless it is included in the name of the product, e.g., "Chili made with beef and binder product."

Meat Ravioli

Product must contain at least 10% meat in ravioli.

Meat Ravioli in Meat Sauce

Product must contain at least 10% meat in ravioli and at least 50% ravioli in total product, and at least 6% meat in sauce.

Meat Ravioli in Sauce

Product must contain at least 10% meat in the ravioli and at least 50% ravioli in the total product.

Meat Sauce

Product must contain at least 6% ground meat.

Meat Spreads

Product must contain at least 50% meat or 35% cooked meat. When another major component is considered a significant source of protein such as cheese is added the requirement is reduced to 25% cooked meat. Product must show a true product name, e.g., "Sausage and Cheese Spread."

Meat Stick and Cheese Combination Products

The following criteria are used for dry meat stick and cheese combination products that need not bear a "keep refrigerated" handling statement.

1. The dry meat stick portion must have a water activity of less than 0.90, the cheese portion must have a water activity of less than 0.94, and the equilibrium of the water activity of the two components must be no greater than 0.92;
2. the dry meat portion, if fermented, must be fermented by an active fermentation culture (typically to a pH 5.0 or below) and;
3. for products where the meat portion and the cheese portion are packaged together, there must be a heat seal between the dry meat stick and cheese components which separates the meat stick from the cheese stick by at least 4 mm.
4. Dry meat stick and cheese combination products not meeting these criteria must be labeled with a "keep refrigerated" statement in lieu of compelling data that establish safety.

Products not meeting the criteria stated above can be labeled without a "keep refrigerated" statement if a control program ensuring safety and shelf stability is established by the establishment.

Meatballs

Uncooked or cooked pork, beef, veal, and lamb, and other ingredients in a ball form.

1. Product must contain at least 65% meat.
2. Binders and extenders are limited to 12% of the total product. 6.8% of isolated soy protein is considered the equivalent to 12% of the other binders or extenders. The permitted binders and extenders include, but are not limited to, cereal, bread crumbs, cracker meal, soy flour, soy protein concentrate, isolated soy protein, and textured vegetable protein.
3. Cheeks, hearts, and tongues are not allowed, but product may contain head meat, cheek meat, heart meat, and tongue meat when declared in the ingredients statement.

4. Partially defatted chopped (PDC) (species) may be used up to 25% of the meat block. PDC (species) can be identified as (species) in the ingredients statements. [See entry for Partially Defatted Chopped (species).]

Meatballs in Sauce

Requires a 50% minimum of meatballs, by weight in finished product.

Meatball Stew

Meatball stew contains at least 25% meatballs and usually contains vegetables such as potatoes, peas, carrots, etc., and gravy or thick broth resulting from cooking all ingredients together. The meatballs must meet the Meatball Standard.

Meatballs, Swedish Style

Product must contain at least 65% fresh meat. "Swedish Meatballs" or "Swedish Style Meatballs" are small in size and usually contain two or three different varieties of meat, nutmeg and/or allspice, potatoes, and milk. "Swedish Brand Meatballs Made in USA" means any meatball.

Meatballs, Turkey

Product must contain at least 65% raw turkey meat. Skin is permitted in natural proportions of meat used, if skin is in excess of natural proportions, it shall be reflected in the product name.

Mediterranean Style

Acceptable identification for product containing onion or garlic, olive oil and four of any of the following groups:

1. Vegetable or fruit: dried apricot, artichoke, dried date, dried fig, eggplant, tomato, pepper (green or red), squash, lemon or lemon juice, raisin and olives.
2. Legume or nut: fava bean, chick pea, white cannelloni bean, green bean, lentil, almond, pine nut, pistachio.
3. Seasoning: dill, coriander, cinnamon, cumin, fennel, basil, oregano, thyme, saffron, rosemary, parsley, mint, sumac, turmeric.
4. A regional dish as component, e.g., pita bread, yogurt, Italian or Greek type cheese, pasta, couscous or bulgur.

Merguez, Mergues or Merghez Sausage

A hot and spicy fresh sausage originating in North Africa and common in France which contains hot pepper and/or paprika. The meat component must contain beef and may contain lamb or mutton when labeled as "Merguez Sausage." When pork is used as part of meat component, the product is labeled as "Merguez Sausage with Pork." When pork is the only meat ingredient, the product is labeled "Pork Merguez Sausage."

Methyl Cellulose

May be used as an ingredient in formulas for meat and vegetable patties and various poultry products (mainly patties) at a level of 0.15% of the total weight of the product, which includes batter and breading of these products.

The internal technical effect is to extend and to stabilize products as well as to act as a carrier.

See: 421.24(4) and 9 CFR 381.147(f)(4).

Mettwurst

An uncooked cured smoked sausage in which byproducts and extenders are not permitted. Beef heart meat is acceptable. Water is limited to 3% and the fat content shall not exceed 50%.

Mettwurst, Cooked

Mettwurst which is cooked must be labeled "Cooked Mettwurst," and may contain up to 10% water based on the finished product.

Metz Sausage

Cured lean beef and pork and bacon are finely chopped, seasoned, and stuffed into beef middles. It is air-dried for 5 days, then given a cool smoke. It is classed as a semi-dry sausage.

Mexican Style

Acceptable for products that contain at least four of the following: jalapeno peppers, chili peppers, green chilies, cumin, cayenne peppers, red or green peppers, chili powder, jalapeno powder, Monterey Jack cheese, or cheddar cheese. This policy applies to a single food and does not supersede Policy Memo 068.

Mexican Style Dinners

Products like tamales, enchiladas, and tacos must make up 25% of the dinner or entree to qualify as "Mexican Style." The individual product standard must also be met.

Mexican Style Sauces

A garnish (decoration) of cheese in or on the sauce of Mexican style foods does not require the presence of the cheese to be declared in the product name or qualifying statement.

Milan or Milano Salami

A dry sausage with a maximum MPR of 1.9:1. It is an Italian-type salami, except the meat is finely cut. It is made with beef, pork fat, spiced with garlic, and has a distinctive cording.

Mince Meat

Product must contain at least 12% fresh meat or 9% cooked meat. Heart meat may be substituted. In addition to "Mince Meat," the product name should include kinds of meat, e.g., "Mince Meat with Beef" or "Mince Meat with (species) Heart Meat." When 2% or more cooked meat but less than 9% cooked meat is present in the formula, the product is amenable and the name must state that the product is "Mince Meat Flavored With ____."

A product marketed as "Mince Meat" which contains less than 2% cooked meat or contains only beef suet as the ingredient of animal origin, is not considered as a meat food product and is not amenable.

Mixtures

Mixtures of nonfat dry milk (NFDM), calcium reduced dry skim milk (CRDSM), or dried whey, reduced lactose whey, reduced minerals whey, and whey protein concentrate with other substances are not allowed, except in batter and gravy mixes and breaders. Mixtures of cereal, soy preparations and/or sodium caseinate with other substances are permitted to come into the plant for use in batter and gravy mixes, but they must be labeled to show their intended use, e.g., "Patty Mix" or "Gravy Mix." The labels of the mixtures must show the ingredients in order of their predominance.

Mock Drumsticks

An imitation product; nonspecific.

Mock Turtle Soup

Product must contain at least 10% beef and may be made with beef and beef byproducts.

Mofongo

Pork skins and plantain type product with at least 20% pork skins in the total formulation. It must show true product name, e.g., "Pork Skin Filling Wrapped in Plantain."

Moisture Protein Ratio (MPR)

Frizzes 1.6:1 Ukrainian Sausage 2.0:1 Jerky 0.75:1 Kippered Beef 2.03:1 Pepperoni 1.6:1 Dry Salami 1.9:1 Dry Sausage 1.9:1 Genoa Salami 2.3:1 Tropic Cure Pork 3.25:1 Sicilian Salami 2.3:1 Thuringer 3.7:1 Italian Salami 1.9:1 Dried Meat 2.04:1 Roast Beef, Canned 2.25:1 Chipped Beef 2.04:1 Farmer Summer Sausage 1.9:1.

Moisture Protein Ratio (MPR) — PH

Nonrefrigerated or shelf-stable sausages must have an MPR of 3.1:1 or less and a pH of 5.0 or less, unless commercially sterilized. This does not apply to products containing more than 3.5% binders or 2% isolated soy protein.

Mondongo

A mixture of one or more of the following: (a) beef tripe, (b) cattle feet with or without hide on, (c) chitterlings, and (d) beef intestines.

See: Beef Tripe Stew.

Morcella Blood Pudding

Nonspecific. The product is made from pork fat, beef blood and/or pork blood, and may contain meat.

Mortadella

Normally a cooked sausage but can be dry or semi-dry. It is similar to salami and cervelat except that it has large chunks of pork fat. Red sweet peppers up to 4% and pistachio nuts up to 1% are acceptable as long as they are shown in the true product name.

Mortadella (Canned)

Canned items designated "Mortadella" must be labeled with the phrase "Perishable, Keep Under Refrigeration" and must have an MPR of 3.85:1 or less.

Mortadella — Poultry

Poultry Mortadella is a dry, semi-dry, or cooked sausage formulated with poultry. The sausage must contain large chunks of pork fat and may contain extenders and/or binders. Red sweet peppers are permitted up to 4% and pistachio nuts up to 1% and shown as added in the true product name.

If product is canned, the MPR must not exceed 3.85:1, the internal temperature must have reached 160°F and the product labeled "Perishable, Keep Under Refrigeration" or similar wording.

Mortadella without Fat Cubes or Chunks

Product must meet the standard for Mortadella and the label be qualified to indicate the absence of Fat Cubes or Chunks, e.g., "Mortadella without Fat Cubes" or "Mortadella without Fat Chunks."

Mousaka, Moussaka, Musaka (GK)

Must contain at least 25% meat. Mousaka is a casserole containing layers of meat and eggplant made in various

ways throughout the Middle East. A true product name is required, e.g., "Eggplant and Meat Casserole."

Mullicatawny Soup

Product must contain at least 2% cooked poultry meat and enough curry powder and pepper to characterize the product. The label must show a true product name, e.g., "Chicken Mullicatawny Soup."

Mulligan Stew

Product must contain at least 25% fresh meat or meat and poultry. Mulligan stew is a mixture of vegetables and meat combined in a gravy or sauce. The label must have a true product name, e.g., "Chicken and Meat Mulligan Stew."

Mustard Bran

This is not considered a spice and must be declared as "Mustard Bran." It is not acceptable in sausage.

Mustard Flour

It is a spice that is commonly used in sausage products.

Myvacet

(Distilled Acetylated Monoglycerides). Acceptable for use as a coating on sausage casings. Sausages coated with Myvacet shall show, adjacent to the product name, a qualifying statement disclosing the presence of the compound, e.g., "Summer Sausage Coated with a Solution of Distilled Acetylated Monoglycerides."

Nacho Style, Nacho Flavor, and Similar Terms

Acceptable terminology for products possessing the commonly expected flavor characteristics associated with "Nachos," a Mexican hors d'oeurve. The characterizing flavor components generally include, but are not limited to, cheese (Cheddar or Monterey Jack), tomato (tomato solids, tomato powder), spices, or other natural seasonings and flavorings (usually garlic and onion), and chili peppers (mild or hot). Romano and Parmesan cheese are also often present. However, these cheeses may not be used to satisfy the above cheese requirement.

Natural Claims

The term "natural" may be used on labeling for meat products and poultry products, provided the applicant for such labeling demonstrates that:

1. The product does not contain any artificial flavor or flavoring, coloring ingredient, or chemical preservative (as defined in 21 CFR 101.22), or any other artificial or synthetic ingredient; and
2. The product and its ingredients are not more than minimally processed. Minimal processing may include:
   (a) those traditional processes used to make food edible or to preserve it or to make it safe for human consumption, e.g., smoking, roasting, freezing, drying, and fermenting, or
   (b) those physical processes which do not fundamentally alter the raw product and/or which only separate a whole, intact food into component parts, e.g., grinding meat, separating eggs into albumen and yolk, and pressing fruits to produce juices.

Relatively severe processes, e.g., solvent extraction, acid hydrolysis, and chemical bleaching would clearly be considered more than minimal processing. Thus, the use of a natural flavor or flavoring in compliance with 21 CFR 101.22 which has undergone more than minimal processing would place a product in which it is used outside the scope of these guidelines. However, the presence of an ingredient which has been more than minimally processed would not necessarily preclude the product from being promoted as natural. Exceptions of this type may be granted on a case-by-case basis if it can be demonstrated that the use of such an ingredient would not significantly change the character of the product to the point that it could no longer be considered a natural product. In such cases, the natural claim must be qualified to clearly and conspicuously identify the ingredient, e.g., contains refined sugar.

All products claiming to be natural or a natural food should be accompanied by a brief statement which explains what is meant by the term natural, i.e., that the product is a natural food because it contains no artificial ingredients and is only minimally processed. This statement should appear directly beneath or beside all natural claims or, if elsewhere on the principal display panel, an asterisk should be used to tie the explanation to the claim.

The decision to approve or deny the use of a natural claim may be affected by the specific context in which the claim is made. For example, claims indicating that a product is natural food, e.g., "Natural chili" or "chili — a natural product" would be unacceptable for a product containing beet powder which artificially colors the finished product. However, "all natural ingredients" might be an acceptable claim for such a product.

Natural Smoked Color

Approval can be properly granted to labels with this statement when the products involved are "Smoked" and not artificially colored. The results of the use of artificial smoke materials can, by means of a number of processing operations, result in a color characteristic being acquired by the

frankfurters, bologna, and the like. The term "Natural Smoked Color" can be used to properly identify this point.

Navarin

Navarin is a stew containing lamb or mutton and vegetables and considered a national dish of France. It must meet the meat stew standard of 25% meat. Show true product name, e.g., "Navarin-Lamb Stew."

Negative Labeling

1. Negative labeling is allowed if it is unclear from the product name that the ingredient is not present. For example, the use of the term "no beef" on the label of "turkey pastrami" would further clarify that the product does not contain beef.
2. Negative labeling is allowed if the statement is beneficial for health, religious preference, or other similar reasons. For example, highlighting the absence of salt in a product would be helpful to those persons on sodium-restricted diets.
3. Negative labeling is allowed if the claims are directly linked to the product packaging, as opposed to the product itself. For example, flexible retortable pouches could bear the statement "no preservatives, refrigeration or freezing needed with this new packaging method."
4. Negative labeling is allowed if such claims call attention to the absence of ingredients because they are prohibited in a product by regulation or policy. The statement must clearly and prominently indicate this fact, so as not to mislead or create false impressions. For example, "USDA regulations prohibit the use of preservatives in this product" would be an acceptable statement for ground beef.
5. Negative labeling is allowed to indicate that absence of an ingredient when that ingredient is expected or permitted by regulation or policy. This could also apply to ingredients which are not expected or permitted by regulation or policy if the ingredients could find their way into the product through a component. For example, the use of "no preservatives" on the label of "spaghetti with meat and sauce" (where regulations do not permit the direct addition of preservatives) would be acceptable if the product contained an ingredient, such as cooking oil, which could contain antioxidants but do not.

These guidelines do not preempt the requirements of the nutrition labeling regulation. Therefore, negative claims such as "unsalted" would have to comply with the provisions stated in the nutrition labeling regulations.

Net Quantity of Contents on Combination Packages

The guidelines for stating the net quantity of contents on combination packages containing both liquid and solid products are as follows:

1. The declaration of net quantity of contents for a combination package shall be expressed in terms of fluid measure for individual products that are liquid and in terms of avoirdupois weight for individual products that are solid, semisolid, or viscous, provided the quantity statements for identical packages or units are combined. For example, the fruit drink would be expressed in fluid measure and the meat, cheese, crackers, and cookies would be expressed in the combined avoirdupois weight.
2. The declaration of quantity shall be preceded by one of the following terms, as appropriate: "Net Weight," "Net Wt.," or "Net Contents."

   The net quantity of contents declaration may appear in more than one line. Therefore, both stacked and side-by-side declarations would be considered appropriate.
   - Descriptive terms may be used to identify the liquid and solid components of the package, e.g., entree, meal, or drink; however, such terms shall not include brand names.
   - Connecting words such as "and" or "plus" are permitted to be used as part of the declaration of contents.

   Examples of acceptable net content declarations are as follows:
   - Entree Net Wt. 8 oz., Drink 4 fl. oz. (120 ml)
   - Net Contents: lunch 8 oz. plus fruit drink 4 fl. oz.
   - Net Wt. 8 oz. Drink 4 fl. oz. (120 ml)
   - Net Weight 8 oz. and 4 fl. oz.

Federally inspected meat and poultry products are exempt from the requirements of the Fair Packaging and Labeling Act (FPLA), including the mandatory metric labeling provisions that went into effect February 14, 1994. However, if metric labeling is included voluntarily, such labeling should comply with the FPLA.

The guidelines contained in this policy memo will be subject to the provisions prescribed in 9 CFR 317.2(h) and 9 CFR 381.121 of the Federal regulations.

Net Weight Statement

1. Divider Pak

On a product where two cans are taped together, one of which contains the meat or poultry item and the other a

vegetable, e.g., "Chicken Chow Mein," the meat or poultry label may include the net weight on the 20% panel. The vegetable can bears the true name of the product with the total net weight of the other can and the drained weight of the vegetable can.

2. Double Packing

When a poultry product and a non-poultry product are separately wrapped and placed in a single immediate container bearing the name of both products, the net weight shown on the immediate container may be the total net weight of the two products or the net weight of the poultry product and the non-poultry product separately.

3. Additional Net Weight Information

Nonregulatory information of a net weight nature, e.g., 4–3 oz. packages, accompanying a net weight statement is acceptable and need not adhere to the size and spacing restrictions.

4. Open Net Weights

Open net weights may be presented in pounds and ounces, decimals, decimal fractions, or fractions, e.g., 1½ lbs., 1.6 lbs.

5. Net Weight Requirements

The statement of net quantity of contents is required on all products intended for sale at retail intact. In addition, shipping containers must bear a net quantity of contents statement if product inside is not uniform in weight (i.e., random weight). Piece counts may not be used in lieu of a required net quantity of contents statement on a shipping container but may be used as additional information.

6. Multi-Unit Retail Packages

Fully labeled packages of more than one of the same meat or poultry product packages in an open (i.e., clear) overwrap do not have to include a net weight statement.

See: 9 CFR 317.2(h), and 9 CFR 381.121(b).

Net Weight Statements on Packages with Header Labels

The guidelines for determining the size and location of net weight statements on meat food product packages with header labels are as follows:

1. The entire front of the package is considered the principal display panel of the package and its area is used to determine the size of the net weight statement. Print size specifications for the net weight statement specified by the regulations must be followed.
2. The net weight statement should be placed within the lower 30% area of the header label if no other mandatory labeling features are printed on the rest of the principal display panel of the package. If mandatory features do appear below the header label, the net weight statement must be placed within the lower 30% of the total area containing any mandatory information.

A "Header Label" is a small label applied across the top of a package usually bearing all of the mandatory labeling information. The rest of the package is most often a clear film containing a meat or poultry product, e.g., luncheon meat. This type of packaging is designed to be used on pegboard type displays.

"New" and Similar Terms

Terms like "new," "now," "improved," and similar terms may be used within the following guidelines:

1. The terms may only be used for a period of 6 months from the date of the initial approval, except as noted in 2, 3, and 4 below.
2. Extensions to the 6-month period may be granted if:
   a. Processors can demonstrate that production or distribution delays precluded the use of the approved labeling as scheduled. In such situations, the lost time can be restored.
   b. Processors can demonstrate that labeling inventory needs for the 6-month period were over estimated due to poor sales. The processors must maintain records which indicate the amount and the date the labeling was originally purchased. In this situation, up to an additional 6 months can be granted. No further extension will be considered.
3. In those situations where it is customary to distribute "new" products to various geographical regions, each geographic area may receive a sketch approval for 6 months if the processor can assure adequate controls over the segregation and distribution of the products.
4. In situations where it is customary to test market product in no more than approximately 15% of the intended total marketing area before total distribution begins, labeling for the test market area can receive a sketch approval and also be included in the 6-month sketch approval given to the labeling of the product distributed to the total marketing area. Processors must be able to assure that only 15% of the total market is involved in test marketing.

New England Boiled Dinner

Product must contain at least 25% cooked "Corned Beef."

New Orleans Style

Acceptable for products that contain any five of the following ingredients:

Roux base, rice, onion, green onions garlic, celery, bell peppers, cayenne pepper, white pepper, parsley, or tomato.

The product may contain various protein sources including seafood and game.

Nitrite

Calculations should be based on the total meat block including the muscle tissue, fat and blood (e.g., "Blood Pudding"). If the product is cured, the blood would be included and considered part of the meat.

Non-Amenable Product/Voluntary Inspection

[Examples of non-amenable products are sandwiches containing meat or poultry, clam chowder which has less than 1% bacon for export to Japan, and natural casings for export]. Any non-amenable product can be produced under voluntary inspection when requested [9 CFR 318.13 and Subchapter B, Part 350.3(c)]. However, most FSIS requirements have to be met concerning labeling, i.e., mandatory labeling features, an accurate ingredients statement, handling statement, etc. Safe Handling Instructions are not required even for raw non-amenable products. FDA nutrition labeling rules apply to such products.

Non-Dairy White Sauce or Non-Dairy Sauce

A sauce made with a non-dairy creamer. If this type of a sauce is proposed for use with "Chipped Beef," a suitable name would be "Non-Dairy White Sauce with Chipped Beef" or "Non-Dairy Sauce with Chipped Beef." The reference to "Cream" or any of its derivations should not appear in the product name.

Nonspecific Meat Food Products

Red meat items of this type do not have specific requirements, i.e., they do not possess a standard of identity or composition. Consequently, these products shall be identified by one of two ways: (1) A descriptive name that identifies characterizing components and/or ingredients, or (2) a fanciful or coined name that is accompanied by an ingredients statement. The latter approach should be used when the use of a descriptive name is not practical, e.g., when the descriptive name would read like an ingredients statement.

When a fanciful name or coined name is used, the ingredients statement should appear contiguous to the product name on the principal display panel of an immediate container.

Nonstandardized Cooked Sausage Products Containing Both Livestock and Poultry Ingredients

The labeling of nonstandardized cooked sausage products must comply with 9 CFR 319.180.

Meat food products are those in which more than 50% of the livestock and poultry product portion consists of livestock ingredients. Such cooked sausage products which contain poultry ingredients at more than 15% of the total ingredients (excluding water) must have product names that indicate the species of livestock and kind(s) of poultry ingredients, e.g., "Beef and Turkey Frankfurter" or "Frankfurter Made From Beef and Turkey."

Poultry food products are those in which more than 50% of the livestock and poultry products portion consists of poultry. Livestock ingredients at more than 20% of the total poultry and livestock ingredients must have product names that indicate the kind(s) of poultry and species of livestock ingredients, e.g., "Turkey and Beef Frankfurter" or "Frankfurter Made from Turkey and Beef." Such cooked sausage products which contain livestock ingredients at 20% or less of the total poultry and livestock ingredients must have product names that are appropriately qualified to indicate the inclusion of livestock ingredients, e.g., "Turkey Frankfurter — Pork Added or Turkey Frankfurter" — With Pork." (The product names of cooked sausage products which contain no livestock ingredients designate the kind(s) of poultry ingredients, e.g., "Turkey Frankfurter.") Cooked sausage products containing over 50% meat ingredients would carry the red meat legend while those containing over 50% poultry ingredients would carry the poultry legend.

Noodle Chicken Vegetable Dinner or Noodle Chicken Dinner with Vegetables

(Canned or in glass jars). Product must contain at least 6% cooked chicken.

Nugget Labeling

Nuggets are irregularly shaped, usually bite-sized meat and/or poultry products which are usually breaded and deep fat fried and intended to be used as finger foods. There are a number of different types of nuggets, the labeling for which is:

1. Products made from a solid piece of meat or poultry may use the term "Nugget" as part of the product name without further qualification (e.g., "Chicken Nugget," "Beef Nugget").
2. Products made from chopped and formed meat or poultry may use the term "Nugget" as part of the product name, provided a qualifying statement describing such process is shown

contiguous to the product name (e.g., "Chicken Nugget, Chopped and Formed" or "Beef Nugget, Chopped and Formed").

3. Products made from chopped meat or poultry and containing binders, extenders and/or water may use the term "Nugget" as a fanciful name, provided a descriptive name immediately follows "Species" or "Kind" nugget (e.g., "Breaded Nugget-Shaped Chicken Patties").
4. Products described in (1), (2), and (3) above which are breaded shall be labeled as "breaded" and shall be limited to 30% breading.

Oat Fiber

"Oat fiber," should be identified in the ingredients statement as "isolated oat product." It may be used in non-standardized products and in products, such as, "taco fillings."

Oleomargarine

The Establishment Number may be omitted from the outer container, provided that articles are completely labeled including Establishment Number inside.

See: 9 CFR 317.2(i).

Omelet, Denver or Western Style

Product must contain at least 18% ham with onions and green and/or red peppers.

Omelet, Florentine

Product must contain at least 9% cooked meat and must contain spinach.

Omelets with

Bacon — must contain at least 9% cooked bacon
Chicken Livers — must contain at least 12% cooked liver
Corned Beef Hash — must contain at least 25% corned beef hash
Creamed Beef — must contain at least 25% creamed beef
Ham — must contain at least 18% cooked ham
Sausage — must contain at least 12% dry sausage
Sausage and Cheese (omelet with pepperoni, cheese and sauce) — must contain at least 9% sausage in the total product.

Open Dating

Labels showing further qualifying phrases in addition to the explanatory phrase must submit with the application sufficient documentation to support these additional claims. See [9 CFR 317.8(b)(32) and 9 CFR 381.129(c)]. Some local authorities require that packaged foods heated and sold hot from industrial catering vehicles be dated with the day the foods were placed in the warming units (e.g., Tuesday, Friday, etc.). When assured by the local authorities that the foods are under a rigid local inspection program, the designations may be approved without an explanatory statement as required by the regulations. To date, only the county of Los Angeles, California, has provided this assurance.

The packing date should be shown on immediate or shipping containers of poultry food products as required by regulations [9 CFR 381.126 and 381.129(c)]. When meat or poultry products are packed and held in freezer storage for later repacking, the explanatory phrase on repacked product should be in terms of "sell by" or "use before." However, if a "packed on" phrase is desired, the date shown shall be that of the original packing of the product.

Ostrich and other Ratites (Emu)

Products that do not contain 3% of beef, pork, chicken or turkey, can not contain cure ingredients, i.e., Nitrite, nitrate.

Paella Con Bacalao (SP)

Product must contain at least 35% cooked meat or poultry meat and include seafood and no more than 25% cooked rice. The label must show true product name, e.g., "Beef and Fish with Rice."

Papain

Meat and poultry products that are dipped in a solution containing papain shall show in conjunction with the product name a statement, e.g., "Tenderized with a solution of (list ingredients of solution)." Carcasses of animals treated with papain by ante-mortem injection shall be roller branded "Tendered with Papain." Parts not so marked shall be labeled as "Tendered with Papain."

See: 9 CFR 317.8(b) (25) 9 CFR 381.120

See Enzymes-Proteolytic.

Paprika

Generally, paprika and/or oleoresin of paprika are not permitted in or on fresh red meat products, fresh ground poultry, or fresh poultry sausage. They are permitted under the following conditions:

1. In both red meat and poultry products where such ingredients are acceptable and expected, including Italian Sausage, Salisica, Chorizo, Longaniza, and Hungarian Style products. All requests for additional products should be referred to the Labeling and Consumer Protection Staff to determine their acceptability.

2. On red meat products where their use does not misrepresent the leanness or freshness, e.g., application to a surface layer of fat and not to the muscle tissue. However, the name must be appropriately qualified, e.g., "coated with paprika" or "artificially colored."
3. In or on products where they are expected and the product name discloses this fact, or the product name refers to a component expected to contain the ingredients. Examples include: "Beef with Barbecue Sauce," "Beef — Barbecue Flavor," "Chicken Paprikash," "Chicken with Orange Sauce," or similar type products.
4. In fresh whole muscle poultry products, provided their presence is properly described, e.g., "coated with paprika," or "artificially colored," as appropriate.

Partially Cooked

1. Partially cooked bacon — acceptable nomenclature if shrink requirement for fully cooked bacon is not met must meet requirements for trichinae treatment. Cooking instructions are required.
2. Partially cooked poultry — unacceptable for cooked poultry products.

Partially Defatted (Beef or Pork) Fatty Tissue

These are byproducts produced from fatty trimmings containing less than 12% lean meat. These ingredients may be used in meat products in which byproducts are acceptable. Products include nonspecific loaves, beef patties, frankfurters with byproducts, bologna with variety meats, imitation sausage, potted meat food product, sauces, or gravies. May be used in excess of the amounts of meat necessary to satisfy the standard for only the products listed in the Policy Book. However, in this situation, the PDCB or PDCP must always be declared in the ingredients statement.

See: 9 CFR 319.15(e) 9 CFR 319.29(a).

Partially Defatted Chopped (Beef or Pork) (PDCB, PDCP)

1. Partially Defatted Chopped Beef is not permitted in hamburger, ground or chopped beef. The School Lunch Program requires that when PDCB is used in products like taco mix, which later may be used in preparing other products

The Amount and Labeling of PDCB and PDCP in Food Products

Class	Food Category	Amount	Labeling
I	Beef Patties	No Limit	Beef or Pork, or both
	Imitation Sausage	No Limit	Beef or Pork, or both
	Non Specific Loaf	No Limit	Beef or Pork, or both
	Potted Meat Food Product	No Limit	Beef or Pork, or both
	Patty Mix	No Limit	Always must be declared
	Beef for Roasting	12% of Meat Block	
II	Chinese Eggroll and other Chinese Specialties	Up to 12% of the Meat Block	Beef or Pork
	Chopped Beef Steak	Up to 12% of the Meat Block	Beef or Pork
	Corned Beef Hash	Up to 12% of the Meat Block	Beef or Pork
	Fabricated Steaks	Up to 12% of the Meat Block	Beef or Pork
	Pepper Steak	Up to 12% of the Meat Block	Beef or Pork
	Salisbury Steak	Up to 12% of the Meat Block	Beef or Pork
	Luncheon Meat (nonspecific)	Up to 25% of Meat Block	
	Pizza Meat Topping	Up to 25% of Meat Block	Beef or Pork
	Pizza With Meat	Up to 25% of Meat Block	Beef or Pork
	Cooked Sausage (9 CFR 319.180 (b))	Up to 15% of Meat Block	Always must be declared
	Pepperoni	Up to 15% of Meat Block	Must be declared
III	Chili	Up to 25% of Meat Block or larger	As beef; or pork, if larger must be declared
	Meat Loaf	Up to 25% of Meat Block or larger	As beef; or pork, if larger must be declared
	Meat Balls	Up to 25% of Meat Block or larger	As beef; or pork, if larger must be declared
	Meat Fillings for Tacos, Burritos, Enchiladas, Tamales and other Mexican Foods	Up to 25% of Meat Block or larger	As beef; or pork, if larger must be declared
IV	Corned Beef Hash	Up to 12% of Total Product Formulation	Beef

Note: All percentages as calculated on the basis of the fresh weight of meat content.

(e.g., tacos or patties), the PDCB or PDCP must always be declared in the ingredients statement on the labeling of the taco mix. All Beef or 100% Beef is acceptable as product name.

2. Partially Defatted Chopped may be used in excess of meat necessary to satisfy the standards on only the products listed in the Policy Book. However, in this situation, the PDCP must always be declared in the ingredients statement.

Partially Defatted Cooked (Beef or Pork) Fatty Tissue

This product may be used as an ingredient in: beef patties (cooked and uncooked), potted meat food product, sauces, gravies, imitation sausage, and nonspecific loaves. No limit on quantity is made. It is believed to be self-limiting.

Partially Hydrolyzed Whey Protein

An acceptable ingredient name for a binder.

Pastelles (SP)

Product must contain at least 10% fresh meat. Product is always made with pork in Puerto Rico. The label must show the true product name, e.g., "Pork Pastelles."

Pastellillos (SP)

Puerto Rican Style product containing at least 8% cooked meat. Species is part of the product name. The label must show the true product name, e.g., "Pork Pastellillos."

Pastitsio

(Greek for casserole). Product must contain at least 25% fresh meat or 18% cooked meat. A product containing macaroni, ground beef, tomato paste, wine, white sauce, and Parmesan cheese that may be labeled "Greek Style Pastitsio."

Pastrami

Cooked cured beef with spices, generally made from the plate but other cuts can be used. The product must be smoked or treated with smoke flavoring. "Pastrami, Water Added" is not permitted, although similar products labeled according to Policy Memo 084A are permitted. The term "Unsmoked Cooked Pastrami" must be used when the product is not smoked or does not contain smoke flavoring. Pastrami may or may not be coated with spices. When product is coated, a qualifier is not required.

Pastrami Jerky

Acceptable name for product processed as pastrami prior to meeting the requirements for jerky.

Pastrami, Turkey

A cured turkey product that is cooked. The product must be smoked or treated with smoke flavoring. The term "Unsmoked Cooked Turkey Pastrami" must be used when the product is not smoked or does not contain smoke flavoring. Cured turkey thigh meat is an acceptable name.

Pate De Foie

Product must contain at least 30% liver. Pate means paste; foie means liver.
See: **Foile Gras Products**.

Pattie Fold Over Mit Dressing

Product must contain at least 50% pattie.

Patties

Chopped and shaped and similar terms not required on products labeled patties.

1. Paprika not permitted in fresh meat patties.
2. PDCB or PDCP may be listed as beef or pork, except in patties with mechanically separated (species) product and school lunch labeled products.
3. PDBFT and PDPFT permitted. Must show as such in the ingredients statement.
4. Meat patties, with added fat up to 20% of the meat block, from a source other than that shown in the name, show as added (ex., Veal Patties, Beef Fat Added): over 20% to be part of the product name, e.g., "Veal and Beef Fat Patties."
5. Ground beef patties — no extenders or water added. Hamburger patties — no extenders or water added. Same requirement as hamburger.
6. Pre-broiled beef patties with simulated stripes (patties are deposited on conveyor and pre-broiled). Parallel stripes are applied with a solution of caramel coloring and water through parallel spigots. Product name will identify artificial color marks on the label.
7. Antioxidants are permitted in pork or beef patties both raw and cooked.
8. Beef Patties: If beef byproducts are added which are not permitted by the standard, the list of ingredients must immediately follow the product name. See: 9 CFR 319.15(c).
9. Pork Patties: The standard for beef patties 9 CFR 319.15(c) shall be applied with the exception that the species is pork.

Paupiette (FR)

Thinly sliced pieces of meat stuffed and rolled. Same standard as "Beef Roulade," which is at least 50% cooked meat.

Peanut Flour

Can only be used in nonspecific products that are not subject to moisture controls.

Pectin

Can be used at a maximum use level of 3% in nonstandardized meat and poultry food products. The common and usual name of the ingredient, regardless of its source, is "pectin" (21 CFR 184.1588).

Pepper

The term "pepper:" as used in the Italian sausage regulation refers to the pungent spices, such as: black, white, cayenne, or red pepper. "Paprika" as an optional ingredient is less pungent and is used primarily for its coloring qualities. Bell peppers, chilies, paprika and cayenne or red pepper, are from the capsicum pepper family. These products have specific uses and are recognized by specific names. "Paprika" should not be substituted for "pepper" in a meat or poultry food product.

Pepperoni

A dry sausage prepared from pork or pork and beef. Combinations containing more than 55% beef are called beef and pork pepperoni. Pepperoni made with beef must be called beef pepperoni. Pepperoni must be treated for destruction of possible live trichinae and must have an MPR of 1.6:1 or less. Antioxidants are permitted in pepperoni. The casing, before stuffing, or the finished product, may be dipped in a potassium sorbate solution to retard mold growth. Extenders and binders are not permitted in pepperoni. Hearts, tongues, and other byproducts are not acceptable ingredients.

Pepperoni, Cooked

Cooked pepperoni is not an acceptable product name.

Pepperoni with Poultry

Poultry may be added to pepperoni if properly labeled. If the meat block contains 20% or less poultry, the product is labeled "Pepperoni with Turkey (kind) Added." When poultry over 20% of the meat and poultry block product is labeled "Pork and Turkey (kind) Pepperoni," an MPR of 1.6:1 is applied. If the amount of poultry exceeds that of the meat, the product label reads "Turkey and Pork Pepperoni." This would carry a poultry legend.

Peppers and Cooked Sausage in Sauce

Product must contain at least 20% cooked sausage in total formulation.

Perishable Uncured Meat and Poultry Products in Hermetically Sealed Containers

Establishments seeking approval of label applications for perishable, uncured products which have received a less rigorous heat treatment than traditionally canned product (9 CFR 318 and 381, SUBPARTS G and X, respectively) must submit a sufficiently detailed processing procedure either incorporated on or attached to the FSIS Form 7234-1, APPLICATION FOR APPROVALS OF LABELS, MARKING OR DEVICE. The procedure must include a description of product formulation, method(s) of preparation, cooking and cooling temperatures, type of container, and cooking and handling instructions.

Hermetically sealed containers include glass jars, metal cans, flexible retortable pouches, plastic semi-rigid containers, etc., that are airtight and/or impervious after filling and sealing.

The policy does not apply to raw meat or poultry, cooked or roast beef, cooked poultry rolls and similar products, whole or uncut cured products, or products that are distributed and marketed frozen. However, products containing cured meat or poultry as components in combination with raw vegetables, e.g., pasta salads and other chilled meat/poultry meals or entrees containing raw or partially cooked vegetables, are covered under this policy, provided the above-mentioned procedural attributes are indicative of the manufacturing process.

In addition, an approved partial quality control program (PQCP) is required which must address the critical points in the manufacturing process. As such, the PQCP must contain a detailed description of: ingredient storage controls, product formulation and preparation, container filling and sealing, any heat treatment (times/temperatures) applied, including a description of the equipment used, any other treatments applied, cooling procedures (times/ temperatures), lot identification procedures; finished product storage conditions, inplant quality control procedures, and records maintenance procedures. The PQCP must be forwarded to the Processed Products Inspection Division (PPID) for appropriate review and approval before the product label may be used. Guidelines for development of PQCP's for these products may be obtained from PPID upon request.

Pet Food

1. Certified pet food is manufactured under fee-for-service inspection in a facility approved for the manufacture of animal food. Labeling regulations for certified animal food specify that approval is granted by the labeling staff. However, final approvals are not granted since LCPS no longer grants final approvals. Rather, the company should keep a copy of the final label attached to the sketch approval.

2. Most food for animal consumption produced in a Federal facility is non-certified. It is not an inspected product; therefore, it is inedible product and does not bear any mark of inspection. The product has to be conspicuously labeled to distinguish it from human food. Additionally, the labeling must be in conformance with 21 CFR Part 501, Animal Food Labeling since animal food labeling is also under the jurisdiction of the Food and Drug Administration.

Pfefferwurst (GR)

Product should conform to sausage standard and contain whole peppercorn. Pork livers, pork stock, and beef blood are not acceptable ingredients.

Phosphated Trimmings in Loaves

Trimmings from preparation of pork cuts, cured with approved phosphates besides other curing ingredients, may be used without limitation in loaves other than meat loaves. When such trimmings are used, phosphates may be listed in the ingredients statement using the term "sodium phosphates" or other applicable generic terms.

Phosphates in Dipping Solutions Containing Proteolytic Enzymes

Phosphates have been approved for use as buffering agents in dry mixtures intended for solutions containing proteolytic enzymes. The phosphates should not exceed 0.1% of the "tenderizing" solution if they are to be considered incidental additives.

Picadillo (SP)

Product must contain at least 35% cooked meat. A Mexican style hash usually made with beef, garlic, onions, vinegar, and raisins. The species should be in the product name, e.g., "Beef Picadillo."

Pickled Products, Dry Packed

Products that are pickled and dry packed should be qualified with the name of the pickle as part of the product name, e.g., "Knockwurst Pickled with Vinegar," or "Knockwurst Pickled." The weight of the package shall be the weight of the product less the weight of the pickle that will weep out of the product.

Pie Filling

Product must contain at least 37% meat. Poultry pie filling must contain at least 18.75% cooked poultry meat.

Pies

Product must contain at least 25% meat. Meat in the gravy may be counted. Poultry pies require at least 14% cooked poultry meat.

Pies, English Style–Australian Style

Product must contain at least 25% meat or meat byproduct. Contains gravy and no vegetables with a puff pastry top.

Pimento (SP)

Refers to allspice, but must be specifically named. It is also known as Jamaica pepper.

Pimiento Sausage

Pimientos permitted when declared in product name as "Pimiento Sausage."

Pinkelwurst (GR)

A cooked product that is stuffed in a casing with a diameter of from 1½ to 2 inches and a length of about 10 to 12 inches. It is formulated with beef fat, pork fat, onions, oat groats, water, and sufficient spice to satisfy seasoning requirements.

Piroshki or Pirogi

Product must contain at least 10% cooked meat. A Russian or Jewish dish made of thin rolled dough or pastry that is filled and either steamed, baked, or fried. They resemble small turnovers, pockets, or raviolis.

Pizza

The required meat fill is to be calculated on the stated net weight of the product, not on the formula weight.
(See: 9 CFR 319.600) with

Meat: At least 15% meat
Sausage: At least 12% cooked sausage or 10% dry sausage (e.g., pepperoni)
Poultry: At least 12% cooked poultry meat.
Bacon: At least 9% cooked bacon.
Chili with beans: At least 25% chili with beans.
Meat Pattie Crumble: At least 15% pattie crumbles (fresh) or 12% cooked.

An antioxidant used in pepperoni or sausage need only be reflected in the ingredients statement as "BHA or BHT added to improve stability."

Pizza, Chicago Style

Acceptable labeling for a product which has been manufactured by first placing the cheese on the crust, then following with the meat and then the sauce. Condimental

quantities of a grated cheese may then be placed on the top. The product usually has the deep dish characteristics. The requirements for pizza as designated in 9 CFR 319.600 and various policies must be met.

Pizza, Combination or Deluxe

Product must meet the requirements for pizza as designated in 9 CFR 319.600. In a combination pizza, e.g., "Sausage and Pepperoni Pizza," the component declared last must be at least 25% of its required level in a pizza containing a single meat component.

Pizza Containing Cheese Substitutes

Meat requirements of 9 CFR 319.600 must be met. Labels which contain cheese in a ratio less than one part cheese to nine parts cheese substitute must contain additional qualifying information. Example: Pizza — Sausage, cheese substitute and cheese; Combination Pizza — Sausage — Pepperoni — Imitation Cheese and Cheese.

Pizza Dogs

A nonspecific product.

Pizza, Pan Style

Pizza that is marketed in a pan and contains a thick crust.

Pizza Pups

Product has two crusts, filled with a mixture of pork, tomato puree, and condimental substances. The finished article is approximately 8 inches in length, 2½ inches wide with a thickness of ¾ inches. It is a type of pizza. The label must show a true product name, e.g., "Pork and Sauce Filling in A Crust."

Pizza Roll

This is a nonspecific meat food product. When the name appears on a label, there must be a contiguous statement identifying the major components of the product or a complete ingredient listing. There are two major types of pizza rolls. One is a cooked sausage-like meat food product that contains cheese, usually contains peppers and has no water limitation. The second type consists of a roll-shaped dough enclosure with various fillings. A manufacturer of the latter type of product has asserted trademark protection of the term "pizza roll."

Pizza Sausage

Not an acceptable name. Product must be labeled "Sausage for Pizza."

Pizza, Sicilian Style

A thick crust pizza. The crust is usually 50% or greater of the total pizza product.

Pizza Topping Containing Sausage

The sausage portion of cooked pizza topping is permitted to contain up to 10% water and 3.5% binders (9 CFR 319.140). In addition, the application must indicate the sausage portion within the pizza topping formula. However, the ingredients statement of the cooked pizza topping does not have to list "sausage" in its sublisting. There are no restrictions on the amount of seasonings in the sausage portion.

1. Pizza topping must be cooked
2. In the sausage portion:
   a. Water $<10\%$ of the sausage portion
   b. Binders including TV $<3.5\%$ of the sausage portion
   c. Seasonings are unlimited
3. The ingredients statement of the pizza topping can be arranged in different ways:
   a. Composite e.g., cooked pizza topping [port, water, TVP (…), Seasonings (…)]
   b. Component, e.g., cooked pizza topping [sausage (pork, water, seasonings (…), TVP (…), water (…)].

These parameters do not apply when specific sausage products are governed by other regulations, e.g., Italian Sausage. In these situations, the specific regulation (i.e., Italian Sausage) dictates the requirements, such as, the amount of water permitted and binders are permitted.

Pizza Topping Mix

A nonspecific product, including those products which indicate the type of meat or poultry in the product name (e.g., Chicken and Pork Pizza Topping or Beef Pizza Topping). Antioxidants are permitted, see 9 CFR 318.7(c)(4). Water, extenders, and binders are acceptable.

Pizza, Word Size

When a pizza has a true product name, e.g., "Combination Sausage and Pepperoni Pizza," the true product name must be prominent, conspicuous, and legible, with all words at least one-third the size of the largest letter in any word of the product name. If on the label the manufacturer also elects to display elsewhere the word "Pizza" in exaggerated fashion, the word "Pizza" is not considered in the determination of the size of the letters within the true product name.

PFF (Protein Fat Free) Adjusting for Use

Protein Fat Free (PFF) controlled cured pork products with qualifying statements, e.g., "Ham-Water Added," may be

used in place of PFF controlled cured pork products without qualifying statements, e.g., Ham, to meet the minimum meat requirements of various products. However, the amounts of the PFF controlled cured pork products with qualifying statements used will need to be increased. For example, if a standard requires a certain amount of Ham and a processor wishes to use "Ham-Water Added," a greater amount of the "Ham-Water Added" will be needed to meet the standard. The magnitude of the additional amount is directly related to the relationship between the respective PFF values.

Example: Ham Salad requires 35% Cooked Ham. "Ham Water Added" will be used in the product formula.
Calculation: Multiply the PFF value for Ham (20.5) by the amount of required Ham (35%). Divide this answer by the PFF value of the product being used to formulate the product. (In this example, PFF value for "Ham-Water Added" is 17.0.)
Answer: [(0.35 × 20.5)/17.0] × 100 = 42.21% "Ham-Water Added" needed in the formula.

Example: Ham Pie requires 25% Ham based on green weight. "Ham with Natural Juices" will be used in the product formula.
Calculation: Multiply the PFF value for Ham (20.5) by the amount of required ham (25%). Divide this answer by the PFF value of the product being used to formulate the product.
(In this example, PFF value for "Ham with Natural Juices" is 18.5.)
Answer: [(0.25 × 20.5)/18.5] × 100 = 27.70% "Ham with Natural Juices" needed in the formula.

1. Adjusting for "Ham and Water Product X% of the Weight is Added Ingredients"

Consider a formulated product which is required to contain at least 50% Cooked Ham. If the processor chooses to use a "Ham and Water Product (HWP)" in which 20% of the weight is added ingredients as the source of the Ham in the formulation, this product contains 80% Ham and 20% added ingredients. Clearly, the processor must use more than 50% HWP in the process. Using 50% HWP would result in only 40% Ham in the finished product, i.e., the added ingredients in the HWP represents 25% of the ham content. (If it were a 10 lb. HWP, there would be 8 lbs. of Ham and 2 lbs. of added ingredients (2/8 × 100 = 25%)). Consequently, an additional 25% of HWP is required in the formulation.

The following example may be used to determine the percentage HWP needed to equal Ham:

Ham and Gravy requires 50% Cooked Ham. "Ham and Water Product 20% of Weight is Added Ingredients" will be used in the formulation.

Step 1: Subtract the % added ingredients from 100%. (In this example: 1.00 − 0.20 = 0.80)
Step 2: Determine the amount of Ham needed in the formula. (In this example: 50%)
Step 3: Divide the amount of Ham required. Determined in Step 2 by the answer in Step 1 (In this example: (0.50/0.80 = 0.625))
Step 4: Multiply the answer in Step 3 by 100. Answer for this example is 62.50% "Ham and 20% Water Product" is needed as the equivalent of 50% Ham.

Plantation

The regulations and policies applicable to "Farm" also apply to plantation.

Point of Purchase Materials

Point of purchase materials which refer to specific meat or poultry products are considered labeling under certain circumstances. When printed and/or graphic informational materials (e.g., pamphlets, brochures, posters, etc.) accompany or are applied to products or any of their containers or wrappers at the point of purchase, such materials and the claims that they bear are deemed labeling and they are subject to the provisions of the Federal Meat Inspection Act and the Poultry Products Inspection Act.

Although the Food Labeling Division (FLD) does not exercise its authority to subject point of purchase materials to specific prior approval (materials shipped with the products from the federally inspected establishment are an exception), we do expect point of purchase materials to be in accordance with the Federal regulations and all current labeling policies. Upon request, FLD will review and comment on the point of purchase materials submitted to our office. During the review process, promotional materials will be scrutinized for special claims, particularly those related to nutrition, diet, and animal husbandry practices.

Claims related to nutrition and diet must be made in accordance with all current nutrition labeling regulations. Continuing compliance with stated claims will be assured through periodic sampling, as necessary. Claims are expected to be within the compliance parameters identified in the nutrition labeling regulations.

Animal husbandry claims (e.g., the nonuse of antibiotics or growth stimulants) may be made only for products shipped in containers or wrappers labeled with the same animal production claims.

Polish Sausage

A sausage that is cured, cooked, and usually smoked. Pork and pork byproducts shall comprise at least 50% of the meat and meat byproducts ingredients. To have beef as a predominant ingredient, the product name would be "Beef and Pork Polish Sausage." Green peppers are permitted up to 4% in total formulation.

An uncured (fresh), uncooked variety with no more than 3% water also exists. "Fresh" shall be used in the name when the product is uncured. When Fresh Polish Sausage is cooked or smoked, then the product name is either "Cooked Fresh Polish Sausage" or "Smoked Fresh Polish Sausage." The requirements of Policy Memo 110 apply when these perishable, cooked, uncured products are packaged in hermetically sealed containers.

Polynesian Style Sausage

Product must contain fruit juices, a sweetening agent, and soy sauce.

Polysorbate

Permitted in pickling solutions without declaration.

Pork and Bacon Sausage

Up to 50% bacon permitted provided:

1. Bacon is brought back to green weight before use
2. Product is trichinae treated
3. Product name is "Pork and Bacon Sausage"

The standard for "Pork Sausage and/with Bacon" is 10 to 20% bacon, and for "Pork and Bacon Sausage" is more than 20% but not more than 50% bacon.

Pork and Dressing

Product must contain at least 50% cooked pork.

Pork and Dressing with Gravy

Product must contain at least 30% pork.

Pork Cracklings

Product eligible to be labeled as "Pork Cracklings" must be prepared from fatty tissues from which the skin has been detached. If the skin is not removed from the product before rendering, a descriptive name, e.g., "Pork Cracklings, Fried-Out Pork Fat with Attached Skin," must be used.

Pork Fat

Pork fat shall be declared as such in the ingredients statement. Clear fatbacks and clear shoulder plates must be declared as "Pork Fat." Pork fat may be declared as pork in the ingredients statement if it contains visible lean and it is used in a standardized product which has a fat limitation.

Pork Jowls

Product may be declared as pork if skinned.

See: Pork Skins.

Pork Sausage

Product identified as pork sausage does not include the use of pork cheeks. When such an item is offered as "Whole Hog," tongues, hearts, and cheeks may be used in the natural proportion as found in the hog carcass. "Fresh" shall be used in the name when the product is not cured, cooked and/or smoked.

Pork Skin Residue after Gelatin Extraction

This material consists of back fat skins from which the gelatin has been extracted by means of soaking the skin in acid and subsequent low temperature cooking for the extraction of gelatin. It is not permitted in sausage but may be used in imitation sausage, potted meat food product, loaves (other than meat loaves), and other nonspecific products.

Pork Skins

Not permitted in salami, bologna, frankfurters, Vienna sausage, and braunschweiger. When packed in vinegar pickle, they are not permitted to be artificially colored. When pork skin, either attached to fat and/or muscle tissue or detached from fat and/or muscle tissue, is used to manufacture meat or poultry products, it must be specifically listed in the formulation on the label approval application form and in the ingredients statement on the label, e.g., "Pork Skins," "Unskinned Pork Jowls," "Unskinned Pork Shoulder Trimming," "Unskinned Pork Fat," and "Unskinned Pork Bellies."

"Detached skin" refers to the portion of skin from which most of the underlying fat is removed, e.g., skin from bacon intended for slicing, skin from closely skinned hams, shoulder cuts, fat backs, etc. If removal of skin portions is incidental to removal of a considerable proportion of underlying fat from ham, shoulder, back, etc., preparatory to rendering such fat, portions of skin so removed should not be regarded as detached skin and may be included with fats and rendered into lard. Ham facings are not regarded as detached skin.

Pork Skins, Fried

When prepared from the skin of smoked pork bellies, it may be labeled as "Fried Bacon Skins," "Fried Bacon Rinds," or "Fried Pork Skins." The kind of skin used must be stated on the labeling records when submitted for label approvals.

Pork Spare Ribs, Center Cut

Center cut pork spare ribs refers to pork spare ribs with the loin portion, the brisket (brisket must be removed at a point which is dorsal to the curvature of the costal cartilages), the tail and two ribs from the shoulder removed, this remaining center section may be further portioned or left in one piece.

Pork Spareribs, St. Louis Style

St. Louis Style Spare Ribs are the same as "Pork Spareribs" except that the sternum and the ventral portion of the costal cartilages are removed with the flank portion. This cut is made at a point in which the sternum and costal cartilages are removed dorsal to the curvature of the costal cartilages. If specified by the purchaser, the diaphragm shall be removed.

This anatomical description of the cut must be provided with the information for label approval.

Potato Sausage, Swedish Style or Potato Ring Swedish Style

A cooked or uncooked meat food product with the following requirements:

1. At least 45% meat and no byproducts.
2. Water limited to 3% at formulation.
3. Extenders or binders limited to 3.5% of the finished product, except that 2% of isolated soy protein shall be deemed to be equivalent of 3.5% of any of the other binders or extenders.
4. Contains at least 18% potato.

Poultry

Cuts of poultry that are not identified in 9 CFR 381.168, Table V, may use the maximum amount of poultry skin permitted for that "kind." For example, "turkey" is listed in the table and may contain up to 15% skin. Therefore, a product identified as "white turkey" can be placed in this category for a maximum of 15% skin.

Poultry Standards

Name	**Minimum or Maximum percentage**
Poultry a la King	At least 20% poultry meat
Poultry Barbecue	At least 40% poultry meat
Poultry, Breaded	No more than 30% breading
Poultry, Brunswick Stew	At least 12% poultry meat
Brunswick Stew with Poultry	At least 8% poultry meat
Poultry Burgers	
Poultry Cacciatore	
Poultry Canneloni	
Poultry Chili	
Poultry Chili with Beans	
Poultry Chop Suey	
Chop Suey with Poultry	
Poultry Creole with Rice	
Poultry Chow Mein (w/o noodles)	
Poultry Croquettes	
Poultry, Creamed	
Poultry Dinners	
Poultry Fricassee	
Poultry Fricassee with Wings	
Poultry Gizzards and Gravy	

Name	**Minimum or Maximum percentage**
Poultry Hash	100% meat with skin and fat in natural proportions
Poultry Liver	At least 20% poultry meat or 40% with bone.
Omelet Poultry	At least 7% poultry meat
Meatloaf	At least 28% poultry meat
Poultry Noodle Dinner	At least 17% poultry meat
	At least 4% poultry meat
	At least 2% poultry meat
	At least 35% cooked poultry meat and sauce portion. Not more than 50% cooked rice in total product
	At least 4% poultry meat
	At least 25% poultry meat
	At least 20% poultry meat
	At least 18% poultry meat
	At least 20% poultry meat
	At least 40% poultry wings (cooked basis with bone)
	At least 35% cooked gizzards
	At least 30% poultry meat
	At least 12% cooked poultry liver
	At least 65% raw poultry or 50% poultry meat and at least 15% poultry meat
Poultry Noodle Dinner with Gravy	
Poultry with Noodles or Dumplings	
Noodles or Dumplings with Poultry	
Poultry Paella	
Poultry Parmigiana	
Poultry Pies	
Poultry Ravioli	
Poultry Salad Mix	
Poultry Salad	
Poultry Soup	
Poultry-Flavored Soup	
Poultry Spread	
Poultry Stew	

Name	**Minimum or Maximum percentage**
Poultry Stew with Dumplings	At least 15% poultry meat or 30% poultry meat with bone
Poultry Subgum	At least 6% poultry meat
Poultry Tamales	
Poultry Tetrazzini	

At least 35% poultry meat or 35% poultry meat and other meat, no more than 35% cooked rice, must contain seafood
At least 40% breaded poultry See: Veal Parmigiana
At least 14% poultry meat
At least 2% poultry meat
At least 45% poultry
At least 25% poultry See: Salad, Poultry
At least 2% poultry meat
No minimum requirement (less than 2% poultry meat)
At least 30% poultry
At least 12% poultry meat
Minimum or Maximum Percentage
At least 8.4% poultry meat (Based on 70% of Stew requirement)
At least 12% poultry
At least 6% poultry meat
At least 15% poultry meat
Poultry Turnover
Poultry with Gravy/Sauce
Gravy with Poultry
Poultry with Gravy and Dressing
Poultry with Rice
Poultry Scrapple
Poultry with Vegetables

Poultry, Assorted Pieces

At least 14% poultry meat
At least 35% poultry meat
At least 15% poultry meat
At least 25% poultry meat
At least 15% poultry meat
At least 30% poultry and/or poultry byproducts
At least 15% poultry meat

The product name "Poultry (Kind) Assorted Pieces" is acceptable and does not require the product to be in natural proportions. In addition, the term "piece" is not the same as the term "part," i.e., a piece does not have to be a whole part, e.g., a breast, thigh, or drumstick.

Poultry Bacon

See: Bacon-Like Products.

Poultry Breasts

When poultry breasts with ribs are boned and the resulting product contains portions of the scapula (shoulder) muscles and/or muscle overlying the vertebral ribs, they must be labeled to indicate that fact. Proper names for such products are "Boneless Breast with Rib Meat," "White Chicken Meat or White Turkey Meat," or if the skin is left intact, "White Boneless Chicken or White Boneless Turkey." Product labeled "Boneless Breast" without further qualification may not contain scapula or rib meat.

Poultry Frankfurters (Similar Cooked Sausages)

Products which contain pork fat must be labeled with pork fat added in the product name.

Poultry Grading (Labeling)

Indicates the quality grades of poultry (U.S. grade A, B, or C). The shield design contains the letters "USDA," the U.S. grade of the product, and if not shown elsewhere, the class of poultry. Any letter grade on a consumer package or individual carcass indicates the product was graded by a licensed grader of the Federal or Federal-State grading service, and may not be applied otherwise. Letter grades on bulk packaging or shipping containers only indicate that the product is equal to that particular U.S. Grade.

1. Applying Grademarks to Shipping Containers

All poultry classes and kinds listed in 9 CFR 381.170, except necks, giblets, detached tails, wing tips, skin and stripped backs (below Grade C) are eligible for grading.

In addition, the following poultry parts may be officially graded:

Boneless, Skinless Breast and Thigh Tenderloin or Boneless Breast without Tenderloin
Boneless Breast Quarters
Breast Quarters with Bone in
Boneless Thigh Halves
Wing Portion or Section Breast Halves
Broiler Turkey or Duck Halves
Split Breast Split Fryers
Skinless, bone-in Thighs, Drums and Breasts
Boneless Breast, Thigh Bone-in products marinated in a colorless solution

Poultry cuts other than those identified above may not be eligible for grading; therefore, particular attention should be given to the product name when approving labels for various poultry products which include grade marks (e.g., "Thin Breast Fillets, Thigh Strips").

Grade marks on raw poultry parts processed with solutions that may impart color (e.g., injected with a solution of water, salt, butter) or cooked poultry products must include a statement, e.g., "Prepared from Grade A Poultry." The USDA grader in the plant makes the final determination concerning the necessity of the "Prepared from" statement in situations where it is not apparent at the time of label approval that the added solutions have the ability to impart color to the finished poultry product. Products which may not be grade marked:

Detached Necks
Giblets Packed Separately

Detached Tails Wings, Tips
Stripped Backs
Below C Quality Diced or Shredded Meat

2. Wing Descriptio

The wing is made up of three sections. The section attached to the carcass is the first section. The wing tip is the third section.

3. Grading Backs with Necks

In applying grade standards, when necks are packed with backs following these steps:

1. When backs are graded as provided for in the standards, the name of the product shall read as follows:
   a. Grade A Backs "with necks," or "and necks"
   b. Grade B Backs "with necks," or "and necks"
   c. Grade C Backs "with necks," "Graded backs and necks," or "backs and necks"
2. Necks are to be packed with backs in natural proportions.
3. Necks may or may not be attached to backs. Necks for all officially graded backs are to be free from serious discolorations, feathers, pin feathers, and accumulations of blood and/or excess water.
4. A neck, front, or hind portion of back, when removed from birds which meet the stated quality, may be used to achieve exact weights. Only one of these portions may be used per package. Scraps of backs or necks may not be used.
5. Labels for packages with portions must indicate which portions, e.g., first (1st) portion, 2nd portion, 1st and 2nd portions, 2nd and 3rd portions, etc.

4. Pressure Sensitive Stickers and Tape

1. Inserts or pressure sensitive stickers with the grademark must have plant number.
2. Grademarks on pressure sensitive tape should not be used on consumer packages.
3. Insert with the grademarks are not to be used inside opaque bags.

Poultry Hindquarters

The term "hindquarters" on labels for single cut poultry items is an acceptable alternative to the recognized terminology "Leg Quarter" specified in the regulations. The use of the term "Hindquarters" requires only a specified class of poultry to be considered a true product name, e.g., "Chicken Hindquarters." Either term refers to a poultry thigh and drumstick, with a portion of the back attached.

Poultry Hindsaddles

Poultry hindsaddles are connected poultry leg quarters (the rear of the bird). The product name "Poultry Hindsaddles" may be used alone on the product's label if the product is not intended for retail sale. In contrast, the name "poultry hindsaddles" on the label of a product intended for retail sale must be accompanied by a fully descriptive name (e.g., "Poultry Hindsaddles, Connected Leg Quarters").

Poultry Parts

Specific net weight packages for poultry parts, usually those containing legs or wings, include a single part, e.g., a drumstick or thigh, to make the stated weight. The name on the label must reflect this practice, e.g. "Chicken Legs — Chicken Thigh added to make weight." The single part must be cut at the joint. Wing tips are not permitted as added parts.

Poultry Products

In poultry products where "meat" appears in the product name, e.g., "White Meat Chicken Roll," and "Dark Meat Turkey Loaf," skin and attached fat are permitted in greater than natural proportions. However, the ingredients statement must have the poultry skin or poultry fat listed. When skin and attached fat appear in the ingredients statement, their placement should be in the correct order of predominance and determined by the amount present over the permitted natural proportions.

Poultry Products Containing Meat Ingredients-Labeling

Poultry products containing meat in amounts that exceed 20% of the total meat and poultry product portion of the poultry product must be descriptively labeled to indicate the presence of the meat ingredients, e.g., "Chicken and Beef Stew or Stew made with Chicken and Beef."

Poultry products containing meat ingredients in amounts at 20% or less of the total meat and poultry product portion of the poultry product must have names that are qualified to indicate the presence of the livestock ingredients, e.g., "Chicken Stew-Beef Added."

However, poultry products that do not meet specified minimum poultry ingredient requirements because meat ingredients are replacing any part of the required poultry ingredients must be descriptively labeled to indicate the presence of meat ingredients, e.g., "Turkey and Pork Chop Suey."

Poultry Products with other than Natural Proportions of White and Dark Poultry

Poultry products containing white and dark chicken or turkey of a distinguishable nature and in quantities other

than natural proportions of white to dark meat must bear a qualifying statement identifying the types of poultry meat used in conjunction with the kind of poultry in the product name. The poultry block of white and/dark meat [excluding products labeled as "Mechanically Separated (Kind of Poultry)"] solely determines the usage of the terms "white and dark," "dark and light," "white," "dark," etc. in the product name. Ground poultry (excluding the skin) that bears the terms "white/light," "dark," "breast," "thigh," etc. in the product names is also considered as part of the poultry block for determining the usage of terms "white and dark," "dark and light," "white," "dark," etc. However, products labeled as "Mechanically Separated (Kind)" do not have any bearing on the use of terms "white," "light" or "dark" in the product name since, "Mechanically Separated (Kind)" is as indistinguishable paste-like product that is considered a separated standardized poultry food product ingredient.

Additionally, products with mixture of distinguishable poultry (white or dark) and "Mechanically Separated (Kind)" can not bear claims of "all white," "pure breast," "100% dark," or similar terms. In this situation, the poultry portion of the product contains at least two separated poultry ingredients, or one of which is "Mechanically Separated (Kind)."

See: 9 CFR 381.117(c), Table 1.

Poultry Puffs

Product must contain at least 15% cooked poultry meat. Chicken or Turkey Puffs are classified as hors d'oeuvres and must show a true product name, e.g., "Breaded Chicken and Rice Balls."

Poultry, Raw Solution

Unless addressed by other regulations and policies, water and/or oil based solutions may be added to raw poultry and poultry parts at various levels with an appropriate qualifying statement to the product name.

The statement must include terms adequate to inform the consumer of the amount and manner of the addition and include the common or usual names of the ingredients in their proper order of predominance (e.g., "Injected with up to 12% of a solution of water, salt, and phosphates"). Other similar designations will be considered on their merits. The statement must be contiguous to the product name and printed in a style and color as prominent as the product name. The statement of the manner and amount of addition must be one-fourth the size of the most prominent letter in the product name. The ingredients of the solution can be printed one-eighth the size of the most prominent letter of the product name.

Terms like "Basted," "Marinated," "For Flavoring," and similar terms contemplated within the provisions of Section 9 CFR 381.169 of the poultry products inspection regulation cannot be used if the amount of the solution added is more than needed to baste, marinate, or flavor the product. Bone-in poultry and poultry parts are limited to 3% as prescribed by the regulations. Boneless poultry is limited to 8% to use these terms.

1986 Poultry Roast

May be formulated with up to 10% liquids without a qualifying statement. If more than 10% liquid is used, the name must be qualified with a statement, e.g., "containing up to x% …"

Poultry Salami Products

Poultry sausages prepared to resemble salami and offered to consumers as a salami shall bear product names as follows:

1. "(Kind) Salami" shall be the product name when the moisture-to-protein ratio in the finished product does not exceed 1.9:1. This product resembles a dry salami made from red meats.
2. "Cooked (Kind) Salami" shall be the product name when the product is cooked and the moisture-to-protein ratio is above 1.9:1. This product resembles "cooked salami" made from red meats.

Poultry Sausage

Sausage products made from poultry must be labeled to indicate kind, e.g., "(Chicken) Sausage," "(Turkey) Bologna," etc. Products containing more than one kind of poultry or red meat must declare the added ingredient in the product name, e.g., "Chicken Bologna, Beef Added" and "Turkey Franks, Chicken Hearts Added" per Policy Memo 029 dated September 4, 1981. The basic sausage standards, per meat 9 CFR 319.140, also apply to poultry, except for added water and fat.

Poultry Skin

When determining the amount of poultry skin allowed, refer to 9 CFR 381.168. If the specific part is not identified in this part, use the figure for boneless kind.

Poultry Tenders and Poultry Tenderloins

A "(Kind) Tender" is any strip of breast meat from the kind of poultry designated. A "(Kind) Tenderloin" is the inner pectoral muscle which lies alongside the sternum (breast bone) of the kind indicated.

Poultry Wing Sections (Kind)

Wing Sections is an acceptable designation for a product consisting of equal proportions of the parts of a wing. It may be and is usually used for equal proportions of wing portions and drummettes.

Premier Jus or (Oleo Stock)

The product obtained by rendering at low heat the fresh fat of heart, caul, kidney, and mesentery collected at the time of slaughter of bovine animals. The raw material does not include cutting fats. Premier Jus is not an acceptable name unless accompanied by the term "Oleo Stock."

Pressure-Sensitive Labels

Labels applied to packages shall be of the self-destructive type and must adhere to the packages under all conditions of use.

Pressure-Sensitive Stickers

Pressure sensitive stickers are as a means for manufacturers to use existing labeling material by covering inaccurate and/or misleading labeling information with corrected text or used as a promotional tool, e.g., a starburst encircling sweepstakes terminology. A pressure sensitive sticker must be the type that destroys the underlying label or package if removed, or be self-destructive.

Temporary label approval is not required when the entire label including the pressure sensitive sticker is truthful, not misleading, and the product is not misbranded. Corrected text on the pressure sensitive sticker can cover mandatory or non-mandatory information.

Labeling bearing pressure sensitive stickers falls under the Provisions of the generically approved labeling regulations 9 CFR 317.5 or 9 CFR 381.133, which indicates the conditions for use of final labeling without prior Washington approval. Companies need to create and maintain records of all final labeling, otherwise known as generic approvals.

Consistent with the rules on generic labeling, sketch labeling approval is required for the entire label when pressure sensitive stickers contain special claims [quality, nutrient content, health, negative, geographical origin, other claims (natural, animal production, e.g., "no antibiotics administered," breed claims, etc.), guarantees, foreign language or a change of the nutrition facts serving size].

Primal Parts and Subprimal Meat Cuts

Red meat carcasses, primals, subprimals or cuts can be labeled: 1) as the species of origin, e.g., beef tenderloin bearing the simple product name of "beef," 2) as species without identifying the primal or subprimal when certain terms associated with various sizes are part of the product name, i.e., chop, cutlet, steak, fillet, filet, roast, strips, etc., e.g., "Beef Steak," 3) as species and primal or subprimal cut, e.g., "Veal Shoulder Blade Steak," and 4) as species, coin name (butt, cala, daisy, picnic, etc.) and primal or subprimal cut. The species and coin name are not appropriate as a complete product name since it is missing the primal or subprimal cut, e.g., the phrase "pork picnic" is incomplete without "shoulder."

Recent editions of the "Uniform Retail Meat Identity Standards (URMIS)," published and distributed by the National Livestock and Meat Board, and "The Meat Buyers Guide," published by the National Association of Meat Purveyors, may be used to identify recommended names. These guides have been prepared through extensive review and analysis of the most recent edition of "Institutional Meat Purchase Specifications (IMPS)" and in cooperation with the U.S. Department of Agriculture, Agriculture Marketing Service (AMS) and public and industry associations.

Prime Rib of Beef or Standing Beef Rib Roast for Prime Rib

These products do not have to be derived from USDA prime grade beef.

Principal Display Panel, Alternate

The determination as to whether or not a panel is an alternate principal display panel shall be based on whether or not the panel is likely to be displayed, presented, shown, or examined under customary conditions of sale. If the intent of the panel cannot be determined and demonstrated, and if it has the appearance of a principal display panel, the presence of three or more mandatory labeling features shall serve to characterize the panel as an alternate principal panel. As such, any remaining mandatory features required to be placed on a principal display panel must be also included.

Product Names

1. A product standard should only be applied if the product name is the same as that described by the standard in the regulations or in the Policy Book. For example, the product, "Beef, Cheese and Vegetables in a Crust," would not be required to meet the standard for a "turnover" in the policy book.
2. Products such as "Pizza Pouches" must meet the standard for pizza since they are named "Pizza" even though they are not traditional type pizza. Furthermore, cheese may not be substituted for meat in products named "Pizza."

Product Name Qualifiers

Product name qualifiers have no sizing requirements other than appearing contiguous to the product name and being prominent and conspicuous. Examples of product name qualifiers are "Smoked Flavor Added," "Made in

Sheboygan," and "Colored with Paprika." Examples of phrases that are not product name qualifiers are "Water Added," and "Containing up to X% of a Solution." Such phrases are actually part of the product name and do have particular sizing requirements.

Product Name Qualifiers in Secondary Products

Product name qualifiers, e.g., "binders added," are not required on secondary products with labeling, with the exception of the statement "Calcium Propionate Added to Retard Spoilage of Crust" on pizza labeling. Secondary products are those meal like products that contain a multi-ingredient meat or poultry component, e.g., "Lemon Pepper Seasoned Chicken Breast with Rib Meat, Binders Added in 'Lemon Pepper Chicken Breast with Vegetable Medley.' " The characteristics of the meat or poultry added ingredients, are disclosed in the ingredients statement.

Product of USA

Labeling may bear the phrase "Product of U.S.A." under one of the following conditions:

1. If the country to which the product is exported requires this phrase, and the product is processed in the U.S., or
2. The product is processed in the U.S. (i.e., is of domestic origin). This entry cancels Policy Memo 080 dated April 16, 1985.

Prosciutto

Italian for ham, dry cured. The product name "Prosciutto" is acceptable on labeling to identify a dry-cured ham.

Prosciutto, Cooked

The product name "Cooked Prosciutto" is acceptable on labeling to identify a dry-cured Prosciutto ham that is cooked.

Prosciutto Cotto, Cooked Ham

The product name "Prosciutto Cotto, Cooked Ham" is acceptable on labeling to identify a regular pickle-cured cooked ham. Prosciutto Cotto is the Italian name for cooked ham.

Protective Coverings (Meat) Processed or Prepared Product

Immediate containers, e.g., bags, cardboard cartons, tray packs, and film bags enclosing processed or prepared product can be considered protective coverings and exempt from the marking and labeling requirements if placed in a shipping container which meets all mandatory labeling requirements of an immediate container. This does not exempt the mandatory identification and marking which is specifically required on the immediate container of cooked beef (9 CFR 318.17). In addition, the shipping container must be clearly marked "Packed for Institutional Use" or an equally descriptive statement of intended limited distribution. Unlabeled product may not be removed from shipping containers for further distribution nor displayed or offered for sale.

Unprocessed Meat Cuts — Transparent film bags enclosing individual meat cuts in an unprocessed state can be considered protective coverings and exempt from the marking and labeling requirements if placed in a shipping container which meets all mandatory labeling of an immediate container. These unlabeled meat cuts may only be removed from the shipping container for resale and further distribution to retailers, hotels, restaurants, and similar institutions if the product itself or the film bag bears a clearly legible official mark of inspection and the establishment number.

Protective Coverings (Poultry)

Under provision of the Poultry Products Inspection Act, protective coverings may be exempt from labeling requirements for immediate containers. Under certain circumstances, some protective coverings are considered immediate containers; under different circumstances, they are regarded only as protective product coverings.

When plastic film bags, cardboard cartons, etc., are used for protecting poultry sold for export or to institutions, e.g., hotels, restaurants, and hospitals (where the contents are consumed on the premises), they are exempt from the mandatory labeling of immediate containers, provided the shipping container meets all the labeling requirements for an immediate container. Such product may not be diverted to retail channels and displayed for sale or be sold to household consumers unless they bear all labeling features required for immediate containers.

See: 9 CFR 381.65(p).

Pudding

Nonspecific product.

Pulled Pork

Refers to pork removed from bones by hand or by mechanical means. The meat must retain its natural striated muscle fiber structure, i.e., it can be shredded, chunked, etc., but may not be ground, chopped, or comminuted.

Quality Grade Terms and Subjective Terms on Labels

Terms designated as grades of meat, i.e., prime, choice, select, good, etc., may only be used on red meat which has

been officially graded. However, the Food Labeling Division (FLD) will take no action to rescind currently approved labels which contain the word "select." Labels for new or reformulated products or new product lines will be approved in accordance with the policy for grading terms described above.

Letter grades A, B, C, which are designated grades for poultry, may only be used on poultry (whole birds and parts) that are officially graded and may not be used on red meat. Although poultry grade terms (U.S. grade A, etc.) are not allowed to be used on red meats, the terms prime, choice, and select may be used on poultry (whole birds or parts) that are equivalent to U.S. grade A. The use of a possessive, e.g., XYZ's Prime, does not relieve a company of this requirement. The use of quality grade terms on further processed meat and poultry products will be evaluated on a case-by-case basis to determine if they wrongly imply that the meat or poultry used in these products has been graded.

Terms which are subjective in nature, e.g., but not limited to, fancy, finest, super, supreme, ultimate, premium, greatest, best, old fashioned, homestyle, hotelstyle, deluxe, special, famous, and old time may be used unqualified on labels for meat and/or poultry products. The term "selected" as well as other terms, will be considered individually by the Labeling and Consumer Protection Staff, again to determine if these terms wrongly imply that the meat or poultry has been graded.

Quiche Products

The term "Quiche" does not have to be qualified to indicate it is a custard cheese pie. However, when characterizing ingredients, e.g., bacon, ham, chicken, onion, etc. are used either alone or in combination, the ingredients shall be either clearly identified as part of the product name or prominently displayed elsewhere on the principal display panel (PDP) of the label (e.g., Bacon Quiche, Ham and Onion Quiche, etc.). Similarly, the characterizing ingredients in Quiches bearing fanciful names shall be identified as part of the product name or highlighted elsewhere on the PDP (e.g., Quiche Bercy — made with ham and wine). Since "Quiche Lorraine" is widely recognized, the characterizing ingredients do not have to be identified as a part of the product name or elsewhere on the PDP.

Meat and poultry quiches must contain at least 8% cooked meat or poultry and sufficient cheese so that the combined total at least comprises 18% of the finished product. Quiche Lorraine must contain cooked bacon and/or ham and the only cheeses are Swiss and/or Gruyere.

If other characterizing ingredients (excluding cheese), e.g., onions, peppers, olives, etc., are used in addition to the meat or poultry ingredient in Quiche Lorraine or in any other quiche, the combination of these other characterizing ingredients and the meat or poultry ingredients must comprise at least 8% of the total product, and the cooked meat or poultry portion must be at least 5% of the total product.

Ranch

The regulations and policies applicable to "Farm" also apply to ranch.

Ravioli (Meat)

This product must contain at least 10% meat.

Rehydrated Dehydrated Vegetables

Rehydrated dehydrated vegetables acceptable as name. The specific vegetable must be identified in the ingredient statement.

Relleno De Papa (PR)

This product must contain 8% cooked meat. A Puerto Rican product that must show a true product name, e.g., "Potato Balls with Beef," or "Potato Dough with a Beef Filling."

Rendered Beef Fat Tissue Solids

The solid remains of a fat extraction process from beef that was ground and rendered by a high temperature (180°F) continuous wet rendering system.

See: Beef Gravies.

Rework

Rework is allowed in unlimited quantities when added to a like product. However, if breaded/battered rework is added to similar products, the rework is limited to 2%.

Rice and Meat

The product must contain at least 12% meat.

Roasted

The term "roasted" may be used to describe products that have been subjected to cooking methods that result in a roasted appearance.

Rolls

Six uses exist for the term "Roll" in conjunction with names for meat food products:

1. Items consisting of a solid piece of meat, e.g., "Boned Veal Rib," formed and tied as a roll and usually offered with seasonings.
2. Chopped meat in combination with condiments, also formed and processed. It can be and often is offered in the fresh meat state. Water is not an ordinary or usual ingredient in these two

"Meat Roll" items. If water is an ingredient in these products, then a statement indicating the addition of a solution has taken place must appear contiguous to the product name wherever it appears on the label.

3. "Sausage Rolls" have similar formulas and water limitations to cooked sausage. The finished product may contain up to 10% added water, is in roll shape, and is Cooked, or Smoked and Cured (species) Roll Sausages.
4. Non-descriptive rolls, e.g., "Pizza Roll," "Pickle Roll," "Relish Roll," etc., contain meat with cheese, peppers, pimentos, relishes, and other similar materials. An ingredients statement is required as a part of the product name on the basis of instructions in 9 CFR 317.2(c)(1) and (2), and 317.2(e).
